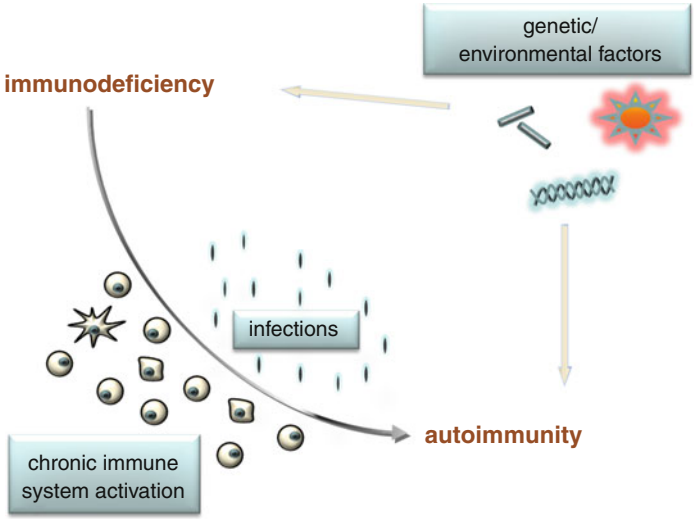
several years prior to disease development in systemic lupus erythematosus (SLE) (Reeves et al. 2011). Increased susceptibility to infection in these patients may very well exist during this long period of preexisting autoimmunity. It is possible that exposure to infections and other environmental factors occurring in a discontinuous fashion may fuel disease flares.

Common Immune Defects in Autoimmune Diseases

A number of evidence shows that the current organization of autoimmune disorders in isolated disease entities may have little to do with underlying pathogenesis. Patients belonging to different autoimmune disorders frequently exhibit common characteristics and overlapping symptoms. Also patients suffering from organ-specific diseases sometimes present with systemic features and vice versa. On the other hand, considerable phenotypic heterogeneity is sometimes encountered within the same disorder, for example, SLE patients can present with as mild a picture as rash and arthritis to as severe as end-stage renal disease and psychosis (Tsokos 2011). This evidence shows that entirely different autoimmune diseases may actually have common etiopathogenic origins. Under this notion, autoimmunity may



Immunodeficiency in Autoimmune Diseases, Fig. 1 From autoimmunity to immunodeficiency. Schematic representation of the proposed link between immunodeficiency and autoimmunity. Subtle immune system abnormalities that accumulate in patients predisposed to autoimmunity may result in a decreased host defense level and allow for more frequent infections to develop. Infectious microorganisms along with the chronic immune system activation ensuing may represent the primary trigger for the development of autoimmunity. Both environmental triggers and other genetic factors seem to contribute to shaping autoimmunity in each individual patient

represent the common denominator with varying clinical phenotypes stemming from individual environmental and genetic contributions.

Indeed, a number of genetic polymorphisms and defects have been found that are associated to not only one, but multiple autoimmune disorders (Table 3). Although for most cases the exact role of these genetic defects in the development of autoimmunity is not certain, some hypotheses have been made based on the function of the encoded proteins. Stemming from this knowledge, defects can be categorized in those associated with suppressed immunity, those associated with an increased immune activation state, and those associated with escape from tolerance.

Polymorphisms Associated with Suppressed Immunity

PTPN22 (protein tyrosine phosphatase nonreceptor 22) polymorphisms are associated with T1DM, rheumatoid arthritis (RA), SLE, scleroderma, myasthenia gravis, Addison's disease, and autoimmune thyroiditis (Rioux and Abbas 2005; Gregersen and Behrens 2006). Together with CSK (an intracellular tyrosine kinase), PTPN22 is responsible for downregulating the action of LCK (another tyrosine kinase). Since LCK is involved in T cell receptor (TCR) signaling, PTPN22 can essentially turn off TCR signaling. PTPN22 polymorphisms associated with autoimmunity have been found to result in an increased threshold of stimulation for TCR signaling. Although the effect of this defect on the immune system is uncertain, decreased TCR signaling may result in infectious agents' antigens to escape recognition.

Another molecule associated to multiple autoimmune diseases is CD3ζ chain (or else CD247). CD3ζ chain constitutes part of the TCR signaling machinery and is responsible for transmitting signals downstream upon antigen recognition. Low expression of CD3ζ chain is found in SLE, T1DM, and scleroderma (Tsokos 2011). Defective TCR signaling has been shown to lead to the development of a lethal, multiorgan autoimmune disease in mice. Mutations in the gene encoding for ZAP70, a downstream signaling target of the CD3ζ complex, also lead to the development of

Immunodeficiency in Autoimmune Diseases, Table 3 Common genetic polymorphisms in autoimmune disorders.

Gene	Associated autoimmune disorders	Function of encoded protein	Result of polymorphism
Associated with suppressed immunity			
PTPN22	Type 1 diabetes, rheumatoid arthritis, SLE, myasthenia gravis, and autoimmune thyroiditis	Turns off TCR signaling	Increased threshold of stimulation for TCR signaling
CD247	SLE, type 1 diabetes, and scleroderma	Transmits signals upon Ag recognition	Defective signaling upon Ag recognition
UBE2L3	Rheumatoid arthritis, SLE, celiac disease, and inflammatory bowel disease	Marks abnormal proteins for degradation	Increased levels of NF-κB/inflammation(?)
RUNX1	Psoriasis, rheumatoid arthritis, and SLE	Transcription factor	Altered expression levels of PDCD1, SLC22A4 SLC9A3R1, and NAT9 genes
FCGR2A, FCGR3A, FCGR3B	Inflammatory bowel disease, autoimmune cytopenias, myasthenia gravis and SLE	Bind the Fc portion of IgG antibodies	Increased susceptibility to infections(?)
Associated with increased immune activation state			
SIAE	Multiple	Regulates inhibitory signals	Enhanced B cell receptor activation
FOXP3	Type I diabetes, thyroiditis, inflammatory bowel disease, atopic dermatitis (IPEX)	T regulatory cell master regulator	Expansion of autoreactive T cells in the periphery
CTLA4	Type 1 diabetes, rheumatoid arthritis, autoimmune thyroiditis, Addison's disease and celiac disease	Inhibitory signaling costimulatory molecule	Enhanced T cell activation
IRF5	Rheumatoid arthritis, scleroderma, Sjögren's syndrome, SLE, and IBD	Involved in the production of type I interferons	Higher serum IFNα activity
Associated with escape from tolerance			
AIRE	Autoimmune hypothyroidism, Addison's disease (APS1)	Regulates thymic expression of self-antigens	Escape from negative selection of self-reactive T cell clones
TNFRFS6, TNFFS6, CASP10, CASP8	Autoimmune hemolytic anemia, idiopathic thrombocytopenic purpura, autoimmune neutropenia (ALPS)	Involved in apoptosis	Failure to delete autoreactive T cells
HLA	Multiple	Antigen presentation	Alteration in peptide affinity

autoimmunity in mice. Infectious agents seem to play an important role because mice that are bred in a microbial-free environment are salvaged from autoimmunity. Low CD3ζ chain expression may result in defective signaling upon foreign antigen recognition and decreased immune response to infectious agents.

UBE2L3 (ubiquitin-conjugating enzyme E2 L3) polymorphisms have been associated with RA, SLE, celiac disease, and inflammatory bowel disease (Wang et al. 2012). UBE2L3 is an enzyme involved in ubiquitination, that is, the process of marking abnormal or short-lived proteins for degradation by conjugating them with ubiquitin. This enzyme has been shown to participate in the ubiquitination of many molecules that are important in immune cells, for example, c-Fos and the NF-κB precursor p105. Cells that carried the risk haplotype were found to have higher levels of UBE2L3 mRNA and its encoded protein. Since NF-κB is upregulated in response to inflammation and UBE2L3 decreases the levels of NF-κB, this variant may result in a diminished innate immune response and a higher rate of infections.

Another example is transcription factor RUNX1 (runt-related transcription factor 1). In three independent studies RUNX1 binding site variants have been associated to three different autoimmune diseases (Wong et al. 2012). The genes that have been found to be associated are PDCD1 with SLE, SLC22A4 with RA and both SLC9A3R1 and NAT9 with psoriasis. Although the precise mechanisms that underlie these associations are not yet clear, disrupted binding of RUNX1 to these genes seems to affect their expression levels. PDCD1 encodes for a cell surface protein that seems to play an important role in B cell development, SLC22A4 for a sodium-ion dependent carnitine transporter, SLC9A3R1 for a sodium/hydrogen exchanger regulatory cofactor, and NAT9 for an acetyltransferase.

Various genes encoding for Fc gamma receptors (FCGRs) have been associated to autoimmune disorders: FCGR2A with inflammatory bowel diseases, autoimmune cytopenias and myasthenia gravis, FCGR3A with autoimmune cytopenias and myasthenia gravis, and FCGR3B with SLE and myasthenia gravis (Fossati et al. 2001). Fc gamma receptors are cell surface receptors that bind the Fc portion of IgG antibodies, thus recognizing IgG opsonized particles. Upon binding, cells respond by releasing inflammatory mediators, initiating phagocytosis and activating antibody-dependent cell-mediated cytotoxicity. These processes serve to eliminate invading pathogens. Although the exact role of the above polymorphisms in disease is yet to be determined, an interesting similarity is that RA, SLE, autoimmune cytopenias, and myasthenia gravis are all antibody-mediated diseases. Furthermore, certain Fc gamma receptor polymorphisms have been associated in the past with increased susceptibility to infections.

Polymorphisms Associated with an Increased Immune Activation State

An interesting molecule that has been associated with many autoimmune disorders is SIAE (sialic acid acetylesterase). SIAE is an enzyme that removes acetyl moieties and thus regulates sialic acid molecules. Defective or loss-of-function mutations of SIAE are identified more commonly in individuals suffering from autoimmune disorders than in controls. Mutation of SIAE in mice causes enhanced B cell receptor activation in peripheral B cells and the development of antichromatin autoantibodies and glomerular immune complex deposits (Cariappa et al. 2009). CD22, a sialic acid-recognizing molecule that transmits inhibitory signals and is constitutively expressed on mature B cells, seems to play a role in this. In SIAE mutations inhibitory signaling from CD22 is suppressed and B cells become hyper-activated.

CTLA4 (cytotoxic T lymphocyte antigen 4) polymorphisms have been associated with T1DM, RA, autoimmune thyroiditis, myasthenia gravis, Addison's disease, and celiac disease (Rioux and Abbas 2005; Gregersen and Behrens 2006). The human risk haplotype is associated with lower levels of a splice variant that encodes for soluble CTLA4. Since CTLA4 is a costimulatory molecule involved in transmitting inhibitory signals to T cells, it seems that these variants may allow for a higher T cell activation state to develop.

IPEX (immune dysregulation, polyendocrinopathy, enteropathy, X-linked) is a syndrome where T1DM, thyroiditis inflammatory bowel disease, atopic dermatitis, and infections coexist. Mutations in FOXP3 (forkhead box P3), the master regulator of T regulatory cells, are known to be responsible for the development of IPEX (Rioux and Abbas 2005). It is well established that regulatory T cells are crucial for decreasing the activation status of various immune system components.

Scleroderma, RA, Sjögren's syndrome, SLE, and inflammatory bowel disease are all examples of diseases in which IRF5 (interferon regulatory factor 5) gene polymorphisms are seen (Gregersen and Behrens 2006). IRF5, or interferon regulatory factor 5, is a transcription factor involved in the production of type I interferons. The engagement of either toll-like receptor (TLR) 7 or TLR8 by single-stranded RNA induces IRF5 activation and subsequent transcription of multiple proteins involved in antiviral defense. Presence of the IRF5 risk variant seems to be associated with a higher serum IFNα activity. High IFNα levels are in turn accused of being central to the pathogenesis of multiple autoimmune diseases, including RA and SLE.

Polymorphisms Associated with Escape from Tolerance

Most autoimmune diseases are strongly associated to one or more HLA (human leukocyte antigen) polymorphisms (Walker and Nepom 2005; Delves et al. 2011). HLA molecules enable antigen presentation and subsequent T cell activation through the HLA–TCR interaction. It has been demonstrated that even one amino acid change in the structure of HLA can cause dramatic alterations in its antigen binding affinity and efficiency of T cell induction. Although this has not been proven yet, such variations may allow self-antigens to induce strong T cell activation and autoimmunity to develop.

Two autoimmune syndromes that have been found to be associated with escape from tolerance are autoimmune lymphoproliferative syndrome (ALPS) and autoimmune polyendocrine syndrome 1 (APS1). ALPS is a syndrome where autoimmune manifestations (hemolytic anemia, thrombocytopenic purpura, and neutropenia) are combined with lymphadenopathy, splenomegaly, and hypergammaglobulinemia (Rieux-Laucat et al. 2003; Vaux 2006). There are multiple forms of ALPS but all of them are associated to some kind of defect in apoptotic pathways. Apoptotic pathways are known to be crucial in the process of central tolerance and autoreactive T/B cell clone deletion. Absence of this process is hypothesized to be responsible for the development of autoimmunity in these patients.

Mutations in AIRE, a gene that encodes for a transcription factor that regulates thymic expression of self-antigens, have been found to be responsible for APS1 (Rioux and Abbas 2005; Lankisch et al. 2009). Expression of self-antigens in the thymus serves as an effective mechanism to avoid the escape of autoreactive T cells in the periphery. In AIRE mutations thymic deletion of autoreactive cells is impaired and multiorgan autoimmunity occurs. Autoimmune hypothyroidism, Addison's disease, and chronic *Candida* infection are the commonest manifestations encountered in these patients. Clinical phenotype is quite diverse, though, implicating an important role for other environmental factors, like infections.

Autoimmune Manifestations in Immunodeficiency Disorders

Not only autoimmunity is linked to immunodeficiency, but the reverse also seems to hold true. Autoimmune phenomena are part of many classic immunodeficiency disorders and a link with specific infections and the development of chronic inflammation has been postulated (Table 4) (Grammatikos and Tsokos 2012).

X-linked lymphoproliferative (XLP) syndrome is one example of an immunodeficiency disorder associated with multiple autoimmune phenomena. XLP is caused by mutations in the gene encoding for SLAM associated protein (SAP), involved in CD8+ T and NK cell signaling pathways (Chapel et al. 2006). The result of this mutation is uncontrolled EBV infection and widespread immune system activation with a hemophagocytic lymphohistiocytosis picture. Fever, hepatosplenomegaly, lymphadenopathy, jaundice, and rash along with laboratory findings of lymphocytosis and histiocytosis are seen in these patients.

A similar example is familial hemophagocytic lymphohistiocytosis (FHL). FHL is a syndrome that is characterized by uncontrolled immune system activation and chronic inflammation. It presents as prolonged fever, rashes, pancytopenia, lymphadenopathy, and hepatosplenomegaly. Half of cases of FHL are known to be caused by mutations in PRF1 and UNC13D genes, two genes that encode for proteins involved in cell cytolytic functions. Cytolysis is an important function in the process of destroying viral-infected cells and these patients have frequent viral infections.

Wiskott–Aldrich syndrome (WAS) is another immunodeficiency syndrome where multiple autoimmune manifestations are encountered. WAS protein (WASp), a protein involved in actin polymerization, is found to be defective in these patients (Cruse 2004). Defective actin polymerization is thought to result in abnormal immunological synapse formation in T cells upon TCR signaling. Apart from recurrent bacterial infections, these patients also exhibit eczema, ITP (immune thrombocytopenia), and AHA (autoimmune hemolytic anemia).

Immunodeficiency in Autoimmune Diseases, Table 4 Autoimmune manifestations in primary immunodeficiency syndromes (Adapted from Grammatikos AP, Tsokos GC (2012))

Disease	Defective molecule (involved in)	Infectious phenomena	Autoimmune/lymphoproliferative manifestations
FHL	*PRF1, UNC13D* (T/NK cell cytotoxicity)	Increased viral infections	HLH (inflammation and tissue destruction)
XLP	*SAP* (CD8+ T/NK cell signaling pathways)	Uncontrolled EBV infection	HLH (inflammation and tissue destruction), lymphoma
WAS	*WASP* (actin cytoskeleton)	Recurrent bacterial infections	ITP, AHA, vasculitis, eczema, lymphoma
CGD	NADPH oxidase (Neutrophil bactericidal mechanisms)	Recurrent bacterial/fungal infections	Chronic gut/lung/GUT inflammation
MGD	*RAG1*, *RAG2* (somatic rearrangement of Ig and TCR genes)	Systemic viral infections (CMV, EBV, VZV)	Caseating granulomas of the nose, sinuses, palate, and upper airways
CVID	*TACI, ICOS, BAFF-R*, *CD19*, *MSH-5* (antibody production)	Recurrent sinopulmonary, GIT infections	IBD, ITP, AHA, LIP, lymphoma
IgAD	*IgA1*, *IgA2*, and *MHC* genes (IgA antibody production)	Recurrent infections	SLE, rheumatoid arthritis, ITP, allergy, asthma
XLA	*Btk* (B cell development/signaling)	Recurrent infections	Arthritis, AHA, scleroderma, type 1 diabetes

Patients with chronic granulomatous disease have defective NADPH (nicotinamide dinucleotide phosphate) oxidase, the enzyme complex responsible for the generation of superoxide and other reactive oxygen species in phagocytic cells (Kumararatne 2009). Inability of phagocytes to produce bactericidal oxidants results in the development of recurrent bacterial and fungal infections. A hallmark of the disease is the development of granulomatous inflammation of hollow viscera; examples are inflammatory bowel disease, urethral strictures, and bladder granulomas.

A recent study reported the presence of hypomorphic RAG (recombination activating gene) mutations in patients suffering from midline granulomatous disease (De Ravin et al. 2010). RAG encodes for enzymes that play an important role in the rearrangement and recombination of the immunoglobulin and TCR genes. In contrast to complete loss of gene function seen in severe combined immunodeficiency syndrome (SCID), hypomorphic RAG mutations allow for 50 % activity of the encoded protein. As a consequence, these patients experience less severe infections and survive longer. In contrast to SCID, their phenotype is primarily autoimmunity-based (e.g., caseating granulomas of the nose, sinuses, palate, and upper airways).

Common variable immune deficiency (CVID) is another typical immunodeficiency syndrome with multiple autoimmune symptoms (Chapel et al. 2006). A number of different genes have been associated to the development of CVID: TACI (transmembrane activator and CAML interactor), ICOS (inducible costimulatory), BAFF-R (B cell activating factor receptor), MSH-5 (mutS homolog 5), and CD19. What these genes have in common is that they all are involved in antibody production. CVID patients exhibit characteristic hypogammaglobulinemia and experience frequent infections. However, autoimmune phenomena are also very commonly seen; for example, inflammatory bowel disease, immune thrombocytopenia, autoimmune haemolytic anemia, and lymphocytic interstitial pneumonitis.

Although patients with IgA deficiency are usually asymptomatic they sometimes exhibit increased frequency of infections, particularly of the respiratory, digestive, and genitourinary systems (Kumararatne 2009). Autoimmune and atopic phenomena like SLE, RA, ITP, allergy, and asthma are also occasionally seen. A higher prevalence of autoimmune manifestations is moreover seen in unaffected relatives of these patients. Interestingly, patients diagnosed with

autoimmune diseases such as SLE and RA are more frequently found to have IgA deficiency than the general population.

A defect in Btk (Bruton's tyrosine kinase), a gene involved in B cell maturation, is responsible for XLA (X-linked agammaglobulinemia) (Chapel et al. 2006). Patients with XLA present with low or absent B cells and low immunoglobulin levels. As a result, recurrent pneumonia, otitis media, diarrhea, and other infectious diseases are experienced by these individuals. Autoimmunity is also frequently seen with arthritis, AHA, scleroderma, and T1DM being the most common manifestations.

Conclusions

Although immunodeficiency and autoimmunity have long been considered as two separate disease entities, it is now becoming evident that they have many characteristics in common and may, at least in some cases, be interconnected. It has long been known that patients with primary immunodeficiency syndromes experience multiple autoimmune phenomena. More recently, it is starting to be recognized that immunodeficiency may represent an important contributor to the development of autoimmune disorders. The common denominator for these findings seems to be an increased preponderance to infections and a subsequent constant state of inflammation. The severity of the genetic abnormality may determine whether a predisposed individual exhibits an immunodeficiency- or an autoimmunity-based phenotype. Future research is expected to help better understand the links between those two disease entities and shed more light into their shared characteristics.

Immunoglobulin Somatic Hypermutation and Class-Switch DNA Recombination

Hong Zan and Paolo Casali
Department of Immunology and Microbiology, University of Texas Health Science Center at San Antonio, San Antonio, TX, USA

Synonyms

Somatic hypermutation (SHM): Immunoglobulin (antibody) somatic hypermutation; Somatic hypermutation of antibody genes; Somatic hypermutation of immunoglobulin genes
Class-switch DNA recombination (CSR): Class-switch recombination; Immunoglobulin (antibody) class switching

Definition

Somatic hypermutation. During B cell responses to antigen, immunoglobulin (Ig) variable region DNA that encodes the antigen-binding site of the antibody undergoes mutation at a high rate, resulting in the generation of variant Igs, some of which bind antigen with a higher affinity. This allows the affinity of the antibody response to increase. These mutations affect only somatic cells (B lymphocytes), and are not inherited through the germline.

Class-switch DNA recombination. The genetic process by which a B cell switches production of antibody or B cell receptor from one class to another, for example, from IgM to IgG, IgA, or IgE, results from an intrachromosomal deletional recombination between switch regions located upstream of exons of the constant heavy-chain (C_H) region. This exchanges the initially expressed C_H exons, such as Cμ, for an alternative set of downstream C_H exons, such as Cγ, Cα, or Cε, therefore, allowing the expression of antibodies that have the same antigen specificity but are of a secondary IgH isotype (IgG, IgA, or IgE) and thereby have a different biological effector function.

Features of Somatic Hypermutation and Class-Switch DNA Recombination

Antibody-mediated immune responses are critical to prevent invasion by pathogens, destroy cancer cells, or neutralize toxins. Antibodies or immunoglobulins (Igs) are produced by B cells or their differentiation elements, plasma cells. Antibody diversity and B cell development are underpinned by sequential Ig gene recombination (Casali 2014). This assembles noncontiguous Ig variable (V), diversity (D), and joining (J) genes into a functional V(D)J DNA segment, thereby producing the diverse pre-immune repertoire of B cell receptors (BCRs), B cell clonotypes, and corresponding antibodies. A BCR consists of the monomeric form of an Ig, which is identical to the secreted antibody (with exception of a transmembrane region instead of secreting region) and transmembrane proteins CD79a and CD79b. Pre-immune naive B cells express IgM with a low-to-moderate affinity for antigen. In response to antigen, selected IgM clones proliferate, differentiate, and undergo Ig gene somatic hypermutation (SHM) and class-switch DNA

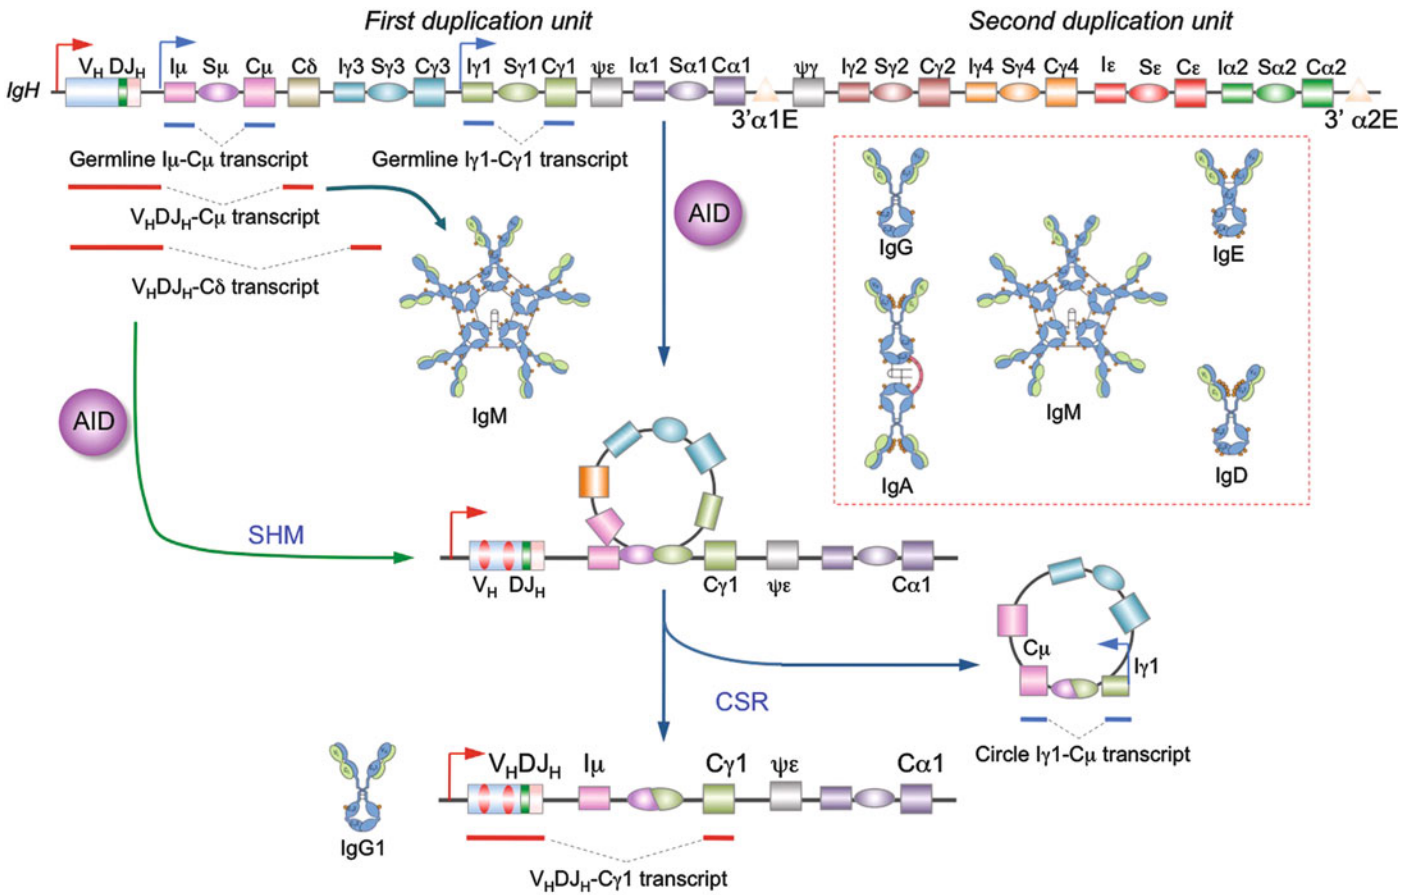
recombination (CSR). SHM and CSR are critical for the maturation of antibody responses to foreign and self-antigens. SHM targets the V(D)J portion of the antibody-encoding genes, thus providing the basis for positive selection by antigen of higher-affinity BCR mutants and, eventually, high-affinity antibodies (Casali et al. 2006). CSR replaces the constant (C)μ region of the heavy (H) chain with a downstream Cγ, Cα or Cε region, thereby providing antibodies with new biological effector functions.

SHM introduces mainly point mutations and, rarely, deletions or insertions into rearranged V(D)J gene sequences, but not C regions. The process is referred to as hypermutation because it introduces mutations at a rate that is a million-fold higher (10^{-3} change/base/cell division) than that of the spontaneous mutation rate in the genome at large (10^{-9} change/base/cell division). Random replacement mutations have unpredictable effects on protein function; some will decrease the affinity of the BCR for the antigen driving the response, whereas others will increase the intrinsic affinity for that antigen. B cells expressing a BCR with the highest affinity for antigen are positively selected and acquire a growth advantage over all other B cells; the other B cells are gradually counterselected for survival and proliferation. Further positive selection of the clone(s) that accumulated mutations conferring the highest affinity for antigen will result in narrowing clonal restriction and accumulation of high-affinity clones. SHM emerged before CSR in phylogeny, being fully functional in sharks, whose antibody responses show evidence of mutational selection. SHM is restricted to the Ig locus and a few other genes because abnormal and widespread mutations in the genome are detrimental to cell homeostasis and favor the emergence of neoplasia and autoimmunity.

CSR changes the antibody and BCR from one class to another by replacing the heavy-chain (IgH) C_H region with a different one, encoded by a downstream cluster of C_H exons through an intrachromosomal deletional DNA recombination. There are five antibody classes: IgM, IgD, IgG, IgA, and IgE, all with distinct tissue distribution and biological effector functions (Fig. 1) (Xu et al. 2012). IgM is the first BCR expressed and the first Ig produced by a differentiating B cell. IgM activates the complement efficiently. IgD is subsequently expressed as the B cell exits the bone marrow and acquires "mature" tracts. IgG comprises four subclasses (IgG1, IgG2, IgG3, and IgG4 in humans and IgG1, IgG2a, IgG2b, and IgG3 in mice) and is the most abundant Ig class in the circulation. While there is only one IgA class in mouse, IgA exists in two subclasses (IgA1 and IgA2) in human. IgMs are secreted as pentamers or hexamers, possess a high avidity for antigens with repetitive motifs (such as those occurring on most microbial pathogens), and activate complement efficiently. They, however, cannot pass into the extravascular space due to their large size. By contrast, monomeric IgG, monomeric IgE, and monomeric or dimeric IgA can distribute systemically to tissues where they mediate a variety of biological effector functions. While naïve B cells express only IgM and IgD, selected Ig classes and/or subclasses (isotypes) of antibodies are elicited during the course of an immune response, depending on the nature of the eliciting antigen and its entry mode. In humans, IgG1 and IgG3 are elicited mainly by viruses, IgG2 by encapsulated bacteria, IgG4 and IgE by large extracellular parasites, and IgA1 and IgA2 by pathogenic bacteria on mucosal surfaces. The constant regions of different immunoglobulin isotypes are encoded by different C_H exon clusters, which are organized in the order of Cμ, Cδ, Cγ, Cε, and Cα in the IgH locus. CSR results in the replacement of the expressed C_H exon cluster – for example, Cμ for IgM – with Cγ, Cα, or Cε, thereby giving rise to IgG, IgA, or IgE, respectively, in which the antigen-binding variable region is unaltered. Of note, IgD is generated not through CSR, but through alternative splicing of the primary transcripts that encode IgM.

DNA Lesions and Repair in SHM and CSR

Both SHM and CSR require transcription of their target DNA. CSR initiates with transcription

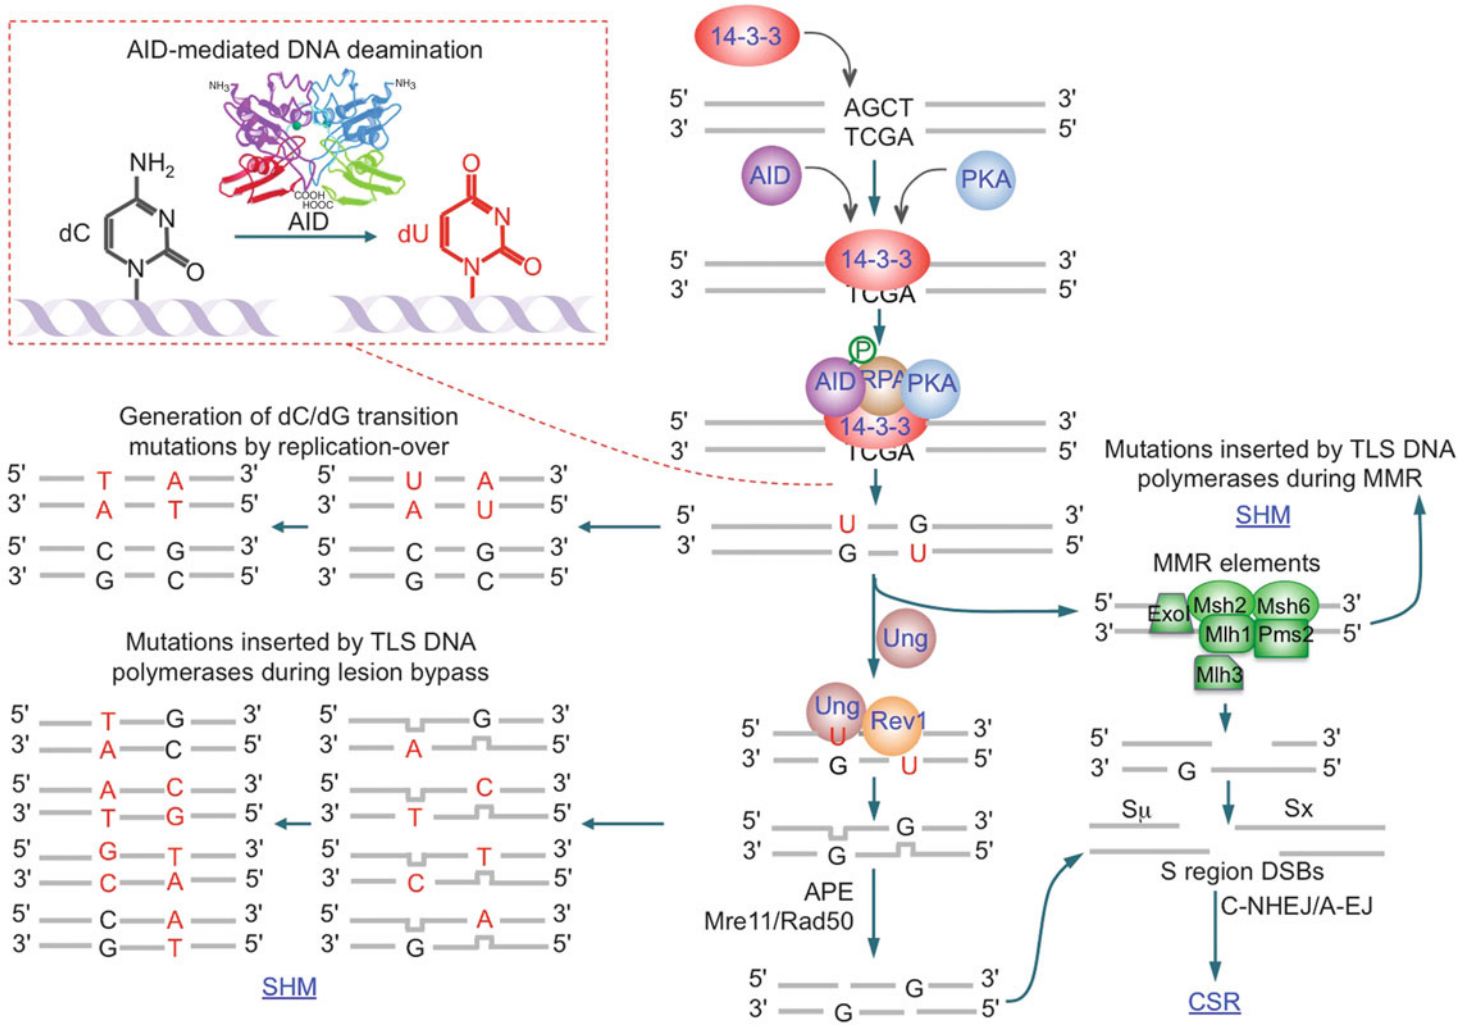


Immunoglobulin Somatic Hypermutation and Class-Switch DNA Recombination, Fig. 1 Schematic diagram of SHM and CSR. SHM introduces mainly point mutations in Ig V_HDJ_H, VκJκ, and VλJλ regions. There are five antibody classes (insert): IgM, IgD, IgG, IgA, and IgE, identified by the different heavy-chain constant (C_H) regions in their heavy chains (IgH). CSR exchanges the gene encoding the C_H region with one of a set of downstream C_H genes (depicted is CSR from Sμ to Sγ1 in the human *IgH* locus). Both SHM and CSR require AID. CSR involves the generation of DSBs in S regions (lying upstream of the constant-region gene) followed by DSB repair. This leads to juxtaposition of rearranged V_HDJ_H DNA with a downstream C_H exon cluster and deletion of the intervening sequence between S regions as an extrachromosomal circle

from the I_H promoters of the C_H regions that will be involved in the DNA recombination event. I_H promoters lie immediately upstream of all S (switch) regions. Such I_H promoters are activated upon binding of transcription factors induced by signaling of CD40, TLR, and receptors of cytokines, such as IL-4 or TGF-β. The I_H promoters that lie upstream of the upstream and downstream S regions that will be involved in the CSR event are activated to induce "germline" I_H–C_H transcripts, which are then spliced at the I_H region to join with the corresponding C_H region. SHM requires V_HDJ_H–C_H, Vκ–Cκ, or Vλ–Cλ transcription. In addition to both requiring transcription of the target DNA, SHM and CSR depend on activation-induced cytidine deaminase (AID)-mediated generation of DNA lesions and subsequent DNA repair (Casali et al. 2006; Muramatsu et al. 2000; Di Noia and Neuberger 2007). AID possesses structural similarities to the members of APOBEC (apolipoprotein B mRNA-editing enzyme, catalytic polypeptide-like), a class of enzymes that act on RNA to deaminate a cytidine to a uridine. AID, however, deaminates deoxycytosine (dC) residues in DNA to yield deoxyuridine (dU)/deoxyguanine (dG) mispairs. These mispairs then trigger DNA repair processes that lead to the introduction of mutations in V(D)J regions, or generation of double-strand DNA breaks (DSBs) in S regions and recombination of the DSB free ends (Fig. 1).

To mediate SHM and CSR, AID and other factors must be significantly upregulated and then targeted to the V(D)J regions where mutations will be introduced or the S regions that will undergo recombination. SHM preferentially targets the 5′-RGYW-3′ (R = A or G, Y = C or T, W = A or T) mutational hotspot. Interestingly, the 5′-AGCT-3′ iteration of 5′-RGYW-3′ is also a preferential target of DSBs in S regions. The dU generated by AID deamination of dC can be "replicated over" by pairing with deoxyadenine (dA) during replication. The emerging mutation is an obligatory dC → dT transition and a dG → dA transition on the complementary strand. The net result is the replacement of the original dC/dG pair with a dT/dA pair in half of the progeny cells. Alternatively, the dU can be removed from DNA by uracil DNA glycosylase (Ung) to give rise to an abasic site. Indeed, the key event in generating a random spectrum of mutations is the creation of an abasic site. This can be replicated over by an error-prone translesion DNA synthesis (TLS) polymerase, such as polymerase (pol) ζ, pol θ or pol η, each of which can insert all three possible mismatches (mutations) across the abasic site (Zan et al. 2001; Casali et al. 2006) or Rev1, which insert preferentially dC across an abasic site or other lesions. If the dC is not replicated over or the dU is not deglycosylated by Ung, the dU/dG mispair recruits the elements of mismatch repair machinery (MMR) machinery, starting with Msh2/Msh6, to excise the stretch of DNA containing the damage, thereby creating a gap that needs to be filled in by resynthesis of the missing DNA strand. This resynthesis is carried out by an error-prone TLS polymerase that will introduce mutations.

While the insertion of somatic mutations in V(D)J DNA requires only a single dC deamination, the generation of DSBs, which are obligatory CSR intermediates, entails processive AID-mediated deamination of dCs, particularly those within the 5′-AGCT-3′ tandem repeats in S regions, yielding high densities dUs in both DNA strands (Fig. 2). These are then processed by Ung, which is recruited to and stabilized on S regions by the scaffold functions of the translesion DNA polymerase Rev1 (Zan et al. 2012) and, possibly, 14-3-3 adaptors and replication protein A (RPA) (Xu et al. 2012), or elements of the MMR machinery, thereby leading to DSBs and/or point mutations. Rev1 is recruited to S region DNA in an AID-dependent fashion, interacts directly with Ung, and enhances Ung-mediated DNA dU glycosylation. Ung is a critical element of the base excision repair (BER) pathway. Excision of the abasic sites it creates by apurinic/apyrimidinic endonucleases (APEs) leads to single-strand DNA breaks (SSBs). Proximal SSBs in opposite strands would readily form staggered DSBs. In addition, key MMR elements such as MSH2 and MSH6 may be recruited to dU/dG mismatches adjacent to the SSB nicks, where they recruit 5′ → 3′ exonuclease I (Exo I) to yield DSBs.



Immunoglobulin Somatic Hypermutation and Class-Switch DNA Recombination, Fig. 2 (continued)

Staggered DSBs can also arise from AID- and Ung-dependent processing of blunt S region DSBs generated by endonuclease G (Zan et al. 2011). The DSB free ends upstream and downstream of the S region are joined by nonhomologous end joining (NHEJ) (Alt et al. 2013). In classic NHEJ (C-NHEJ), DSBs recruit Ku70 and Ku86 that form complexes with DNA-PKcs and play scaffold functions to then recruit other essential factors, such as the XRCC4–DNA ligase IV complex, to complete the end-joining process by the formation of S–S junctions. CSR can also occur, though, albeit at a lower efficiency, in the absence of XRCC4 or DNA ligase IV, through an alternative end-joining (A-EJ) pathway. The S–S junctions generated by A-EJ show higher microhomologies that those formed in C-NHEJ. A-EJ is also frequently associated with chromosomal translocations.

Induction of SHM and CSR

SHM and CSR are highly regulated, starting with their specific induction. AID is expressed late in the natural history of a B lymphocyte, after the B cell encounters antigen and differentiates in germinal centers of peripheral lymphoid organs, restricting SHM and CSR to this stage. In resting naïve or memory B cells, AID transcripts and protein are undetectable. These, however, are readily and greatly upregulated in B cells induced to undergo SHM and/or CSR by the same stimuli that trigger SHM/CSR.

AID expression in B cells is induced by T-dependent (TD) CD154 (CD40 ligand, CD40L)/CD40 engagement or T-independent (TI) TLR engagement by, mainly, microbe-associated molecular patterns (MAMPs), as synergized by BCR cross-linking (Xu et al. 2012; Pone et al. 2012). TI stimuli comprise TI type 1 (TI-1) and TI type 2 (TI-2). TI-1 stimuli generally include MAMPs, such as LPS or CpG, which activate their corresponding pattern recognition receptors (PRRs). The better-characterized PRRs include TLRs, NOD-like receptors (NLRs), RIG1-like receptors (RLRs), CARD helicases, C-type lectins, and scavenger receptors. TLRs, in particular, are highly expressed in B cells. In fact, B cells were known to respond to stimulation by MAMPs, such as LPS or flagellin, decades before the discovery of TLRs. TD and TI stimuli play a major role in the induction of AID and are, therefore, referred to as "primary" CSR- and, possibly, SHM-inducing stimuli. Stimulation of mouse B cells by LPS induces *Aicda* expression and germline Iγ3–S–Cγ3 transcription, leading to CSR to IgG3. In conjunction with cytokines IL-4, TGF-β, or IFN-γ, LPS induces CSR to all other isotypes. During B/T cell interactions, cytokines released by T cells accumulate in the

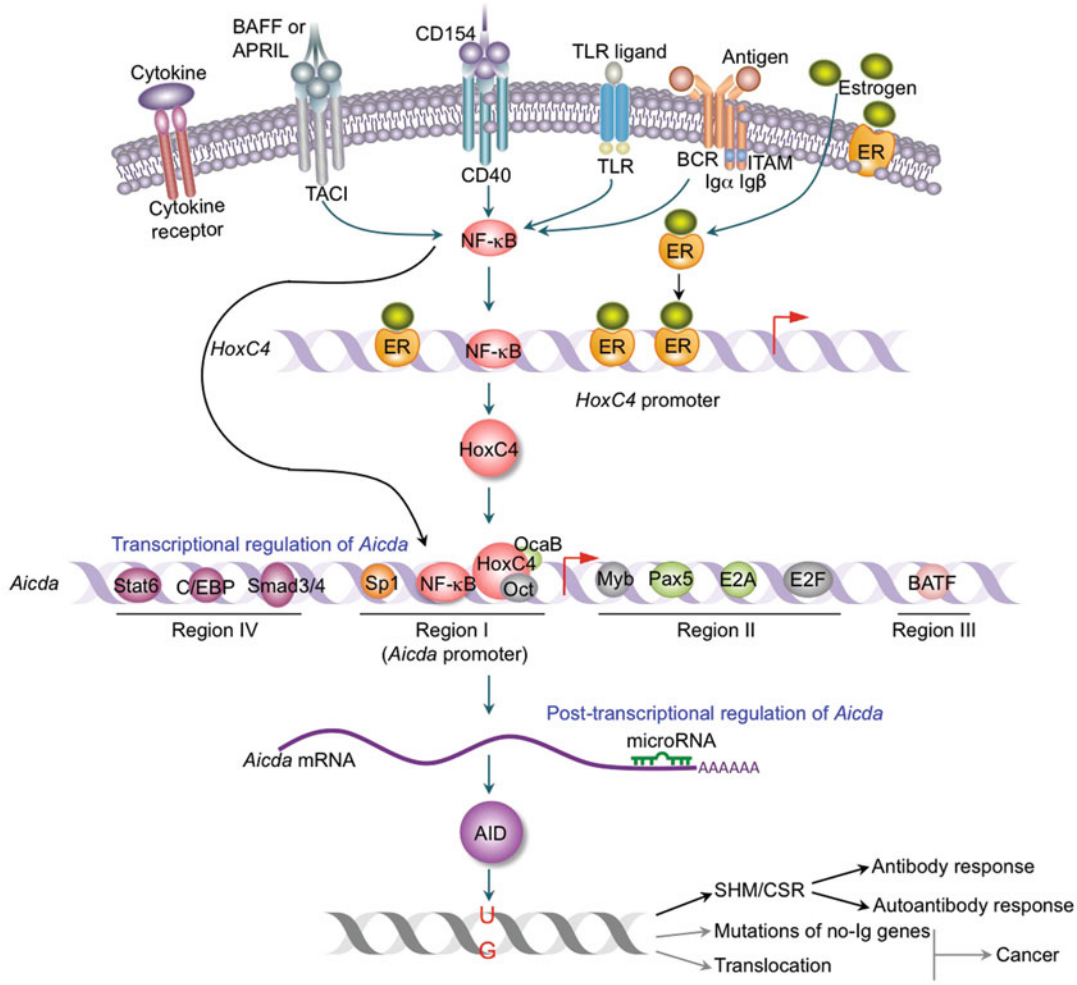
Immunoglobulin Somatic Hypermutation and Class-Switch DNA Recombination, Fig. 2 AID-mediated DNA lesions and lesion repair in SHM and CSR. Both SHM and CSR are initiated by AID-mediated dC deamination (insert). In SHM, the AID-mediated deamination of a dC base leads to the insertion of somatic mutation(s) in different ways. The dU/dG mispairs generated by AID in V(D)J regions can be replicated over and lead to dC to dT or dG to dA transition mutations. Excision of the dU residue by Ung gives rise to an abasic site, replication over which could yield either transition or transversion mutations at dC/dG pairs. The abasic site could also form a substrate for an APE, which can nick the DNA strand that contains the abasic site and allow polymerase-mediated repair by the conventional base excision repair (BER) pathway. Mutations at dA/dT pairs occur by an unidentified form of mutagenic patch repair that is triggered by recognition of the dU/dG mispair by MMR elements. This patch DNA repair process would recruit an error-prone TLS polymerase that introduces both transition and transversion mutations. In CSR, AID is targeted to S regions by 14-3-3 adaptors that specifically bind 5′-AGCT-3′ repeats in the S region core and recruit AID and PKA to S region DNA. AID also binds 14-3-3 proteins through its C-terminal region. RPA enhances AID deamination of dCs in transcribed S region DNA. The resulting dUs are removed by Ung, which is recruited and stabilized on S regions in a fashion dependent on the scaffold functions of Rev1, and possibly, RPA. Rev1 and RPA bind to different regions of Ung. Ung is also stabilized indirectly by AID within a putative macromolecular complex. Excision of Ung-generated abasic sites results in single-stranded breaks, which either directly form DSBs or are converted to DSBs in an Msh2-, Msh6-, and Exo I-dependent fashion. DSB resolution by C-NHEJ or A-EJ leads to formation of S–S junctions and CSR

space between the two cells and bind to their receptors on B cells. In addition to enhancing *Aicda* expression, as induced by primary stimuli, "secondary" CSR-inducing stimuli, i.e., cytokines (IL-4, TGF-β in humans, and IL-4, TGF-β, and IFN-γ in mice), direct CSR. "Primary" stimuli induce AID expression through activation of both the canonical and noncanonical NF-κB pathways. CD154 is expressed on the surface of activated T cells and engages its receptor CD40, which is constitutively expressed on the surface of B cells. CD40 is a member of the tumor necrosis factor receptor (TNF-R) superfamily, which includes other receptors such as B cell-activating factor receptor (BAFF-R) and BCMA (B cell maturation). Signals from activated TNF-Rs are first relayed to TNF-R-associated factors (TRAFs), which then cooperate with IκB kinases (IKKs) to activate the canonical NF-κB (e.g., TRAF6) or the noncanonical NF-κB (e.g., TRAF2/3 complex) pathway. Activated NF-κB heterodimers (canonical, p65/p50; noncanonical, p52/RelB) then translocate to the nucleus, where they synergize with HoxC4 and SP1/SP3 transcription factors to activate the *Aicda* promoter. Additional transcription factors, such as Stat6, C/EBP, Smad3/4, Myb, Pax5, E2A, E2f, and BATF, bind to other *Aicda* regulatory regions and can also play a role in regulation of *Aicda* gene expression.

"Secondary" stimuli induce germline (I_H–S–C_H) transcription through the S regions that are to undergo recombination, thereby specifying isotype selection. IL-4, which characterization of T helper type 2 (Th2) responses, directs B cells to switch to IgG1 and IgE, whose effector functions are tailored for the targeting and elimination of extracellular microbial pathogens and parasites. In the mouse, cytokines such as IFN-γ are secreted during T helper type 1 (Th1) responses, in which they stimulate the production of IgG2a, whose effector functions are suited for targeting and elimination of intracellular pathogens. TGF-β is abundant in mucosal tissues where it critically contributes to the induction of IgA. IgA antibodies control commensal microorganisms and pathogens in the intestine and the upper and lower respiratory tract. TNF-Rs BAFF-R, TACI, and BCMA are widely expressed on B cell surface where they are engaged by their ligands BAFF and APRIL. BAFF and APRIL were initially characterized as secreted TNF-R ligands that stimulate immature B cell proliferation to maintain homeostasis of peripheral B cells. They synergize with ligands of TLRs and BCR to induce enhanced *Aicda* expression and CSR.

Regulation of AID Expression and Activity

As a potent mutator, AID is under stringent transcriptional, posttranscriptional, and posttranslational regulation (Zan and Casali 2013). AID is also regulated in its targeting and enzymatic function. Transcription factors, such as HoxC4 and NF-κB, which are upregulated in a B cell lineage- and/or differentiation stage-specific manner, regulate the induction of AID (Park et al. 2009). HoxC4 acts in synergy with Oct1/Oct2 to induce AID expression by directly binding to the AID gene promoter through an evolutionarily conserved 5′-ATTTGAAT-3′ motif. HoxC4 is induced by the same stimuli that induce AID and CSR (Fig. 3). It is further upregulated by estrogen through three estrogen response elements (EREs) in its promoter region (Mai et al. 2010). *Aicda* transcription is also regulated by four major evolutionarily conserved regions in the AID gene locus through selected *cis*-regulating elements, many of which are binding sites of transcription factors that are activated by IL-4 and TGF-β. For example, signal transducer and activator of transcription 6 (Stat6), which is activated by IL-4, binds Region I located upstream of the promoter, and both Stat6 and TGF-β-activated Smad3 and Smad4 bind Region IV located 9 Kb upstream of the *Aicda* promoter. In addition, paired box protein 5 (Pax5) and E2A proteins bind Region II within the first intron, and the AP1 family transcription factor BATF binds Region III located 17 Kb downstream of the promoter. These transcription factors likely interplay with NF-κB, HoxC4, and Sp1/Sp3 at the promoter and enhancer elements, probably through long-range DNA interactions,



Immunoglobulin Somatic Hypermutation and Class-Switch DNA Recombination, Fig. 3 HoxC4 mediates estrogen-potentiated AID induction in antibody and autoantibody responses. T-dependent CSR-inducing stimuli (CD154) and T-independent CSR-inducing stimuli (namely, dual TLR–BCR, TACI–BCR, or TLR–TACI engagement) and cytokines induce HoxC4, mainly through activation of NF-κB. This induction is further enhanced by estrogen through binding of ERs to three evolutionarily conserved and cooperative EREs in the *HoxC4* promoter. By binding to a conserved HoxC4/Oct-binding site in the *Aicda* promoter, HoxC4 induces AID expression. In this function, HoxC4 acts in concert with transcription factors Oct1/Oct2 as well as Sp1/Sp3/NF-κB. The tissue and differentiation stage specificity of HoxC4 expression contributes to the tight regulation of AID expression. Estrogen enhances TLR- or CD154-mediated HoxC4 expression to induce SHM and CSR, and therefore, antibody and autoantibody responses. After transcription, the *Aicda* mRNA can be negatively regulated by microRNAs, including miR-155, miR-181b, miR-93, and miR-361, which bind to the conserved target sites on the 3′ UTR of *Aicda* mRNA

to induce or sustain *Aicda* expression by primary CSR-inducing stimuli and cytokines.

After transcription, the *Aicda* mRNA can be negatively regulated by microRNAs. A range of miRNAs are involved the regulation of immunity (Belver et al. 2011), including SHM and CSR. microRNAs are a family of single-strand, short (~22 nucleotides) noncoding RNAs that regulate gene expression in a sequence-specific manner. They bind to complementary sequences in the 3′-untranslational region (UTR) of target mRNAs, resulting in gene silencing by

translational repression or target mRNA degradation. microRNAs are abundantly present in all human cells, in which they modulate the expression of a few to hundreds of target genes each. miR-155, miR-181b, mir-361, and miR-93 regulate AID levels by binding to the evolutionarily conserved target sites in the 3′ UTR of *Aicda* mRNA, thereby reducing both *Aicda* mRNA and AID protein levels (Zan and Casali 2013; Li et al. 2013).

AID undergoes a series of posttranslational modifications, such as dimerization/oligomerization, nuclear/cytoplasmic translocation, phosphorylation, and polyubiquitination, all of which are important for AID activity. AID exists in both the nucleus and the cytoplasm of B cells (Zan and Casali 2013). It has been shown to undergo constant nucleocytoplasmic shuttling with a balance toward export to the cytoplasm. Although the molecular mechanism that governs the balance of AID nuclear import/export is unclear, it is conceivable that such a molecular mechanism provides B cells with two important functional features to (i) hamper the highly active and mutagenic AID from accessing DNA, thereby preventing indiscriminate dC deamination, DNA damage, and/or insertion of deleterious mutations, and (ii) generate a cytoplasmic AID reservoir, in which AID could be assembled with either SHM or CSR cofactors into a protein complex that, upon delivery of appropriate stimuli, can be promptly translocated into the nucleus and preferentially targeted to the *Ig* locus. The function of AID is likely also to be regulated in order to attain a balance between immunity and genomic instability, which would predispose to neoplastic transformation. The activity of AID is regulated by phosphorylation. Single-stranded DNA-binding protein RPA associates with phosphorylated AID from activated B cells and enhances AID activity on transcribed dsDNA containing SHM or CSR target sequences. RPA promotes the deamination of transcribed substrates by AID by stabilizing AID interaction with single-stranded DNA, which suggests that the role of RPA in SHM and CSR is to provide access of AID to target DNA. Further, the AID enzymatic activity, and therefore, CSR/SHM, can be inhibited by Fe^{2+}, which could displace Zn^{2+} in AID enzyme catalytic site by virtue of the similar chemical coordination properties of these two metal ions.

Targeting of the SHM and CSR Machinery

The targeting of critical SHM and CSR factors, especially, AID, is tightly controlled. As AID can introduce mutations in DNA, DSBs, and chromosomal translocations, it is tightly regulated not only in the expression and activity but also in its targeting. The specific targeting of the CSR machinery to the S regions that will undergo recombination relies on several factors (Xu et al. 2012). S regions contain a high frequency of 5′-AGCT-3′ repeats, accounting for more than 45 % of Sμ core DNA while for only about 1.3 % of DNA in the genome at large, including C_H regions. 5′-AGCT-3′ repeats are not only the preferred substrates for AID, they are also the specific targets of 14-3-3 adaptor proteins, which selectively target S region DNA and recruit AID, and possibly, other CSR factors, to mediate CSR (Xu et al. 2010). Because of the high density of 5′-AGCT-3′ repeats in all S regions, the inherent targeting of 5′-AGCT-3′ repeats by 14-3-3 adaptors alone cannot ensure the selective targeting by the CSR machinery of the upstream and downstream S regions that will undergo recombination, and not to the other S regions.

The S regions that are involved in CSR undergo high levels of transcription, indicating that they adopt an open chromatin state that allows for the recruitment of CSR factors (Stavnezer 2011). Single-stranded regions of DNA can be transiently exposed on the surface of RNA polymerase during transcription. The transcription-based mechanisms were also thought to provide AID with a single-strand DNA substrate, which is a preferential target of AID in vitro, in the context of a duplex substrate via looping out of the non-template strand. However, AID equally deaminates both substrate DNA strands during SHM and CSR.

The mechanism by which AID accesses the template DNA strand has been a major puzzle. Core RNA exosome complex has been shown to promote AID deamination of both template and non-template strands of in vitro transcribed SHM substrates. Integrity of the RNA exosome complex is required for optimal CSR. In B cells undergoing CSR, the RNA exosome complex associates with AID and accumulates on S regions in an AID-dependent manner, further suggesting that the RNA exosome plays an important role in targeting AID activity to both template and non-template strands of transcribed SHM/CSR targets. The recruitment, stabilization, and enzymatic function of AID require additional interactions, which involve the non-catalytic domains of these enzymes, nonenzymatic adaptors, such as 14-3-3 proteins, and selected histone modifications that are induced in the S region targets of CSR. In addition, CSR is impaired in B cells deficient in AID-binding proteins that also function in transcription or RNA processing. These proteins include Spt5 (AID binding to RNA polymerase II on transcribed S region DNA is likely mediated by Spt5) and Spt6, which regulate transcription; PTBP2, which regulates RNA splicing; RNA exosomes, which degrade RNA; the transcription-associated chromatin modifier; the facilitates chromatin transcription (FACT) complex components SSRP1 and Spt16; and RNA polymerase-associated factor (PAF) complex, which are involved in RNA processing, chromatin remodeling, exosome processing, and RNA pol II transcription elongation/pausing.

Targeting of the SHM and CSR machinery, including AID, also entails selected epigenetic modifications of the *Ig* locus, including the trimethylation of histone H3 lysine 4 (H3K4me3) and the combined acetylation of lysine 9 and phosphorylation of serine 10 in histone H3 (H3K9acS10ph) at the *IgH* locus, mainly in the S regions that are to undergo recombination (Li et al. 2013). These histone modifications not only reflect the open chromatin state of S regions that allows access of AID and other CSR factors but also provide additional specificity for DNA targeting by the CSR machinery. Indeed, H3K9acS10ph constitutes a specific chromatin target of 14-3-3 adaptors and plays a role in the recruitment/stabilization of 14-3-3 to S regions, and therefore, contributes to targeting of AID. SHM can occur only in VκJκ regions that exhibit DNA hypomethylation, suggesting that this epigenetic modification is critical for AID targeting in SHM. Indeed, methylated-CpG motifs have been found to be poor substrates for AID (Li et al. 2013). Further, the recruitment of AID to V(D)J regions can be facilitated by the germinal center-associated nuclear protein (GANP), which mediates histone modification and interacts with transcription elongation factors at V(D)J regions during SHM. One unique signature of hypermutating variable region is mammalian sterile kinase 1 (MST1)-mediated phosphorylation of histone H2B on serine 14 (H2BS14ph). In mammalian cells, phosphorylation of histone H2B is induced at late time points from DNA damage and accumulates in repair foci. It is likely that H2BSer14P plays a role in the recruitment or stabilization of components of the error-prone repair factors that resolve AID-dependent lesions. In addition, it has been shown in human cells that histone mark H3K36me3 is required to recruit the mismatch recognition protein MSH2/MSH6 onto chromatin through direct interactions with the MSH6 PWWP domain. It is possible that combinatorial signals generated through multiple histone modifications together with DNA demethylation orchestrate the execution of locus-specific mutagenesis.

Aberrant SHM and CSR and Diseases

Dysregulation of the SHM and CSR machineries is associated with variety of diseases (Zan and Casali 2013). The levels of CSR and SHM are critical in balancing efficient immunity with an autoimmune state. Lack of CD40, CD154, AID, or Ung results in hyper-IgM (HIGM) syndrome, a primary immune deficiency, in which CSR is reduced and SHM is reduced or altered, and therefore, loses the ability to make high-affinity IgG and IgA antibodies to combat bacterial

and viral infections. Deficiency of specific Ig isotype(s) is associated with some other primary immune deficiencies, such as "IgG subclass deficiency," "selective IgA deficiency," and "selective IgE deficiency." Aberrant CSR and/or SHM results in systemic or organ-specific autoimmunity, allergy, and asthma associated with atopic IgE, to neoplastic transformation.

Systemic lupus is an autoimmune disease characterized by the production of an array of pathogenic autoantibodies, including high-affinity anti-dsDNA IgG antibodies that are mutated and class switched, mainly to IgG, indicating that SHM and CSR are important in their generation. In addition, autoantibodies in which somatic mutations have been reverted to germline V regions showed low or no autoreactivity, further suggesting that anti-dsDNA autoantibodies develop from B cells reactive with self-antigen with low avidity or non-autoreactive B cells by SHM. In systemic lupus, the production of class-switched and hypermutated autoantibodies is associated with dysregulated AID expression, CSR, and SHM (Zan and Casali 2013).

Although the Ig loci constitute the major physiological targets of AID-mediated DNA deamination, yet other non-Ig locus DNA can also be targeted by AID, albeit at a much lower efficiency, especially under conditions of AID overexpression (Di Noia and Neuberger 2007), (Liu and Schatz 2009). A hallmark of mature B cell lymphomas is reciprocal chromosomal translocations involving the Ig locus and a proto-oncogene, which usually results in deregulated, constitutive expression of the translocated gene. In addition to such translocations, proto-oncogenes are frequently hypermutated in germinal center-derived B cell lymphomas. These chromosomal translocations and oncogene mutations play a critical role in the pathogenesis of most B cell lymphomas and are likely caused by aberrant, mis-targeted SHM and/or CSR (Klein and Dalla-Favera 2008). The tumorigenic ability AID was revealed in studies in AID transgenic mice. In addition, experiments with AID-deficient mice clearly showed that AID is required not only for the *c-myc*/*IgH* translocation but also for the malignant progression of translocation-bearing lymphoma precursor cells, probably by introducing additional genetic hits (Robbiani and Nussenzweig 2013). Normally, AID expression is only transiently and specifically induced in activated B cells in GCs. However, recent studies indicate that AID can be induced directly in B cells outside the GCs by various pathogens, including transforming viruses associated with human malignancies. Indeed, AID expression is not restricted to germinal center-derived B cell lymphomas but is also found in other types of B cell lymphoma and even in nonlymphoid tumors, suggesting that ectopically expressed AID is involved in tumorigenesis and disease progression in a wide variety of cell types.

Background, Definition, and Categorization of Alopecia

Hair loss can be divided into various categories (Baden 1987). Clinically, it is often divided into scarring and non-scarring forms of alopecia. It can also be divided by etiology, such as structural, genetic, nutritional deficiency, endocrine, and autoimmune. There is inexact overlap between these two approaches to categorization. For example, many, but not all, autoimmune forms of alopecia are also scarring. This entry focuses on autoimmune skin diseases that also cause hair loss. This includes alopecia from lichen planopilaris (LPP) a form of lichen planus, bullous diseases, discoid lupus erythematosus (DLE), and other forms of hair loss from connective tissue diseases like dermatomyositis, lupus, and scleroderma.

Structure and Function of the Hair Unit

In order to understand alopecia or hair follicle dysfunction, it is important to have a good understanding of the normal structure and function of hair follicles. Although derived from a single layer of multipotent embryonic ectoderm, the hair follicle is a complex, self-renewing structure (Dawber 1988; Muller et al. 1991). The hair follicles begin to form between embryonic days 75 and 80. Formation begins with dermal-epidermal signaling, initiating the formation of focal aggregates of basal epidermal cells, termed placodes or anlages. These first appear on the scalp and progress caudally. The placodes induce the underlying dermis to form primitive dermal papilla before extending down into the dermis itself to form, in combination with the early dermal papilla the bulbous peg hair. At this stage, the hair has two bulges. A superficial one which goes on to become the sebaceous gland and apparatus, and a deeper one which provides the insertion point for the erector pili muscle and the site for a persistent bulge wherein the hair follicle's stem cells are preserved. These points help define different regions of the hair. The infundibulum, superficial to the sebaceous gland, retains the structure of epidermis and keratinizes. Between the sebaceous gland and erector pili muscle lies the isthmus. In this region, there is no granular layer and keratinization does not occur. Below this is the stem or suprabulbar region, followed by the hair bulb or dermal papilla.

In the second trimester, hair follicles differentiate to form the seven concentric layers they will eventually recapitulate throughout their lifetime. From inside to out, these comprise: medulla, cortex, hair shaft cuticle, inner root sheath (Huxley's and Henley's layers and inner root sheath cuticle), and outer root sheath. The hair unit is completely formed at about 19–21-week gestation. At 24–28 weeks, the hairs leave anagen, the period of active growth, and enter catagen a phase of degeneration with resorption of the lower portion of the hair follicle and arrest of matrix cell division. While the epithelial cells at the base of the follicle undergo apoptosis, the dermal papilla itself remains intact and migrates upward, resting next to the follicular bulge. This new phase lasts days to weeks before transition to telogen, the hairs resting phase. Postnatally, the hairs continue to cycle through these phases, but asynchronously with about 80–90 % of hairs in anagen, 2 % in catagen, and 10 % in telogen at any one time. Anagen normally lasts about 7 years, catagen days to weeks, and telogen 3 months.

Immune Privilege and Inflammation of the Hair Follicle

Although perifollicular inflammation can occur in a variety of conditions, the end result can vary from no effect on the hair follicle, to a non-scarring alopecia, to a scarring alopecia (Harries et al. 2009). The difference between the latter two end-points seems to lie in the location of the inflammation with non-scarring alopecias such as alopecia areata having the majority of the inflammation around the bulb or stem of the hair follicle, the sections which normally apoptose or migrate, but subsequently regenerate (Alkhalifah et al. 2010). In contrast, scarring alopecias, like discoid lupus erythematosus (DLE) or lichen planopilaris (LPP), have predominant inflammation around the more superficial, permanent sections of hair wherein lie the stem cells and ostia (Al-Refu and Goodfield 2009). Destruction of the stem cells and fibrosis of the hair tract opening prevent hair follicle regeneration. However, given that certain non-scarring alopecias such as androgenetic alopecia and some non-alopecia inducing dermatitis also attract inflammatory cells to the isthmus, this cannot fully explain the different clinical outcomes.

One theory is that under normal circumstances, the stem cells are protected from immune damage, but in scarring alopecias, they lose their immune privilege. Indeed, studies support that both the anagen hair bulb (Christoph et al. 2000) and the bulge region (Meyer et al. 2008) of human hair follicles are immune privileged tissue. CD200 signaling is one potential means by which immune tolerance or loss of tolerance may be affected. CD200 is a type 1 transmembrane glycoprotein,

signaling of which via the CD200 receptor reduces inflammation and promotes tolerance (Rosenblum et al. 2006). In vitro experiments also show that antigen-presenting cell activity is downregulated by CD200 receptor activation, and CD200+ dendritic cells can inhibit activated T-cells from secreting pro-inflammatory cytokines (Barclay et al. 2002).

While this has not been proven as a mechanism in autoimmune skin disorders, the potential for it as a factor is supported by studies with CD200 knockout mice (Rosenblum et al. 2004). In these studies, skin from CD200-deficient (CD200−/−) mice grafted onto wild-type hosts (CD200+/+) developed inflammation, hair loss, and follicular scarring. In addition, the histopathology showed a peri- and intra-follicular mononuclear inflammatory cell infiltrate. This is likely highly pertinent to hair-pathology as in the bulge region of the hair follicle, CD200 transcripts are significantly upregulated (Ohyama 2007; Tumbar et al. 2004).

In addition to altered CD200 expression, immune suppression is evidenced by low-level MHC class I and ß2-microglobulin expression, as well as increased levels of immunosuppressants such as α-melanocyte-stimulating hormone, transforming growth factor-β1, indoleamine-2,3-dioxygenase, and macrophage migration inhibitory factor. In addition, gene expression profiling studies show upregulation of TGFβ2 mRNA and downregulation of INF-γ receptor expression and β2-microglobulin in bulge inflammation (Morris et al. 2004; Ohyama 2007; Tumbar et al. 2004). How this immune privilege is overcome in part appears to depend on the particular disease entity.

Connective Tissue Diseases: Alopecia of Discoid Lupus

The most well-recognized form of hair loss in connective tissue diseases is that of discoid (DLE) or chronic cutaneous lupus erythematosus (CCLE) which can occur in isolated DLE or as a manifestation of SLE. Scalp involvement occurs in 60 % of these patients, with up to 34 % of these patients experiencing permanent alopecia from inflammatory follicular destruction (Annessi et al. 1999; Fabbri et al. 2004; Trueb 2010; Wilson et al. 1992). DLE lesions are characterized by scaling, erythematous to violaceous papules with variable atrophy, follicular plugging, and telangiectasias and, in advanced lesions, scarring demonstrated by loss of follicular ostia (Fitzpatrick and Wolff 2008).

On histology, DLE lesions shows a superficial and deep, perivascular and periadnexal lymphocytic infiltrate with inflammation-induced interface vacuolar changes, and occasional apoptotic keratinocytes, at the dermal-epidermal junction of the hair follicles and interfollicular epidermis (McKee et al. 2005). Eosinophilic basement membrane zone thickening can be highlighted using special stains (e.g., periodic acid-Schiff [PAS]) and increased dermal mucin is usually present. Laminated keratin plugging of dilated follicular ostia may also be seen, as well as pigmentary incontinence with melanophages in the papillary dermis of older lesions. If performed, direct immunofluorescence studies will show, in 75 % of cases, dense granular deposition of immunoglobulin (most commonly IgG, but IgM and IgA may also be present) and complement factor C3 at the dermal-epidermal junction (Trueb 2010).

Apoptosis in DLE may in part be mediated via binding of the cell surface receptor, Fas (CD95) to its ligand, FasL (CD95L). In DLE, FasL is expressed on infiltrating macrophages and T-cells with a greater concentration of FasL+ macrophages around the hair follicle. Fas itself is upregulated on epidermal keratinocytes, leading to rapid keratinocyte apoptosis (McNally et al. 1997; Nagafuchi et al. 2002; Nakajima et al. 1997). An alternative apoptotic mechanism is via the p53 pathway. p53 allows cell cycle arrest for DNA repair or, when DNA damage is too extensive, can induce cellular apoptosis and is aberrantly expressed in lupus and dermatomyositis (Miret et al. 2003; Pablos et al. 1999) and Bcl-1, which can block cellular apoptosis, is downregulated in the epidermis of DLE lesions. In addition, mice lacking the p53 effector gene Gadd45a develop a lupus-like syndrome (Salvador et al. 2002).

Evidence of this damage to the bulge region, wherein lie the stem cells, is provided by keratin-15

(Al-Refu and Goodfield 2009). Normally, Keratin-15 immunostaining shows upregulation in the bulge region of the outer root sheath (ORS). However, it is reduced in the bulge region of DLE lesions. This may reflect either the irreversible apoptotic damage noted above or that these cells have been induced to differentiate potentially losing their stem cell potential.

As noted above, there is often a significant upregulation of mucin or dermal glycosaminoglycans in DLE lesions. It has been shown that such glycosaminoglycans themselves also possess hair growth- inhibitory properties (Paus 1991).

Connective Tissue Diseases: Other Forms of Alopecia

Although DLE-like lesions may be the most widely recognized and, given its scarring nature, potentially the most serious form of SLE-associated alopecia, it is not the most common form of hair loss in systemic lupus patients. Indeed, in one study, it was reported that of 122 lupus patients, 104 (85.2 %) experienced some form of hair loss, with the most common being a diffuse non-scarring alopecia that occurred in 65.1 % of patients (Yun et al. 2007). This latter, diffuse form of hair loss also occurs in other connective tissue diseases, such as scleroderma and dermatomyositis. The pathogenesis of this form of hair loss is poorly understood. In part, it is likely due to a chronic telogen effluvium, the persistence of which ebbs and flows with the flares in the underlying connective tissue disease, but just as in other forms of telogen effluvium, may lag by up to 3–6 months in its clinical manifestation, making diagnosis and association problematic.

Another clinically recognizable entity is the presence of "lupus hairs" which consist of diminution of the hairs at the peripheral hairline. Most notably cosmetically this results in the appearance of a step back of the anterior hairline. It has been hypothesized that this results from an interruption of the normal hair growth cycle from the induction of a negative nitrogen balance (Trueb 2010). As a result, the hairs become fragile and easily fragment above the skin surface. In its most extreme form, patients experience a dystrophic anagen effluvium. In this situation, severe flares of the underlying illness can result in a temporary shutdown of hair production at the dermal papillae. As in chemotherapy or analogous to Beau's lines in the fingernail, this produces a stricture in the hair shaft (Pohl–Pinkus constriction) that can fracture either intra- or extra-follicularly.

There is also reported a patchy alopecia of SLE which occurs in up to 15 % of patients. This clinical entity is very poorly circumscribed, and it remains debatable whether it really exists, or if it may mimic other forms of alopecia and be somewhat overdiagnosed. In some studies, it is described as a mild erythema but without scarring, leading to the possibility that these are merely mild manifestations of DLE. In other studies, it is reported that almost all of the remaining hairs with such patches are telogen hairs, or dystrophic anagen hairs. Finally, some studies report that on histopathology, a peribulbar infiltrate of lymphoid cells is found surrounding miniaturized anagen hair bulbs and fibrous streamers below telogen hairs. This raises the question as to whether in these cases, this is an incipient form of alopecia areata, a separate autoimmune disease of the hair follicle which can be associated with lupus (Werth et al. 1992).

As in DLE, SLE and other connective tissue diseases also have an upregulation of dermal mucin which has itself anti-proliferative effects on the hair follicle. In the most extreme case of upregulated mucin, this can go beyond mere cytokine signaling and actual invasion of the hair follicle with follicular mucinosis occurring, leading to a scarring destruction of the hair follicle.

Finally, in many patients, the medications used to treat their lupus, such as plaquenil or methotrexate, can themselves exacerbate hair loss problems and should be carefully reviewed in any patient experiencing this problem. A simple test is to reduce the dose of the medication in question. If the hair loss is lupus related, the lupus will worsen and the hair loss increase on the lower dosage. In patients with hair loss from the medication however, provided the lupus itself remains well controlled, the hair loss in these cases will diminish.

Lichen Planopilaris

Lichen planopilaris (LPP) is histologically the follicular form of the inflammatory skin disorder lichen planus (Assouly and Reygagne 2009). They may occur together or separately. Although rare, LPP is the most frequent cause of adult primary scarring alopecia. The disorder is believed to be autoimmune in etiology, in part because of characteristic immunohistology, although no specific serologic markers are known. As with many autoimmune disorders, LPP is more common in women. The typical age of onset is between 40 and 60 years.

Despite a histopathological similarity, clinically LP and LPP are quite distinct and the purple, polygonal flat topped papules of LP are not observed. Instead, in the affected areas, there is perifollicular erythema, acuminate keratotic plugs, and on occasion bigeminate hairs. In these early stages, patients complain of itching, pain, or burning of the scalp. In contrast to DLE lesions, there is no dischromy, telangiectasia, or scale. LPP is usually subdivided into three variants: classic LPP, frontal fibrosing alopecia (FFA), which presents as a progressive symmetric band-like alopecia around the anterior and lateral hairlines, including on occasion the retroauricular areas, and Lassueur Graham-Little Piccardi syndrome, which consists of scarring patchy alopecia of the scalp, noncicatricial axillary and pubic hair loss, and a lichenoid follicular eruption. Some authors add a fourth category, namely, fibrosing alopecia in a pattern distribution (FAPD), which in most instances is clinically similar to the pattern of androgenetic alopecia, but on histopathology, fibrosis is seen.

On histology, LP is characterized by a lichenoid interface inflammation with hypergranulosis, hyperkeratosis, hyperacanthosis, degeneration of basal keratinocytes, and occasional destruction of the basal layer (McKee et al. 2005). Colloid bodies, degenerated keratinocytes that stain deeply eosinophilic, are often seen in the basal layer. In early LPP, these same changes occur around hair follicles most prominently between the infundibulum and the isthmus, with sparing of the stem and dermal papilla. In late-stage lesions, inflammation is minimal and the hair follicles are replaced with fibrous tracts. In 40 % of cases, the DIF can show positive staining for IgM, or less commonly IgA or C3, with a linear band of fibrin or fibrinogen at the dermo-epidermal junction.

While there is debate regarding the mechanism by which LPP causes hair follicle destruction, as in DLE, it is observed that in LPP, keratin-15 is reduced in the bulge region of affected follicles, suggesting that targeting of the bulge region is important (Mobini et al. 2005), and involves either destruction or forced differentiation of the stem cells therein. In addition, bulge cells in LPP-affected follicles show reduced proliferation rates when compared with bulge cells from un-involved follicles.

However, it has also been demonstrated that LPP follicles also exhibit a downregulation of the gene, PPAR-γ. This results in accumulation of lipids within the follicle and abnormal sebum production. This may be relevant as production of a PPAR-γ knockout mouse was shown to recapitulate the lymphocytic, cicatricial LPP phenotype, thus suggesting an alternative pathogenesis and treatment target (Billoni et al. 2000; Karnik et al. 2009).

Bullous Diseases

As noted above, the infundibular portion of the hair follicle is continuous with, and biochemically similar to, the interfollicular epidermis. This includes the basement membrane zone with expression of plectin, 180-kD bullous pemphigoid antigen (BP180), 230-kD bullous pemphigoid antigen (PB230), a6b4 integrin, laminin-311, laminin-332, and type 4 and type 7 collagen. There is also some expression of these factors into the isthmus, where the stem cell bulge exists. All of these are potential targets of autoimmune attack and in the skin produce characteristic bullous diseases (McKee et al. 2005; Miteva et al. 2011; Rosenblum et al. 2004). For example, anti-desmoglein-3 antibodies produce pemphigus vulgaris with blistering of the skin and mucosal surfaces. Given the presence and importance of these proteins in the hair unit, it would be reasonable to expect a similar

end-stage scarring alopecia in these conditions as is found in the foregoing conditions.

However, despite the observation that scalp involvement is common in such bullous diseases as pemphigus vulgaris (PV) and pemphigus foliaceus (PF), in humans, hair loss is rarely reported. A variety of explanations for this are possible. For one the distribution of the proteins may make attack of the stem cell bulge less likely. For example, although in the infundibulum, as in the interfollicular epidermis, desmoglein-3 is present predominantly in the basal cells, it is reduced in the isthmus where the stem cells occur. Alternatively, it may be that the immune privilege collapse of other conditions does not occur in these conditions in humans. Further studies, especially in comparison to animal models such as dogs, cats, goats, and horses, where alopecia does result from these same bullous diseases, are important, to elucidate these differences.

Synonyms

Immunosuppressive therapy; Liver failure; Solid organ transplantation

Definitions

Liver transplantation is an established therapy for people with acute or chronic liver failure. In addition, patients with unresectable hepatocellular carcinoma may require liver transplantation. As the new liver is recognized and rejected by the immune system as foreign, patients need to be treated with agents hampering the immune system.

Introduction

Liver transplantation is the last therapeutic option for patients with acute liver failure or end-stage hepatic disease. Although 1-year graft survival is excellent and currently exceeds 85 %, side effects of the immunosuppressive treatment and recurrence of the underlying liver disease (hepatocellular carcinoma, autoimmune hepatitis, hepatitis C virus infection, etc.) remain major issues in liver transplantation. With approximately 80 % of liver transplant recipients treated, calcineurin inhibitors (CNI) remain the cornerstone of immunosuppression. However, CNI are nephrotoxic and have been suggested to be pro-cancerous and therefore should be avoided in patients with renal impairment or hepatocellular carcinoma. Steroids are often used in addition to CNI but have severe metabolic side effects when used long term. In addition, patients infected with hepatitis C virus (HCV) rapidly progress to cirrhosis within a few years after transplantation, in particular when treated with steroids. Hence, immunosuppressive treatment needs to be adjusted to patients' conditions and underlying diseases. In contrast to the surgical procedures, which are highly standardized, the variety of immunosuppressive agents and possible drug combinations have resulted in center-specific protocols. Current strategies are trying to choose the most suitable, well-tolerated combination of drugs for each patient.

Historical Background

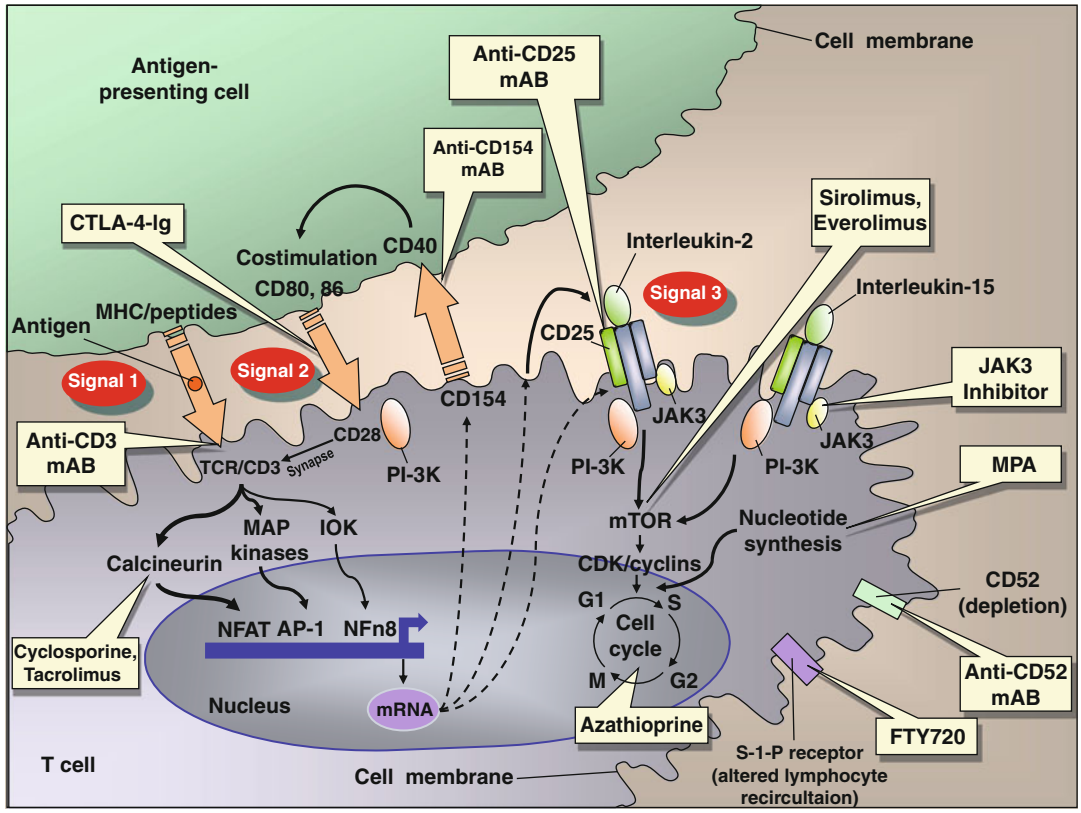
Besides surgical issues, a major hurdle in the beginning of solid organ transplantation was acute rejection of the transplanted organ by the

host immune system. For a long time, whole body irradiation was the only available method to induce immunosuppression. In the 1960s, the first pharmaceutical breakthrough was achieved with the antimetabolite of purine synthesis 6-mercaptopurine and later its less toxic derivate azathioprine (Aza) and glucocorticosteroids (GS). In 1963, Starzl and Murray could show an extension of patient and graft survival using this combination in the kidney transplant setting. After the introduction of antilymphocyte sera (ALS), which had shown immunosuppressive effects in canine models of kidney and liver transplantation, Starzl reported in 1968 the survival of a 1½-year-old girl for more than 13 months following allogeneic liver transplantation using Aza, GS, and ALS. Following this achievement, liver transplant programs were established in several centers around the world, but 1-year survival remained poor ranging from 30 % to 35 %. In 1976, Borel described the immunosuppressive effects of cyclosporin A (CsA), which revolutionized the field of immunosuppressive treatment. Sir Roy Calne reported in 1979 his encouraging results obtained with CsA in renal and liver transplant recipients, which led to the approval of liver transplantation for the treatment of end-stage liver disease in 1983 by a consensus meeting at the National Institutes of Health. In 1994, tacrolimus (Tac), another calcineurin inhibitor, was approved by the FDA for liver transplant recipients. In the early 1990s, Sollinger introduced mycophenolate acid (MPA), a cell cycle inhibitor, in renal transplant recipients, which was subsequently used instead of Aza and later even as monotherapy. In 1999, sirolimus, an mTOR inhibitor, was approved for renal transplant recipients by the US *Food and Drug Administration* (FDA) and raised great interest as besides its immunosuppressive function, sirolimus showed anticancerous and antifibrotic effects. Since then, several new agents have been used in liver transplant recipients, e.g., the IL-2 receptor-blocking antibody basiliximab. However, neither sirolimus nor basiliximab have been approved for treating liver transplant recipients yet.

Immunosuppressive Agents

Often, a combination of different immunosuppressive agents is used in recipients of solid organ transplantation. Figure 1 (adopted from (Post et al. 2005)) shows the molecular mechanism of some of the most often used drugs in liver transplantation, which are described in detail below.

Glucocorticosteroids (*GC*) are used since the beginning of solid organ transplantation and remain an important part of immunosuppression in liver transplant recipients. GC are hormones synthesized from cholesterol in the adrenal glands, and GC have been shown to induce apoptosis of immature T cells and stimulate T cells to home to lymphoid tissue. GC also suppress both B-cell clone expansion and antibody production, and they have an effect on dendritic cells (DC), where they are thought to induce a tolerogenic phenotype. In addition, GC downregulate the expression of Fc receptors on macrophages, thereby reducing their capacity to phagocytose opsonized cells. On a molecular level, GC bind to the intracellular cytosolic glucocorticoid receptor, which can induce three different actions all of which are thought to contribute to the anti-inflammatory action of GC. Upon activation, the glucocorticoid receptor can translocate to the nucleus, where it either induces the transcription of noninflammatory proteins or inhibits the transcription factors lAP-1 and NF-kB, which are important for the transcription of proinflammatory cytokines like interleukin (IL)-1, IL-2, IL-6, and interferon-gamma (IFN-γ). In addition to these two genomic effects, GC can block T-cell activation by interfering with a T-cell receptor signaling complex formed by the glucocorticoid receptor, *Heat Shock Protein 90* (HSP90), *lymphocyte-specific protein kinase* (LCK), and the tyrosine kinase FYN. GC also induce lipocortin-1 synthesis, which binds to the cell membrane and prevents phospholipase A2 from coming into contact with arachidonic acid leading to less eicosanoids. Lipocortin-1 also binds to leukocyte membrane receptors and inhibits epithelial adhesion,



Immunosuppression in Clinical Liver Transplantation, Fig. 1 Molecular mechanism of immunosuppressive agents used in liver transplantation (Adopted from Post et al. 2005)

emigration, chemotaxis, phagocytosis, respiratory burst, and the release of cytokines, chemokines, and lysosomal enzymes from neutrophils and macrophages. GS have several side effects which include hyperglycemia, insulin resistance, diabetes mellitus, osteoporosis, cataract, and hypertension.

Calcineurin inhibitors (*CNI*) revolutionized solid organ transplantation and increased the 1-year survival rates of liver transplant recipients to 85 %. Two different CNI are currently used: *cyclosporin A* (CsA) that binds to cyclophilin and *tacrolimus* (Tac), which binds to *FK-binding protein 12* (FKB12), both leading to inhibition of calcineurin, a calcium-/calmodulin-dependent serine/threonine phosphatase. Although Tac inhibits calcineurin 100-fold more potent than CsA, the same appears to be true for their side effects.

Calcineurin dephosphorylates *nuclear factor of activated T cells* (NF-AT), a lymphocyte-specific cytoplasmatic-based transcription factor, which translocates to the nucleus and binds to the promoter regions of cytokines including IL-2, IL-3, IL-4, granulocyte-macrophage colony-stimulating factor, IFN-γ, and tumor necrosis factor alpha (TNF-α). Therefore, CNI primarily target the activation and proliferation of naïve T cells and the function of effector T cells. A major side effect of CNI is renal toxicity leading to severe tubular atrophy, interstitial fibrosis, and focal hyalinosis of small arteries and arterioles. Nephrotoxicity has been linked to the inhibition of calcineurin, but animal data suggests that the inhibition of cyclophilin A may be responsible for nephrotoxicity of CNI. There is no difference in the nephrotoxicity of Tac or CsA.

Cyclosporin A (*CsA*) is a cyclic polypeptide comprised of 11 amino acids which was discovered as a product by the soil fungus Tolypocladium inflatum in 1972. CsA was

initially released as Sandimmune® (Novartis) and required emulsification prior to intake due to poor solubility in water. However, this formulation was associated with high variations in bioavailability ranging from 1 % to 89 % with a mean of 30 %. Consequently, a newer formulation, Neoral® (Novartis), using microemulsion preconcentrates with a drug in a lipophilic solvent, was released leading to more consistent CsA trough levels. In addition to typical side effects of CNI, cyclosporin A also seems to induce cancer progression, a mechanism, which appeared to be dependent on tumor growth factor beta (TGF-β) (Hojo et al. 1999).

Tacrolimus (*Tac*)*/FK506*, a macrolide compound, was discovered by Fujisawa Pharmaceutical Company in 1984 during the analysis of soil samples from Mount Tsukuba in Japan as a fermentation product of the fungus Streptomyces tsukubaensis. Oral bioavailability is variable ranging from 5 % to 67 % with the highest rate of absorption under fasting conditions and the lowest rate under high-fat meal intake. Unlike CsA, Tac absorption is not influenced by the presence of bile, which may be beneficial in liver transplant recipients. Tac was first sold as Prograf® and later in a different formulation allowing administration once daily as Advagraf® by Astellas.

Cell cycle inhibitors interfere with clonal expansion of T cells following solid organ transplantation. These include the antimetabolites of purine synthesis, mycophenolate acid (MPA), and inhibitors of *mammalian target of rapamycin* (mTOR).

Antimetabolites of purine were used from the beginning of solid organ transplantation. Calne introduced *6-mercaptopurine* in solid organ transplantation, which was soon replaced by the less toxic imidazolyl derivate *azathioprine* (*Aza*). Aza used to be one of the cornerstones of immunosuppression in liver transplantation, but due to its severe side effects, in particular myelosuppression and hepatotoxicity, Aza has now been almost completely replaced by mycophenolate acid. Aza inhibits cell proliferation by interfering with DNA synthesis and has been described to block downstream effects of *cluster differentiation 28* (CD28) by modulating the G protein *ras-related C3 botulinum toxin substrate 1* (Rac1) activity, converting costimulatory into apoptotic signals.

Mycophenolate acid (*MPA*) was first discovered in 1893 by Gosio as a morpholinoethyl ester of mycophenolate produced by the fungus Penicillium. In 1969, MPA was shown to inhibit *type 2 inosine-monophosphate dehydrogenase* (IMPDH), an essential enzyme for lymphocytes to synthesize guanosine nucleotides necessary for DNA replication and proliferation of T and B cells, which are, unlike other cell types, unable to utilize an alternate pathway. MPA inhibits the cell cycle progression from the S to the G2 phase, antibody formation, adhesion molecules, and smooth muscle cell proliferation.

Mycophenolate mofetil (*MMF*) (*CellCept®*, *Hoffmann-La Roche*) is rapidly absorbed in the stomach and converted in the liver to MPA, whereas *EC-MPS* (*Myfortic®*, *Novartis*), a delayed release form of MPA, is released in the small intestine via a pH-dependent dissolution. MPA is conjugated in the liver to the inactive metabolite MPAG, which is excreted primarily in the urine (around 90 %). Therefore, liver disease may impair MPA conjugation and prolong the half-life time of MPA. Dose reduction or even withdrawal due to dose-related gastroenteral side effects or myelosuppression is high, ranging from 24 % to 57 %.

mTOR inhibitors used in solid organ transplantation include *sirolimus* (Rapamune®, Pfizer) and its derivate *everolimus* (US: Zortress®, EU: Certican®, Novartis), which has a shorter half-life time. Sirolimus was discovered in 1975 in the soil of the Easter Island, also called Rapa Nui, giving sirolimus its other name, rapamycin, as a product of the fungus Streptomyces hygroscopicus.

mTOR inhibitors act as antiproliferative agents by binding to FKB12, the same protein that Tac binds to. In contrast to Tac, mTOR inhibitors do not inhibit calcineurin, and both drugs act synergistically. The complex formed by sirolimus and FKBP12 inhibits mTORC1 (*mammalian target of rapamycin complex 1*) resulting in cell cycle arrest in the G1 to S phase

transition, an effect also observed in tumors. mTORC1 is also essential for the development of conventional effector T cells, and sirolimus has been shown to prevent B-cell differentiation into plasma cells with subsequent reduction in the production of antibodies (IgM, IgG, and IgA). In addition to their immunosuppressive functions, mTOR inhibitors show antifibrotic effects by inhibition of hepatic stellate cell proliferation. Sirolimus also blocks *phosphoinositide-3-kinase* (PI3K)*/protein kinase B* (PKB, syn: AKT)-dependent tumor growth and displays antiangiogenic properties by inhibition of vascular endothelial growth factor (Guba et al. 2002). In contrast to CNI, mTOR inhibitors are thought to be not nephrotoxic. However, this has recently been questioned in patients with renal impairment, and mTOR inhibitors were shown to potentiate CNI-induced nephrotoxicity if used in combination. As mTOR inhibitors affect wound healing, they are usually introduced 4–6 weeks after transplantation. Other side effects include elevated blood lipids, leg edema, and mouth ulcers, while initial reports of increased hepatic artery thrombosis could not be confirmed in later studies (Dunkelberg et al. 2003). Although approved for renal and heart transplantation, both sirolimus and everolimus are not approved as monotherapy for liver transplantation. However, several studies are currently testing both compounds, in particular in patients with hepatocellular carcinoma or preexisting renal dysfunction.

Antibodies used in liver transplantation are heterogeneous in their origin, target, and mode of action. They can be subdivided in polyclonal antibodies isolated from animals previously challenged with certain antigens and monoclonal antibodies. Currently, around 20 % of liver recipients receive either polyclonal or monoclonal antibodies. The advantage of monoclonal antibodies is their specificity, selectivity, safety, and lack of toxicity in comparison to other drugs such as CNI or mTOR inhibitors.

Polyclonal antibodies include *antilymphocyte serum* (ALS), *antilymphocyte globulin* (ALG), *equine antithymocyte globulin* (eATG) (Atgam®, Pfizer), and *rabbit antithymoglobulin* (rATG) (Thymoglobulin®, Genzyme). ALS and ALG were successfully used at the beginning of liver transplantation. The mechanisms of action of polyclonal antibody sera and globulins are not fully understood, but it is thought that they cause the clearance of T cells from the circulation and modulate T-cell activation, homing and cytotoxic activities. rATG induces a more intense immunosuppression than eATG with less infusional side effects (fever, hypotension, serum sickness) (Brennan et al. 1999). While ALS and its globulin fraction ALG were produced by priming a species with human splenocytes, thymuses, or lymph node cells, antithymocyte globulins are produced by priming a species with human thymocytes/lymphocytes resulting in a more specific effect against T cells with less side effects caused by other proteins/antibodies.

eATG and rATG are approved for the treatment of acute rejection in renal transplant recipients but are also used to prevent and treat acute rejection of liver and other organ transplants. Side effects include fever, chills, leukopenia, pain, headache, diarrhea, hypertension, nausea, thrombocytopenia, peripheral edema, infection, dyspnea, and tachycardia in up to 25 % of patients. In addition, an increased risk of infections and the development of posttransplant lymphomas have been associated with the application of polyclonal antibodies.

Monoclonal antibodies target different antigens and display different kinds of action. *Muromonab* (OKT3®, Janssen-Cilag) is a murine-depleting anti-CD3 antibody-targeting T cell. Side effects mirror those observed by the cytokine release syndrome and include pulmonary edema, fever, rigor, and gastrointestinal toxicity. *Basiliximab* (Simulect®, Novartis) and *daclizumab* (Zenapax®, Hoffman-La Roche, discontinued) bind and block the alpha-chain of the IL-2 receptor (CD25) expressed on recently activated T cells and on T regulatory cells. While basiliximab is a chimeric molecule with the variable region of murine and the constant region of human origin, daclizumab is almost completely humanized. Significant reduction in rejection rates without an increase in infectious complications or malignancies was observed in

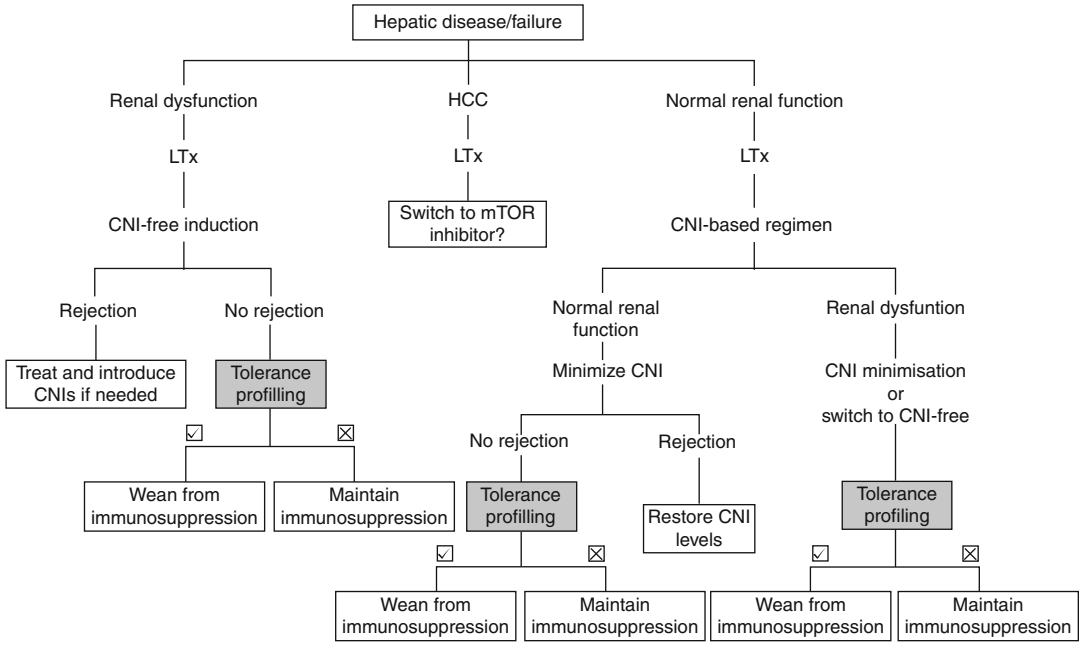
liver transplant recipients in combination with CsA, Aza, and steroids. As these antibodies are highly specific and not depleting, they have only minor side effects. Both are approved for the prophylaxis of acute rejection in renal transplant recipients. *Alemtuzumab* (Campath®, Genzyme) was introduced in 1984 by Waldmann and colleagues. It is a humanized depleting antibody against CD52 expressed on mature lymphocytes as well as monocytes and certain DC subsets, while memory lymphocytes and plasma cells seem to be spared. It shows pronounced depletion of lymphocytes in blood and lymph nodes. The most important side effects are infections due to the severe leukopenia.

Immunosuppression in Liver Transplantation

Despite the existence of very potent agents, immunosuppressive treatment remains a challenge as the use and combination of immunosuppressive drugs has to be adjusted to the patients' underlying disease and conditions like renal impairment or history of hepatocellular carcinoma (see Fig. 2, adopted from Geissler and Schlitt (2009)). It is generally accepted that a higher dose of immunosuppression needs to be given in the early phase after transplantation (*induction phase*) and often a combination of steroids, a CNI and an antiproliferative agents, (MPA or Aza) is given. In addition, an antibody (e.g., basiliximab) can be administered with the aim of lowering the dose of immunosuppressive drugs. In the *maintenance phase*, a cornerstone immunosuppressant (CNI or mTOR inhibitor) with or without low-dose steroids plus antiproliferative agent (MPA/Aza) is often used. *Acute rejection* episodes, suspected or histologically proven, need more intensive treatment, which is typically performed by the administration of high-dose steroids, e.g., methylprednisolone 500–1,000 mg over 3 days. If rejection persists (so-called steroid-refractory rejection), polyclonal (eATG, rATG) or depleting monoclonal (muromonab, alemtuzumab) antibodies are given. If rejection is suspected to be mediated by host antibodies, plasmapheresis and/or the administration of rituximab (MabThera®, Hoffman-La Roche; Rituxan®, Biogen Idec/Genentech), an anti-CD20 antibody, may be considered.

Typical immunosuppressive protocols use a combination of two or three different drugs with or without an antibody in the induction phase. Despite nephrotoxicity and other severe side effects, CNI remain the cornerstone in the treatment of liver transplant recipients. A meta-analysis could demonstrate an advantage of Tac over CsA with regard to overall survival (Haddad et al. 2006), and therefore, most liver transplant centers use Tac. In addition to CNI, a cell cycle inhibitor is often added. Due to its better side effect profile, MPA is preferentially used. High doses of methylprednisolone (500–1,000 mg/d) are typically given just prior to reperfusion followed by rapid tapering. Steroids can be continued on a low dose (typically 25–50 mg or less/d), but many centers try to completely wean steroids to avoid long-term side effects like hypertension, diabetes mellitus, osteoporoses, and cataract. According to the Scientific Registry of Transplant Recipients (SRTR, www.srtr.org), the most frequently used maintenance therapies in the United States were Tac in around 90 %, steroids round 85 %, and MMF in around 60 % of liver transplant recipients with stable immunosuppression for 6 months (Toso et al. 2010). Although mTOR inhibitors are potent immunosuppressive agents in liver transplantation, a warning by the FDA was announced in November 2009: a trial by the manufacturer (*NCT00086346) showed increased mortality in stable liver transplant patients after conversion from CNI to sirolimus. Therefore, mTOR inhibitors should currently be restricted to clinical trials, patients that are not suitable for CNI (e.g., due to renal impairment), and patients with cancer (e.g., hepatocellular carcinoma) due to its antiangiogenic and antiproliferative properties.

Renal impairment is frequently observed in patients with hepatic failure and decompensated cirrhosis (hepatorenal syndrome). In addition, organ allocation programs based on the Mayo End-Stage Liver Disease (MELD) score system,



Immunosuppression in Clinical Liver Transplantation, Fig. 2 Suggested algorithm for immunosuppressive treatment in liver transplant recipients (Adopted from Geissler and Schlitt 2009)

which includes renal function (serum creatinine) as one of the parameters to assess the urgency of liver transplantation, favor patients with impaired renal function. Also, early acute renal dysfunction is frequent after liver transplantation and associated with high morbidity and mortality. The use of antibodies (eATG/rATG or basiliximab) during the induction phase has demonstrated reduced requirement of CNI over time and therefore minimizes the risk for CNI-induced side effects like renal impairment. However, although antibodies effectively induce immunosuppression, complete cessation of CNI is associated with an increased risk of acute rejection. Another approach is to keep patients on MPA and low-dose CNI. MPA monotherapy with complete cessation of CNI is possible but has been associated with an increased risk of acute rejection (Schlitt et al. 2001; Stewart et al. 2001). Until recently, mTOR inhibitors were thought to not be nephrotoxic and here was a hope that they could reverse renal dysfunction. Although an initial study supported this view, later studies showed only minor improvement. Therefore, mTOR inhibitors should be introduced rather early after wound healing has been completed (typically 4–6 weeks after transplantation) before irreversible renal damage has occurred.

Hepatitis C virus (*HCV*) *infection*-induced liver cirrhosis has become the leading cause for liver transplantation in many countries, and reinfection of the new graft frequently occurs. After transplantation, the outcome is heterogeneous. Immunosuppression, as seen in HIV co-infected patients, seems to be associated with progressive disease requiring a new graft within 5–7 years after transplantation. The effects of immunosuppressive agents on the recurrence and progression of HCV-induced cirrhosis after transplantation are not fully understood. However, steroids, in particular pulse therapy, are known to accelerate liver damage and fibrosis due to HCV reinfection. A meta-analysis of protocols that taper or completely avoid using steroids in liver transplant recipients showed a significant reduction in HCV recurrence in the steroid-free groups without an increase in acute rejection, when steroids were replaced by MPA or antibodies

(eATG/rATG, basiliximab) (Segev et al. 2008). However, in cases of acute rejection, steroids can safely be used without increasing fibrosis of the graft, when steroid tapering is performed gradually (Vivarelli et al. 2007). When using a steroid-free protocol, it needs to be considered that critically ill liver patients often suffer from hepatoadrenal syndrome/insufficiency, which appears to be associated with a high mortality when no steroids are given.

Some experimental studies suggest that CsA, but not Tac, may inhibit HCV replication, but this could not be confirmed in a clinical meta-analysis (Berenguer et al. 2007). Aza and MPA were compared to their ability to inhibit virus replication using an in vitro system of bovine viral diarrhea virus, a close relative of hepatitis C virus. Aza showed a tenfold higher decrease in replication compared to MPA (Stangl et al. 2004), but, again, clinical trials comparing Aza and MMF treatment in liver transplant recipients could not demonstrate a difference in viral RNA titers (Zekry et al. 2004). Alemtuzumab spares memory lymphocytes and plasma cells, and it was hoped that it may be beneficial in patients with HCV infection. However, the opposite seemed to be the case as an increase in HCV viral load was observed following lymphocyte depletion with alemtuzumab (Marcos et al. 2004). In summary, in HCV-positive patients, the optimal protocol would be one minimizing the use of steroids and consisting of a CNI and either AZA, MPA, or anti-CD25 antibody.

Hepatocellular carcinoma (HCC) accounts for up to 10 % of all liver transplants. Tumor recurrence after transplantation remains a major problem as immunosuppression is thought to inhibit tumor surveillance by the immune system. Except for mTOR inhibitors, all other immunosuppressive drugs have either no (e.g., MPA) or a negative effect on tumor progression (Schlitt et al. 2011). CsA enhanced tumor growth in a TGF-β-dependent mechanism in a mouse model, which was independent off the immunosuppressive function (Hojo et al. 1999). In addition, CNI seem to increase tumor angiogenesis via stimulation of VEGF and is thought to inhibit DNA repair mechanisms. Clinically, both CsA and Tac are associated with high rates of HCC recurrence (Vivarelli et al. 2008).

Sirolimus has been shown to be associated with a beneficial outcome in patients transplanted for HCC (Toso et al. 2010), although expression of phosphorylated mTOR was found in only 15–40 % of HCCs. mTOR inhibitors also possess anticancer effects as they inhibit cell cycle progress and by blocking many growth factors including VEGF which is important in angiogenesis. So far, only retrospective studies analyzed the effect of mTOR inhibitors in patients transplanted for HCC suggesting a beneficial effect. The results of a prospective, randomized, international multicenter study (SiLVER05, *NCT00355862) addressing this question are expected for 2013.

Autoimmune liver diseases can reoccur after liver transplantation, but no clear association between the selection of immunosuppressive agents and the recurrence of autoimmune hepatitis (recurrence rate 22 %), primary biliary cirrhosis (recurrence rate 18 %), or primary sclerosing cholangitis (recurrence rate 11 %) has been found (Gautam et al. 2006). While most centers try to wean steroids within the first year to avoid steroid-induced side effects, it is believed that steroids might prevent or delay the reoccurrence of underlying disease and treatment is therefore often continued. If autoimmune hepatitis affects the new graft, mTOR inhibitors may be beneficial due to their antifibrotic properties, but no study testing this hypothesis has been performed yet.

Trends and Future Outlooks

New immunosuppressive agents are currently tested in solid organ transplantation: several *antibodies* are under investigation in liver transplantation, e.g., *Belatacept* (Nulojix®, Bristol-Myers Squibb) (*NCT00555321), which has shown promising data in kidney transplant recipients. Belatacept is a fusion protein comprised of the extracellular CTLA-4 domain and the Fc portion of IgG1, which binds to CD28 expressed on

T cells and therefore blocks co-stimulation by CD80 and CD86. Another promising antibody was *efalizumab* (Raptiva®, Merck Serono), a nondepleting monoclonal humanized antibody against LFA-1 expressed by both T and B cells. The blockage of LFA-1 inhibits the formation of the immunological synapse of lymphocytes to the antigen-presenting cell, and efalizumab did not only inhibit T-cell activation but also prevented alloantibody responses. Efalizumab was initially approved for psoriasis and tested in kidney transplant recipients but was withdrawn from the market in 2009 due to increased risk for the development of progressive multifocal leukoencephalopathy. *Small molecules* interfering with intracellular signaling have become of major interest in the transplant field. Although treatment with *fingolimod* (FTY720, Gilenya®, Novartis), an antagonist for sphingosine-1 phosphate signaling important for lymphocyte homing, had to be stopped in transplantation trials due to severe side effects, it illustrated the fact that new drugs targeting novel pathways are arising. Other promising molecules include *tofacitinib* (CP-690550, no assigned trade name, Pfizer) that targets the Janus tyrosine kinase 3, which associates with the common gamma chain and therefore may inhibit IL-receptor signaling, including IL-2 signaling, and *sotrastaurin* (AEB071, no assigned trade name, Novartis) (*NCT01128335) that targets protein kinase C, which is important in T-cell activation and IL-2 production.

Cell-based therapies in solid organ transplantation are becoming increasingly popular due to encouraging results that were obtained in graft-versus-host disease following allogeneic stem cell transplantation. Their advantage is that cells are able to migrate to certain anatomical sites and interact with the immune system in an antigen-specific way. It is hoped that this approach might help to minimize the necessity of currently used agents. However, cell-based therapies are still in the experimental setting and neither the cell type(s) used nor the number of cells that needs to be administered nor the route of administration are clearly defined. Examples of cell types currently tested are *T regulator cells* (Tregs), *mesenchymal stem cells* (MSC), *multipotent adult progenitor cells* (MAPC), *regulatory macrophages* (Mregs), dendritic, and other cells. An international study (ONE Study, www.onestudy.org) is currently trying to define the most potent cell type in solid organ transplantation using kidney transplant recipients. However, a major problem in the use of cells is that their production is often not standardized, and therefore, the comparison of reports from different centers is almost impossible. In addition, the application of living cells, which have been expanded ex vivo, may carry the risk of malignant transformation, in particular as not the cells with the highest immunosuppressive potency but cells with the highest proliferation rate preferentially expand.

Induction of immune tolerance, which has been observed to occur spontaneously after liver transplantation in a variety of species including pigs, rats, and mice, is still the holy grail of solid organ transplantation. However, despite the discovery of several tolerogenic properties of liver allografts (Benseler et al. 2007) and reports of humans with stable liver function completely off immunosuppression, antigen-specific tolerance cannot be induced in the human setting in a reliable and predictable way. However, some evidence exists, which agents are more likely to promote or inhibit the induction of tolerance. Small animal studies demonstrated that T-cell activation is an important step in the active process of antigen-specific tolerance induction, and agents that inhibit T-cell activation like CNI are thought to inhibit rather than promote tolerance. Contrary to CNI, mTOR inhibitors are thought to promote tolerance, as they do not interfere with T-cell activation but prevent proliferation of conventional effector T cells, and promote the induction of Tregs. Treatment with MPA in conjunction with MSC was able to induce tolerance in a small animal model of heart transplantation, but information about liver allografts is missing. The induction of tolerogenic Tregs was reported by the infusion of eATG and rATG, while anti-CD25 antibodies might inhibit tolerance as CD25 is also expressed on Tregs. As alemtuzumab was highly effective in depleting lymphocytes,

it was hoped that alemtuzumab may also induce tolerance. However, the use of alemtuzumab in renal transplant recipients did not lead to tolerance. This might be due to the fact that this drug does not deplete memory lymphocytes.

Conclusion

Immunosuppression in liver transplant recipients is characterized by an individual approach based on the specific side effects of current drugs and the patients' conditions and diseases. Due to their potency, calcineurin inhibitors remain the cornerstone of immunosuppressive therapy in the maintenance phase, but due to their side effects, in particular nephrotoxicity, other agents, e.g., mTOR inhibitors, are currently tested. In addition, the use of monoclonal antibodies during the induction phase may lower the need of subsequent immunosuppressive treatment and thereby decreasing both side effects of drugs and susceptibility of infection. This might be even more realized with the use of molecular agents and cell therapies, a strategy, which might finally lead to the ultimate goal of solid organ transplantation: the induction of immunological tolerance for the transplanted organ.

Impact of Recurrent Autoimmune Diseases in Renal Transplant Outcomes

Synonyms

Diseases affecting transplant renal allografts; Relapsing glomerulonephritis

Definition

Glomerulonephritis encompasses various autoimmune diseases, either systemic or renal limited, that affect renal function and may lead to end-stage renal disease. These diseases may relapse in the transplanted kidneys causing dysfunction or even loss of function.

Introduction

Primary and secondary glomerular diseases are some of the leading causes of advanced chronic kidney disease (CKD) worldwide leading to renal replacement therapy. As with any other etiology of end-stage renal disease (ESRD), kidney transplantation is the preferred choice of renal replacement therapy (RRT) in patients with advanced CKD caused by glomerulonephritis (GN). Transplantation improves the longevity as well as the quality of life compared to dialysis in these patients.

The paradigm of posttransplant recurrence of GN is highly intriguing for at least two reasons. The concept of placing an allograft into immunologically hostile environment is in itself challenging, and to consider adding the risk of a recurrent GN because of the ostensibly persistent pathogenetic mechanisms is even more so. Secondly, counterintuitive to the original notion, these immunological diseases relapse in the allograft in the face of maintenance immunosuppression which is sufficiently intensive to prevent acute rejection. This is probably an illustration of the complex pathogenetic pathways and redundancy of the immune system.

Due to the immunological mechanisms of the GN, disease recurrence in the transplant kidney is well recognized and potentially affects the allograft function. Risk factors for recurrence must be identified during the pre-transplant evaluation based the specific disease and discussed with the patient. All attempts must be made to explore strategies to minimize the risk of recurrence and its impact on the allograft function. With the availability of more potent immunosuppression therapies in the past two decades, acute rejection has become an uncommon cause for graft loss,

and therefore, the attention is now being directed towards strategies to improve long-term allograft function. As will be seen in the later sections, recurrent GN represents an important cause of allograft loss, and it is critical to have in place surveillance protocols to prevent, identify, and treat recurrent disease.

Many systemic diseases, such as diabetes mellitus, hypertension, Fabry's disease, and primary hyperoxalosis, would also obviously affect the renal allograft function either very early or in the long term. However, the discussion in this entry will be limited to immunologically mediated diseases that ultimately lead to various types of GN.

That the underlying GN recurs in the allograft was observed since the days of successful kidney transplantation. The first successful kidney transplant from 1954, performed between identical twins, functioned for more than 9 years without requiring immunosuppression before failing from recurrent "Bright's disease," the eponym used to describe all glomerulonephritis before specific GN were described with the advent of techniques such as immunofluorescence and electron microscopy. Glassock et.al in 1968 published the first classic description of recurrent GN in kidney transplant patients using microscopic techniques, thus raising awareness of such recurrence posttransplantation (Glassock et al. 1968).

One of the unique but indirect benefits of kidney transplantation in patients with GN is the ability to study the natural history and pathogenesis of the various GN in the setting of a new kidney. This has certainly been the case with focal segmental glomerulosclerosis (FSGS) with many new insights gained recently with regards to its pathogenesis when studied in the context of transplantation.

Epidemiology

The true prevalence of GN in pre-transplant patients is difficult to estimate because of the underutilization of diagnostic kidney biopsies. This, in turn, is because either the etiology is presumed given the appropriate clinical context (e.g., diabetes mellitus) or clinical presentation is very late with low diagnostic yield from a biopsy. Even among posttransplant recipients, a recurrent GN is only suspected in case of renal dysfunction and then confirmed by a biopsy. Patients with stable renal allograft function but with subclinical recurrent GN may not come to the clinician's attention.

Despite this conundrum, recurrent GN is now well known to be an important cause of death-censored graft loss in the long term. In a study of 1,505 cases with both native kidney and kidney allograft biopsies documenting recurrent glomerular disease, graft loss due to recurrent GN was the third most frequent cause for graft failure 10 years after kidney transplantation (Briganti et al. 2002). The clinical presentation and course are dependent on the individual disease and highly variable between diseases. In the majority of the cases, this occurs as a subacute or chronic event with the only exception being the FSGS, in which recurrence can be "catastrophic," that is, immediately following transplantation sometimes as early as within 1–2 days. In the absence of aggressive and immediate treatment, this type of recurrence can potentially lead to "primary nonfunction" and ultimate graft loss.

Clinical Presentation

While GN encompasses a wide variety of individual diseases, certain general remarks can be made with regard to the pattern of recurrence posttransplantation, with the exception of FSGS which will be discussed in more detail later. In others, the recurrence is subacute over several months to a few years posttransplant. In some instances, proteinuria is the sole manifestation of disease recurrence. Subclinical cases without appreciable proteinuria are discovered fortuitously when kidney biopsies are done for other indications. There may not be any appreciable changes in serum creatinine initially, but it is now well accepted that recurrent GN leads to earlier allograft loss than in those without recurrence. Very occasionally, recurrence may present as a rapidly progressive glomerulonephritis (RPGN) which may then lead to early graft loss.

Screening and Diagnosis

Routine monitoring for recurrent GN is recommended in all renal transplant patients regardless of the native kidney etiology for the following reasons:

1. Native kidney biopsy is not available in all the patients either because of their late presentation with advanced CKD or because the diagnosis is presumed (e.g., diabetes mellitus, autosomal dominant polycystic kidney disease). These individuals may have had GN as the primary disease or as a coincidental comorbid condition.
2. De novo glomerulonephritis may occur posttransplant. Membranous GN and IgA nephropathy are well known to occur de novo posttransplant.

Screening is valuable because recurrent disease may affect allograft function, and with early detection and treatment, it is possible to delay or prevent disease progression. With increasing experience in kidney transplantation, with evolving practices and treatment protocols, it has become clear that disease recurrence in allografts is very difficult to predict and that clinical presentation can be highly variable. Since GN recurrence is clinically silent in the majority of cases, screening is recommended on a timely basis to detect, confirm, and treat these recurrences.

1. Detection of proteinuria is perhaps the only reliable, inexpensive, and noninvasive method to monitor and detect disease recurrence in transplant kidneys. This monitoring is done with urine dipstick followed by urine protein/creatinine ratio or timed urine collection. Since FSGS is known to recur early and aggressively, it is recommended that screening be done frequently – daily for the first 1 week, weekly for 4 weeks, every 3 months for 1 year, and then annually. For all the other diseases, a less frequent monitoring is recommended – once during the first month, every 3 months during the first year, and then annually (KDIGO 2009).
2. Timed protocol biopsies are practiced in some centers as a tool to detect subclinical acute rejection, at least for the first few years. A coincidental detection of disease recurrence may also be an added benefit with such a practice.
3. Once proteinuria is detected, with or without graft dysfunction, a renal biopsy is recommended. In addition to the routine H&E staining, immunofluorescence and electron microscopy may be valuable depending on the underlying GN.
4. Once a disease is identified, supporting evidence may be obtained by various serological studies (e.g., anti-glomerular basement membrane (GBM) antibodies or antineutrophil cytoplasmic antibodies (ANCA) may be ordered).

Treatment

In general, treatment of recurrent diseases is unsatisfactory as is the case with GN in general. Some of the available treatments are discussed under the individual GN with controversies highlighted. Regardless of the etiology of posttransplant GN, anti-proteinuric therapies are generally recommended and usually effective in limiting the amount of proteinuria. These therapies include drugs like ACE inhibitors and angiotensin receptor blockers, optimal control of hypertension, low protein diet, and other less proven therapies such as maintenance of hemoglobin and lipid levels within normal range.

For the sake of convenience, the specific description of each GN will be discussed under the broad categories of primary and secondary glomerular disease. Also, to stay within the scope of this entry, discussion will be centered on the patterns of recurrence and pathogenic mechanisms. Discussion will also be limited to the recent advances in this field and concepts that have wide acceptance.

Primary (Idiopathic) Glomerular Diseases

Focal Segmental Glomerulonephritis

Idiopathic FSGS tends to recur in about 30 % of all first renal allograft recipients (Couser 2005).

The rate approaches 100 % with subsequent allografts if the first allograft was lost due to recurrent disease. Recurrence is unpredictable with any individual case, and currently there are no treatments that are known to prevent recurrence, including preemptive plasmapheresis. Interestingly, recurrence is uncommon in familial forms of FSGS indicating different pathogenic mechanisms at play in the causality. Clinically, two patterns of recurrence are well recognized: (a) a catastrophic early recurrence with massive proteinuria that leads to anuria and graft loss in the absence of aggressive treatment and (b) a subacute recurrence characterized by gradual increase in proteinuria over months to years. The relative risk of allograft loss with recurrent disease is as high as 2.25 times compared to those without (Hariharan et al. 1999).

A circulating factor in the serum causing disease recurrence was postulated long ago and further strengthened by recent experimental data. The reasons behind this hypothesis are several: (1) relapse of the disease in transplant recipients is rapid and frequent, (2) aggressive plasma exchange or immunoadsorption using staphylococcal A columns lead to remission in many cases indicating that the pathogenic factor is amenable for removal, (3) injection of the FSGS plasma removed by apheresis into experimental animals can cause proteinuria immediately (Sharma et al. 2002), and (4) use of anti-B cell therapies led to disease remission in some cases. However, despite years of intense research, the nature of putative circulating factor is only recently being unraveled. A circulating soluble urokinase receptor (suPAR) is now shown to be not only elevated in subjects with FSGS before transplant but is also associated with higher disease recurrence following transplantation (Wei et al. 2011). These investigators demonstrated, using mouse models, that circulating suPAR activates podocyte β_3 integrin in both native and grafted kidneys, causing foot process effacement, proteinuria, and FSGS-like glomerulopathy. Renal disease developed only when suPAR sufficiently activated podocyte β_3 integrin leading to the hypothesis that the disease can be abrogated by lowering serum suPAR concentrations.

Patients with familial forms of FSGS have mutations of genes encoding for various podocyte slit-diaphragm proteins such as podocin, nephrin, and α-actinin-4. Up to 8 % of these patients may also develop recurrent FSGS although the pathogenic mechanism is not well understood. Disease relapse based on a circulating factor is supported by an experimental rat model. The Buffalo/Mna rat develops FSGS because of a defective autosomal recessive gene. The gene, *Pur1*, is mapped to chromosome 13 in a region syntenic with the long arm of chromosome 1 which contains the gene coding for the podocin, a podocyte protein with a major role in selective filtration function. When affected kidneys were transplanted into normal Lew.w1 rats, proteinuria and renal lesions disappeared (Bertelli et al. 2003). But when normal Lew.w1 kidneys were transplanted into Buffalo/Mna rats, proteinuria occurred, possibly by developing a de novo alloantibody against the normal podocin. This mechanism might explain why some of the familial FSGS cases have disease relapse following transplantation.

Currently available treatments are controversial, unsatisfactory and not consistently effective. These include high-dose intravenous cyclosporine, plasma exchange, and rituximab. In addition to the well-known inhibition of cytokine production by the T cells, cyclosporine was reported to inhibit calcineurin-mediated dephosphorylation of synaptopodin, a protein critical for stabilizing the actin cytoskeleton in podocytes. Corticosteroids have not been shown to be consistently effective in either achieving or maintaining remission. Rituximab was reported to be successful in achieving remission but was ineffective in many other reports. With any of these therapies, only approximately 60–70 % of patients achieve complete or partial remission.

While the mechanism for rituximab's benefit in the treatment of recurrent FSGS is not clear, recent experimental data indicate that it may operate in a B cell-independent fashion. Patients who had recurrent FSGS were found to have fewer podocytes with sphingomyelin phosphodiesterase acid-like 3b (SMPDL-3b) protein in kidney biopsies. This disrupts the actin cytoskeleton

and leads to loss of podocyte function. Rituximab binds to the SMPDL-3b and prevents its downregulation. This may lead to preserved podocyte viability and prevention of FSGS recurrence (Fornoni et al. 2011).

Immunoglobulin A Nephropathy (IgAN)

IgAN usually has an indolent clinical course and causes ESRD in 30–50 % individuals after many years of disease progression. It is characterized by the deposition of aberrant galactose-deficient IgA_1 in the glomerular mesangium as aggregates or as IgA-IgG immune complexes. Recurrent IgAN is an example of a classical subclinical presentation of a glomerular disease where patients have only microscopic hematuria and proteinuria without significant allograft dysfunction. This may not be an indication for renal biopsy at many centers and therefore the recurrence may be missed. The relapsed disease takes many years to progress, and the longer patients are followed, the higher the chances of discovering or recognizing a recurrence. Posttransplant recurrence probably occurs in about 33 % individuals, but reported recurrences were highly variable, between 9 % and 61 % (Ponticelli et al. 2004). Recurrence tends to occur in younger individuals and those with rapid progression of original disease, but as with other GN, this is hard to predict.

In addition of recurrent disease, there appears to be another pathogenic mechanism at play in a small number of individuals. Recipients of either deceased or living kidneys with preexisting "hidden" IgA deposits at the time of transplant may develop de novo IgA nephropathy (Suzuki et al. 2009). The putative mechanism is that people with circulating antibodies to the abnormal IgA would react to the "planted" IgA deposits in the donor kidney triggering an IgAN-like disease. Unfortunately, at present there are no commercially available assays to measure the titers of such circulating autoantibodies.

While it is widely accepted that the type and intensity of immunosuppression protocols do not influence the posttransplant recurrence of IgAN, a few single center reports suggest that either steroid avoidance protocols or steroid withdrawal in late posttransplant period may be associated with higher recurrence rate as well as faster disease progression. However, only large randomized controlled trials can lead to any useful conclusions in this matter. In those few instances of rapidly progressive recurrent IgAN intense immunosuppression with high-dose corticosteroids, cyclophosphamide and/or plasmapheresis is suggested but is not of proven benefit.

There are many overlapping pathological and clinical features between IgAN and Henoch-Schönlein purpura (nephritis) HSP, but a few unique features of HSP deserve discussion: (a) it is a systemic small vessel vasculitis involving many extrarenal organs including skin, joints, and the gastrointestinal tract; (b) recurrent disease with crescents and necrotizing lesions have a very rapid and high incidence of graft loss; (c) a circulating IgA-ANCA (antineutrophil cytoplasmic antibody) has been reported in some patients and seems to have a high correlation with early recurrent disease; and (d) recurrence is very high (up to 75 %) in those patients who had a rapid progression of native disease with necrotizing, crescentic lesions on biopsies.

Various reports indicate that histological recurrence is very common, similar to the IgAN. One study reported a 78 % recurrence at 5-year follow-up (Meulders et al. 1994). However, another study with a 15-year follow-up reported similar graft survival between those with or without recurrent HSP and a 42 % incidence of recurrence. Among those with recurrent disease, graft loss was almost 50 % (Moroni et al. 2008). Histological findings included IgA immune complex deposits in the mesangium, focal/segmental necrotizing lesions, and in some cases crescents. Early clinical features include hematuria, moderate proteinuria, and hypertension. Treatment of recurrent disease is unsatisfactory at present.

Idiopathic Membranous Nephropathy (IMN)

IMN is characterized histologically by the subepithelial deposition or accumulation of immune complexes. This leads to the thickening and loss of integrity of the basement membrane. Like IgAN, IMN has a slow, indolent course that leads to ESRD in about 40–50 % of patients. Recurrence of IMN is typically observed 2–3

years posttransplant. But the rate of recurrence is probably much higher than reported because of the widely varying indications for kidney biopsy. Another confounding factor is the development of de novo IMN in allografts, which histologically is almost identical to IMN.

While the mechanisms of recurrent IMN are still unclear, recent advances suggest IMN patients have autoreactivity to podocyte proteins, such as neutral peptidase and aldose reductase (Prunotto et al. 2010). Alloreactivity to podocyte antigens is possible in allografts. This was confirmed when anti-phospholipase A_2 receptor antibodies were found to be responsible for posttransplant IMN recurrence (Stahl et al. 2010).

The clinical outcomes for allografts that experience IMN recurrence are similar to those of nonrecurrence. Overall prognosis, similar to any recurrent GN, is determined by the degree of proteinuria.

Treatment of IMN is basically empiric. No specific therapy was proven to be beneficial including corticosteroids. Rituximab was reported to be beneficial in some patients but this is anecdotal.

Membranoproliferative Glomerulonephritis (MPGN)

MPGN includes a complex combination of diseases and can be either idiopathic or secondary to chronic infections, cryoglobulinemia, or systemic autoimmune disorders. A large variety of other etiologies also result in the clinical phenotype of MPGN. Pathogenesis involves chronic complement activation and depressed complement levels. The end result of these varying etiologies is the deposition of immune complexes in glomeruli, diffuse proliferative lesions, and widening or duplication of the basement membrane. Based on the histological findings, MPGN is divided into three types. Recurrence after transplantation is common in all the types. It is sometimes difficult to distinguish MPGN from a similar appearance in transplant glomerulopathy. Clinical context and serological studies help in separating MPGN from transplant glomerulopathy.

Recurrent MPGN type I is reported in 20–30 % of cases and may present not only with nephrotic syndrome but in some cases rapid decline in renal function. Therefore, it can have significant impact on graft survival. Histopathology demonstrates subendothelial deposition of immune complexes containing C3 and IgG. The mechanism of recurrence is presumably the ongoing systemic disease that caused the original kidney lesions, such as hepatitis C infection or hereditary complement deficiency leading to chronic low-grade complement activation.

MPGN type II, also known as dense deposit disease (DDD), is characterized by the replacement of the glomerular basement membrane by an extremely dense band of homogenous material ("dense deposits") consisting of C3 and other complement products but without immunoglobulins. The major defect is the excessive activation of the alternative complement pathway. Recurrence of MPGN type II is very high with 80–100 % of the patients developing it. This doubles the relative risk of graft loss. A monoclonal antibody to the C5a complement split product is being studied to prevent posttransplant MPGN recurrence and may have a crucial role as part of induction treatment at the time of transplant. Patients with genetic deficiencies of either factor H or I may benefit from having combined liver and kidney transplantation which would then restore the deficient factors.

Since prevention and treatment are difficult at present, pre-transplant investigation to identify active disease and counseling for possible graft loss is very important. Patients with persistently low complement levels are at the highest risk, and transplantation may have to be postponed until all possible efforts are made to treat the underlying disease (e.g., hepatitis C-related cryoglobulinemia, monoclonal gammopathies) first.

Secondary Glomerular Diseases

Lupus Nephritis

Approximately 30 % of all patients with established lupus nephritis (LN) progress to ESRD, most commonly the class IV disease with proliferative lesions. The onset of renal failure in LN seems to be associated with partial or complete

resolution of extrarenal and serological manifestations of systemic lupus erythematosus (SLE) in many but not all the patients. The specific mechanisms for this phenomenon are not known. Recurrence of LN after renal transplant is very rare, reported to be <5 %. However, some studies reported recurrence rates as high as 30 % and 54 %, based on stringent investigations with serologies and renal biopsies processed for immunofluorescence and electron microscopy. The histologic lesions of recurrent LN are usually mild, mostly consisting of mesangial lesions or atypical pauci-immune proliferative GN, even in studies that employed protocol biopsies. However, histological recurrence is not commensurate with clinical symptoms or signs.

The clinical course of recurrent lupus nephritis is usually indolent and does not seem to have any impact on the allograft function. Likewise, different immunosuppression regimens do not confer any specific advantages, even with steroid avoidance protocols.

Two precautionary strategies are probably critical in peri-transplant management. Patients receiving aggressive immunosuppressive therapies may benefit from delaying transplantation while receiving dialysis, to reduce complications from cardiovascular and infections from prior immunosuppression. Secondly, patients with antiphospholipid antibody syndrome with hypercoagulable syndrome might be at high risk for vascular thrombosis in the peri-transplant period which may include the transplant renal artery leading to early graft loss. Peri-transplant anticoagulation may improve outcomes in such patients.

Amyloidosis

Amyloidosis is a general term describing a group of diseases with deposition of a characteristic proteinaceous material in various organs in the form of fibrils. The principal types that lead to renal involvement are the AL type, with immunoglobulin light chain deposition, and the AA type, with SAA apolipoprotein deposition. Both are systemic disorders affecting many other organs, and therefore, many patients do not get considered for kidney transplantation. AL amyloidosis is particularly a problem because of the high incidence of cardiac involvement.

In the small number of patients with AL amyloidosis who receive transplantation, recurrence has been described frequently, but graft survival appears to be similar to control groups. Patient survival was also comparable in this carefully selected cohort with 95 % 1-year survival and 67 % 5-year survival (Sattianayagam et al. 2010).

AA amyloidosis is caused by many chronic systemic inflammatory diseases, and therefore, recurrence in transplant kidney is based on the specific underlying disease. For instance, presence of rheumatoid arthritis may cause a posttransplant recurrence of AA amyloid deposition in up to 26 %, but there are no reports of recurrence with Behcet's disease.

Combined organ transplantation may be an option for patient with cardiac involvement (heart-kidney) and in those with rare forms of amyloidosis caused by genetic diseases leading to renal involvement (liver-kidney).

ANCA-Positive Vasculitis (Small Vessel Vasculitis)

Small vessel vasculitis (SVV) is another important cause of ESRD and includes several systemic diseases such as Wegener's granulomatosis, Churg-Strauss syndrome, and microscopic polyangiitis. They are all associated with circulating antineutrophil cytoplasmic antibodies (ANCA) which play an important role in the disease pathogenesis. Posttransplant recurrence in kidney in the modern era of immunosuppression is low at 6–7 % cases. Even among the recurrent disease, allograft loss is about 7.7 % at 10 years according to large database trial, which is similar to control population (Briganti et al. 2002). The lower incidence is widely believed to be because of maintenance immunosuppression. Microscopic hematuria and proteinuria are the earliest clinical signs of recurrence. Histopathological findings include focal or diffuse necrotizing glomerulonephritis without immune complexes. Clinical relapse may also occur in extrarenal organs. None of the pre-transplant clinical features including the ANCA tires are useful in predicting recurrence. In fact,

transplantation in spite of persistent high ANCA titers was not detrimental to the allograft. Transplantation should be delayed until clinical remission is maintained for more than a year, since disease relapse within 1 year of treatment is associated with high mortality. A few reports indicate that treatment with cyclophosphamide, plasmapheresis, and rituximab all have a role in achieving successful remission of the recurrent disease but definitive knowledge is lacking.

Anti-glomerular Basement Membrane Antibody Disease (Anti-GBM)

Anti-GBM disease is another interesting clinical paradox in that the native kidney disease is often rapidly progressive and results in ESRD. However, once the disease activity subsides, as evidenced by disappearance of circulating anti-GBM antibodies, transplantation is effective. Recurrence in the allografts is only rarely reported but does occur in the context of increasing anti-GBM antibody titers.

A de novo anti-GBM disease can occur in patients with Alport's syndrome and kidney transplantation. These patients lack the tissue-specific type IV collagen chains in the glomerular basement membrane due to a genetic mutation. These chains, expressed in the normal donor kidney, may elicit an alloimmune response by the recipient. In the presence of conventional immunosuppression, most patients do not develop clinical anti-GBM disease even though histopathologically they can have linear deposition of IgG along the GBM of the transplanted kidney. About 5 % of patients may develop clinical disease indistinguishable from the rapidly progressive Goodpasture's disease but without pulmonary involvement. This probably occurs in the presence of a large gene deletion instead of a point mutation. Evidence suggests that recurrence of anti-GBM disease occurs earlier with subsequent transplants (Browne et al. 2004).

Division of Nephrology, The Ohio State University Medical Center, Columbus, OH, USA

Synonyms

AKI: Acute kidney injury; ANCA: Antineutrophil cytoplasmic antibodies; Anti-GBM: Anti-glomerular basement membrane; CKD: Chronic kidney disease; GN: Glomerulonephritis; Renal biopsy: Kidney biopsy

Definition

Variety of autoimmune diseases can be associated with renal involvement. Furthermore, these diseases can lead to various clinical presentation including isolated glomerular hematuria, nephrotic syndrome, isolated non-nephrotic proteinuria, and acute nephritic syndrome. A kidney biopsy is an important diagnostic tool and can provide precious information including establishment of the pathological diagnosis, as an aid to decide optimal therapy and to determine the degree of active and chronic changes (Appel 1993).

History

Percutaneous renal biopsy was first described in the early 1950s by Iversen and Brun (reviewed in Iversen and Brun (1997)). Not surprisingly, an adequate tissue diagnosis was achieved in less than 40 % of these early cases given a variety of technical limitations including performing the procedure in the sitting position, use of a suction needle, and intravenous urography for guidance. In 1954, Kark and Muehrcke described a modified technique using a Franklin-modified Vim-Silverman needle with the patient in a prone position (Kark and Muehrcke 1954). An exploring needle was used to localize the kidney before insertion of the biopsy needle. Since then, the basic renal biopsy procedure has remained fundamentally unchanged, although the use of real-time ultrasound and refinement of biopsy needle design have led to considerable improvements both in terms of increasing the diagnostic yield and minimizing procedural complications (Topham and Chen 2010) (Fig. 1).

Diagnostic Utility of the Kidney Biopsy

Although renal biopsy is now able to provide a tissue diagnosis in more than 95 % of cases with little risk of life-threatening complications (<0.1 %), very few patients with kidney disease undergo kidney biopsy (Toto 2009). For instance, only a fraction of the patients with a clinical

diagnosis of diabetic nephropathy undergo a kidney biopsy to confirm the diagnosis (Toto 2009). Yet, when kidney biopsy is performed in patients with type 2 diabetes and kidney disease, more than half reveal a histological diagnosis other than, or in addition to, diabetic nephropathy (Toto 2009). The overall rate of native kidney renal biopsy varies from over 250 procedures per million populations in Australia to less than 75 procedures per million populations in the United States (Briganti et al. 2001). These differences in renal biopsy rate are largely driven by opinion regarding the usefulness of the procedure rather than differences in the spectrum of renal pathology.

Several studies have demonstrated that therapeutic interventions are modified considerably after diagnosis is obtained by a kidney biopsy (Cohen et al. 1989). Renal histopathologic lesions are very difficult to predict based on clinical grounds alone. For instance, in a prospective single center study of 276 native renal biopsies, changes in the management as a direct result of the biopsy occurred in 86 % of cases with nephrotic-range proteinuria, 71 % of cases with acute renal failure, and 45 % cases of CKD (Richard et al. 1994). In another prospective study of 80 patients, prognosis changed in 57 % of patients and therapy changed in 31 % of patients (Turner et al. 1986). Overall, these studies strongly suggest that when in doubt about the cause of the kidney disease, a kidney biopsy should be performed. Figure 2 shows a core of kidney tissue obtained by a native kidney biopsy in a patient with suspected glomerulonephritis. Figure 3 shows the kidney biopsy core under a dissecting microscope, and several glomeruli are seen.

General Biopsy Principles

Renal biopsy may be obtained for a variety of reasons, including establishment of the pathological diagnosis, as an aid to decide optimal therapy or to help determine futility of treatment and to determine the degree of active and chronic changes (Fuiano et al. 2000). In addition, kidney

biopsy can be performed to help assess genetic diseases. Although renal biopsy is not always able to accomplish all these tasks, it remains a valuable diagnostic tool in the following clinical scenarios.

Acute kidney injury (AKI)

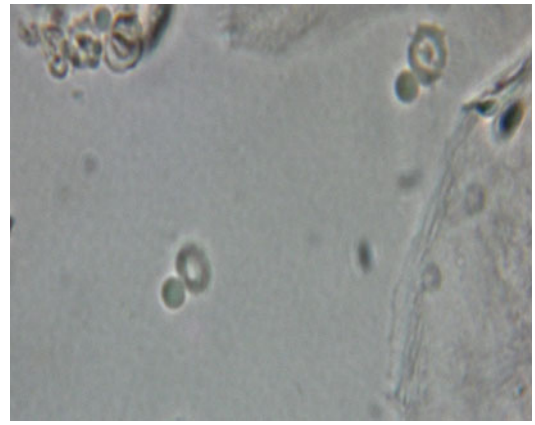
In most cases of AKI, the common causes – prerenal azotemia, acute tubular necrosis, and urinary tract obstruction – can be diagnosed clinically. In a minority of patients, however, a confident diagnosis cannot be made. In these circumstances, a renal biopsy should be performed to aid the clinical diagnosis, especially in the setting of AKI with active urine sediment, or if drug-induced or infection-related kidney diseases are suspected.

Chronic Kidney Disease (CKD)

Renal biopsy can be informative in the patient with unexplained CKD because, in contrast to AKI, it is often difficult to identify the underlying cause on the basis of clinical data alone. Studies have shown that in this setting, the biopsy will demonstrate disease that was not predicted in almost half of cases (Richard et al. 1994). However, in patients with small kidneys bilaterally (<9 cm), the risks of the biopsy might outweigh the diagnostic utility, as these kidneys often show extensive and currently irreversible glomerulosclerosis, tubulointerstitial fibrosis, or both.

Isolated Glomerular Hematuria

Patients with persistent and isolated microscopic hematuria should initially be evaluated for lesions such as kidney stones or genitourinary neoplasm. A glomerular source should be considered if these lesions are not found and particularly if dysmorphic red blood cells (RBCs) known as acanthocytes are present (Figs. 4 and 5). When biopsies are performed in these patients, the histology is often normal or shows IgA nephropathy or thin glomerular basement membrane disease. Because the prognosis for these conditions is excellent in the absence of nephrotic proteinuria, renal impairment, or hypertension, and because specific therapies are not yet available, renal biopsy is not routinely performed for isolated hematuria (Fuiano et al. 2000). However, these patients require close monitoring for the development of proteinuria or renal insufficiency, as this significantly increases the risk of progression to CKD (Szeto et al. 2001).



Indications for Biopsy in Autoimmune GN, Fig. 4 Dysmorphic red blood cells found in the urine of patients with glomerular diseases. Those cells with membrane blebs are called acanthocytes, a subset of dysmorphic RBCs that are fairly specific for glomerular bleeding (Source: Brad Rovin)

Indications for Biopsy in Autoimmune GN, Fig. 5 Acanthocytes (Source: Brad Rovin)

Primary Nephrotic Syndrome

The term nephrotic syndrome is specifically defined by the presence of heavy proteinuria (protein excretion greater than 3.5 g/24 h), hypoalbuminemia (less than 3.0 g/dL), and peripheral edema. Hyperlipidemia and thrombotic disease are also frequently observed.

Most patients with nephrotic syndrome or nephrotic-range proteinuria and no evidence of other systemic disease should be biopsied. One exception may be children aged between 1 year and puberty, as over 90 % will have minimal change disease (Lennon et al. 2010), unless they also have hematuria, positive serology, or renal impairment, or their disease does not respond to empiric corticosteroids. In the absence of a systemic disease (see below), the common differential diagnoses of primary nephrotic syndrome include membranous nephropathy, minimal change disease, or focal segmental glomerulosclerosis (accounting for over 80 % of all cases) (Braden et al. 2000).

Isolated Non-nephrotic Proteinuria

The importance of renal biopsy in patients with non-nephrotic proteinuria is controversial. A renal biopsy generally is not performed in a patient presenting with low-grade proteinuria (less than 500–1,000 mg/day) in the absence of glomerular hematuria, abnormal renal function, and clinical or serologic evidence of a systemic disease. Many nephrologists routinely perform a renal biopsy in patients with somewhat higher degrees of non-nephrotic proteinuria (1–2 g/day), except in settings where this may be explained by conditions such as long-standing diabetes mellitus or hypertension.

Renal Dysfunction Associated with Systemic Diseases

A number of systemic diseases may affect the kidney, and sometimes a kidney biopsy is the best way to diagnose a systemic disease. Alternatively, a systemic disease may be presumed by clinical characteristics or specific serologic tests, but the kidney biopsy is required to determine prognosis. Treatment often entails the treatment of the primary disease, but kidney involvement may require additional or more intense therapies. Common systemic disorders involving the kidney are:

Diabetes Mellitus: Patients with diabetes mellitus and renal dysfunction do not usually require a biopsy if the clinical setting is compatible with diabetic nephropathy (diabetes of long duration, evidence of other microvascular diabetic complications, isolated proteinuria). However, in patients with an atypical presentation (proteinuria associated with glomerular hematuria, absence of retinopathy or neuropathy, rapid onset of proteinuria <5 years from documented onset of diabetes, rapid decline in renal function, the presence of immunologic abnormalities), a renal biopsy should be performed.

Antineutrophil Cytoplasmic Antibodies (ANCA)-Associated Vasculitis and Anti-glomerular Basement Membrane (Anti-GBM) Antibody Disease: Serologic testing for ANCA and for anti-GBM antibodies helps support a diagnosis of renal small-vessel vasculitis or Goodpasture's disease. However, a renal biopsy should still be performed to confirm the diagnosis and to clarify the extent of active inflammation versus chronic fibrosis. This information can be crucial not only in making decisions about the immunosuppressive therapy but can also give an idea about potential for recovery.

Systemic Lupus Erythematosus (SLE): Renal involvement occurs in approximately 60 % of patients with SLE (Beck and Salant 2009). There are multiple histological subtypes of lupus nephritis (LN) and the optimal treatment varies with the subtype (Waldman and Appel 2006). Although lupus nephritis can be identified by noninvasive criteria (autoantibodies, urine protein excretion, renal function, and urine sediment abnormalities), a renal biopsy elucidates the histological subtype of LN, the level of acute activity, and the extent of chronic fibrosis, thereby providing robust guidance for immunosuppressive therapy (Faurschou et al. 2006).

Miscellaneous: Other systemic diseases, such as amyloidosis, sarcoidosis, and myeloma, can be diagnosed with a renal biopsy. However, because these diagnoses can often be made by other approaches, a renal biopsy is indicated only if the diagnosis remains in doubt or when the knowledge of renal involvement might alter the therapy.

Renal Transplant Dysfunction

Renal allograft dysfunction requires a renal biopsy to determine the cause, particularly in the absence of other identifiable etiology such

as ureteral obstruction, urinary sepsis, or renal artery stenosis (Colvin 2007). In the early posttransplantation period, this is most useful in differentiating acute rejection from acute tubular necrosis (Solez et al. 2008). Later, renal biopsy can differentiate late acute rejection from chronic allograft nephropathy, recurrent or de novo glomerulonephritis, calcineurin inhibitor toxicity, and BK nephropathy.

Familial Renal Disease

A renal biopsy can be helpful in the investigation of patients with a family history of renal disease, and a biopsy performed on one affected family member may secure the diagnosis for the whole family.

Limitations of the Kidney Biopsy

It is important to recognize that prognostication based on renal pathology alone may be affected by the sample size and may not be very accurate in biopsies with few glomeruli (i.e., $\leq$5). Sampling errors can occur particularly if the disease is focal in nature, such as in renal sarcoidosis (Shah et al. 2011). The findings in renal biopsy always need to be interpreted in the context of the clinical and laboratory features. Chronic changes (interstitial fibrosis and tubular atrophy), for example, are a sign of the magnitude and duration of prior injury. The final decision to conduct a biopsy should, in most cases, be based on whether or not the biopsy will change the therapeutic plan (Toto 2009).

Because the kidney biopsy is an invasive procedure, it is generally not repeated on a serial basis to evaluate the effect of treatment on kidney injury. Treatments are followed with clinical markers such as changes in the urine sediment, level of proteinuria, and kidney function. None of these clinical parameters are sensitive or specific enough to be surrogates of kidney pathology. However, ongoing studies using urine proteomics are beginning to find biomarkers that accurately reflect renal pathology (Bramham et al. 2009; Zhang et al. 2012; Brunner et al. 2012). The goal of these studies is to develop urine biomarker panels that can be used to noninvasively follow the effects of treatment on renal pathology over time.

The Future of the Kidney Biopsy

Given the advances in molecular diagnoses through a multitude of "omics" platforms, it is anticipated that expanded analyses of kidney biopsies, beyond light, immunofluorescence, and electron microscopy, will be used to understand the molecular pathogenesis of kidney diseases (Satoskar et al. in press; Sarwal et al. 2003; Peterson et al. 2004). Examination of the glomerular genome, proteome, or transcriptosome will distinguish differences between phenotypically similar renal lesions (Sarwal et al. 2003; Peterson et al. 2004). This information can then be used to more precisely classify an individual's disease and personalize therapy by targeting pathways activated in that individual (Rovin et al. 2009; Hodgin et al. 2010; Yasuda et al. 2006).

Inflammatory Bowel Disease

Elisa Boden
Department of Gastroenterology, Virginia Mason Hospital Benaroya Research Institute, Seattle, WA, USA

Synonyms

Crohn's disease; IBD; Ulcerative colitis

Definition

The inflammatory bowel diseases (IBDs) include Crohn's disease (CD) and ulcerative colitis (UC) and are chronic diseases characterized by relapsing inflammation in the intestinal tract.

Epidemiology

The prevalence of IBD in North America has been reported to be between 44–201/100,000 (CD) and 37–238/100,000 (UC) (Cosnes et al. 2011). However, the number of people diagnosed with IBD is increasing, particularly in countries such as Asia and India where the incidence has historically been low (Molodecky et al. 2011). The peak age of onset of IBD occurs between 20 and 40 years of age. Smoking is a significant risk factor for the development of CD but may be protective in patients with UC (Mahid et al. 2006). Appendectomy before the age of 20 years appears to protect against development of UC (Koutroubakis et al. 2002).

Clinical and Pathologic Features of Ulcerative Colitis

Patients with UC typically present with symptoms of bloody diarrhea and abdominal cramping. Diarrhea may be absent in patients with disease limited to the rectum (proctitis), and symptoms may arise insidiously in these patients. Severe disease may be accompanied by fevers, abdominal pain or abdominal distension, anemia, elevated white blood cell count, and inflammatory markers (erythrocyte sedimentation rate and C-reactive protein). Patients with severe colitis involving the entire colon (pancolitis) are at risk for developing colonic dilation and impaired motility termed toxic megacolon. While the exact mechanism underlying toxic megacolon is unknown, increased inducible nitric oxide synthase has been found in the colonic wall of patients with toxic megacolon (Mourelle et al. 1995). These patients are at high risk for perforation of the colon and may require urgent surgery.

The diagnosis of UC is made by colonoscopy with endoscopic biopsies. The endoscopic appearance is characterized by diffuse mucosal erythema and ulceration with loss of vascular markings due to mucosal edema. In addition, there may be friability of the mucosa with contact or spontaneous bleeding, and exudates may be present. In severe ulcerative colitis, deep ulcers may be encountered. Inflammation always involves the rectum and extends towards the cecum in a continuous diffuse pattern. In one-third of patients, disease is limited to the rectum, while an additional one-third have colitis proximal to the splenic flexure. One quarter of patients have pancolitis (Moum et al. 1999). In patients with severe pancolitis, the adjacent ileum may be inflamed in a process called backwash ileitis.

The histopathology of the colon in UC is characterized by inflammation limited to the mucosa and superficial submucosa of the colon. In active disease, increased neutrophilic and mast cell infiltrates are present in the lamina propria and may cause crypt abscess (neutrophils within the crypt lumen). Chronic inflammatory infiltrate with lymphocytes, plasma cells, and eosinophils may be present in the lamina propria. Evidence of chronicity is a diagnostic feature of IBD and is characterized by crypt distortion and branching, crypt atrophy, and Paneth cell metaplasia. Granulomas are not seen in ulcerative colitis.

Clinical and Pathologic Features of Crohn's Disease

Crohn's disease may have a varied clinical presentation depending on the site and nature of the disease involvement. Nonspecific symptoms can delay the time to diagnosis in patients with CD (Pimentel et al. 2000). Symptoms occur when disease causes pain, systemic inflammation including extraintestinal manifestations (see Extraintestinal Manifestations in IBD below), diarrhea, malabsorption, nutritional deficiency, or weight loss. Diarrhea is often non-bloody and less severe than that seen in UC. Alternatively, patients may present with symptoms when transmural inflammation leads to stricture or penetration causing fistula or abscess. Colonic Crohn's disease typically causes diarrhea with or without rectal bleeding.

Unlike UC where inflammation is limited to the rectum and extends upwards to involve the

entire colon, inflammation in Crohn's disease can involve any part of the intestinal tract, most commonly the ileum and colon. Ten to fifteen percent of patients will have upper gastrointestinal involvement of the esophagus, stomach, or duodenum (Cosnes et al. 2011). Disease location tends to be stable over time (Louis et al. 2001). Inflammation in CD is transmural, and this can result in complications over time including penetrating disease or strictures. Almost one-half of patients with Crohn's disease will develop perianal complications including perianal abscess, fistula, stenosis, or fissures (Schwartz et al. 2001, 2002; Cosnes et al. 2008).

CD is typically diagnosed by tissue biopsy during esophago-gastroduodenoscopy or colonoscopy. Imaging techniques such as CT, MRI, small bowel follow through, and capsule endoscopy can be helpful at defining the location and extent of disease. The endoscopic appearance of CD is characterized by discontinuous deep ulcerations of the intestinal mucosa often called cobblestoning or can be limited to aphthous ulcerations of the small bowel and colon. Large areas of the intestine may be uninvolved, and these have been termed "skip" areas.

The histopathology of CD is characterized by inflammation that may involve any layer of the intestinal wall from the mucosa to the serosa. Early in the disease, pathology in the colon may be identical to UC with neutrophilic and lymphoplasmacytic infiltrate and crypt architectural distortion. However, with time, the pathologic picture is marked by T lymphocyte and macrophage infiltration. Noncaseating granulomas are present in about 30 % of biopsies in Crohn's disease (Heresbach et al. 2005), but are not present in ulcerative colitis. In some cases, ulcerative colitis may be difficult to distinguish clinically and histologically from Crohn's colitis, and this has been referred to as indeterminate colitis.

Extraintestinal Manifestations of IBD

Patients with IBD may develop inflammation in organs outside the intestines. The most common extraintestinal manifestation of IBD is arthropathy with a prevalence of 10–35 % (Larsen et al. 2010). Joint manifestations can include sacroiliitis or polyarticular arthritis of the large joints. Recurrent aphthous ulcers of the mouth occur in up to 20 % of patients with IBD. Skin manifestations associated with IBD include pyoderma gangrenosum and erythema nodosum. Ocular inflammation including iritis, episcleritis, and uveitis occurs with increased frequency in patients with IBD.

The aforementioned symptoms generally mirror intestinal symptoms, and often treatment directed towards intestinal inflammation leads to improvement in extraintestinal manifestations. However, in the case of sacroiliitis, uveitis, and pyoderma gangrenosum, the course may progress independent of intestinal inflammation. Patients with IBD are also at increased risk for development of Primary Sclerosing Cholangitis (PSC), an inflammatory disorder of the bile ducts that leads to scarring and recurrent cholangitis. The disease course of PSC progresses independent of intestinal activity.

Other non-intestinal manifestations may occur as a complication of intestinal disease or treatment. These include development of gallstones (secondary to fat or bile acid malabsorption), kidney stones (exacerbated by dehydration and excess oxalate absorption), and osteoporosis (secondary to calcium and vitamin D deficiency and exacerbated by low body mass index and steroid use).

IBD Pathogenesis

Three specific factors contribute to the initiation and perpetuation of the inflammatory process in IBD. These include the host genetics, intestinal microbial factors, and the response of the mucosal immune system.

Genetics of IBD

Twin studies provided initial evidence that there is a strong genetic contribution to the development of IBD. In Crohn's disease, the effects appear to be more pronounced with an estimated

50 % genetic contribution versus 20 % in ulcerative colitis (Kaser and Blumberg 2011). While a very rare autosomal recessive form of early IBD has been found to result from defects in IL-10 and the IL-10 receptor genes, most genes associated with IBD are common, low penetrance variants. Of these, NOD2 mutations have the highest contribution to CD with homozygous mutations conferring a 20-fold increased risk. However, most other gene associations confer less than a 1.5-fold risk (Cho and Brant 2011).

Genome-wide association studies (GWAS) recently identified over 100 genetic loci associated with IBD. The precise functional allele or causative genes for the majority of these loci have not been defined, but candidate genes have been identified that highlight novel pathways for investigation. These pathways include genes involved in microbe sensing and recognition (NOD2), autophagy (ATG16L1, IRGM, LRRK2), lymphocyte activation, function and regulation (HLA Class II, IL-10, IL-2RA, IL-23R, IL12B, JAK2, STAT3, SMAD3, ICOS, PTPN22), endoplasmic reticulum stress responses (Xbp1), and intestinal barrier function (MUC1, MUC19, ARPc, CDH, OCTN1/2, LAMB1). There is significant overlap between genes found to be associated with CD and UC. However, unique genetic associations with each disease are present and suggest differences in disease pathogenesis. In addition to overlap within CD and UC, genetic polymorphisms associated with IBD are shared with other autoimmune diseases including PSC, type I diabetes, psoriasis, lupus, multiple sclerosis, and ankylosing spondylitis.

Role of the Intestinal Microbiota

Substantial evidence suggests that the intestinal microbiota play a significant role in initiating and/or perpetuating the intestinal inflammation in IBD. In animal models of IBD, colitis does not develop under germ-free conditions (Round et al. 2009). In humans, it has been demonstrated that diversion of the fecal stream after surgery for Crohn's disease ameliorates inflammation; however, disease recurs quickly once the fecal stream is reconstituted (Rutgeerts et al. 1991). Additionally, antibiotic therapy has been shown to be effective as a treatment for both Crohn's disease and pouchitis. Defects in tolerance to commensal bacteria, an altered balance of bacterial populations and host-environmental and genetic factors that impact bacterial sensing and clearance, have been implicated in development of IBD.

Defects in Tolerance

Patients with IBD and their family members have defects in the establishment of oral tolerance, the phenomenon by which antigens administered via the oral route lead to suppression of the systemic immune response upon subsequent challenge (Kraus et al. 2004). A percentage of patients with IBD have serum antibodies against endogenous microflora, suggesting a similar lack of tolerance to commensal flora. Antibodies identified at a higher rate in patients with IBD include anti-Saccharomyces cerevisiae antibodies (ASCA), anti-E. coli outer membrane porin C (OmpC), anti-bacterial flagellin (cBir1), and anti-Pseudomonas fluorescens 12(12).

Altered Microbial Populations

In addition to a loss of tolerance to commensal bacteria, studies have demonstrated that the composition of commensal bacterial flora is significantly altered in patients with IBD. However, no specific causative microbe has been identified. This IBD-specific microbial signature is characterized by reduced bacterial diversity (Frank et al. 2007, 2008, 2010; Qin et al. 2010). There is a relative reduction in Bacteroidetes and clostridial firmicute species. Among the groups of bacteria depleted in patients with IBD are symbiont bacteria that have been shown to have anti-inflammatory properties. For example, *Bacteroides fragilis* produces an immunomodulatory molecule, Polysaccharide A (PSA), which induces FoxP3+ regulatory T cells (Round et al. 2010). Another bacteria that appears to be selectively depleted in Crohn's disease is *Faecalibacterium prausnitzii*. *F. prausnitzii* secretes soluble factors that inhibit NF-$_{\kappa}$B activation and increase IL-10 production. Patients undergoing resection for Crohn's disease

with low numbers of this organism have been shown to be at increased risk for early recurrence of disease (Sokol et al. 2009). In addition to depletion of protective species, patients with IBD have higher numbers of mucosa-associated bacteria, particularly invasive E. coli species. Whether these changes in the content and diversity of bacterial flora in IBD occur as a secondary response to inflammation or constitute a primary event remains an issue of debate.

Defects in Bacterial Sensing and Elimination

Genetic defects resulting in the inability to sense or eliminate bacteria may also contribute to increased mucosa-associated bacteria in Crohn's disease. Mutations in the bacterial sensing protein, NOD2, are significantly associated with ileal and stricturing Crohn's disease. NOD2 is expressed in both hematopoietic and epithelial cells and responds to the bacterial product muramyl dipeptide (MDP) leading to the activation of $NF_{\kappa}B$ and MAP kinase signaling. Primary cells isolated from patients homozygous or heterozygous for NOD2 mutations have defects in $NF_{\kappa}B$ activation in response to MDP (Abraham et al. 2006). Mice lacking NOD2 do not develop spontaneous intestinal inflammation but have been shown to express reduced antimicrobial defensins and demonstrate defects in efficient bacterial clearance (Kobayashi et al. 2005).

Studies of the autophagy genes associated with IBD (ATG16L1, IRGM, LRRK2) have highlighted the importance of this pathway in mucosal homeostasis in response to microorganisms. Autophagy is the process by which cytosolic contents are engulfed via a double-layered membrane and targeted via fusion for lysosomal degradation. Degraded cellular contents can be presented by MHC Class II molecules or be recognized by Toll-like receptors (TLRs). Autophagy is important for the removal of damaged organelles, generation of energy by recycling of proteins, and removal of intracellular microorganisms. Macrophages derived from ATG16L1-deficient mice demonstrate enhanced IL-1β and IL-18 response to stimulation with lipopolysaccharide (LPS) and TNFα (Saito et al. 2008), suggesting that autophagy regulates the inflammatory response to bacterial endotoxin. Recent studies have also highlighted a role for ATG16L1 in altered response to intestinal viral infections. Mice expressing hypomorphic Atg16L1 have been found to have abnormal Paneth cell morphology and function (Cadwell et al. 2008). Paneth cells are epithelial cells found at the base of intestinal crypts that secrete antimicrobial peptides. Interestingly, the Paneth cell abnormalities in these mice are dependent on persistent infection with a specific mouse Norovirus strain. While mice did not develop spontaneous intestinal inflammation, when challenged with dextran sulfate sodium (DSS) in the drinking water, they exhibited increased severity with transmural ileocolonic inflammation that was responsive to antibiotics (Cadwell et al. 2010). Paneth cell morphologic abnormalities and defects in antimicrobial peptide secretion have similarly been observed in CD patients with the ATG16L1 risk allele (Cadwell et al. 2008) and in patients with NOD2 mutant alleles. These data show that in the right genetic context, an infectious trigger can lead to alterations in host defenses that result in inappropriate immune responses to the intestinal microbiota.

The Mucosal Immune Response in IBD

Defects in Immune Regulation

In health, the LP contains a large number of activated immune cells. However, inflammation is actively restrained through multiple mechanisms including regulatory T cells and secretion of immunoregulatory cytokines (TGFβ and IL-10). It is postulated that a breakdown in homeostatic immune regulation may contribute to the development of IBD. A number of subsets of regulatory T cells that can inhibit T cell effector function have been described to be active in the intestinal mucosa and include Tr1 and Th3 cells, the natural and induced CD4+FoxP3+ Tregs, and CD8+ Tregs. These populations inhibit the immune response through the secretion of the anti-inflammatory cytokines IL-10 and TGFβ and/or inhibit by contact-dependent mechanisms.

While defects in FoxP3+ Tregs have been described in many animal models of colitis

CD4+FoxP3+, T cells are increased in number in the inflamed intestines in patients with IBD compared to healthy controls (Makita et al. 2004; Maul et al. 2005; Holmen et al. 2006) and have normal suppressive function in vitro. Despite increased numbers and normal function, they are unable to suppress inflammation in IBD. It has been proposed that there may be a relative deficiency of Tregs compared to other inflammatory diseases. It is also possible that there are local environmental factors within the LP that render Tregs ineffective in vivo, while able to function ex vivo. Alternatively, T effectors in the LP of patients with IBD may be resistant to Treg-mediated suppression. This has been suggested by data demonstrating T effector resistance associated with increased expression of the TGFβ inhibitory protein, SMAD7, in LP T cells from patients with IBD (Fantini et al. 2009). Lastly, it has recently been demonstrated that the lamina propria of patients with Crohn's disease contains a subset FoxP3+ T cells that co-express IL-17 (Hovhannisyan et al. 2011). These data suggest that the Tregs are able to acquire an inflammatory phenotype that may perpetuate disease in the microenvironment of the inflamed intestine.

It is possible that alternative Treg subsets, such as CD8+ Tregs, play a dominant role in maintaining intestinal homeostasis. CD1d-restricted CD8+ Tregs can be generated by the interaction with normal intestinal epithelium and are also isolated from the LP of normal individuals (Allez et al. 2002). These Tregs are able to suppress T effector function in a contact-dependent manner. However, CD8+ T cells isolated from patients with Crohn's disease exhibit a reduction in suppressor function that may contribute to uncontrolled inflammation (Rabinowitz et al. 2013).

IL-10 and TGFβ are immunoregulatory cytokines that have been implicated in regulation by both FoxP3+ and FoxP3-negative regulatory cells (Tr1 and Th3). The importance of these cytokines in the maintenance of intestinal homeostasis has been clearly demonstrated in animal models, where deficiency in IL-10 results in spontaneous colitis and deficiency in TGFβ1 in FoxP3+ Tregs results in inability to control colitis (Li et al. 2007). Evidence that alterations in these cytokine pathways might contribute to human IBD has been supported by recent GWAS demonstrating association with IL-10, IL-10 receptor, and SMAD3 polymorphisms.

Role of Inflammatory Cytokines

Crohn's disease and ulcerative colitis are characterized by distinct patterns of cytokine expression in the lamina propria (LP). Crohn's disease was initially described to be a Th1-mediated disease, characterized by the expression of large amounts of IFN_{γ}, TNF_{α}, and IL-12 (Fuss et al. 2006). In contrast, LP from UC patients demonstrates increased secretion of IL-5 and IL-13 (Fuss et al. 1996, 2004). Others have shown there is also an increased production of IFN_{γ} and TNF_{α} in the LP of UC patients. While UC was initially described to be a Th2-mediated disease, it probably derives input from several different T cell subsets.

More recently, it has been recognized that IL-17 is also secreted by LP T cells in both CD and to a lesser extent in UC (Fujino et al. 2003; Nielson et al. 2003; Kobayashi et al. 2008; Sakuru et al. 2009). IL-23 maintains and expands IL-17-expressing T cells. Association of genes involved in the IL-23 signaling pathway identified by GWAS in CD and UC has cemented a role for the Th17 cytokines in IBD. GWAS have identified IL-23 receptor mutations as protective for both CD and UC. In addition, IL-12β (p40), the shared subunit of IL-12 and IL-23, and downstream signaling molecules JAK2 and STAT3 have also been associated with IBD. Peripheral blood from patients with CD have increased number of IL-23 receptor-bearing cells and respond to IL-23 with more robust IL-17 and IFN_{γ} production (Kleinshack et al. 2009) suggesting that IL-23 may drive inflammation in CD. Supportive of a role for IL-23 in IBD, in a mouse model of colitis that results from transfer of effector T cells into immunodeficient mice, a lack of IL-23 receptor on T cells resulted in protection from colitis. In this model, IL-23 appeared to be a negative regulator of FoxP3 induction in the colon such that T cell transfer into IL-23-deficient immunodeficient

mice resulted in increased numbers of colonic FoxP3+ regulatory T cells (Iscue et al. 2008). It is unclear whether IL-23 exerts its effects in IBD via restraint of regulatory T cell induction or an enhancement of IL-17-producing T cells.

The proinflammatory cytokine, TNF_{α}, is elevated in tissue and blood of patients with both UC and CD and is secreted as a secondary response to tissue inflammation by innate immune cells. TNF_{α} activates $NF_{\kappa}B$ and mitogen-activated protein (MAP) kinases and perpetuates inflammation through increased production of proinflammatory cytokines IL-1β, IL-6, and IL-12; recruitment of inflammatory cells; initiation of acute phase response; and inhibition of apoptosis. The success of anti-TNF_{α} agents in the treatment of IBD has demonstrated a clear role for this cytokine in its pathogenesis.

Medical Therapy for Inflammatory Bowel Disease

There is significant overlap in medical therapy for UC and Crohn's disease. The medical context of therapy is important as certain medications are effective at inducing remission, while others prevent disease relapse. Specific medications may be better suited to treat extraintestinal manifestations of IBD and fistulizing Crohn's disease. Recent attention has also been given to those medications that may prevent relapse after surgery in Crohn's disease.

Aminosalicylates (Sulfasalazine, Mesalamine)

Mechanism of Action: 5-ASA agents block both cyclooxygenase and lipoxygenase pathways reducing prostaglandin and leukotriene synthesis (Sharon et al. 1978; Ligumksy et al. 1981; Hawkey et al. 1985). They can act as free radical scavengers and minimize tissue damage (Ahnfelt-Ronne et al. 1990). 5-ASAs also inhibit T cell activation and IL-2 production (Stevens et al. 1995) and can directly inhibit TNF_{α} (Shanahan et al. 1990). 5-ASAs may also exert effects through activation of peroxisome proliferator-activated receptor-gamma (PPAR-gamma), a nuclear receptor critical for maintenance of colonic antimicrobial peptides called beta-defensins (Rousseaux et al. 2005; Peyrin-Biroulet et al. 2010).

Ulcerative Colitis: The aminosalicylate (5-ASA) medications are first-line therapy for induction and maintenance therapy in mild to moderate UC. Dosing of 5-ASAs may be important in patients with moderate disease activity where higher doses may improve response rates (Hanauer et al. 2005). Topical mesalamine can be used to induce and maintain remission in patients with distal UC (Cohen et al. 2000; Marshall et al. 2000).

Crohn's Disease: While studies have clearly shown the benefit of 5-ASAs in the maintenance and remission of UC, the benefit in Crohn's disease is unclear. Two recent meta-analyses showed no benefit for mesalamine over placebo in inducing remission in CD. One of these studies showed a small benefit of sulfasalazine over placebo in induction of remission, while the other study demonstrated a trend towards benefit. The benefits of sulfasalazine appeared to be greatest in patients with colitis. No significant benefit was seen for 5-ASAs for maintenance of remission in CD (Lim et al. 2010; Ford et al. 2011).

Corticosteroids

Mechanism of Action: Corticosteroids bind to glucocorticoid receptors expressed in multiple cell types and lead to transcription of a gene program with diverse effects. Corticosteroid effects include inhibition of prostaglandin synthesis, blockade of MAP kinase signaling pathways, and $NF_{\kappa}B$ transcription (Rhen et al. 2005).

Ulcerative Colitis: Corticosteroids are effective at inducing remission in ulcerative colitis and are used in patients with moderate to severe symptoms who have not responded to 5-ASAs. In patients not responding to prednisone, intravenous steroids may be effective. Patients with symptoms that have not improved after 3–5 days of intravenous steroids are unlikely to respond, and an alternative medical or surgical strategy should be initiated. Systemic steroids are not used in the maintenance of remission for

ulcerative colitis. Topical steroid preparations are effective for induction of remission in distal ulcerative colitis (Mulder et al. 1996).

Crohn's Disease: Steroids have been demonstrated to induce remission in Crohn's disease. However, a population study in Olmstead county revealed 28 % of patients with CD could not be tapered off steroids by a year (Faubion et al. 2001), arguing that alternatives to steroids should be sought in this disease. Budesonide is a nonsystemic steroid preparation that delivers glucocorticoid to the terminal ileum and right colon with high first-pass metabolism in the liver, resulting in fewer systemic side effects. Budesonide is as effective as systemic steroids in patients with ileal or ileo-right colonic disease (Rutgeerts et al. 1994; Gross et al. 1996; Bar-Mier et al. 1998; Campieri et al. 1997).

In doses less than 6 mg/day, randomized studies have not shown a benefit of budesonide in maintenance of remission (Papi et al. 2000; Simms and Steinhart 2001).

Antibiotics

Mechanism of Action: Although a causative organism has not been identified in patients with IBD, evidence supports a role for an aberrant response to commensal bacteria, and antibiotics have been used in its treatment.

Data regarding the effectiveness of antibiotics in Crohn's disease and ulcerative colitis has been conflicting and difficult to interpret due to heterogeneity in antibiotic type, combination, dosing, and duration. A meta-analysis looking at antibiotic therapy for the induction and remission of UC and CD revealed a modest effect for the treatment of active CD and UC and maintenance of remission in CD. However, larger studies of individual antibiotic regimens are necessary (Kahn et al. 2011).

Immunomodulators (6MP/Azathioprine)

Mechanism of Action: The immunomodulator class of drugs, including 6MP and its prodrug azathioprine (AZA), are purine analogues. These drugs are converted into their metabolites 6-thioguanine (6-TG), 6-methyl-mercaptopurine (6MMP), and 6-thiouric acid and can become incorporated into DNA and interfere with nucleic acid synthesis. In addition, 6MMP has been shown to inhibit de novo purine synthesis (Maltzman et al. 2003). Azathioprine has also been shown to induce apoptosis in CD4+ T cells (Tiede et al. 2003).

Ulcerative Colitis: Studies of AZA withdrawal have demonstrated a higher rate of relapse in patients withdrawn to placebo versus those continued on AZA. A study of steroid-dependent UC patients randomized to receive mesalamine 3.2 g/daily or AZA 2 mg/kg daily demonstrated increased endoscopic and clinical remission and steroid tapering in the group randomized to AZA. Based on these studies immunomodulators are primarily used for steroid sparing and maintenance of remission in UC.

Crohn's Disease: A number of studies have been performed evaluating immunomodulators for the treatment Crohn's disease and have been reviewed in a meta-analysis of trials looking at induction (Sandborn et al. 2000) and maintenance of remission (Pearson et al. 2000). Immunomodulators were found to be effective at both induction and maintenance of remission for CD. However, the maximal clinical benefit of these medications is seen after 3–4 months, generally necessitating the use of another induction agent when starting these medications.

Methotrexate

Mechanism of Action: Methotrexate is a folate analog that inhibits folate-dependent enzymes important for purine and pyrimidine synthesis and inhibits cell division of rapidly dividing cells including lymphocytes. Methotrexate may also control lymphocyte function by inducing apoptosis of activated CD4+ T cells (Nielson et al. 2007). In addition, methotrexate inhibits 5-aminoimidazole-4-carboxamide ribonucleotide (AICAR) transformylase, an enzyme involved in de novo purine synthesis. In the absence of AICAR transformylase, increased AICAR leads to elevations in both intra- and extracellular adenosine (Krener et al. 2004). Adenosine has anti-inflammatory properties including inhibition of neutrophil adherence

(Cronstein et al. 1991) and inhibition of cytokine response by hematopoietic cells and has been implicated in regulatory T cell (Treg) function (Ernst et al. 2010). Studies in both animals and humans have suggested that adenosine antagonists can partially inhibit the effects of methotrexate in vivo (Montesinos et al. 2000; Nesher et al. 2003).

Crohn's Disease: Intramuscular methotrexate has been shown to induce and maintain remission in Crohn's disease (Feagan et al. 1995, 2000).

Ulcerative Colitis: Randomized controlled trials using oral methotrexate in ulcerative colitis failed to demonstrate benefit in induction or maintenance of remission (Oren et al. 1996; Mat-Jimenez et al. 2000). Studies utilizing parenteral dosing effective in Crohn's disease have not been evaluated in UC to date.

Cyclosporin

Mechanism of Action: Cyclosporin (CSA) binds cyclophilin and blocks the phosphatase activity of calcineurin. Calcineurin blockade prevents nuclear translocation of the transcription factor NFATc and downstream transcription of genes critical for T cell activation including production of IL-2 (Ho et al. 1996).

Ulcerative Colitis: In randomized controlled trials studying patients with IV steroid-refractory UC, CSA induces response in 82 % of patients (Lichtiger et al. 1994). Retrospective studies have reported long-term colectomy-free survival at 16–78 months in 40–90 % of patients transitioned to oral CSA transitioned to immunomodulator therapy (Fernandez-Banares et al. 1996; Cohen et al. 1999; Campbell et al. 2003; Message et al. 2005).

Crohn's Disease: Randomized studies of oral CSA for the treatment of CD have not consistently demonstrated benefit (McDonald et al. 2005). Intravenous dosing analogous to treatment for UC has not been tested in CD.

Anti-TNF Agents (Infliximab, Adalimumab, Certolizumab)

Mechanism of Action: TNF_α is a proinflammatory cytokine that perpetuates tissue damage IBD. Specific TNF_α blockade in IBD has been accomplished through the development of anti-TNF antibodies (infliximab and adalimumab) and an anti-TNF F(ab)' fragment linked to polyethylene glycol (Certolizumab). In addition to neutralization of soluble TNF_α, infliximab and adalimumab are capable of binding to cells expressing transmembrane-bound TNF_α. These antibodies can fix complement and allow for antibody-mediated cytotoxicity of TNF_α-bearing cells. In addition, binding of transmembrane TNF_α has been reported to induce reverse signaling in monocytes and lead to apoptosis, cell cycle arrest, and IL-10 production (Mitoma et al. 2005). Induction of apoptosis has been observed in the intestinal mucosa of patients undergoing infliximab therapy (Ten Hove et al. 2002; Van Den Brande et al. 2007). However, induction of apoptosis is not necessarily a critical mechanism of anti-TNF therapy, as certolizumab is not capable of inducing apoptosis in vitro and is effective in the treatment of CD (Bourne et al. 2008).

Crohn's Disease: Three anti-TNF agents infliximab, adalimumab, and certolizumab have been shown to be effective for induction and maintenance therapy in Crohn's disease.

Infliximab: Infliximab is a chimeric IgG1 anti-TNF antibody administered by intravenous infusion. Infliximab is effective as induction therapy for the treatment of moderate to severe Crohn's disease (Targan et al. 1997). Studies have demonstrated that scheduled maintenance therapy every 8 weeks is associated with increased remission rates, reduced steroid utilization, reduced development of antibodies of infliximab, and fewer hospitalizations (Rutgeerts et al. 1999; Hanauer et al. 2002; Rutgeerts et al. 2004). Infliximab has also been shown to be effective in reducing drainage and closing perianal and abdominal fistulas (Present et al. 1999).

Adalimumab is a fully humanized IgG1 anti-TNF antibody. Certolizumab pegol is an anti-TNF F(ab)' fragment linked to polyethylene glycol. Adalimumab and certolizumab are administered subcutaneously and are effective as induction and maintenance therapy for moderate to severe CD. Although

Adalimumab, certolizumab, and infliximab have not been directly compared, induction and remission rates are similar based on data from RCT (Hanauer et al. 2006; Rutgeerts et al. 2006; Sandborn et al. 2007; Schrieber et al. 2007). Like infliximab, adalimumab and certolizumab appear to be effective at inducing and maintaining fistula closure (Colombel et al., 2007; Screiber et al. 2011). Adalimumab and certolizumab are effective in patients who have lost response to or are intolerant of infliximab, although response rates are reduced compared to anti-TNF-naïve patients (Schreiber et al. 2007; Sandborn et al. 2007, 2010; Colombel et al. 2007; Feagan et al. 2011).

Ulcerative Colitis: Infliximab has been found to be effective for the induction of remission and maintenance in moderate to severe ulcerative colitis. Patients receiving infliximab have reduced steroid requirements and healing of the colonic mucosa (Rutgeerts et al. 2005). Recent data has also suggested that infliximab may be used as rescue therapy in severe, IV steroid-refractory ulcerative colitis (Janerot et al. 2005).

A recent small study of adalimumab in patients with moderate to severe UC has suggested efficacy in induction of remission (Sandborn et al. 2010). Studies assessing the effectiveness of additional anti-TNF agents approved for Crohn's disease (adalimumab and certolizumab) are ongoing.

Natalizumab

Mechanism of Action: Natalizumab is a humanized monoclonal antibody that targets the alpha4 integrin. Alpha4 in a complex with beta7 integrin is expressed on lymphocytes homing to the gastrointestinal tract, where its ligand, mucosal addressin cell adhesion molecule-1 (MAdCAM-1), is expressed on high endothelial venules (HEVs) within the lamina propria. Natalizumab prevents binding of alpha4 with MAdCAM-1 and limits entry of lymphocytes into gastrointestinal tissues.

Crohn's Disease: In a trial where inclusion criteria included elevated CRP, a significant increase in response and remission was achieved in patients with Crohn's disease receiving natalizumab (Targan et al. 2006). Maintenance trials have yielded consistently positive results in patients who responded to natalizumab (Sandborn et al. 2005; Panaccione et al. 2006).

Ulcerative Colitis: No randomized controlled trials of natalizumab in UC have been published to date.

Patients receiving natalizumab are at risk for developing progressive multifocal leukoencephalopathy (PML), a debilitating neurologic disease that is frequently fatal. PML occurs from reactivation of JC virus, and the risk of development is 1/1000 (Sandborn et al. 2006).

Special Considerations

Combination Therapy of Immunomodulators and Anti-TNF Therapy for Moderate to Severe CD

A recent study of patients naïve to therapy with moderate to severe CD has suggested that combination therapy with an immunomodulator plus an anti-TNF agent resulted in increased remission rates at 1 year compared to monotherapy with either drug alone (Colombel et al. 2010). However, there has been some concern regarding the safety of combination therapy, particularly with regard to a rare lymphoma called hepatosplenic T cell lymphoma (HSTCL). HSTCL is a rare, usually fatal, hematologic malignancy that has been associated with immunosuppressive use in young males (Kotlyar et al. 2011). Thus, the risks of serious complications must be weighed against the benefit of therapy on an individual basis.

Postoperative Prophylaxis in CD

Following surgical resection, endoscopic recurrence occurs in 28–93 % of patients at 1 year (Achkar et al. 2000), and clinical recurrence rates are 20 % and 34 % at 1 and 3 years (Rutgeerts et al. 1990). One-third of patients will ultimately require repeat surgery within 10 years (Achkar et al. 2000). Identifying strategies that prevent postoperative recurrence is of great interest.

Results from two meta-analyses have demonstrated that postoperative azathioprine or 6MP was associated with a significantly decreased risk of clinical recurrence and endoscopic

recurrence of disease. Studies of mesalamine have shown minimal prevention of relapse and have been shown to be inferior to 6MP in the postoperative setting (Camma et al. 1997; Lochs et al. 2000; Sutherland et al. 2000; Hanauer et al. 2004). Postoperative therapy with metronidazole (20 mg/kg/day) for 3 months resulted in fewer endoscopic lesions at 1 year and delayed clinical recurrence (Rutgeerts et al. 1995). Ornidazole 1 g/day given for 1 year and started immediately after resection also reduced endoscopic recurrence at 1 year (Rutgeerts et al. 2005). Clinical use of these antibiotics has generally been limited by peripheral neuropathy and gastrointestinal side effects. A small randomized controlled study of infliximab for postoperative prophylaxis showed significant benefit over placebo in rates of endoscopic recurrence (Regueiro et al. 2009). Further evaluation of a larger cohort of patients is necessary to determine the role of anti-TNF therapy in the postoperative setting.

Surgical Management in IBD

Surgery for Ulcerative Colitis

Despite medical options for therapy, 8–30 % of patients with UC will ultimately require colectomy (Ananthakrishnan et al. 2009). Elective surgery is indicated for medically refractory disease in patients with ongoing moderate symptoms or steroid dependency despite maximal medical therapy. In addition, elective surgery is indicated for the treatment of colitis-associated cancer or dysplasia. Options for elective surgical management in UC include total proctocolectomy with end ileostomy or restorative proctocolectomy, most commonly with ileoanal pouch anastomosis (IPAA). Total proctocolectomy with end ileostomy may be recommended for patients with impaired anal sphincter function, rectal cancer, or those unwilling or unable to undergo a multistage procedure. Complications of this procedure may include stomal stenosis, parastomal hernia, and skin breakdown, occasionally requiring stomal revision. Elective IPAA is commonly performed in two or three stages and involves the generation of a neo-rectum from the ileum anastomosed to the anal transition zone. A diverting ileostomy is performed at the time of pouch creation to allow the anastomosis to heal prior to restoration of continuity. Complications of IPAA include anastomotic separation, pouch fistulas, and pouch inflammation, called "pouchitis." A small percentage of patients (less than 5 %) have severe pouch complications requiring pouch excision (Stahlber et al. 1996; Simchuk et al. 2000). IPAA is associated with significantly reduced fertility in women (Waljee et al. 2006). In addition, patients with IPAA have an average of six loose bowel movements per day including nocturnal bowel movements. IPAA can be performed with a hand-sewn or stapled anastomosis, the latter being required when laparoscopic surgery is performed. Stapled anastomosis leaves a small rectal cuff that is at risk for development of inflammation called "cuffitis" and also for development of precancerous changes. Despite these potential complications, health-related quality of life is significantly improved in patients undergoing IPAA surgery (Heikins et al. 2010). The indications for urgent colectomy in UC include acute severe colitis not responding to medical therapy, toxic megacolon, or perforation. In the emergent setting, subtotal abdominal colectomy with ileostomy is performed. Following a period of recovery, elective IPAA or a completion proctectomy may be performed.

Surgery for Crohn's Disease

Epidemiologic data collected prior to the common use of anti-TNF agents has demonstrated that after 10 years of disease, 30–50 % of patients with CD require surgery. While new data suggest that anti-TNF therapies are having a modest impact on surgical rates, surgical intervention remains an important therapy for CD. In addition, postoperative recurrence rates are about 50 % at 10 years and many of these patients will eventually require a second operation (Bernstein et al. 2012). The major indications for the surgical management of Crohn's disease include disease refractory to medical therapy, management of

stricturing or penetrating complications, malignancy or dysplasia, and fecal diversion for severe perianal CD.

The appropriate surgery for Crohn's disease is based on disease behavior and location. In treating small intestinal disease, conservation of bowel is important given the high rate of recurrence and reoperation. Studies have suggested that large disease-free resection margins are not necessary and that gross inspection of bowel is adequate in determining length of resection rather than histology (Fazio et al. 1996). In addition, when multiple or long segments of strictures are present, stricturoplasty may be performed to conserve small bowel length. Surgical therapy may also be indicated for mesenteric abscesses, enterocutaneous, enterovesicular, or enteroenteric fistulas. For segmental Crohn's colitis, a meta-analysis of segmental resection versus total abdominal colectomy with ileorectal anastomosis has suggested similar outcomes, although there is a longer time to recurrence in patients following total colectomy (Tekkis et al. 2006). In the case of extensive colitis involving the rectum, IPAA results in a high rate of morbidity in CD including pouchitis, fistula, and pouch failure. It is therefore recommended that these patients undergo total proctocolectomy with end ileostomy. Surgery may be indicated in patients with perianal abscess or fistula. For simple abscesses, incision and drainage procedures may be adequate. In the case of fistulas, exam under anesthesia with seton placement, plug, or mucosal advancement flaps may be performed. For severe medically and surgically refractory perianal disease, diverting ileostomy may be temporarily effective in 80 % of patients. However, restoration of continuity is rarely successful (Yamomoto et al. 2000).

Cancer and IBD

Colorectal cancer has been recognized as a consequence of longstanding inflammatory bowel disease for almost 100 years (Crohn et al. 1925). A meta-analysis in 2001 including over 100 studies suggested that the risk of development of colon cancer was 2 % by 10 years, 8 % by 20 years, and 18 % by 30 years. Recent data also suggest that patients with extensive Crohn's colitis share similar increased risk.

There are distinct biologic differences between sporadic colon cancers and colitis-associated cancers (CAC). In sporadic colon cancer, carcinoma typically develops from a raised localized dysplastic precursor lesion, the adenomatous polyp. However, in the setting of IBD, dysplasia can be flat or polypoid and is often multifocal, suggesting the presence of a common underlying defect.

The molecular events leading to dysplasia also have some distinct differences. In sporadic tumors, loss of function of APC gene is an early event that leads to formation of a sporadic adenoma. Loss of p53 function occurs late and is important for the adenoma to carcinoma sequence. While chromosomal instability occurs with the same frequency in CAC, APC loss of function occurs less frequently and is a late event, while p53 mutations occur early and can be present in adjacent non-dysplastic tissue.

Several lines of evidence suggest that chronic inflammation is a key factor in predisposing to dysplasia. The risk of colon cancer in patients with IBD increases with duration and extent of disease. Further, a greater histologic severity of IBD is associated with an increased risk of colorectal cancer (Rutter et al. 2004; Gupta et al. 2007). Other risk factor for development of CAC is a family history of colorectal cancer which imparts a 2-fold increased risk. In addition, Primary Sclerosing Cholangitis (PSC) appears to be an independent risk factor for development of colitis-associated colon cancer reported in some, but not all studies.

Endoscopic surveillance colonoscopy has been shown to reduce the development of colorectal cancer in IBD (Itzkowitz et al. 2004) and to detect colon cancers at an earlier stage (Collins et al. 2006). Current surveillance

recommendations are that colonoscopy should commence at 7–8 years after diagnosis of ulcerative colitis or extensive Crohn's colitis and consist of four quadrant nontargeted biopsies every 10 cm with biopsies taken of any raised lesions or strictures. Surveillance should be performed every 1–2 years. PSC patients undergo a screening colonoscopy at the time of diagnosis to determine whether colitis is present. In patients with PSC and colitis, it is recommended that screening for dysplasia begins at the time of diagnosis. Patients with low-grade or high-grade dysplasia identified in flat tissue should be considered for colectomy. Newer techniques for surveillance colonoscopy, such as chromoendoscopy, have been shown to improve the diagnostic yield of surveillance, but are not standard of care.

Conclusions

The inflammatory bowel diseases, Crohn's disease and ulcerative colitis, are chronic conditions that result from inappropriate inflammation in the intestinal tract. Clinical presentation is characterized by diarrhea with or without blood, abdominal pain, weight loss, and systemic inflammation. The diagnosis is confirmed by pathologic examination demonstrating acute and chronic intestinal inflammation. IBD is thought to result from an inappropriate immune activation in response to the commensal bacterial flora. Medical therapies for IBD are generally aimed at suppressing the adaptive arm of the immune response. However, surgery remains an important adjunct to medical therapy for both Crohn's disease and ulcerative colitis.

Acute-phase response; Cytokines; Defense; Liver regeneration; Lymphoid lineage; Myeloid lineage; Progenitors

Definition

Large populations of innate immune cells reside in healthy liver, poised to detect potential harm, damage, or infection, locally or systemically. The factors produced by these cells are critical to successful initiation and resolution of inflammation. Over- or underproduction of these immunomodulatory and effector proteins will lead to pathology.

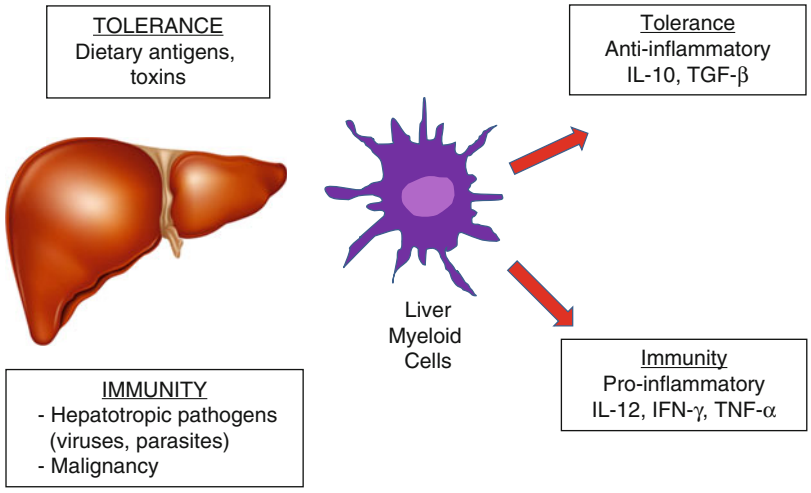
Introduction

The liver is a site of complex immune activity, capable of responding to major pathological challenges such as metastasis and infection, while remaining tolerant of most of the foreign material it encounters (O'Farrelly and Crispe 1999; Doherty and O'Farrelly 2000; Racanelli and Rehermann 2006). In its healthy state, the liver immune system tolerizes harmless proteins of dietary and commensal origin that are constantly being transported from the gut by the portal system. However, the oxygenated, nutrient-rich environment of the healthy liver provides a natural target for all types of pathogens including viruses, bacteria, fungi, nematodes, and protozoa, while constant perfusion with circulating blood makes the liver a primary target for metastasis. A complex repertoire of immunocompetent cells in the liver, in particular large populations of innate immune cells, including macrophages, dendritic cells (DCs), and natural killer receptor + (NKR+) lymphoid cells, makes sure that pathogenic and metastatic challenges are identified and dealt with appropriately, while harmless molecules and cells are tolerated (O'Farrelly and Crispe 1999; Gao et al. 2008, Fig. 1). Hepatocytes and endothelial cells also contribute to local and systemic inflammation and should be considered members of the hepatic innate cellular catalogue. The anatomical location of the liver and its rich blood supply, together with its complex collection of immune surveillant cells, equip it for detection of any signs of danger or damage in other parts of the body. Molecular signals, carried to the liver from sites of inflammation, infection, or damage, are detected by hepatocytes, which are activated to synthesize acute-phase proteins. These alert the whole body to danger, mobilizing immune components, opsonizing pathogens, and inducing cellular proliferation and additional synthesis of cellular and molecular immune components. So, the products of liver cells initiate, mediate, regulate, and resolve systemic and local immune responses and also contribute to the liver pathology often associated with inflammatory and immunological activity (Liaskou et al. 2012). Reptilian, avian, and amphibian livers also have roles in local and systemic defense, as does the "fat body," the organ responsible for metabolism in insects. Co-localization and coevolution, in such disparate species, of immunological and metabolic activities, requiring effective circulation for efficient implementation, emphasizes a highly conserved role for the liver in mediating the interphase between metabolism and defense. Key to this role are the innate immune cell populations of myeloid and lymphoid lineages that reside in healthy liver (Doherty and O'Farrelly 2000; Gao et al. 2008).

Hepatic Innate immune Cells: Myeloid Lineage

Liver Macrophages (Kupffer Cells)

Myeloid cell populations in the liver are particularly varied, with considerable overlap among

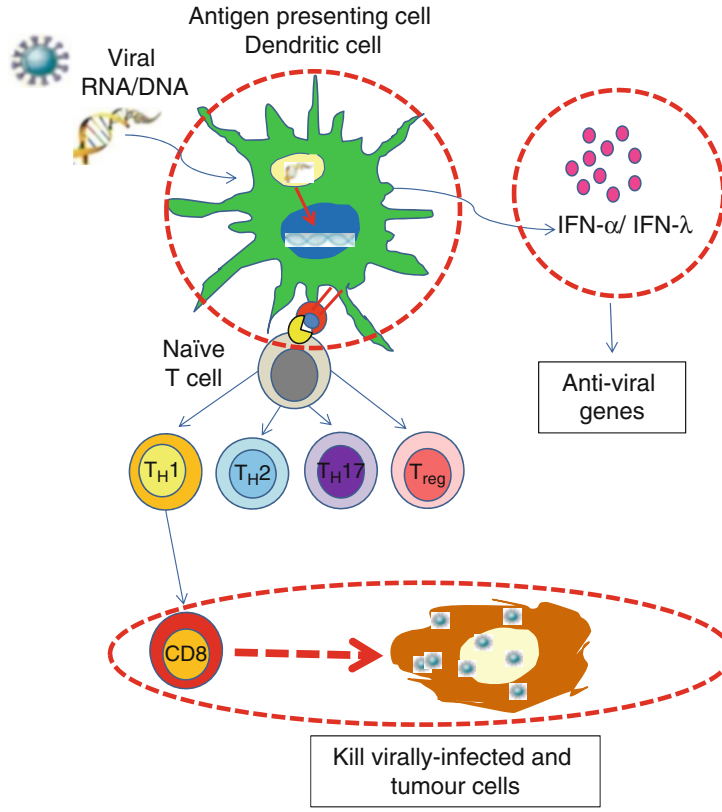


Innate Immune Cells in the Liver, Fig. 1 Liver myeloid cells contribute to both tolerance and immunity in the liver by secreting cytokines

fixed and newly resident macrophages, dendritic cells, myeloid progenitors, and myeloid regulatory cells (Lloyd and Phillips 2008). Liver-resident macrophages (also known as Kupffer cells), the primary innate immune cell type in the liver, are equipped with powerful pathogen detection and protein production potential (McCuskey et al. 1987; Bilzer et al. 2006). Kupffer cells represent 80–90 % of all tissue-fixed macrophages of the body, and 15 % of the total cell population in the healthy liver, where they are interspersed with fenestrated liver sinusoidal endothelial cells. Kupffer cells are therefore the most numerous components of the "reticuloendothelial system," characterized by versatile phagocytic function, found at sites of potential pathogenic invasion including the gut, skin, and lungs, as well as liver. Macrophages recognize microbes and their products through pattern recognition receptors (PRRs) that stimulate cell activation and pathogen phagocytosis (Medzhitov and Janeway 2002). Major protein synthesis is induced, resulting in production of antimicrobial peptides, chemokines, and cytokines, especially TNF, IL-1, IFNγ, and IL-6. Liver macrophages are potent producers of inflammatory cytokines and therefore they can help induce, mediate, and regulate systemic as well as local inflammation (O'Farrelly and Crispe 1999; Gao et al. 2008; Sitia and et al. 2011; Nemeth et al. 2009). In the liver, these messenger molecules stimulate hepatocyte synthesis of acute-phase proteins which are critical for driving, mediating, and regulating the systemic response to inflammation and ultimately restoring homeostasis (Moshage 1997; Baumann and Gauldie 1994; Gabay and Kushner 1999; Bode et al. 2012). Liver-derived acute-phase proteins, complement components, and inflammatory cytokines have major impact on liver repair and regenerative capacity (Diehl 2000; Strey et al. 2003; Rutkowski et al. 2010) and are known to influence inflammatory, physiological, and homeostatic activities in other organs, such as the brain, bone marrow, and hypothalamic-pituitary axis. In addition to their role in local and systemic inflammation, subpopulations of liver macrophages have significant regulatory activity and may contribute to the tolerogenic potential of the liver (Callery et al. 1989).

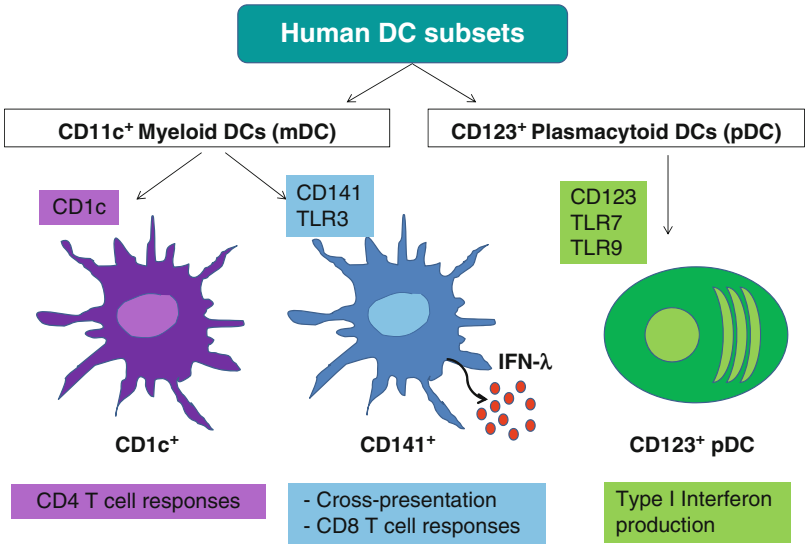
Dendritic Cells

Dendritic cells (DCs), also powerful phagocytic cells of the myeloid lineage and potent producers of messenger molecules, such as cytokines, chemokines, and growth factors (Steinman 1991), are found in much smaller numbers in healthy liver (Thomson and Knolle 2010). Classically, DC play an important role as antigen-presenting cell in initiating and directing activation and polarization of T lymphocytes in lymph nodes (Shortman and Liu 2002, Fig. 2).

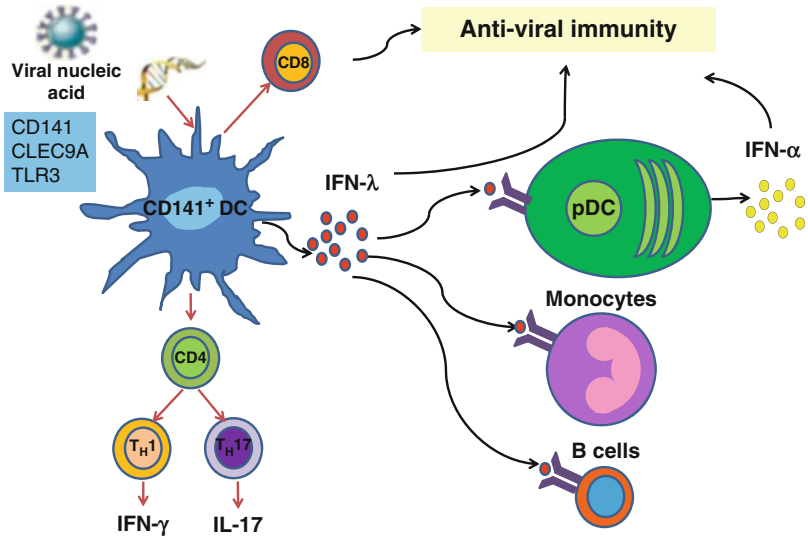


Innate Immune Cells in the Liver, Fig. 2 General role of dendritic cells as antigen-presenting cells in antiviral and antitumoral immunity

Three subsets of human DCs are classically distinguished: CD11c DCs (classical Dcs or cDCs) include CD1c+ and CD141+ subsets that activate CD4 and CD8 T cells and plasmacytoid CD123+ DCs that produce type I interferon (Fig. 2). cDCs are equipped with an extensive array of PRRs and other detection molecules such as the C-type lectin, DC-SIGN (DC-specific ICAM-3 grabbing non-integrin), and CLEC-9A and can sense the presence of pathogens, cell damage, and metastatic danger (Thomson and Knolle 2010; Doherty and O'Farrelly 2001, Fig. 3). They are major antigen-presenting cells and potent cytokine secretors, although not primarily of IFN-α (Hsu et al. 2007, Fig. 4). Plasmacytoid DCs (pDC), also well equipped with viral detection systems, are involved in antiviral responses, primarily secrete interferon-α, and are poor antigen presenters (Fig. 4). The liver contains all three DC subsets, but CD141+ DCs are more represented than in the blood (Fig. 5). Hepatic DCs often are more potent phagocytic cells and produce more cytokines than their counterparts in classical lymphoid organs, including spleen and lymph nodes (Jomantaite et al. 2004). Therefore, although present in small proportions, hepatic DCs are powerful initiators, drivers, and regulators of local innate and adaptive innate immune responses (Thomson and Knolle 2010; Doherty and O'Farrelly 2001; Jomantaite et al. 2004). Some populations of liver DCs have an immature, tolerogenic phenotype, express lower co-stimulatory molecules, secrete low levels of IL-12 and high levels of the suppressive cytokine IL-10, and thus induce anergy in naïve, allogeneic T cells (Sallusto and Lanzavecchia 1994). Subpopulations of hepatic DCs are therefore considered key drivers of immunological tolerance in the liver (Thomson and Knolle 2010; Thomson and Lu 1999; Goddard et al. 2004; De Creus et al. 2005). However, other hepatic DC populations seem capable of activating



Innate Immune Cells in the Liver, Fig. 3 Different subsets of human DCs and their role in immune responses

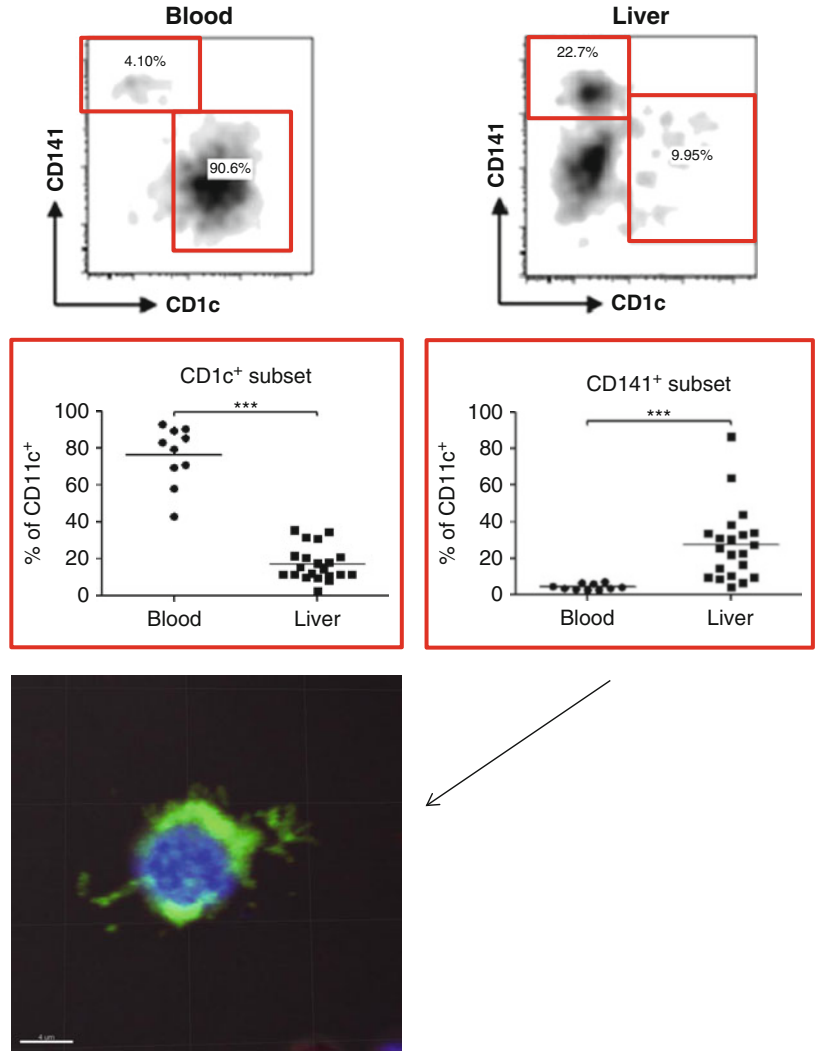


Innate Immune Cells in the Liver, Fig. 4 Role of CD141$^+$ DCs and IFN-λ in the antiviral immune response

T lymphocytes (Kelly et al. 2014) and may therefore initiate and mediate specific adaptive immunity to hepatotropic pathogens. Because hepatic DCs have such major roles in activating and regulating responses to infectious and autoimmune liver disease (Protzer et al. 2012) as well as mediating oral and portal tolerance, they have been proposed to be key to determining the balance between liver tolerance and immunity (Thomson and Knolle 2010; Doherty and O'Farrelly 2001; Duffield 2012).

Regulatory Myeloid Cells

Other heterogeneous populations of myeloid cells in the liver have potent regulatory function. Some combine features of myeloid progenitors and neutrophils and suppress T cell activity by secreting the regulatory cytokines IL-10 and TGF-β. They also produce the metabolic inhibitors, arginase and IDO, which control immune cells by depleting the immediate environment of the key amino acids, arginine and tryptophan, and are known as myeloid-derived suppressor cells



Innate Immune Cells in the Liver,
Fig. 5 Characterization of dendritic cell (*DC*) subsets in healthy donor liver perfusate

(Gabrilovich and Nagaraj 2009). These cells are considered important for inhibiting inappropriate responses to harmless antigens of dietary and commensal origin, thus promoting the tolerogenic capacity of the liver. However, increased numbers of this population have been demonstrated in tumor-bearing liver where they seem to inhibit antitumor immunological activity and so facilitate tumor growth (Ilkovitch and Lopez 2009). Immunoregulatory properties have also been ascribed to granulocyte populations (neutrophils, basophils, and eosinophils) often involved in the pathologies associated with inflammation and the immune response to parasites but found in tiny numbers in healthy liver (Siracusa et al. 2011; Jaeschke et al. 1996).

Hepatic Innate Immune Cells: Lymphoid Lineage

Natural Killer Receptor+Cells

The healthy liver is packed with large, heterogeneous populations of innate cells of lymphoid origin that are critical for local defense against viruses and tumors as well as homeostasis (Doherty and O'Farrelly 2000; Crispe 2011). These innate lymphoid cells, originally termed

"pit cells" (Hata et al. 1991), are characterized by expression of natural killer receptors (NKR) and include classical natural killer cells and populations of T lymphocytes which combine phenotypic and functional characteristics of T cells and natural killer cells (Wisse et al. 1976; Norris et al. 1998; Crispe and Mehal 1996). All respond swiftly to stimulation, producing large amounts of cytokines and having potent killing capabilities, and are therefore major components of the hepatic innate immune arsenal, with particular roles in tumor surveillance and antiviral immunity.

Natural Killer Cells: Antiviral, Antitumor, and Tissue Remodeling Activities

NK cells are more abundant in the human liver than any other organ (Crispe and Mehal 1996; Gao et al. 2009) accounting for 30–50 % of intrahepatic lymphoid cells. Hepatic NK cells have critical roles in the immune response against hepatotropic viruses such as hepatitis C and are also important components of the hepatic antitumor immune repertoire. NK cells detect changes in membrane glycoprotein expression on target cells, usually induced by viral infection, proliferation, or transformation – in other words, they detect "altered self" (Biron et al. 1999; Caligiuri 2008). When activated, NK cells kill their targets by delivering cytotoxic granules into bound target cells. NK cells are also potent cytokine producers, with subpopulations secreting so much cytokine protein that they are thought responsible for the liver pathology that often accompanies the response to local infection or malignancy (Caligiuri 2008). We now know that NK cells also have potent tissue regeneration and remodeling capabilities (Vivier et al. 2009) and must have equivalent roles in the liver. Differential expression of NK cell surface molecules, cytokine receptors, and cytoplasmic cytokines identifies subpopulations of NK cells in the liver that are responsible for local responses to pathological challenge, resulting in pathogen clearance, tissue remodeling, and return to homeostatic normality or liver scarring and damage.

The hepatic cytokine milieu, generated by local myeloid and lymphoid populations, critically influences NK phenotype and activity. In particular, G-CSF, GM-CSF, IFN-α, IFNγ, IFNλ, IL-2, IL-12, and IL-15 all impact on differentiation, phenotype, and function of NK cells and other hepatic immune cells. DC populations are potent producers of these cytokines (Shortman and Liu 2002), emphasizing the complex interplay between these two innate immune populations required for effective homeostasis or immune activity in either healthy or challenged liver.

Innate (Natural) T Lymphocytes

Classical T cells express variant receptors that are coded for by gene segments which undergo rearrangement during T cell development in the thymus. This process results in a myriad of TCR specificities (in the region of 10^9). Because of positive and negative selection in the thymus, successfully matured T cells have TCRs that only recognize foreign antigen presented in the context of self class 1 or class II major histocompatibility (MHC) molecules. In the periphery, activation of these T cells requires appropriate ligand recognition, co-stimulation, and cytokine environment. Populations of T cells have been discovered that express TCRs of limited specificity, that are coded for by restricted classes of gene segments, and that are not restricted by classical class 1 or class II major MHC molecules. Because of limited gene usage and lack of extra nucleotide insertion during the gene rearrangement events that accompany T lymphocyte development, these T cells are termed "invariant" (Bendelac et al. 2007).

One population of invariant NKT cells (iNKT) with potent antitumor capability (Bendelac et al. 2007; Cui et al. 1997) is found in relatively large numbers in human liver (Norris et al.). These iNKT cells recognize glycolipids presented by the nonclassical MHC molecule CD1d (Bendelac et al. 2007). Other invariant T cell populations include mucosal-associated invariant T (MAIT) cells which are CD161+, IL-17-secreting cells with antimicrobial activity and are restricted by the stress molecule MR1. These cells are found in high numbers in the gastrointestinal tract (Dusseaux et al. 2011) and in the liver (Billerbeck et al. 2010).

Other invariant T cell populations, in particular γδ TCR+ T cells, which recognize conserved molecules on cell surfaces such as MICA and MICB, often induced by cellular stress caused by infection or transformation are found in higher numbers in the liver than in the circulation (Crispe 2011; Norris et al.). One subpopulation of γδ TCR+ T cells (expressing Vδ3) seems to be specific to the liver (Kenna et al.). Expression of CD161 by the majority of these populations is an indication of their targeted homing (Norris et al.; Billerbeck et al. 2010; Lalor and Adams 2002).

Innate Immune Populations May Differentiate and Mature in Adult Liver

Major advances are being made in identifying and defining how populations of immune cells traffic to the liver during health and disease (Lalor and Adams 2002; Lee and Kubes 2008; Shetty et al. 2008). However it remains possible that some of these cells differentiate locally (Sato et al. 1993; Golden-Mason and O'Farrelly 2002). The myelopoietic and lymphopoietic potential of fetal liver is well recognized (Payushina 2012). Healthy adult liver also seems to support self-renewal of hepatic macrophage and innate lymphoid cell populations as well as differentiation from liver-derived, hematopoietic stem cells (HSCs). Functional HSCs have been demonstrated in mouse (Li et al. 2006), rat (Yovchev et al. 2008), and human adult liver (Crosbie et al. 1999; Golden-Mason et al. 2000) capable of proliferation and differentiation. Moreover, high levels of IL-7 and IL-15, two cytokines required for lymphoid maturation and activation, are found in healthy liver (Golden-Mason et al. 2001, 2004). Significant proportions of hepatic HSCs express lymphoid and myeloid lineage markers as well as the receptors for IL-7 and IL-15, suggesting that they are progenitors of hepatic macrophage and innate lymphoid populations. HSCs expressing the myeloid marker CD33 are expanded in tumor-bearing liver (Golden-Mason et al. 2000) and are thought to be responsible for increased immature, neutrophil populations with suppressor function seen in tumor-bearing liver tissue.

Nonclassical Innate Immune Cells in the Liver (Hepatocytes, Epithelial, and Endothelial Cells) and the Acute-Phase Response

Classically, innate immune cell populations have included myeloid phagocytic cells and NKR+ lymphoid cells exclusively. However, other nonimmune cell types, particularly in the liver, have key roles in recruiting and homing of immune cells (Edwards et al. 2005) as well as in local and systemic innate immune responses; they should therefore be considered components of the hepatic innate immune system. The acute hepatic response to systemic injury requires re-prioritization of liver protein synthesis by all hepatic cells, particularly hepatocytes as well as endothelial and epithelial cell populations. Inflammatory cytokines and other stress factors produced at distal sites of inflammation, are detected by receptors on nonhematopoietic as well as immune cells. These factors may induce a major shift of available synthetic capacity and amino acid resources from constitutive production of proteins such as albumin and transferrin, to production of non-constitutive acute-phase proteins (APP). Positive acute-phase reactants include fibrinogen, pentraxins such as C-reactive protein (CRP), serum amyloid A, and haptoglobin as well as effector molecules such as complement components, defensins, and hepcidin (Edwards et al. 2005; Rowell et al. 1997; Strnad et al. 2011). These multipotent molecules alert the body to potential danger, mediate significant antimicrobial activity, and drive appropriate systemic physiological, metabolic, and immunological responses. They therefore have major roles in the restoration of homeostasis after injury and metabolic stress as well as inflammation and defense.

Conclusion

Relative over- and underproduction of acute-phase proteins, cytokines, and growth factors in the liver, products of myeloid and lymphoid innate immune cells, determine the clearance efficiency of any inflammatory or pathological

insult locally or anywhere in the body. They will also regulate the effectiveness of local and distal inflammatory activity, act to resolve inflammation and regenerate tissue, as well as control the extent of resulting hepatic scarring. The liver innate immune system is therefore pivotal to immunological and physiological homeostasis.

Summary

The liver is in constant monitoring mode, not only of metabolic activity and the body's metabolic requirements but also of signs of potential or actual internal harm anywhere in the body. If none are detected, the main focus for the organ remains normal physiological and metabolic activity, which requires immunological homeostasis. If under pathological threat, the liver switches from metabolic mode towards mobilizing itself and the body for defense. Innate immune cells are responsible for many of the detection, regulatory, and effector activities required for immune homeostasis and responsiveness in healthy and diseased liver.

Definition

Interleukin-6 (IL-6), originally identified as a B cell differentiation factor, is a typical cytokine featuring pleiotropic and redundant activity. It is an immunoregulatory cytokine providing host defense against infections and injuries, while dysregulation of persistent IL-6 synthesis causes the development of various diseases.

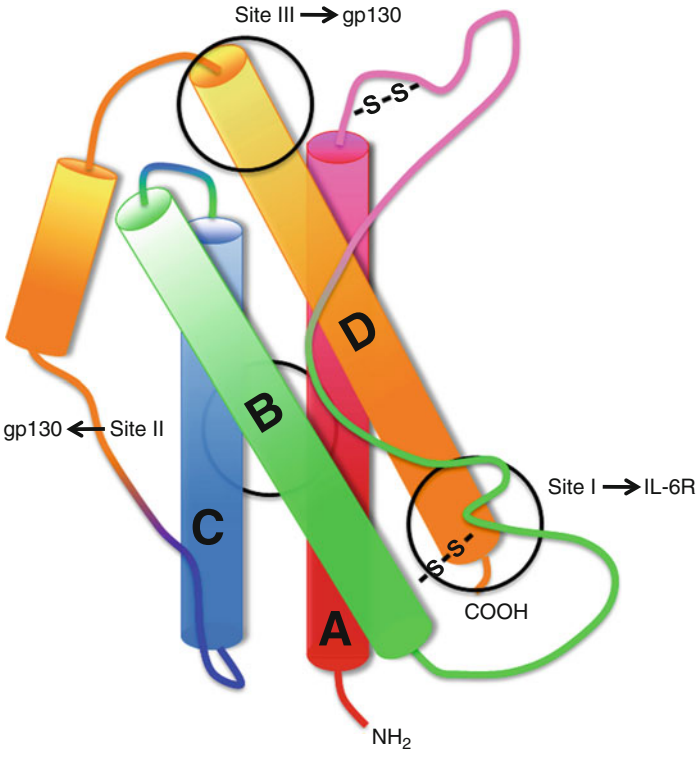
Historical Background

IL-6 was first recognized as a T cell-derived factor, which induces B cell differentiation into antibody-producing cells (Kishimoto and Ishizaka 1973). It was therefore purified and molecularly cloned on the basis of an assay for B cell differentiation activity. This cytokine was variously known as B cell-stimulating factor 2, B cell differentiation factor, or by various other names before it was recognized that all these entities were identical and the name was unified as IL-6 (Kishimoto 1989). Subsequent in vitro studies and analyses of IL-6 transgenic mice and experimental animal models have shown that IL-6 acts not only on B cells but also on T cells, hepatocytes, hematopoietic progenitor cells, and neuronal cells, in addition to performing a variety of functions (Kishimoto 1989; Akira et al. 1993). In spite of this wide range of biological activities, IL-6-deficient mice develop well except for low immune response, which indicates that IL-6 is induced by infection or injury and performs as an SOS signal (Kopf et al. 1994). Along with the identification of its multiple biological activities, numerous studies have demonstrated the pathological significance of IL-6 for various autoimmune and inflammatory diseases.

Structure of IL-6 and Its Receptor System

Human IL-6 (GenBank: X04602) consists of 212 amino acids including a 28-amino-acid signal peptide (Hirano et al. 1986), whereas mouse IL-6 (GenBank: X06203) and rat IL-6 (GenBank: M26744) consist of 211 amino acids with a 24-amino-acid signal peptide. Mature IL-6 protein contains 184 (human) or 183 (mouse) amino acids and includes two disulfide bridges between Cys44-Cys50 and Cys73-Cys83 (human) or Cys46-Cys52 and Cys75-Cys85 (mouse). The molecular mass of human IL-6 has been calculated from the amino-acid sequence as 20.7 kDa, but the weight of secreted IL-6 as 21-26 kDa, depending on posttranslational modifications such as N- or O-linked glycosylation. The human IL-6 gene has been mapped to chromosome 7p21. The structure of IL-6 includes four α-helix bundles (labelled A to D in Fig. 1) and three loops (two long A-B and C-D loops and a short B-C loop), with the four α-helix bundles arranged in an up-up-down-down topology. The amino-acid sequence of human IL-6 is 42 % homologous with that of mouse IL-6, while the homology between the sequences of mouse and rat is 93 %.

The IL-6 receptor (IL-6R) system consists of two chains, IL-6R and gp130, both of which have a Trp-Ser-X-Trp-Ser motif and belong to the cytokine receptor family. IL-6R (GenBank: X12830; alternative name: CD126) is the 80-kDa IL-6-binding subunit with an extracellular region of 339 amino acids, a membrane-spanning region of 28 amino acids and a cytoplasmic region of 82 amino acids (Yamasaki et al. 1988). The soluble form of IL-6R, which lacks the cytoplasmic region, also induces cellular responsiveness to IL-6, indicating that the IL-6 signal is transduced by another molecule. The IL-6 signal-transducing component is gp130 (GenBank: M57230; alternative name: CD130), which is a 130-kDa transmembrane glycoprotein with an extracellular region of 597 amino acids, a membrane-spanning region of 22 amino acids, and a cytoplasmic region of 277 amino acids (Hibi et al. 1990). Although IL-6R has a low IL-6 binding affinity (Kd = 5 nM), IL-6R combined with gp130 shows a high IL-6 binding affinity (Kd = 40–70 pM). The broad range of expression of gp130 on various cells explains why IL-6 has pleiotropic effects; since naturally occurring soluble IL-6R (sIL-6R) is present in human serum at



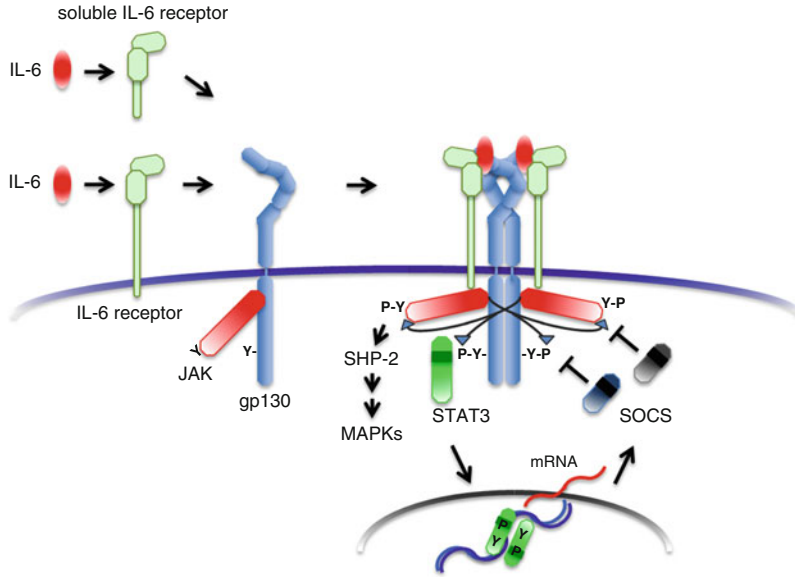
Interleukin-6, Fig. 1 Schematic representation of the domain structure of human IL-6, showing the four long α-helices, A (*red*), B (*green*), C (*blue*), and D (*orange*), and three connecting loops. Two disulfide bonds are in loop A-B. Site I on the C-terminal end of helix D interacts with IL-6R, site II located on helices A and C interacts with one gp130, and site III on the N-terminal end of helix D interacts with another gp130 (Reference; Paonessa G et al. 1995)

a concentration of around 80 ng/ml, and even in cells lacking transmembrane IL-6R, the IL-6/sIL-6R complex can transduce the IL-6 signal on gp130-expressing cells. The soluble form of gp130 is also present in human serum at a concentration of around 400 ng/ml (Narazaki et al. 1993).

After binding of IL-6 to IL-6R or soluble IL-6R (sIL-6R), the resultant IL-6/IL-6R or IL-6/sIL-6R complex associates with gp130 and the activated IL-6 receptor complex is formed as a hexameric structure comprising two molecules each of IL-6, IL-6R, and gp130. Site I of IL-6 associates with IL-6R and site II and site III interact with gp130 (Paonessa et al. 1995). Homodimerization of gp130 triggers activation of the JAK (Janus kinase)-STAT3 (signal transducer and activator of transcription 3) pathway and the JAK-SH2 domain-containing protein-tyrosine phosphatase-2 (SHP-2)-mitogen-activated protein (MAP) kinase pathway. STAT3 regulates transcription for various sets of IL-6 responsive genes including suppressor of cytokine signaling (SOCS), and then SOCS proteins turn off the IL-6 signal transduction by binding with JAK or tyrosine-phosphorylated gp130 in a negative feedback loop (Naka et al. 1997) (Fig. 2). IL-6R is a unique binding receptor for IL-6, whereas gp130 is shared by IL-6 family cytokines including leukemia inhibitory factor (LIF), oncostatin M (OSM), ciliary neurotrophic factor (CNTF), IL-11, cardiotrophin 1 (CTF1), cardiotrophin-like cytokine (CLC), and IL-27. These cytokines often show overlapping functions with those of IL-6. The model in which various cytokines use the common signal transducer gp130 explains clearly why various cytokines show functional redundancy (Kishimoto et al. 1992; Kishimoto et al. 1994; Kishimoto et al. 1995; Heinrich et al. 2003).

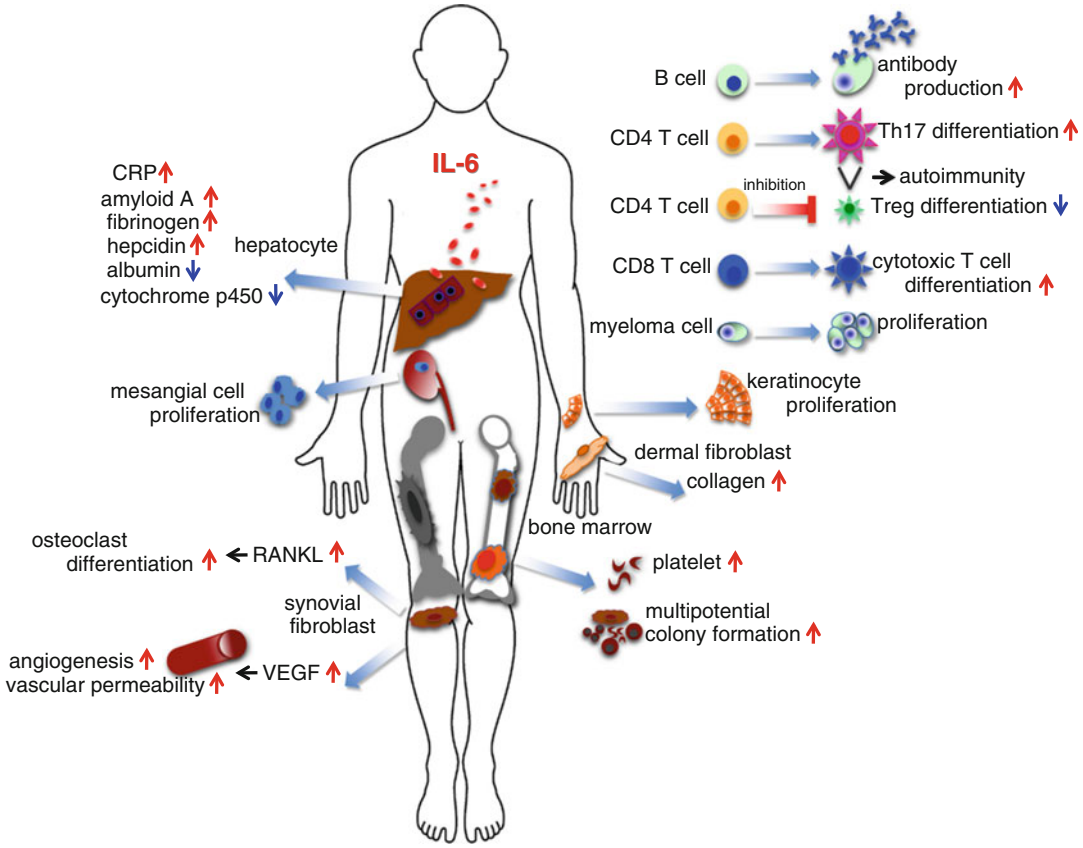
Biological Activities of IL-6

In the early phase of infectious inflammation, IL-6 is produced by monocytes and macrophages after the stimulation of Toll-like



Interleukin-6, Fig. 2 The IL-6 receptor system. After binding of IL-6 to interleukin-6 receptor (*IL-6R*), the resultant IL-6/IL-6R complex associates with gp130 and induces homodimerization of gp130, which triggers activation of JAKs and tyrosine phosphorylation of gp130. The phosphorylated gp130 then recruits STAT3 via the SH2 domain. Next, activated STAT3 translocates into the nucleus and regulates transcription for various sets of genes including SOCS. SOCS proteins bind to JAK or gp130 and turn off IL-6 signals. Tyrosine-phosphorylated gp130 also recruits SHP-2 and activates the MAP kinase pathway. Abbreviations: *JAKs* Janus kinase family tyrosine kinases, *STAT3* signal transducer and activator of transcription 3, *SOCS* suppressor of cytokine signaling, *SHP-2* SH2 domain-containing protein-tyrosine phosphatase-2, *MAP* mitogen-activated protein

receptors (TLRs) with distinct pathogen-associated molecular patterns (PAMPs). In noninfectious inflammations, such as burn or traumatic injury, damage-associated molecular patterns (DAMPs) from damaged or dying cells stimulate TLRs to produce IL-6. IL-6 possesses pleiotropic activities that play a central role in host defense (Fig. 3). IL-6 strongly induces a broad spectrum of acute-phase proteins such as C-reactive protein (CRP), serum amyloid A (SAA), fibrinogen, hepcidin, haptoglobin, and antichymotrypsin, whereas it reduces albumin, cytochrome P (CYP) 450, fibronectin, and transferrin in liver. Changes in the levels of these proteins are also observed in acute and chronic inflammatory diseases, and prolonged inflammation leads to a pathological state. For example, high levels of hepcidin block iron transporter ferroportin 1 on macrophages, hepatocytes, and gut epithelial cells, leading to hypoferremia and anemia of chronic inflammation, whereas a high level of SAA over long periods results in amyloid A (AA) amyloidosis. In lymphocytes, IL-6 induces B cell differentiation into immunoglobulin-producing cells. When CD4-positive naïve T cells are primed, a specific cytokine directs their differentiation into an effector T cell subset. IL-6 together with TGF-β preferentially promotes differentiation of IL-17-producing T helper cells (Th17) that play a crucial role in the induction of autoimmune tissue injury, whereas IL-6 inhibits TGF-β-induced regulatory T cell (Treg) differentiation. This Th17/Treg imbalance leads to breakage of immunological tolerance and is of pathological importance for the development of autoimmune and chronic inflammatory diseases. IL-6 also acts on CD8-positive T cells to induce cytotoxic T cells. In hematopoiesis, IL-6 induces maturation of megakaryocytes into platelets as well as activation of hematopoietic stem cells.



Interleukin-6, Fig. 3 IL-6 induces cell differentiation and specific gene expression. It induces production of acute-phase proteins such as CRP, serum amyloid A, fibrinogen, and hepcidin, whereas it reduces synthesis of albumin and cytochrome P450 in hepatocytes. In addition, IL-6 promotes immunoglobulin synthesis in activated B cells and induces Th17 differentiation from naïve CD4 T cells, whereas it inhibits Treg differentiation. In bone marrow, IL-6 induces maturation of megakaryocytes into platelets and activation of hematopoietic stem cells. IL-6 also acts on synovial fibroblasts to produce RANKL and VEGF, which promote differentiation of osteoclasts and angiogenesis, respectively. Furthermore, IL-6 stimulates dermal fibroblasts to produce collagen and the growth of cells such as keratinocytes, myeloma/plasmacytoma cells, and mesangial cells. Abbreviations: *CRP* C-reactive protein, *Treg* regulatory T cells, *RANKL* receptor activator of NF-κB ligand, *VEGF* vascular endothelial growth factor

IL-6 production in bone marrow stromal cells induces the receptor activator of NF-kappaB ligand (RANKL), which is an essential factor for the differentiation and activation of osteoclasts and bone resorption, leading to osteoporosis. Enhanced angiogenesis and increased vascular permeability are pathological features of inflammation, and these characteristics are due to the excess production of vascular endothelial growth factor (VEGF), which is induced by IL-6 in inflamed lesions such as seen in synovium tissue of rheumatoid arthritis. The promotional activities of IL-6, for example, the proliferation of keratinocytes or collagen production in dermal fibroblasts, may contribute to autoimmune skin diseases including psoriasis and systemic sclerosis, respectively. Furthermore, IL-6 stimulates the growth of cells such as myeloma/plasmacytoma cells and mesangial cells.

Pathological Role of IL-6 in Development of Diseases

IL-6, when synthesized transiently, promptly participates in the host defense against

environmental stress such as infection and injury and, at the same time, provides an SOS (warning) signal by triggering a broad spectrum of biological events. Once the source of stress is removed from the host, IL-6-mediated activation of the signal transduction cascade is terminated by negatively regulated systems in conjunction with the normalization of serum IL-6 and CRP levels. However, dysregulated persistent IL-6 production has been implicated in the development of various autoimmune, chronic inflammatory diseases, and even cancers (Akira et al. 1993; Kishimoto 2005). The pathological significance of IL-6 was first demonstrated in a case of cardiac myxoma, in which excess production of IL-6 from myxoma tissues was thought to be possibly responsible for clinical symptoms and abnormal laboratory findings such as fever, arthritis, anemia, autoantibody production, and hypergammaglobulinemia (Hirano et al. 1987). Dysregulation of IL-6 production from the involved lymph nodes, synovial tissues, and myeloma cells was demonstrated to play a key role in the pathogenesis of Castleman's disease, rheumatoid arthritis, and multiple myelomas, respectively. Subsequent studies have also provided evidence of the pathological role of IL-6 in various other diseases. Elucidation of the mechanism(s) underlying persistent IL-6 synthesis in such diseases is, thus, of particular importance, while it was found that in HIV-positive cases of multicentric Castleman's diseases, all patients were infected with the Kaposi sarcoma-associated herpes virus and that sustained synthesis of both virus-derived IL-6, which directly binds to and stimulates human gp130, and host-derived human IL-6 contributes to the development of the disease.

As mentioned earlier, IL-6 is capable of breaking the immunological tolerance to autoantigens as well as of inducing systemic and local inflammation so that long-lasting overproduction of IL-6 may cause the development and progression of various autoimmune and chronic inflammatory diseases, while it also promotes growth of certain types of cancer cells, modifies immunosurveillance against cancers, and induces paraneoplastic syndrome. Numerous animal models of diseases have also shown the pathologic role of IL-6 in disease development and that IL-6 blockade by gene knockout or administration of anti-IL-6 or anti-IL-6R antibody can suppress such disease development either preventatively or therapeutically. For example, IL-6 blockade strategy demonstrated limited susceptibility to Castleman's disease-like symptoms in IL-6 transgenic mice, antigen- or collagen-induced arthritis, experimental autoimmune encephalomyelitis, experimental autoimmune uveoretinitis, spontaneous development of systemic lupus erythematosus (SLE), bleomycin-induced scleroderma, C-peptide-induced myositis, pristane-induced plasmacytomas, and other diseases.

Therapeutic Application of IL-6 Blockade Strategy for Diseases

Because of the pathological role of IL-6 in various diseases, IL-6 blockade was expected to constitute a novel treatment strategy for these diseases (Kishimoto 2005; Kishimoto 2010; Tanaka et al. 2012). Consequently, a humanized anti-human IL-6R monoclonal antibody (chemical name: tocilizumab, generic name: ACTEMRA outside of the EU or RoACTEMRA inside the EU) was developed, by grafting the complementarity-determining regions of a mouse anti-human IL-6R antibody onto human IgG1. Tocilizumab blocks IL-6-mediated signal transduction by inhibiting IL-6 binding to transmembrane and soluble IL-6 receptors. In clinical terms, if free tocilizumab concentration is maintained at more than 1 μg/ml, CRP remains negative so that serum concentration of CRP is a hallmark for determining whether IL-6 activity is completely blocked in vivo.

Clinical trials of tocilizumab demonstrated its outstanding efficacy for rheumatoid arthritis, systemic juvenile idiopathic arthritis, and Castleman's disease. For patients with moderately to severely active rheumatoid arthritis, tocilizumab is now used as an innovative drug

in more than 90 countries worldwide. As a monotherapy or in combination with disease-modifying antirheumatic drugs, it has significantly suppressed disease activity and radiographic progression of joint deformity and improved daily functional activity. Tocilizumab was also approved as the first-line biologic for the treatment of systemic juvenile idiopathic arthritis in Japan, India, and the USA and for Castleman's disease in Japan and India.

In recent years, it has been found that an imbalance of new CD4-positive T cell subsets consisting of Th17 and regulatory T cells (Treg) is crucial for the development of autoimmune and chronic inflammatory diseases. As described elsewhere, dysregulated continuous production of IL-6 may be responsible for such an imbalance in which tocilizumab may be able to repair, so that it could be used for the treatment of various autoimmune and chronic inflammatory diseases. Results of pilot studies, case series, or case studies have recently suggested the possibility (Tanaka et al. 2012). These diseases include the systemic autoimmune diseases such as SLE, systemic sclerosis, polymyositis, and vasculitis syndrome; organ-specific autoimmune diseases including Crohn's disease, relapsing polychondritis, acquired hemophilia A, and autoimmune hemolytic anemia; and chronic inflammatory diseases including adult-onset Still's disease, amyloid A amyloidosis, polymyalgia rheumatica, remitting seronegative, symmetrical synovitis with pitting edema, spondyloarthritis, Behcet's disease, uveitis, and graft-versus-host diseases; and hereditary autoinflammatory syndromes (Table 1). Moreover, since it was observed that during tocilizumab treatment of patients with rheumatoid arthritis, HbA1c levels and insulin resistance indices such as HOMA-IR (homeostasis model assessment of insulin resistance) and the leptin-to-adiponectin ratio improved and serum levels reactive oxygen metabolites decreased, it can be expected that long-term tocilizumab treatment may offer protection against the progression of atherosclerosis leading to cardiovascular events. For the broad clinical indications of tocilizumab for various diseases, however, further clinical studies will be essential to determine its efficacy and safety.

On the basis of the outstanding beneficial effect of tocilizumab, other biologics of IL-6

Interleukin-6, Table 1 Clinical application of IL-6 blockade strategy for the treatment of diseases

I. Indicated diseases
1. Rheumatoid arthritis (in more than 90 countries worldwide)
2. Systemic juvenile idiopathic arthritis (in Japan, India, and the USA)
3. Polyarticular juvenile idiopathic arthritis (in Japan)
4. Castleman's disease (in Japan and India)
II. Candidate diseases
1. Autoimmune diseases
(i) Systemic lupus erythematosus
(ii) Systemic sclerosis
(iii) Polymyositis and dermatomyositis
(iv) Vasculitis syndrome (Takayasu arteritis and giant cell arteritis)
(v) Crohn's disease
(vi) Relapsing polychondritis
(vii) Acquired hemophilia A
(viii) Autoimmune hemolytic anemia
(ix) Multiple sclerosis and neuromyelitis optica
2. Chronic inflammatory diseases
(i) Adult-onset Still's disease
(ii) Amyloid A amyloidosis
(iii) Polymyalgia rheumatica
(iv) Remitting seronegative, symmetrical synovitis with pitting edema
(v) Spondyloarthritis
(vi) Behcet's disease
(vii) Uveitis
(viii) Graft-versus-host diseases
(ix) Hereditary autoinflammatory syndromes
(x) Schnitzler syndrome
(xi) Type II diabetes mellitus
3. Neoplastic diseases
(i) Multiple myeloma
(ii) Pancreatic cancer
(iii) Prostate cancer
(iv) Malignant mesothelioma

The anti-IL-6 receptor antibody, tocilizumab, has been approved as a biological drug for the treatment of rheumatoid arthritis, juvenile idiopathic arthritis, and Castleman's disease and is expected to be used for the treatment of various other autoimmune, chronic inflammatory diseases and cancers

I

blockers are also being developed. These include fully human anti-IL-6R antibody, anti-IL-6R nanobody, anti-IL-6 antibody, and anti-IL-6/anti-Fc avimer protein consisting of the IgG-binding domain fused to the N-terminus of a 3-domain IL-6-binding region, which results in a 19-kDa heterotetrameric avimer and soluble gp130-Fc fusion protein. These novel biologics are now being evaluated in clinical trials (Jones et al. 2011). It should further be pointed out that tocilizumab may not merely have a steroid-sparing effect as do other immunosuppressive drugs but may also replace corticosteroids and anti-inflammatory drugs because of its ability to normalize immunological abnormalities in addition to its anti-inflammatory activities.

Conclusion

IL-6, originally identified as a B cell differentiation factor, is a typical cytokine featuring pleiotropic and redundant activity. IL-6 is immediately generated to contribute to host defense in response to environmental stress such as infection and injury. The discovery of IL-6, IL-6 receptors, and receptor-mediated signal transduction system has made a major contribution to a better understanding of the molecular basis of pleiotropy and redundancy, which are the characteristic features of cytokines. Of similar importance is the clinical application of IL-6 blockade strategy for the treatment of intractable diseases. Based on the clarification of the pathologic role of IL-6 in disease progression, tocilizumab, a humanized anti-IL-6R antibody, was developed and clinical trials have verified that this antibody is a first-in-class biologic for the treatment of rheumatoid arthritis, systemic juvenile idiopathic arthritis, and Castleman's disease. Since dysregulation of continuous IL-6 production plays a key role in the development of various other autoimmune, chronic inflammatory diseases and even cancers, it is expected that tocilizumab will prove to be an innovative drug for the treatment of various diseases.

Juvenile dermatomyositis (JDM)

Definition

Juvenile dermatomyositis (JDM) is a multisystem disease of presumably autoimmune etiology that primarily involves the skin and skeletal muscles, but may affect many other organs.

Introduction

Juvenile dermatomyositis is the most common of the juvenile idiopathic inflammatory myopathies (Feldman et al. 2008). It is a rare condition, with an incidence of 2.5–4.1 cases per million children in the United States (Mendez et al. 2003) and of 1.9 cases per million children in the United Kingdom (Symmons et al. 1995). The average age at disease onset is 7 years, but around 25 % of patients are younger than 4 years at presentation (Guseinova et al. 2011). The female-to-male ratio is 2–5:1. The disease is characterized histopathologically by perivascular inflammation, often chronic, which may lead to irreversible damage, if not appropriately treated. Over the last decades, the advances in the management of JDM, including introduction of biologic agents, have provided novel therapeutic options for use in severe cases and have dramatically decreased the disease-related morbidity and mortality.

Etiopathogenesis

Juvenile dermatomyositis is thought to be the result of the interaction between environmental factors and the host's genetic susceptibility, leading to immune dysfunction and tissue inflammation (Rider et al. 2011). The environmental trigger hypothesis is raised by reports of geographical and seasonal clustering of disease onset. Although the evidence is mostly indirect, it is also assumed that infectious agents may play a role in inducing the disease. Several children with JDM with a history of infectious illnesses prior to disease onset have been reported (Pachman et al. 2005). These infections were primarily in the upper respiratory and gastrointestinal tracts and preceded the onset of myositis by a few months. Cases of infection with parvovirus, influenza, coxsackievirus B, and group A β-hemolytic streptococci have been described. Little is known about the responsibility of noninfectious environmental factors, including stressful life events, medications,

I.R. Mackay, N.R. Rose (eds.), *Encyclopedia of Medical Immunology – Autoimmune Diseases*,
DOI 10.1007/978-0-387-84828-0, © Springer Science+Business Media New York 2014

chemicals, excessive sun exposure, and immunizations. The genetic susceptibility is supposed to be linked to specific HLA alleles, such as B*08, DRB1*0301, DQA1*0501, and DQA1*0301, which have been observed more frequently in subjects with JDM. The activation of dendritic cells, with upregulation of genes induced by type-1 interferon in muscle tissue, seems to be pivotal for the pathogenesis. Although the pathogenetic role of type-1 interferon is still unclear, it induces an increased and sustained inappropriate expression of MHC class I molecules on the cell surface of muscle fibers, an overproduction of pro-inflammatory cytokines and chemokines, and the upregulation of both intercellular and vascular cell adhesion molecules on endothelial cells (Sugiura et al. 2000). Upregulation of MCH class I on muscle cell surface is associated to the activation of the NF-kB pathway which can, in turn, cause tissue damage. The overproduction of cytokines and adhesion molecules is crucial for the recruitment of inflammatory cells, which infiltrate the affected muscles. Cytokine polymorphisms, such as tumor necrosis factor (TNF) alpha-308 promoter polymorphism, may be risk factors in Caucasian patients (Pachman et al. 2000). Together, these immunological abnormalities are thought to contribute to the inflammatory response of JDM, and lead to dysregulation of apoptosis in myofibrils, muscle degeneration and regeneration, progressive atrophy of myofibers, and consequent functional impairment. However, the specific temporal sequence of the pathogenic events remains uncertain and, presumably, other undiscovered factors may play a role in causing the disease.

Histopathology

The mechanisms underlying vasculopathy in JDM are not yet fully explained. Histopathologically, the disease is characterized by a diffuse and often chronic, perivascular inflammation of skeletal muscle tissue (Feldman et al. 2008). Perifascicular atrophy of myofibers is typically associated with microvascular capillary pathology. Usually, swelling of the capillary endothelium and obliteration of the lumen lead to decreased number and enlargement of remaining vessels. Other changes may include disruption of myofibrils and tubular system, muscle tissue degeneration, and regeneration, which result in variation in fiber size and subsequent functional impairment. During healing, it is possible to detect an interstitial proliferation of connective tissue. A scoring system for muscle biopsy findings based on four domains of change (inflammatory, vascular, muscle fiber, and connective tissue) has been recently proposed (Wedderburn et al. 2007).

Diagnostic Criteria

The diagnosis of JDM is mainly based on the constellation of clinical and laboratory features which are part of the Bohan and Peter criteria (Table 1) (Bohan and Peter 1975a, b). These criteria include the presence of characteristic skin rashes (Gottron's papules over the extensor joint surfaces and/or the heliotrope rash over the eyelids), symmetrical proximal muscle weakness, increased serum level of one or more muscle enzymes, electromyographic demonstration of myopathy, and muscle biopsy showing characteristic histopathological changes. A diagnosis of definitive JDM requires the presence of at least one of the pathognomonic skin rashes with three other criteria; the classic rash plus two other criteria are required for a diagnosis

Juvenile Dermatomyositis, Table 1 Diagnostic criteria for juvenile dermatomyositis

I.	Pathognomonic skin rash (Gottron's papules over the extensor joint surfaces and/or heliotrope rash over the eyelids)
II.	Symmetrical proximal muscle weakness
III.	Increased serum level of one or more muscle enzymes
IV.	Electromyographic demonstration of the characteristic myopathy
V.	Muscle biopsy showing typical histopathologic changes

The diagnosis of juvenile dermatomyositis requires the presence of the pathognomonic skin rash with 3 of the other 4 criteria

of probable JDM. An international survey has shown that a sizable number of pediatric rheumatologists do not use electromyography or muscle biopsy to pursue the diagnosis and consider magnetic resonance imaging (MRI) as one of the most important additional diagnostic methods (Brown et al. 2006).

Disease Onset and Course

The onset of JDM is quite variable, with some patients experiencing the insidious development of progressive muscle weakness and skin rash, and others having a more acute onset with fever, profound muscle weakness, widespread cutaneous manifestations, and, occasionally, ulcerative lesions. The disease course is heterogeneous as well, and may range from a monocyclic course, with good response to treatment and full recovery within 2 years after diagnosis without relapse, to a chronic polycyclic or continuous course, with relapsing-remitting disease, or persistently active disease for longer than 2 years after diagnosis, and a greater likelihood of development of disease-related complications, such as calcinosis or lipodystrophy (Rider et al. 2011).

Clinical Manifestations

The three most typical, and most common, cutaneous manifestations of JDM are heliotrope discoloration of the upper eyelids, Gottron's papules, and periungual erythema with capillary loop abnormalities (Vitale et al. 2004). The heliotrope rash occurs over the upper eyelids and the periorbital region as a dusky, violaceous-reddish purple erythema, which may be associated with a malar rash resembling that of systemic lupus erythematosus (SLE) in its distribution, though less well demarcated (Fig. 1), or to a more confluent erythema involving the entire face. The malar rash of JDM is also distinguished from that of juvenile SLE by the involvement of nasolabial folds, that is typically absent in lupus. In the acute phase, the heliotrope rash is often accompanied by edema of the eyelids or the face or both, resulting

Juvenile Dermatomyositis, Fig. 1 Malar erythema

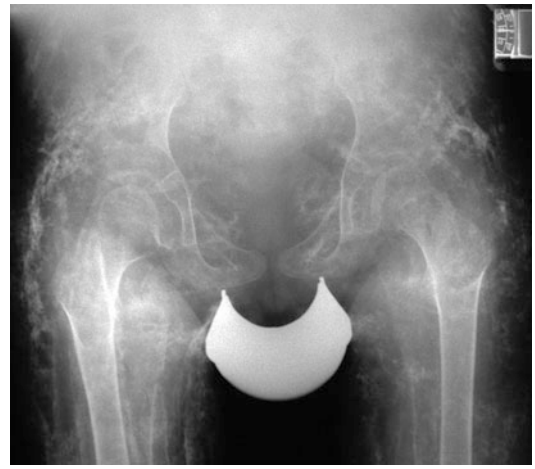
in sensation of tightness. JDM rash is photosensitive in up to 30 % of patients. Capillary telangiectasias along the lid margin may persist long after the other signs and symptoms of disease activity have resolved. Gottron's papules are pink-red to violaceous, flat-topped papules and plaques that are located most commonly over the extensor surfaces of the proximal interphalangeal joints of the hands and less so over the metacarpophalangeal and distal interphalangeal joints (Fig. 2). The skin over the thumbs is rarely, if ever, affected. The extensor surfaces of the elbows and knees and, less frequently, the malleoli and the vertebral apophyses may be involved as well. A macular erythematous or violaceous eruption may involve discrete areas of the body, producing specific signs: the "V-sign" for the V of the neck and upper chest; the "shawl-sign" for the nape of the neck, upper back, and posterior aspect of the shoulders. In the most active and severe forms of JDM, the cutaneous rash may extend considerably and lead to total body erythema (erythroderma). Nailfold capillary abnormalities due to a widespread capillary vasculopathy, which is the underlying pathologic lesion of JDM, and periungual erythema are detectable in 50 % to 100 % of patients with JDM. The most common abnormalities are capillary dropout, dilatation of

Juvenile Dermatomyositis, Fig. 2 Gottron's papules over the knuckles

Juvenile Dermatomyositis, Fig. 3 Large tumorous calcium deposit overlying the left hip region

isolated loops, thrombosis, and hemorrhage. Arborized clusters of giant capillary loops, which are secondary to post-ischemic neovascularization, are distinctive of JDM. These changes have been correlated with a more severe disease course or with the development of cutaneous ulceration or calcinosis, and have been found to abate with disease remission. Cutaneous ulceration affects less than 10 % of children with JDM, but may predict a severe course of illness.

Muscle inflammation usually results in weakness of proximal muscles, especially the limb girdle musculature (Rider et al. 2011). In addition, abdominal, back, and anterior neck flexor muscles are often affected and lead to protrusion of abdomen, inability to hold the head upright and to maintain a sitting posture. The child may experience difficulties in walking, or inability to dress or climb stairs. Physical examination shows symmetrical muscle weakness, particularly pronounced in the hip muscles, neck flexors, and abdominal musculature. Muscles may be tender, painful, and develop contractures. Edema of the overlying subcutaneous tissue of affected muscles is not uncommon. Gower's sign is often present. Palatal, hypopharyngeal, and pharyngeal muscles may be involved in case of severe disease, resulting in difficulty in swallowing, dyspnea, and dysphagia. Sometimes patients may complain of arthralgia/arthritis. Gastrointestinal vasculitis may be heralded by the occurrence of hematemesis and melena, and may cause ulceration of mucosa



Juvenile Dermatomyositis, Fig. 4 Pelvis radiograph showing extensive dystrophic calcification

and perforation. Severe cardiac involvement such as pericarditis and myocarditis, and interstitial pneumonitis are rare complications of JDM.

Calcinosis is an important complication and may occur in more than 20 % of children with JDM (Figs. 3 and 4) (Pachman et al. 2005; Ravelli et al. 2010). Although it develops more frequently as a late manifestation of illness, it may present at any time. Calcinosis has been associated with a longer duration of active disease (Ravelli et al. 2010). Pressure points are more commonly involved in the form of nodules and plaques, which may produce local erythema or skin ulceration and cellulitis. Calcinosis may

Juvenile Dermatomyositis, Fig. 5 Facial lipodystrophy

also extend along muscles and fascial planes or even form an exoskeleton, particularly when active myositis is severe or inappropriately treated. Regression is possible spontaneously or through extrusion.

Acquired lipodystrophy is seen in approximately 10 % of cases (Ravelli et al. 2010) and is characterized by a progressive loss of subcutaneous and visceral fat that may be generalized, partial (affecting mainly extremities), or focal (often involving sites of calcinosis) (Fig. 5). This condition is commonly associated with insulin resistance, acanthosis nigricans, abnormal glucose tolerance, dyslipidemia, hyperandrogenism, and amenorrhea.

The main clinical manifestations of JDM are summarized in Table 2.

Juvenile Dermatomyositis, Table 2 Clinical features of juvenile dermatomyositis

Constitutional	Fever Anorexia Fatigue Lethargy
Cutaneous	Heliotrope rash Malar or facial rash Gottron's papules Nailfold capillary changes Edema Cutaneous or mouth ulcerations Calcinosis Lipodystrophy
Musculoskeletal	Proximal muscle weakness or myalgia Arthralgia or arthritis Joint contractures
Pulmonary	Dysphonia Dyspnea
Gastrointestinal	Dysphagia Gastrointestinal symptoms

Laboratory Abnormalities

At disease onset, muscle inflammation is generally accompanied by the elevation of serum level of muscle enzymes, including creatinine kinase (CK), lactate dehydrogenase, transaminases, and aldolase. However, muscle enzymes are not particularly sensitive, as more than 20 % of patients have normal CK at diagnosis (Ramanan and Feldman 2005). Furthermore, muscle enzymes frequently become normal with therapy, even during active disease or disease exacerbations. Of the remaining serological abnormalities, autoantibodies, mainly antinuclear antibodies (ANAs) and anti-aminoacyl transfer RNA synthetases (anti-Jo1), have been reported with variable frequency.

Disease Assessment

Assessment of the extent and severity of muscle inflammation is of pivotal importance in evaluating disease activity and response to treatment in children with JDM, and muscle strength is the principal clinical parameter to estimate muscle involvement. Manual muscle testing (MMT) by Kendall is the most widely used method for muscle strength measurement in therapeutic trials and assesses a representative subset of eight proximal, distal, and axial muscles tested unilaterally, in the dominant side of the patient. Assessment of physical function in JDM is based on the estimation of muscle function,

which includes evaluation of muscle endurance and fatigue. The tool commonly used for assessment of muscle function is the Childhood Myositis Assessment scale (CMAS), which measures the ability of the patients in performing 14 maneuvers. Overall disease activity is assessed through the Disease Activity Score (DAS) and the Myositis Disease Activity Assessment VAS (MYOACT). Physical function can be evaluated through the Childhood Health Assessment Questionnaire (C-HAQ), whereas health-related quality of life can be determined through the parent version of the Child Health Questionnaire (CHQ). Cumulative damage is estimated based on the Myositis Damage Index (MDI). MRI is able to detect muscle inflammation as edema. It is also useful in selecting a site to perform electromyography or muscle biopsy, which helps reduce the rate of false-negative results. MRI is also a valid indicator of muscle disease activity and may help distinguish activity from damage. The tools used in the assessment of JDM have been reviewed recently (Rider 2002; Ravelli et al. 2006).

Management

So far, there have been no randomized controlled trials of any medications for children with JDM. As a result, disease management remains largely empiric and only based on observational studies and clinical experience (Feldman et al. 2008; Rider et al. 2011). There is a common agreement that corticosteroids are the mainstay of treatment, although the regimens for such medications in induction, maintenance, or tapering are variable among physicians and depend on clinical experience. High doses of steroids are frequently administered intravenously at the time of diagnosis because of the potentially poor gastrointestinal absorption due to the vasculopathy. This approach is usually followed by oral administration of steroids coupled with second-line drugs, namely methotrexate (15–20 mg/m^2 weekly sc) or cyclosporine (3–5 mg/kg per day orally), which are given as steroid-sparing agents. It has been suggested that early administration of methotrexate may reduce the risk of disease-related morbidity, particularly the development of calcinosis. Once disease control is achieved, corticosteroids are tapered slowly until discontinuation; this frequently takes 2 years or more. A low dose is usually maintained for a long period to prevent disease flares. In severe or refractory cases and in the presence of specific clinical features, patients may benefit from other medications. Hydroxychloroquine (3–5 mg/kg per day orally) is frequently used for cutaneous manifestations and monthly intravenous immunoglobulin has proven to be effective for resistant skin rash. Azathioprine (1–2 mg/kg per day orally) and cyclophosphamide (2 mg/kg per day orally) are recommended in case of methotrexate or cyclosporine intolerance or failure, or as adjunctive treatments for aggressive disease. Little is known about the role of biologic agents in the management of JDM. Although use of B-cell-depleting therapy with rituximab is not supported by strong scientific evidence, anecdotal data suggest it can be a promising therapeutic option for refractory cases. A recent randomized clinical trial of rituximab in refractory adult and pediatric myositis patients did not show a significant difference in the time to achieving the definition of improvement between patients who received rituximab early or late. However, 83% of adult and juvenile myositis patients met the definition of improvement (Oddis et al. 2013). Photoprotective agents and topical medications (tacrolimus, steroids) may be effective in localized skin rashes. Physiotherapy is often needed to avoid functional impairment due to calcinosis or joint contractures, and to shorten the time to recover full muscle strength.

Outcome and Prognosis

Prior to the introduction of corticosteroids in the 1960s, almost one-third of patients with JDM died, one-third were left with permanent disabilities, and only one-third recovered without complications (Huber and Feldman 2005). Since then, the mortality has decreased to less than 2 %, and there has been considerable improvement in

functional outcome. However, there are still many patients who are refractory or respond suboptimally to current treatments and are at risk of developing irreversible damage from the disease activity or its treatment. A recent large multinational study (Ravelli et al. 2010) has shown that patients with JDM had favorable functional outcomes, with only a few experiencing severe muscle weakness or physical disability at follow-up assessment. Furthermore, most patients had a good quality of life and were satisfied with the outcome of the illness. However, many patients continued to have chronic disease activity and had evidence of cumulative damage. Furthermore, a chronic course of the illness was the most consistent predictor of a poorer long-term outcome in terms of muscle weakness, continued disease activity, cumulative damage, and functional impairment. Development of calcinosis and lipodystrophy were associated with greater duration of active disease. These findings underscore the critical need for treatments and treatment strategies that have the ability to better control disease activity over time and to reduce the development of non-reversible organ damage.

Synonyms

Juvenile-onset SLE; Pediatric SLE

Definition

Systemic lupus erythematosus (SLE) is a systemic autoimmune disorder that can affect any organ of the human body. Presentation and clinical courses are highly variable which is why 11 diagnostic criteria were introduced and 4 must be fulfilled to make a diagnosis of SLE (Tsokos 2011; Hochberg 1997).

The pathophysiology of SLE is not completely understood; genetic, hormonal, and environmental factors, all contribute to the development of the disease (Hedrich et al. 2011). Women are affected more frequently with an overall female to male ratio of 10:1 (Tsokos 2011). Approximately 10–20 % of all SLE manifestations occur in the pediatric age group (before 16 years of age) and are classified as pediatric SLE (or juvenile-onset SLE) (Ardoin and Schanberg 2012; Brunner et al. 2011). Cases with a disease onset before 5 years of age, referred to as early-onset SLE, are extremely uncommon and appear to be more severe when compared to other forms of SLE (Hedrich et al. 2011; Zulian et al. 2008). Interestingly, the gender distribution varies significantly in the pediatric age group with an almost equal gender distribution in the first decade of life and development of the "classical" female predominance during the second decade (female:male 4:1 in the second decade, 10:1 in cases >20 years) (Mina and Brunner 2011; Brunner et al. 2011). Disease onset in the pediatric age group peaks around 12–14 years. This implies that hormonal influences may be more important for the pathophysiology of adult-onset SLE when compared to pediatric SLE. Though symptoms and diagnostic criteria for pediatric and adult-onset SLE are generally identical, pediatric SLE is characterized by a more acute and aggressive disease onset, higher chronic disease activity, and a higher frequency of severe organ involvement, including the kidneys, the central nervous system (CNS), and hematologic manifestations (Hedrich et al. 2011; Zulian et al. 2008; Ardoin and Schanberg 2012; Hersh et al. 2010; Livingston et al. 2011, 2012).

The differences in gender distribution, disease activity, severity, and outcome in pediatric SLE,

Juvenile Diseases: SLE in Children, Table 1 Organ involvement *at the time of presentation* and outcome in adult vs. early-onset SLE (N/A: no data available) (Zulian et al. 2008; Hedrich et al. 2011; Gaubitz and Schotte 2005)

Organ involvement	Adult SLE (European Caucasian)	Early-onset SLE (Mostly Caucasian)
Kidneys	16 %	~93 %
CNS	12 %	~33 %
Serositis	17 %	N/A
Mucous membranes	11 %	N/A
Skin	49 %	60 %
Raynaud's	18 %	N/A
Musculoskeletal system	69 %	~33 %
Lymphadenopathy	7 %	~27 %
Fevers	N/A	60 %
Irritability	N/A	40 %
Survival rate	86 % (10-year survival)	~67 % (after months to >20 years)

combined with the increased prevalence of genomic mutations and risk alleles in pre-pubertal autoimmune disorders (Haas 2010), suggest that a number of potentially distinct disorders may be contained within the term "pediatric SLE."

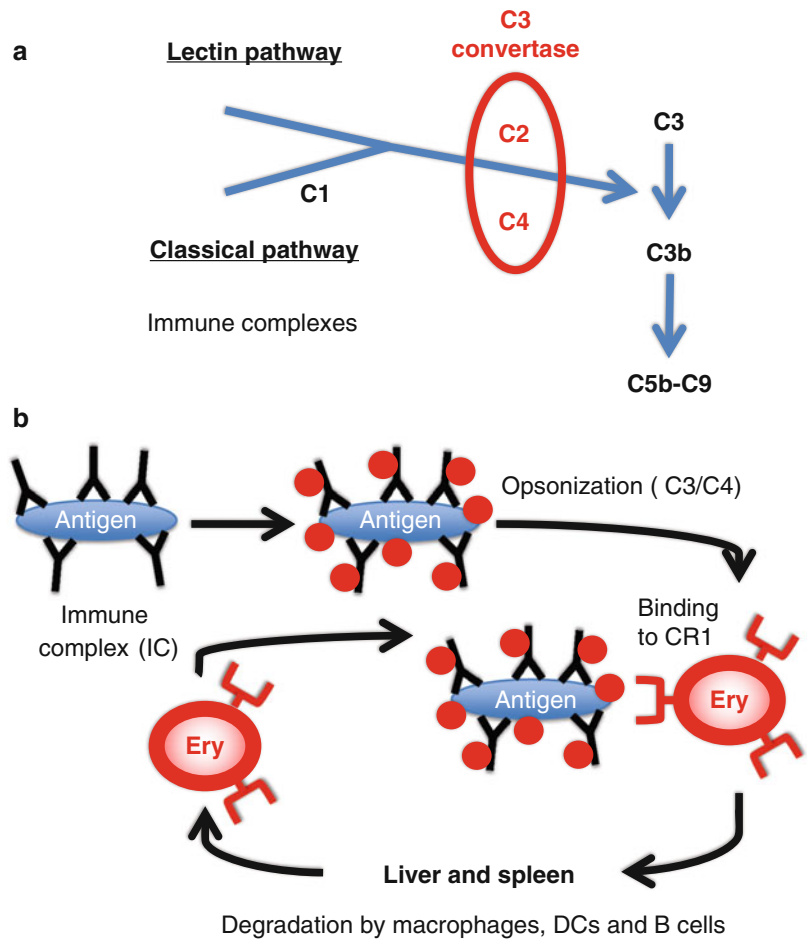
Early-Onset SLE

Early-onset SLE involves extremely rare and heterogeneous disease presentations with more variable and severe symptoms as compared to any other form of SLE (Hedrich et al. 2011; Zulian et al. 2008; Brunner et al. 2011; Ardoin and Schanberg 2012). To our knowledge, only 15 patients have been reported, some still within the first year of life at disease onset. A review of the available literature suggests more severe disease courses in the early-onset SLE age group when compared to adult-onset SLE cases (Table 1) (Hedrich et al. 2011). Early-onset SLE patients seem to develop more severe organ manifestations with a higher rate of complications at the time of diagnosis. More than 90 % of reported patients presented with kidney involvement, and one third suffered from CNS disease that manifested with calcifications, seizures, or cerebral hemorrhages. Survival rates were markedly reduced when compared to other age groups (Table 1) (Zulian et al. 2008; Hedrich et al. 2011; Gaubitz and Schotte 2005). However, epidemiological and predictive information in the early-onset SLE age group needs to be handled with caution secondary to the lack of clinical studies or surveys, the very small number of reported cases, the potential of under-diagnosing milder cases in this young age group, and the potential of an over-representation of severe cases in the literature.

Unfortunately, all early-onset SLE patients have been reported as single case reports or small case series and genetic data is lacking (Hedrich et al. 2011; Zulian et al. 2008). However, it appears likely that hormonal and environmental factors, which in the case of adult SLE accumulate over time, play a less central role in the pathophysiology of early-onset SLE, and that genetic factors are largely responsible for the disease.

Monogenic SLE: Complement Deficiencies

Several rare genetic disorders result in lupus-like disease. Mutations within the class III or complement region of the human histocompatibility (MHC) complex on chromosome 6 can result in SLE or lupus-like disease (Truedsson et al. 2007). The genes encoding for the complement factors C4A, C4B (a duplication of C4A), factor B and C2 are located within that region. Another example for monogenic SLE can be found in the gene encoding for C1q (chromosome 1). Regardless of not being located in the MHC cluster (Truedsson et al. 2007; Flierman and Daha 2007; Atkinson and Yu 2011), C1q is essential for the classical complement activation pathway, and mutations in the C1 coding region frequently result in autoimmune phenomena and lupus-like disease. The risk for developing SLE or lupus-like disorders varies between the reported defects: 90 % of the patients with C1q deficiency develop SLE, while 60 % of the individuals with



Juvenile Diseases: SLE in Children, Fig. 1 Both the lectin and the classical complement activation pathways are essential for the clearance of immune complexes (**a**). The complement system is involved in the opsonization and removal of immune complexes. Activated complement factors C3b and C4b opsonize immune complexes which results in the binding of opsonized immune complexes to complement receptors (CR1) on erythrocytes and subsequent degradation in the liver or spleen by antigen-presenting cells (**b**)

C4 deficiencies and 30 % of the patients with C2 deficiency develop SLE-like disorders. Complement factor deficiencies down-stream of C3 are less likely to manifest as SLE, but do result in severe infections (Truedsson et al. 2007; Flierman and Daha 2007; Atkinson and Yu 2011).

The development of lupus-like disorders results from the central involvement of C1, C2, and C4 in the early stages of complement activation. C2 and C4 are both required for the initiation of the lectin pathway and the classical activation pathway. C1 complement factors are required for sufficient complement activation in the classical pathway (Fig. 1a). In response to activation, C2 and C4 together form the so-called C3 convertase that is responsible for C3 cleavage and the activation of down-stream complement factors (Atkinson and Yu 2011).

The observation that a large percentage of individuals with deficiencies of "early" complement factors of the classical and/or the lectin pathway develop SLE or lupus-like disorders together with findings in complement-deficient mice led to the conclusion that these defects result in an accumulation of necrotic or apoptotic material and an increase in circulating and tissue immune complexes. Immune complex deposition in vessels and organs results in tissue damage and systemic inflammation (Botto 1998). Under physiological conditions, complement factors C3b and C4b are involved in the opsonization of immune complexes. Opsonization of immune complexes allows the binding to complement

receptors on erythrocytes and subsequent immune complex degradation in the liver or spleen by antigen-presenting cells (Fig. 1b). A lack of activated complement factors C3b and C4b results in inappropriate formation and impaired handling of immune complexes. The subsequent precipitation of immune complexes in the vascular bed or organs and tissues results in local inflammation and vasculitis. Furthermore, inappropriately removed intracellular antigens from apoptotic or necrotic cells may be recognized as "foreign" and become autoantigens, accelerating autoimmune pathology (Truedsson et al. 2007; Flierman and Daha 2007; Atkinson and Yu 2011; Hauck et al. 2011).

Genetic Susceptibility and the Hypothesis of "Oligogenic" SLE

The case for a strong genetic component of SLE is emphasized by an increased risk for the development of SLE with a positive family history (30-fold) and high concordance rates between monozygotic (55 %) and dizygotic twins (5 %) (Tsokos 2011; Mina and Brunner 2011; Brunner et al. 2011). In addition to the aforementioned complement deficiencies, which represent distinct monogenic forms of SLE, several nucleotide exchanges in coding or noncoding regions of lupus susceptibility genes have been reported (Box 1). Some of which can, by themselves, cause lupus-like symptoms that are usually limited to single organ manifestations.

Examples are mutations in the 3′ DNA repair exonuclease TREX1, which cause chilblain lupus erythematosus (CLE) (Lee-Kirsch et al. 2007a). CLE is a chronic disorder that is characterized by inflammatory skin lesions on the fingers, toes, ears, nose, and cheeks in response to temperature change or cold and damp climate (Hedrich et al. 2008; Lee-Kirsch et al. 2007a). While spontaneous cases in middle-aged women are most common, familial cases affect both genders and are caused by missense mutations in *TREX1*. A subset of CLE patients (18–20 %) later on develop SLE and 0.5–3 % of SLE patients in large cohorts in Europe and the USA exhibit mutations in *TREX1* (Lee-Kirsch et al. 2007b; Namjou et al. 2011). Two pathophysiological mechanisms have been proposed for TREX1 mutations: (1) mutations in regions with exonuclease activity (which occur in familial CLE) may result in an accumulation of cytoplasmic single-stranded DNA that results in increased IFN-α signaling, and (2) mutations in regions without exonuclease activity (as those found in the SLE cohorts) may interfere with TREX1's ability to associate with the SET complex, thus affecting granzyme A–mediated caspase-1-independent cell death (Aringer et al. 2012).

Given that mutations in single SLE susceptibility genes can cause organ manifestations that are part of the clinical picture of SLE (e.g., *TREX1* in CLE) (Lee-Kirsch et al. 2007a, b), and familial clusters of SLE are not uncommon resulting in an increased risk for children and their siblings (especially twins) (Mina and Brunner 2011; Brunner et al. 2011), one can hypothesize that the combination of such risk alleles may result in SLE (Aringer et al. 2012). In such cases, epigenetic and/or hormonal factors may be less important than in "classical" SLE of the adult age group (Hedrich and Tsokos 2011). The combination of genomic variants in susceptibility genes may result in early disease onset and the almost equal gender distribution in the first decade of life. At this point, genetic studies in pediatric SLE cohorts are, for the most part, limited to the confirmation of the findings in adult SLE and cannot explain the differences in disease presentation, activity, chronicity, and outcome (Brunner et al. 2011; Ardoin and Schanberg 2012; Hedrich et al. 2011). However, findings from larger cohorts suggest that pediatric autoimmune disorders (mostly juvenile idiopathic arthritis) have a stronger genetic basis when compared to adult disease (rheumatoid arthritis) (Haas 2011). In light of the limited data on pediatric SLE, the hypothesis of a stronger genetic background in pediatric SLE remains somewhat speculative and warrants genetic studies in large cohorts, including patients with early-onset, pediatric, and adult-onset SLE.

Box 1: Risk Alleles in the Pathophysiology of SLE (Tsokos 2011; Crispín et al. 2010)

Gene variants that are associated with increased susceptibility to SLE affect immune signaling pathways. This is an exemplary overview of several candidate genes, involved in:

1. The clearance and processing of immune complexes through, e.g.,
   (a) The Fc Receptors for immunoglobulin G (FcγR) which are involved in immune complex removal and antibody-dependent immune responses
   (b) Complement factors C1q (SNPs or complete deficiency), C2 and C4 (deficiency)
   (c) C-reactive protein (CRP) that is involved in immune activation and the clearance of necrotic and apoptotic debris
2. Toll-like receptor/Type I interferon signaling through, e.g.,
   (a) Single base exchanges (SNPs) in *STAT4* that are associated with SLE and/or more severe outcomes
   (b) *TREX1* mutations affecting its exonuclease activity or its association with the SET complex, resulting in defective caspase 1-independent apoptosis
   (c) TLR7 and TLR9 variants that affect immune complex clearance and IFN-α responses
3. The transduction of immune signals through, e.g.,
   (a) *IL10* promoter polymorphisms, which are associated with increased IL-10 expression and B cell activation in SLE.
   (b) *BANK1* variants that may increase calcium flux in B cells.
   (c) *PP2A* polymorphisms in the first intron, which may result in increased PP2A expression and down-stream activation of protein kinases.
   (d) Variants in the interferon regulatory factor-5 (*IRF5*), a transcription factor in the type I IFN pathway. *IRF5* variants are furthermore associated with macrophage activation syndrome in pediatric SLE.

Post-pubertal SLE

Pediatric SLE patients that manifest after the onset of puberty usually present very similarly or identically when compared with adult-onset SLE patients. Comparably to adult-onset SLE, the ACR diagnostic criteria for SLE from 1997 reflect the clinical spectrum with its wide range of organ manifestations (Hersh et al. 2010; Brunner et al. 2011; Ardoin and Schanberg 2012; Tsokos 2011). Furthermore, the gender distribution changes from an almost equal ratio between boys and girls in early-onset SLE to the "classical" picture with a female predominance (4:1 in the second decade and 10:1 after the 20th year of age) (Mina and Brunner 2011; Brunner et al. 2011; Tsokos 2011). Thus, the general manifestation and epidemiology of post-pubertal pediatric SLE generally reflect the "classical" picture of adult-onset SLE. However, a number of studies demonstrated a more acute and severe onset of post-pubertal pediatric SLE followed by chronically active disease courses, resulting in more severe organ damage and increased mortality rates (Hersh et al. 2010; Brunner et al. 2011; Ardoin and Schanberg 2012; Silverman and Eddy 2011). To this point, differences in the pathophysiology of pediatric and adult-onset SLE remain to be elucidated. It remains speculation whether differences in the contribution of genetic predisposition vs. environmental and/or hormonal influences account for these distinct differences in disease severity and outcome.

Treatment of Pediatric SLE

Treatment of pediatric SLE is complex and less standardized when compared to adult-onset SLE. The lack of large controlled multicenter trials in the pediatric age group complicates treatment decisions. Furthermore, potential toxic and treatment-related side effects need to be considered in the context of physical and mental development. Regardless of these concerns, pediatric patients require higher steroid doses and immune

Juvenile Diseases: SLE in Children, Table 2 Treatment considerations in pediatric SLE

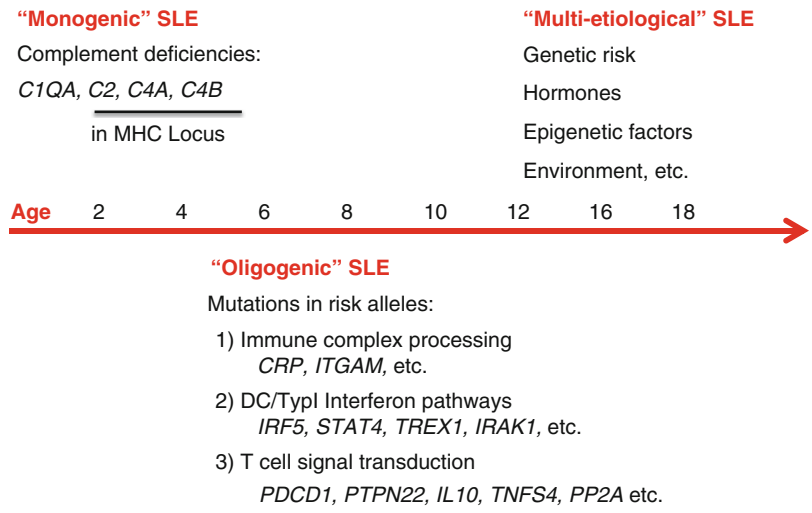
Therapeutic agents	Used for	Special considerations
NSAIDs	Mild disease	Musculoskeletal involvement
Anti-malaria drugs	Mild disease	Cutaneous involvement, vasculitis
		Arthritis
		Autoinflammation: TLR interference
Corticosteroids	Control of acute disease	Glomerulonephritis (Fauci/NIH, Euro-lupus)
	Treatment induction	Liver disease
	Low-dose maintenance	Vasculitis
DMARDs		
Azathioprine Mycophenolate	Vasculitis Glomerulonephritis Liver disease	Glomerulonephritis induction and/or maintenance therapy (Fauci/NIH and Euro-lupus protocols) >Depending on type and severity of kidney disease
Methotrexate	Arthritis, skin disease (CNS disease)	Cave: Not in kidney or liver disease
Cyclophosphamide	Vasculitis Glomerulonephritis CNS disease	Glomerulonephritis induction therapy (Fauci/NIH and Euro-lupus protocols) >Depending on type and severity of kidney disease
Biologicals		Clinical data is very limited. The use of biologicals can only be recommended on an individual basis and in a center experienced in the treatment of pediatric SLE patients
Anti-CD20	Complement deficiencies	
	Treatment-resistant SLE	
Anti-TNF	Treatment-resistant SLE	
	Vasculitis	

suppressants, considering the more aggressive course of pediatric SLE (Hersh et al. 2010; Brunner et al. 2011; Ardoin and Schanberg 2012; Silverman and Eddy 2011).

For certain subgroups of pediatric SLE patients, more or less target-directed forms of treatment are available. Since complement deficiencies result in altered clearance of apoptotic and necrotic material, defective clearance of circulating and organ immune complexes, and subsequent B lymphocyte activation, B cell depletion with recombinant antibodies has proven effective and may be superior to other immune suppressants (Atkinson and Yu 2011; Hauck et al. 2011). Limited but consistent reports suggest that treatment decisions can be based on organ involvement and disease severity (Table 2). The translation of scientific evidence into clinical practice will allow more target-directed treatment with reduced toxic effects. This will also increase the compliance of pediatric patients, which will further improve the clinical outcome (Mina and Brunner 2011; Silverman and Eddy 2011).

Conclusions

Pediatric SLE takes a more acute, aggressive, and chronically active course when compared to adult-onset SLE. Age-related differences in organ involvement, disease course, and outcome as well as marked differences in the gender distribution strongly suggest varying pathomechanisms within the entity pediatric SLE. Monogenic disorders usually manifest early in childhood. It appears likely that the combination of two or more risk alleles can result in



Juvenile Diseases: SLE in Children,
Fig. 2 Hypothetical model of the influence of genetic, hormonal, and environmental factors to the pathophysiology of pediatric SLE

SLE or lupus-like manifestations in childhood in the absence or presence of hormonal and environmental factors (Fig. 2). Further studies are warranted, investigating genetic predisposition for the development of SLE. A better understanding of the pathophysiological mechanisms in early-onset, pediatric, and adult-onset SLE will help to establish more individually tailored, target-directed, and effective forms of treatment with reduced toxicity.

Juvenile Idiopathic Arthritis

Alberto Martini
Department of Pediatrics, University of Genoa, Pediatria II, Istituto G Gaslini Largo Gaslini, Genoa, Italy

Definition

Juvenile idiopathic arthritis (JIA) is defined as any arthritis of unknown origin that begins before the age of 16 years and persists for more than 6 weeks.

Introduction

JIA is not a single disease, but a diagnosis of exclusion that gathers together all forms of chronic arthritis of unknown origin that occurs in children and adolescents.

Historical Background

Different classification criteria have been used in the past in order to identify discrete clinical subsets that could correspond to different diseases. The more recent classification is the one proposed by the International League of

Associations for Rheumatology (ILAR) (Petty et al. 2004). The goal of this classification was to solve the problem of the previous heterogeneity in nomenclature and criteria between Europe and North America. The term JIA was adopted instead of those of juvenile chronic arthritis (JCA) or juvenile rheumatoid arthritis (JRA) previously in use in Europe and North America, respectively.

Epidemiology/Prevalence

Studies in Western populations have reported an incidence and a prevalence varying from 2 to 20 and from 16 to 150 per 100,000, respectively (Ravelli and Martini 2007).

The ILAR Classification

Seven disease categories were recognized, based on the features presented during the first 6 months of illness (Ravelli and Martini 2007; Cassidy et al. 2011; Prakken et al. 2011). However, some aspects of this classification have been recently challenged and suggestions for reconsidering classification and nomenclature have been proposed (Martini 2012).

Systemic Arthritis

It is considered the equivalent of "adult-onset Still's disease" and accounts for 10–15 % of JIA. It is characterized by prominent systemic features, such as high spiking fever, an evanescent, erythematous rash, hepatomegaly or splenomegaly, generalized lymphadenopathy, and serositis. Arthritis may be absent at onset and develop during the course of the disease. Laboratory investigation demonstrates leukocytosis (with neutrophilia), thrombocytosis, a high erythrocyte sedimentation rate (ESR) and C-reactive protein concentration, and marked elevations in serum ferritin levels. A microcytic anemia is also common.

The outcome is variable. In about half of patients, the disease is mainly characterized by the systemic features while the arthritis usually remits when systemic features are controlled. In the other half of patients, the disease follows an unremitting course; systemic symptoms may eventually resolve, leaving chronic arthritis as the major long-term problem.

About 5–8 % of children with systemic JIA develop a life-threatening complication, named macrophage activation syndrome (MAS). It is a form of reactive hemophagocytic lymphohistiocytosis and is characterized by sustained fever, pancytopenia, hepatosplenomegaly, liver insufficiency, coagulopathy, and neurological symptoms. Laboratory features include elevated triglycerides, and markedly increased ferritin concentrations. The demonstration of active phagocytosis of hematopoietic cells by macrophage in the bone marrow is common. Early recognition and treatment of MAS is essential.

Rheumatoid Factor Positive Polyarthritis

It is of rare occurrence (5 % of patients with JIA) and represents the childhood equivalent of adult rheumatoid factor (RF) positive rheumatoid arthritis; in fact, it is the only form of JIA with positive antibodies to cyclic citrullinated peptides.

Enthesitis-Related Arthritis

This is a form of undifferentiated spondyloarthritis characterized by the presence of enthesitis and arthritis. Most patients are HLA-B27 positive. The disease can be mild and remitting but a variable proportion of patients, who are impossible to identify at disease onset, develops the involvement of sacroiliac joints during disease course. All the different forms of adult spondyloarthritis (e.g., psoriatic arthritis, reactive arthritis, enteropathic arthritis, axial spondyloarthritis) may develop in children; the major difference in children is the much higher proportion of the undifferentiated forms.

Oligoarthritis

This is defined by inflammation of four or fewer joints during the first 6 months of disease. In Western countries, the large majority of patients belongs to a quite well-defined disease entity observed only in children and characterized by

an asymmetric arthritis, involving mainly large joints, an early onset (before 6 years of age), a female predilection, a high frequency of positive antinuclear antibodies (ANA), a high risk of developing chronic iridocyclitis, and consistent HLA associations.

Arthritis can remain limited to four or fewer joints (oligoarticular persistent) or can extend to affect five or more joints after the first 6 months of disease (oligoarticular extended); this second group of patients has a more guarded long-term prognosis.

Iridocyclitis may cause severe visual impairment and affects about 30 % of patients. The onset is insidious and is often entirely asymptomatic in contrast with the painful, acute uveitis that can be observed in spondyloarthritis. ANA positivity represents a strong risk factor for developing uveitis. Since uveitis is asymptomatic, children with ANA-positive JIA should be screened at least every 3 months by slit-lamp examination.

Rheumatoid Factor Negative Polyarthritis

This subset of JIA is defined by the involvement of five or more joints during the first 6 months of disease and is heterogeneous. At least two separate subsets can be identified: (a) one, characterized by a symmetric synovitis of large and small joints, onset in school age, and negative ANA, is similar to adult-onset RF-negative rheumatoid arthritis; (b) the second is similar in every respect to the above-mentioned early-onset, ANA-positive oligoarthritis, except for the number of joints affected in the first 6 months of disease. The similarities between this second subset and early-onset oligoarthritis strongly suggest that they represent different expressions of the same disease.

Psoriatic Arthritis

This is another heterogeneous category. If Vancouver criteria (presence of arthritis and psoriasis or some psoriatic features) are used to define psoriatic arthritis, two populations of patients are identified: (a) one that represents, as adult psoriatic arthritis, a form of spondyloarthropathy; (b) a second form that shares the same above-mentioned characteristics of ANA-positive, early-onset oligoarthritis. So it appears that the association of psoriasis with arthritis leads to the identification of two different subsets of patients, one that is similar to adult psoriatic arthritis and the other that overlaps with ANA-positive, early-onset oligoarthritis. The ILAR classification criteria for psoriatic arthritis, in which patients with enthesitis are by definition excluded, limit the identification of those patients that have a form of psoriatic arthritis similar to that observed in adults.

Undifferentiated Arthritis

This subset of JIA does not represent a separate subset, but a category which includes, by definition, patients that do not fulfill inclusion criteria for any other category, or are excluded by fulfilling criteria for more than one category.

Pathogenesis

As mentioned above, most of the forms of chronic arthritis in children represent the childhood counterpart of diseases also observed in adults. This is not the case for early-onset, ANA-positive oligoarthritis which is observed only in children; on the other hand, systemic JIA is much more common in childhood than adult-onset Still's disease and has therefore been studied mostly in children. Thus, in order to avoid overlaps with other entities only those immunological aspects that belong to systemic JIA and to early-onset ANA-positive arthritis will be discussed. For the other diseases, there are no relevant, specific immunological findings characteristic of childhood-onset forms.

Systemic JIA

Systemic JIA sets well apart from all the other forms of JIA (De Benedetti and Martini 1998; Mellins et al. 2011; Prakken et al. 2011). The systemic features, the marked inflammatory response, lack of sex bias, peak age at onset, lack of association with autoantibodies or HLA

antigens are all consistent with what is observed in autoinflammatory diseases.

Consistent with the supposed autoinflammatory nature of sJIA, gene expression studies on peripheral blood mononuclear cells (PBMCs) have shown an upregulation of genes associated with the activation of monocyte/macrophage lineage and a downregulation of the gene networks involving NK cells, T-cells, and MHC antigen-related biological processes. Two pro-inflammatory cytokines, interleukin (IL)-6, and IL-1, appear to play a major pathogenic role.

Circulating levels of IL-6 are markedly elevated, increase during the peak of fever, and correlate with the extent and severity of joint involvement. Synovial fluid levels of IL-6 are also significantly higher than those observed in other form of childhood or adult arthritis. The marked microcytic anemia is different from that observed in rheumatoid arthritis and is consistent with the effect of IL-6 on erythropoiesis. High circulating levels of IL-6 have been shown to cause growth failure, another feature of the disease. The important role of IL-6 has been confirmed more recently by the marked therapeutic effect of tocilizumab, a monoclonal antibody against the IL-6 soluble receptor (sIL-6R).

Evidence for the important role of IL-1 in the pathogenesis of sJIA came from the serendipitous finding of the marked therapeutic efficacy of anakinra, an IL-1 inhibitor which is the recombinant version of the naturally occurring soluble IL-1 receptor antagonist (IL-1 Ra). The role of IL-1 is not in contrast with that of IL-6 since IL-1 is upstream to IL-6. Of note, it has been shown that the response to anakinra can identity two different populations of patients. One (accounting for about 40 % of patients) shows a dramatic response to IL-1 blockade, similar to that observed in cryopyrin-associated autoinflammatory syndromes, leading to complete normalization of clinical as well as laboratory features in a few days. The other is resistant to treatment or shows an intermediate response. The main difference observed between these two groups was the number of active joints; patients with fewer joints affected had a higher probability of responding to anti-IL-1 therapy. The group with a more dramatic response could represent a separate entity in which the autoinflammatory component has the leading pathogenic role while autoimmune mechanisms may have also a more relevant role for the group with more joints involved.

It remains a mystery why sJIA is so strongly associated with macrophage activation syndrome (MAS). Of note, MAS is seldom observed in autoinflammatory diseases. As mentioned above, MAS bears a strong resemblance to a group of histiocytic disorders collectively known as hemophagocytic lymphohistiocytosis (HLH). The etiopathogenesis of MAS remains unknown. Immunologic abnormalities that are similar to those seen in HLH (poor NK cell cytolytic activity often associated with abnormal levels of perforin expression) have been reported, although these abnormalities may be reversible when associated with sJIA. However, in many instances of sJIA/MAS, no such defects in cytotoxic cell function have been identified. This suggests that MAS represents an end-stage clinical syndrome that can be elicited by different mechanisms.

Oligoarthritis

The homogeneity of this form of arthritis, characterized by an early onset and by ANA positivity, is witnessed by consistent associations with HLA antigens. Positive associations include HLA-A2, HLA-DRB1*11 (a subtype of HLA-DR5), and HLA-DRB1*08. On the contrary, HLA-DRB1*04 and HLA-DRB1*07 have been found to be significantly decreased (Ravelli and Martini 2007). HLA associations support an autoimmune pathogenesis and the early onset suggests that the disease could be elicited by a common infectious agent that could be encountered early in life. Of note, Barnes and coworkers (Barnes et al. 2010), studying gene expression, found that patients with early-onset arthritis ($\leq$6 years) had a characteristic B-cell signature, independent of the number of joints involved. An expansion of

activated switch memory B-cells and of IgG-secreting plasma blasts has been found in the SF of oligoarticular JIA patients (Corcione et al. 2009). Memory B-cells belonged to either the CD27+ or the CD27− subsets and expressed CD86, suggesting their involvement in antigen presentation to T-cells (Corcione et al. 2009). Another study (Morbach et al. 2011) has also confirmed that activated immunoglobulin class–switched CD27+ and CD27− memory B-cells – accumulate in the joints, further suggesting that B-cells play an antibody-independent immunopathologic role in oligoarthritis.

Synovial fluid Th17 cells have been showed to switch from a Th17 phenotype to a mixed Th1/Th17 phenotype, and, then, to a Th1 phenotype and that this switch was linked to the presence of IL-12 in the synovial fluid (Cosmi et al. 2011; Nistala et al. 2010). Moreover, within the joint, an inverse relationship between IL-17+ T-cells and FoxP3+ T-regulatory (Treg) cells has been found (Nistala et al. 2008). In JIA, Tregs are fully functional; nevertheless, Treg-mediated suppression of effector cells from the site of inflammation has been shown to be severely impaired. This resistance to suppression has been shown to be secondary to the activation of protein kinase B (PKB)/c-akt in inflammatory effector cells (Wehrens et al. 2011).

The fact that joint involvement can remain limited to 4 or less joints (oligoarticular persistent) or can extend to affect five or more joints after the first 6 months of disease (oligoarticular extended) provides an opportunity to study factors that are associated with disease extension. IL-17+ T-cell numbers were found to be higher and the ratio between SF regulatory and activated effector CD4 cells was found to be lower in patients with extended oligoarthritis as compared with patients with persistent oligoarthritis (Ruprecht et al. 2005; Nistala et al. 2008). Synovial CCL5 levels were found to be higher and SF CD4:CD8 ratio to be lower in children whose disease extended to a more severe phenotype during disease follow-up (Hunter et al. 2010). Gene expression profiling revealed increased levels of genes associated with inflammation and macrophage differentiation in patients with extended disease and of genes associated with immune regulation in patients with persistent oligoarticular disease (Hunter et al. 2010). CD4 expression and B-cell infiltrates are significantly higher and vascularization more pronounced in patients in whom arthritis extended to involve more joints with respect to those with persistent oligoarthritis (Finnegan et al. 2011).

The fact that persistent oligoarticular JIA is self-limiting and in about half of cases even self-remitting suggests that the disease may be responsive to endogenous regulation. Heat shock proteins (HSPs) are endogenous proteins that are expressed upon cellular stress, are able to modulate immune responses, and are ubiquitous at sites of inflammation, including the inflamed joints of JIA patients. Studies of patients with JIA have demonstrated the presence of antigen-specific T-cells directed against peptides derived from two types of HSPs, HSP60 and DnaJ (Prakken and Albani 2009). T-cell recognition of some peptides was associated with a regulatory functional phenotype. These responses were significantly augmented in patients with persistent oligoarticular JIA, suggesting a direct role in modulation of autoimmune inflammation. The identification of HSP tolerogenic peptides could have therapeutic implications in the future.

Management

With the exception of RF-positive polyarthritis, it is difficult to predict outcome at disease onset. Treatment (Ravelli and Martini 2007; Cassidy et al. 2011; Prakken et al. 2011) should therefore be tailored during disease course according to disease severity. Patients are initially treated with nonsteroidal anti-inflammatory drugs (NSAIDs) and intra-articular corticosteroid injections (e.g., with triamcinolone hexacetonide) which have played an important role in preventing deformities secondary to joint contractures. In children who do not respond to

this approach (especially those with polyarthritis), methotrexate (MTX) has been shown to be effective in randomized trials. Although a trial has shown the efficacy of leflunomide in polyarticular JIA, the published experience with this drug in children is still limited. Patients who do not have an adequate response to MTX are often treated with biological agents usually added to MTX therapy. As in adult RA, the marked efficacy of anti-TNF agents and abatacept has been demonstrated in controlled trials of JIA while a phase III controlled trial with tocilizumab has just been completed.

Systemic JIA is initially treated with NSAIDs, but in most patients, corticosteroid therapy (e.g., prednisolone) is required. Patients who are steroid dependent often respond well to anti-IL-6 (tocilizumab) or to anti-IL-1 (e.g., anakinra or canakinumab) therapies. Response to MTX and anti-TNF agents is less dramatic in sJIA than that observed in the other JIA categories. The treatment of sJIA-associated MAS often relies on high-dose steroids and cyclosporine.

In iridocyclitis, early diagnosis is important for the success of therapy. The initial approach consists of glucocorticoid eye drops with mydriatics. For patients with resistant disease, systemic steroids may be required. If disease remains controlled, MTX, cyclosporine, monoclonal antibodies against TNF, and abatacept have been anecdotally reported to be effective.

Conclusions

JIA is not a single disease but an umbrella term that gathers together all forms of chronic arthritis with onset before 16 year of age. These forms appear to represent the childhood equivalent of adult disease with the exception of early-onset, ANA-positive arthritis which is a disease observed only in children. The other major difference between childhood and adult disease is the much higher frequency of systemic JIA compared with adult-onset Still's disease.

The last decade has witnessed a dramatic improvement in JIA treatment, thanks to the use of biological agents. TNF-blocking agents as well as abatacept have been shown to be effective in a high proportion of patients with polyarticular JIA. Systemic JIA has a peculiar immunological profile with marked involvement of innate immunity and responds well to IL-6 and to IL-1 inhibition (De Benedetti et al. 2012; Ruperto et al. 2012).

Synonyms

Juvenile chronic polyarthritis; Juvenile rheumatoid arthritis

Definition

Juvenile idiopathic arthritis (JIA) is a group of chronic arthritides with different presentations, disease courses, and outcomes. It is defined by the presence of inflammatory arthritis in children less than 16 years of age and lasting for at least 6 weeks duration. The International League of Associations for Rheumatology (ILAR) has classified JIA into seven subtypes based on prominent clinical and lab features. This classification system was revised in 2001 (Petty et al. 2004).

Historical Background

JIA is the most common chronic rheumatic disease in children and is an important cause of short- and long-term disability. In 1864, Cornil first described a young adult who developed inflammatory polyarthritis in her early teen years. Dr. Still described a classic case of chronic childhood arthritis in 1897. The terms "juvenile rheumatoid arthritis" and "juvenile chronic arthritis" were used for many years in the

United States (USA) and European countries, respectively, until a common terminology was introduced by ILAR in 1993 (Cassidy et al. 2011).

Epidemiology

One in every 1,000 children worldwide has JIA (Huang 2012). The incidence in the USA ranges from 9.2 to 13.9 per 100,000. The incidence is comparable to that in European countries.

JIA presents in children less than 16 years of age, but most commonly is seen between 1 and 6 years of age. Girls are affected twice as often as boys, but sex distribution varies by disease subtype.

Etiology and Pathogenesis

Infection has long been suspected to play a major role in the initiation and augmentation of JIA, especially parvovirus B19, Epstein-Barr virus, *Mycoplasma*, and *Streptococcus* (Cassidy et al. 2011; Gilliam et al. 2009; Reed et al. 2009). Molecular mimicry may be the mechanism by which these organisms lead to an increased risk of JIA.

Abnormalities in the adaptive or innate immune system leading to auto-reactive T-cell and autoantibody production in a genetically susceptible individual may lead to JIA (Lin et al. 2011). HLA genes especially A2, DRB1*04, DRB1*07 have been associated with oligoarticular JIA. HLA-DR4 has been associated with polyarticular JIA and HLAB27 with enthesitis-related arthritis.

There may be an imbalance of Th1/Th17 and Tregulatory (Treg) cells in favor of increased inflammatory cytokine production such as interferon-γ, IL-17, and IL-22. There is a decrease in the number and function of Treg cells, which subdue inflammation, because of Foxp3 deficiency.

Cytokines, especially tumor necrosis factor α (TNF-α) and IL-1 and IL-6, cause significant chronic inflammation, leading to tissue destruction. There is increased CD4+ T-cells and clonal expansion in the synovial fluid of JIA patients.

Presentation and Classification

As per ILAR classification, the different subtypes of JIA are noted in Table 1.

Systemic Arthritis (Systemic Onset Juvenile Idiopathic Arthritis (SoJIA))

SoJIA makes up 10 % of the JIA population. Though this form may present at any age, most often children are less than 5 years of age (Behrens et al. 2008). It is characterized by daily or twice daily high-grade fevers, temperatures exceeding 103 °F, known as quotidian fevers, which last for at least 2 weeks. These fevers are accompanied by an evanescent salmon colored rash, which may become more prominent during fever spikes, lymphadenopathy, hepatosplenomegaly, or serositis. Joint involvement may be delayed or initially may only present as migratory joint pain (Cimaz et al. 2012). The number of joints involved also varies. The anti-nuclear antibody (ANA) may be positive in 5–10 % of the patients, but rheumatoid factor (RF) is rarely seen in this subgroup. This form of JIA may mimic severe localized infections, sepsis, or malignancy, and thus, there may be delay in diagnosis and treatment. These patients are at risk of developing macrophage activation syndrome (MAS), a potentially life-threatening complication due to activation of T-cells and macrophages.

Oligoarthritis

Oligoarthritis is arthritis affecting one to four joints. It is the most common subtype of JIA,

Juvenile Idiopathic Arthritis: Pathogenesis, Presentation, and Treatment, Table 1 ILAR classification of JIA

Systemic arthritis
Oligoarthritis:
Persistent
Extended
Polyarthritis (rheumatoid factor negative)
Polyarthritis (rheumatoid factor positive)
Psoriatic arthritis
Enthesitis-related arthritis
Undifferentiated arthritis

accounting for 30–60 % of the JIA patients. It is more common in girls than boys and is seen in children younger than 4 years of age. Fifty percent of the time the child presents with monoarthritis with additional joints recruited later. This subtype is divided into persistent or extended. Persistent oligoarthritis affects four or fewer joints throughout the disease course. Extended oligoarthritis affects more than four joints after 6 months of disease onset. Uveitis, often "silent" or asymptomatic, accompanies this subtype of arthritis in 30 % of cases, especially those children with a positive ANA (Gowdie and Tse 2012). Ninety percent of JIA patients with uveitis have an elevated ANA titer (Moore 2010). Exclusions for this subtype of JIA are psoriasis or history of psoriasis in the patient or first-degree relative, arthritis in an HLA B27-positive male beginning after the sixth birthday, ankylosing spondylitis, enthesitis-related arthritis, sacroiliitis with inflammatory bowel disease, reactive arthritis, acute anterior uveitis, or a history of one of these disorders in a first-degree relative (Petty et al. 2004).

Polyarthritis, Rheumatoid Factor Negative

By definition, this subgroup has more than four affected joints and RF is negative on serological testing. These patients have a variable disease onset (acute or insidious) and course (large or small joints involved). This subgroup, especially those with a positive ANA, may be hard to distinguish from ANA-positive extended oligoarticular JIA patients.

Polyarthritis, Rheumatoid Factor Positive

RF-positive children with polyarthritis have a clinical course similar to adult rheumatoid arthritis patients. These patients tend to be in their adolescence, and the arthritis tends to be aggressive, presenting with symmetric small joint involvement, especially of the hands and wrists. The anti-cyclic citrullinated peptide is often positive, the disease tends to be aggressive, and the prognosis is poor (Syed et al. 2008). This subgroup accounts for 5–10 % of all JIA patients. These patients may also develop rheumatoid nodules and are at higher risk for vasculitis.

Psoriatic Arthritis (Psoriatic Juvenile Idiopathic Arthritis, PsJIA)

This subgroup classically has arthritis and psoriasis. The clinical features include dactylitis (swelling of entire digits beyond the joint margin), nail changes (pitting: minimum of two, or onycholysis), or family history of first-degree relatives with psoriasis. The arthritis may precede the psoriasis by several years. RF tends to be negative. Patients with PsJIA are further divided into two groups. The first is those that appear similar to oligoarticular JIA, are younger, are more often female, and have an asymmetric oligoarticular presentation along with dactylitis. These children may also have asymptomatic anterior uveitis. The second group tends to be older, male, and have a higher incidence of spondyloarthritis (Gowdie and Tse 2012).

Enthesitis-Related Arthritis (ERA)

ERA is characterized by the presence of arthritis and/or enthesitis with at least two of the following: sacroiliac joint tenderness or inflammatory lumbosacral back pain, presence of HLA-B27 antigen, onset of arthritis in a male over 6 years of age, acute painful anterior uveitis (unlike oligoarticular JIA which tends to be silent), history of ankylosing spondylitis, sacroiliitis with inflammatory bowel disease, reactive arthritis, or acute anterior uveitis in a first-degree relative (Petty et al. 2004). More males than females tend to be affected by ERA. The arthritis tends to involve the lower extremity especially the hip joint and intertarsal joints of the feet. Entheses are sites of tendinous, ligamentous, or joint capsular insertions on bones. Typical entheses involved in ERA are in the lower extremities especially at the iliac crest, posterior and anterior superior iliac spine, femoral greater trochanter, ischial tuberosity, patella, tibial tuberosity, Achilles, and planter fascia. The axial skeleton is at risk of involvement in ERA. Some children will develop ankylosing spondylitis within 10–15 years of diagnosis. The HLA-B27 antigen is present in 80–90 % of these patients.

Undifferentiated Arthritis

JIA that fulfills criteria in none of the other categories listed above or fulfills two or more of the above categories is considered undifferentiated JIA.

Complications of JIA

Anterior uveitis is the most significant complication of JIA, mainly affecting the iris and ciliary body. It is insidious in onset and asymptomatic; thus, the recommendation is to refer all children diagnosed with JIA to an ophthalmologist for regular evaluation. Factors that increase the risk of uveitis are a positive ANA and age younger than 4 years. Females with oligoarticular JIA are at higher risk for uveitis than males. Children with a positive ANA should be seen every 3 months for a number of years and then every 6 months. All JIA patients should be monitored at least once a year for an indefinite period. Children with ERA mostly present with acute symptomatic uveitis.

Oligoarticular JIA patients are at risk for leg length discrepancy due to abnormal localized growth disturbance. Active inflammation leads to accelerated growth at the ossification center and premature epiphyseal closure of the affected limb, eventually leading to shortened limb on the involved side. The temporomandibular joint may also be affected, leading to micrognathia. Patients with severe active polyarticular JIA and SoJIA can have generalized linear growth disturbance because of circulating proinflammatory cytokines especially IL-6, which suppress growth at the growth plate as well as impair the production and function of insulin-like growth factor-1 (IGF-1) (Wong et al. 2008).

MAS, as mentioned earlier, is a complication mainly seen with SoJIA and is potentially life-threatening. MAS may be difficult to distinguish from a flare of SoJIA and is characterized with sustained fevers, hepatosplenomegaly, anemia, liver dysfunction, rashes, coagulopathy, decreasing white cell counts and platelets, decreasing ESR, increased ferritin level, and hemophagocytosis on bone marrow aspirate (Gowdie and Tse 2012).

Children with JIA are at risk for osteopenia and osteoporosis. Potential risk factors for abnormal bone density include chronic active and persistent inflammation, the chronic use of corticosteroids, decreased physical activity, and decreased sunlight exposure. Besides controlling the disease with medications, patients are encouraged to exercise and follow a nutritionally balanced diet. Vitamin D supplementation is important. Multiple studies have shown vitamin D enhances the innate immune system and helps dendritic cells differentiate and mature in response to antigen presentation and enhances the function of Treg cells. Vitamin D also downregulates proinflammatory cytokines such as IL-12 as well as Th17 cells (Huang 2012).

Treatment

Physical and occupational therapy are crucial parts for the treatment of JIA to preserve/improve joint function and gain muscle strength. Splints or braces are sometimes required to allow for better function and joint stabilization. Aquatic therapy is an excellent means of strengthening muscles and stabilizing joints without significant strain on joints.

The initial pharmacologic treatment of JIA is usually nonsteroidal anti-inflammatory agents (NSAIDs). Corticosteroids may be required for more severe and widespread disease or if there is systemic involvement such as serositis, fevers, rash, or lymphadenopathy as in the case of SoJIA or polyarticular JIA. The different classes of medications are listed in Table 2.

Recently, Beukelman and colleagues published the 2011 ACR JIA treatment guidelines based on consensus among pediatric rheumatologists and the review of the literature. This is a good resource for physicians caring for JIA patients (Ringwold et al. 2013).

Oligoarticular JIA will often respond to initial treatment with an NSAID. These agents work via inhibition of the cyclooxygenase pathway of arachidonic acid metabolism and prevention of proinflammatory prostaglandin production (Kahn 2011). The main side effect is abdominal pain or headaches.

Juvenile Idiopathic Arthritis: Pathogenesis, Presentation, and Treatment, Table 2 Medication classes used in JIA

Nonsteroidal anti-inflammatory (NSAIDs)
Naproxen[a]
Ibuprofen[a]
Meloxicam[a]
Tolmetin[a]
Diclofenac sodium
Nabumetone
Indomethacin[a]
Sulindac
Celecoxib[a]
Disease-modifying antirheumatic agents (DMARDs)
Methotrexate
Hydroxychloroquine
Sulfasalazine
Leflunomide
Corticosteroids
Prednisone
Prednisolone
Intra-articular triamcinolone injection
Intravenous methylprednisolone
Biologic DMARDs
Anti-tumor necrosis factor agents (anti-TNFs)
Etanercept
Adalimumab
Infliximab
IL-1 receptor antagonist – Anakinra
CTLA-4 costimulatory blockade – Abatacept
IL-6 receptor antibody – Tocilizumab

[a]NSAIDs FDA approved for children <18 years of age

If swelling persists in oligoarticular JIA after a trial of NSAIDs, often the caregiver will choose to inject corticosteroid, preferably triamcinolone hexacetonide in the affected joint to help resolve the swelling and avoid leg length discrepancy. Once the arthritis is noted to be in remission, the NSAID treatment may be continued for another 6 months, when the patient is reassessed. If the patient continues to show no signs of active disease, discontinuing the NSAIDs may be considered.

The oligoarticular extended JIA patients should be treated like polyarticular patients. In most cases, these patients will require DMARDs to bring their disease under control. Because these medications take some time to show their effects, systemic corticosteroids will often be recommended in low doses as bridging therapy. Methotrexate is the most commonly prescribed DMARD as multiple studies have confirmed its benefits in JIA and overall it is well tolerated in children (Kahn 2011). This medication is prescribed orally once weekly along with folic acid to minimize side effects. It is available in tablets (2.5 mg each) or liquid 25 mg/ml. The dosage in a pediatric patient is 10–20 mg/M^2. Since methotrexate can cause liver abnormalities, leucopenia, or thrombocytopenia, labs should be checked routinely every 6–8 weeks. Methotrexate can also rarely cause pneumonitis, manifested by a chronic dry cough. This is most commonly seen in the initial 6–12 weeks of exposure but may be seen any time in the treatment course.

Hydroxychloroquine (HCQ) is an antimalarial antibiotic, which exerts anti-inflammatory effects via stabilization of lysosomal membrane. It inhibits lysosomal function by impairing lysosomal acidification which, in turn, inhibits TLR-7 and -9 activation (Ventuturupalli et al. 2012). By inhibiting lysosomal function, it also causes cytokine inhibition, including IL-6. In JIA, it is not usually the first DMARD to be used, but is often added to methotrexate or other DMARDs to potentiate effects. HCQ is only available in tablet form and the recommended dosage is 6 mg/kg per day.

Sulfasalazine is less often used in the USA than in Europe. It may be used as monotherapy or in combination with other DMARDs. It is started at 50 mg/kg.

Leflunomide is a pyrimidine synthetase inhibitor, which has also been shown to be effective in children with JIA. It should be used with caution in female JIA patients because of its teratogenic effects and long half-life.

Biologic DMARD therapy is often used in juvenile arthritis refractory to conventional NSAIDs and DMARDs. In 1999, etanercept was the first biologic to receive FDA approval for polyarticular JIA (Lovell et al. 2000). It is a soluble fusion protein consisting of human p75 TNF receptor fused to the Fc region of human IgG1. It is available as a weekly subcutaneous injection at a dose of 0.8 mg/kg/week.

Its main side effects are infection risk, demyelinating disease, decreased capability to mount response to vaccine, and possibly malignancy, mainly lymphomas. In adult RA patients, an increased rate of *Mycobacterium tuberculosis* (TB) was noted in patients initiated on anti-TNF agents and thus, all patients should be screened for TB with skin testing and a chest x-ray prior to initiation and annually while on treatment.

Adalimumab is a humanized IgG monoclonal anti-TNF-α antibody, which was FDA approved for polyarticular JIA in 2008. It is also a subcutaneous injection available in a 20-mg dose (for children weighing 10–30 kg) or 40-mg dose (for children weighing >30 kg), injected once every 2 weeks. It has similar side effects as mentioned above for etanercept.

Infliximab is a chimeric (mouse-human) IgG1 monoclonal antibody administered intravenously. It binds to both membrane-bound as well as soluble TNF-α. Though it is not FDA approved for JIA, a 2007 multicenter, randomized, double-blind placebo-controlled trial in 122 polyarticular JIA demonstrated ACR Pedi 50 and 70 responses in 70 % and 52 % of the patients, respectively (Ruperto et al. 2007). Because of its chimeric nature, some patients form human anti-chimeric antibodies (HACAs) and deceased efficacy. It is dosed at 3–10 mg/kg every 6–8 weeks.

Anakinra is a recombinant IL-1 receptor antagonist available as daily subcutaneous injections. It is used for SoJIA patients because IL-1 is increased in this subtype. The systemic symptoms of fever, rash, and elevation of white cells, platelets, and other acute phase reactants tend to improve with Anakinra. It is dosed at 1–2 mg/kg/daily. There is a higher rate of injection site reaction with Anakinra than with anti-TNF agents.

Not all JIA patients will respond to anti-TNF therapy or IL-1 therapy, suggesting other cytokines may play a role in certain patients. Abatacept is another option; it is a soluble fully humanized fusion protein consisting of an extracellular domain of CTLA-4 linked to modified Fc portion of human IgG. It gained FDA approval for polyarticular JIA in 2008. It binds to CD80/CD86 on antigen-presenting cells, inhibiting binding of CD28 on T-cells and consequently inhibiting T-cell activation. It is administered at a dose of 10 mg/kg every 4 weeks after an initial loading regimen. Infections are the most concerning side effect for abatacept. Like anti-TNF agents, it may also increase the risk of malignancy. In adult patients with chronic obstructive pulmonary disease (COPD), abatacept may cause exacerbation of underlying lung disease.

Tocilizumab is a humanized monoclonal antibody directed against IL-6 receptor, which was FDA approved for SoJIA in 2011 and is undergoing trials for polyarticular JIA. It is intravenously administered at a dose of 12 mg/kg for children weighing <30 kg and 8 mg/kg for children weighing >30 kg every 2 weeks. Its side effects include infections, infusion reactions, blood dyscrasias (especially leucopenia), liver enzyme abnormalities, and hyperlipidemia.

Summary

JIA has many phenotypically different presentations classified by the ILAR into seven subtypes. If left untreated, it can cause leg length discrepancy, generalized stunted growth, micrognathia, uveitis, and systemic complications such as MAS, which has high mortality. The uveitis tends to be asymptomatic (thus termed "silent" uveitis). Children with oligoarthritis should have regular eye exams every 6 months and more often (every 3 months) for those JIA patients with a positive ANA.

Elevated levels of TNF, IL-1, IL-6, and other cytokines have been found in patients with JIA, and treatments have been targeted to these cytokines. The initial treatment for oligoarthritis and ERA is NSAID while corticosteroids and DMARDs (especially methotrexate) are used often in early polyarthritis and SoJIA. Biologic DMARDs are initiated in refractory cases in most onset types or as first line should a JIA patient have axial disease (sacroiliitis).

More trials are underway to better understand JIA and to design better treatments. Childhood Arthritis and Rheumatology Research

Alliance (CARRA) is currently working on a multicenter registry for children with rheumatic diseases. More than 60 pediatric rheumatology centers are involved in the registry and more than 7,000 children have already been enrolled.

Definition

Discussing kidney involvement in thrombocytopenic purpura (TTP)/hemolytic uremic syndrome (HUS) is complicated because exactly what disease is identified by these diagnoses has been a moving target ever since 1925. This work focuses on the kidney involvement to that associated with *idiopathic* TTP/HUS. What is meant by this terminology and how we got to that point are important to the topic. It is discussed below.

Introduction

In 1925 Moschcowitz reported autopsy findings of widespread arteriolar hyalin thrombi in a 16-year-old girl who presented with unexplained fever and heart failure and then lapsed into coma and died (Moschcowitz 2003). By the 1930s, additional similar cases were recognized. These showed that the thrombi were composed mainly of platelets and that central nervous system involvement was more common than kidney involvement (Baehr et al. 1936). By the 1950s, further detail emerged, particularly that the affected generally were adults, a thrombotic microangiopathy was present (causing a microangiopathic hemolytic anemia), and the patients often were severely thrombocytopenic. By this time the diagnostic term "thrombotic thrombocytopenic purpura (TTP)" was accepted.

In the late 1950s, the field once again became unsettled when Glasser reported a group of patients with a thrombotic microangiopathy that matched that of TTP except that the affected were children, and severe kidney failure was the dominant clinical presentation. Because of its strong association with acute kidney injury (AKI), this condition was termed "hemolytic uremic syndrome" (HUS). During the ensuing years, TTP and HUS were generally regarded as separate entities. Indeed, by the mid-1980s, it became apparent that many cases of HUS could be attributed to infections, particularly E. coli 0157:H7. This form of HUS was later termed D-HUS

I.R. Mackay, N.R. Rose (eds.), *Encyclopedia of Medical Immunology – Autoimmune Diseases*,
DOI 10.1007/978-0-387-84828-0, © Springer Science+Business Media New York 2014

(diarrhea-associated HUS). A further differentiation within the diagnosis of HUS emerged when it was discovered that genetic or acquired deficiency of regulators of the alternative pathway could also cause HUS. This condition, which is rare, was termed "atypical (a) HUS" to differentiate it from the "typical" HUS, which is associated with diarrhea (Noris and Remuzzi 2009; George 2010).

Despite these clarifications there remained a large number of patients who presented with microangiopathic hemolytic anemia and target organ injury in whom their condition was neither post-diarrheal nor associated with unregulated alternative complement pathway activation or any other known cause of thrombotic microangiopathy. From this emerged the notion that *idiopathic* TTP and *idiopathic* HUS were different aspects of the same disease (Remuzzi 1987). On this basis, it could be argued that the term "*idiopathic* HUS" is redundant when used in conjunction with *idiopathic* TTP. However, many experts discuss them together to ensure that they receive the same treatment. So, this work will continue the tradition of linking HUS to TTP, if the HUS is *idiopathic* (i.e., not "typical" HUS or "atypical HUS," as will be discussed later).

Diagnostic Approach to *Idiopathic* TTP/HUS

A potentially defining moment in differentiating *idiopathic* TTP/HUS from non-idiopathic HUS/TTP occurred in the late 1990s when it was determined that many patients with syndromes consistent with TTP or HUS had severely decreased activity of the plasma enzyme ADAMTS-13 (a disintegrin-like and metalloprotease with thrombospondin type 1 repeats) (Tsai and Lian 1998; Furlan et al. 1998). This enzyme degrades the ultra large (UL) polymers of von Willebrand's factor (vWF) thereby mitigating their ability to induce platelet aggregation and the platelet thrombi that characterize TTP. Unfortunately, this remarkable advance still did not allow an absolute separation of *idiopathic* and non-idiopathic forms of TTP/HUS for the following reasons:

1. Not all patients with the clinical syndromes of *idiopathic* TTP/HUS have severe ADAMTS-13 deficiency (George 2010). Also, in rare instances, severe ADAMTS-13 deficiency may not be fully expressed until later in the patient's course. This may be for methodological reasons related to the assay (Froehlich-Zahnd et al. 2012).
2. Not all patients with severe ADAMTS-13 deficiency develop a thrombotic microangiopathy (George 2010).
3. Treatment aimed at restoring ADAMTS-13 levels towards normal by repeated plasma exchange using fresh frozen plasma is highly effective in reversing *idiopathic* TTP/HUS and preventing death, even in those who do not have severe ADAMTS-13 deficiency (Vesely et al. 2003).

Despite these gaps in understanding of the role of ADAMTS-13 in the pathogenesis of TTP and HUS, the diagnostic puzzle has begun to fit together much better, enough so that many experts in the field now regard *idiopathic* TTP and *idiopathic* HUS as variations of the same condition. These same experts (Wolf 2004; George 2010; Zheng et al. 2010; Lasik and Silva 2007) are comfortable in making a working diagnosis of *idiopathic* TTP/HUS on the basis of the following:

- The patient presents with evidence of a microangiopathic hemolytic anemia (Table 1).
- Target organ injury is present (e.g., central nervous system, kidney, heart, skin, and intestinal tract).
- The microangiopathic hemolytic anemia and target organ injury are not explained by *any other* condition that can mimic *idiopathic* TTP/HUS (Table 2).

Current expert opinion is that to make a working diagnosis of *idiopathic* TTP/HUS does not require documentation that ADAMTS-13 activity is severely decreased: <5 % of normal (Zheng et al. 2010) or <10 % of normal (George 2010). That documentation can occur later. The rationale is for both methodological reasons

Kidney Involvement in Idiopathic TTP/HUS, Table 1 Criteria for the diagnosis of microangiopathic hemolytic anemia[a]

Criterion	Comment
Anemia	The reticulocyte count eventually becomes elevated indicating that the anemia is not the result of low red cell production
Schistocytes on blood smear	Usually 2 % or more if red cells in the peripheral smear are schistocytes, although rarely they are absent (Brilliant et al. 1996; Daram et al. 2005)
Low plasma haptoglobin	This indicates that the anemia is from intravascular destruction of red cells rather than blood loss
Elevated serum LDH	This is evidence of red cell hemolysis and release of LDH from ischemic tissue (Cohen et al. 1998)
Thrombocytopenia[b]	This results from either the primary consumption of platelets (e.g., the platelet thrombi of *idiopathic* TTP/HUS) or from the secondary consumption of platelets in fibrin thrombi (e.g., catastrophic antiphospholipid syndrome)

[a]Microangiopathic hemolytic anemia is the hallmark of thrombotic microangiopathies such as TTP/HUS. However, microangiopathic hemolytic anemia can occur in disease states that generally are not classified as a thrombotic microangiopathy (see Table 2)

[b]The diagnostic usefulness of measuring high-sensitivity D-dimer in thrombocytopenic patients in order to differentiate those in whom the thrombocytopenia is the result of lack of platelet production, or platelet consumption in a thrombotic process, has not, to the best of our knowledge, been carefully studied. It is reported that fibrin degradation products are not elevated in TTP (George 2011) or they are elevated only in those with "tissue ischemia" (Leung 2010). However, the latter reference is from an era before high-sensitivity D-dimers were measured and, presumably, the assays were less sensitive. Also, the former reference does not describe how tissue ischemia was validated. It is plausible that those with elevated LDH had elevated D-dimers because they had a more extensive thrombotic arteriopathy. This, in turn, caused the tissue ischemia. So, elevated D-dimer may be a measure of the thrombotic process

(standardized assays for ADAMTS-13 are not widely available) and practical reasons (the assay may not be available in time to inform patient management). The latter is a crucial point because, if the patient does have acute *idiopathic* TTP/HUS, it is essential to begin treatment with fresh frozen plasma exchange as soon as feasible in order to protect the patient from the severe acute manifestations of *idiopathic* TTP/HUS (George 2010).

Although the above approach may seem straightforward, it is complicated for the following reasons:

1. There are a large number of other conditions that must be differentiated from the patient's condition before a diagnosis of *idiopathic* TTP/HUS can be made and plasma exchange is justified (Table 2).
2. The diagnostic and therapeutic approach to the patient must also take into account those conditions that are not *idiopathic* TTP/HUS but still may be benefitted by plasma exchange with fresh frozen plasma or 5 % albumin (Table 2).
3. The decision to deploy plasma exchange should not be made lightly because of the costs and risks of plasma exchange (Howard et al. 2006).

Although severe ADAMTS-13 deficiency is not required to establish a diagnosis of *idiopathic* TTP/HUS, it is widely believed that severe ADAMTS-13 deficiency (<5 % of normal) is highly sensitive and specific in differentiating *idiopathic* from non-idiopathic TTP/HUS (Bianchi et al. 2002; Raife et al. 2004; George 2010).

Pathogenesis of *Idiopathic* TTP/HUS

Severe deficiency of ADAMTS-13 activity may be either genetic or acquired. Acquired *idiopathic* TTP/HUS is usually caused by IgG autoantibodies to ADAMTS-13 and particularly the IgG1 and IgG4 subtypes. IgA and IgM isotypes have also been described (Zheng et al. 2010; Tsai 2010). If ELISA is used for detection, inhibitors are detectable in approximately 97 % of cases with severe ADAMTS-13 deficiency but in only 50–90 % of cases when functional assays are used (Zheng et al. 2010). These autoantibodies have also been found in the TTP/HUS associated with systemic autoimmune conditions such as SLE.

In patients with genetic deficiency of ADAMTS-13, homozygous or compound heterozygous mutations of ADAMTS-13 protease are found (Tsai 2010). This causes severe deficiency of ADAMTS-13 activity and causes TTP/HUS.

Kidney Involvement in Idiopathic TTP/HUS, Table 2 Conditions that mimic *idiopathic* TTP/HUS because they present with a microangiopathic hemolytic anemia and target organ injury. They are stratified according to whether they are benefitted by plasma exchange[a]

Conditions that present with microangiopathic hemolytic anemia and, like idiopathic TTP/HUS, may be benefited by plasma exchange	
Condition	Comment
1. Severe *primary* antiphospholipid syndrome	Systemic anticoagulation is also needed for acute and chronic management. High-dose steroid therapy is also recommended for initial management. Plasma exchange with fresh frozen plasma is recommended, but 5 % albumin may also be beneficial
2. Severe *secondary* antiphospholipid syndrome	Usually these patients have SLE. If the SLE is active, this must also be treated with steroids and immunosuppression
3. TTP/HUS associated with SLE	If the SLE is active, this must also be treated
4. ANCA-associated vasculitis	Anemia and schistocytes in the peripheral blood smear are not uncommon in this condition. Usually the anemia is mild. Plasma exchange with 5 % albumin is indicated if severe renal failure is present
5. Severe type 1, 2, or 3 cryoglobulinemia	Plasma exchange with 5 % albumin is acutely helpful. Some may have severe hypertension mimicking the microangiopathic hemolytic anemia of malignant hypertension (George 2010)
6. Congenital TTP	This is a rare genetic polymorphism of the ADAMTS-13 molecule. Plasma exchange can be used, although plasma infusion usually is sufficient (George 2010)
7. Atypical (a) HUS	This is a rare condition that may be benefited by plasma exchange with fresh frozen plasma until the diagnosis is established. After than eculizumab, a monoclonal antibody that targets C5 of the terminal complement pathway may be more effective
Conditions that present with microangiopathic hemolytic anemia, but plasma exchange has not been shown to be beneficial	
Condition	Comment
1. Typical HUS (diarrhea associated)	Resolution usually occurs with conservative care
2. Drugs:	
Cancer chemotherapy	Mitogenic C, bleomycin and cisplatin, anti-VEGF
Immunosuppressives	Cyclosporin, tacrolimus
Anti-VEGF	As cancer chemotherapy or as intraocular injections for macular degeneration
Quinine for muscle cramp	Quinine is also contained in beverages
Ticlopidine, clopidogrel	Ironically, these are antiplatelet drugs
Therapies associated with stem cell transplant	Multiple drugs may be involved
Other drugs	Oral contraceptives, valacyclovir
3. Malignant hypertension	This can be a difficult condition to separate from conditions that are benefited by plasma exchange because they are sometimes associated with acute severe hypertension
4. Severe preeclampsia, HELLP syndrome	Rarely these may actually be TTP/HUS triggered by pregnancy. So, plasma exchange may be indicated
5. Acute and subacute infection	Bacterial, fungal, parasitic, and viral infection (including HIV) may trigger microangiopathic hemolytic anemia (Booth et al. 2011; Blum et al. 2011). Antimicrobial therapy generally is beneficial
6. Scleroderma renal crisis	Malignant hypertension is usually present. Blood pressure control usually is beneficial
7. Active SLE in the absence of antiphospholipid syndrome, ADAMTS-13 deficiency, or demonstrable clot (venous, artery, or arteriole)	These patients have elevated D-dimers consistent with platelets being consumed in a thrombotic process. These patients recover with steroid and immunosuppressive therapy. Likely this condition is the result of immune complex-mediated endothelial injury that resolves with steroid and immunosuppressive therapy (Wu et al. 2008)
8. Disseminated malignancy	Mucin-producing tumor may be particularly involved

(*continued*)

Kidney Involvement in Idiopathic TTP/HUS, Table 2 (continued)

Conditions that present with microangiopathic hemolytic anemia, but plasma exchange has not been shown to be beneficial	
Condition	Comment
9. Atheroembolism	This can be acute or subacute embolism. It can closely mimic *idiopathic* TTP/HUS
10. Severe "bath salts" intoxication	Bath salts are illegal methamphetamines (unpublished personal observations)

[a]Recommended as a general reference is the current section in UpToDate titled "Causes of TTP/HUS in adults"

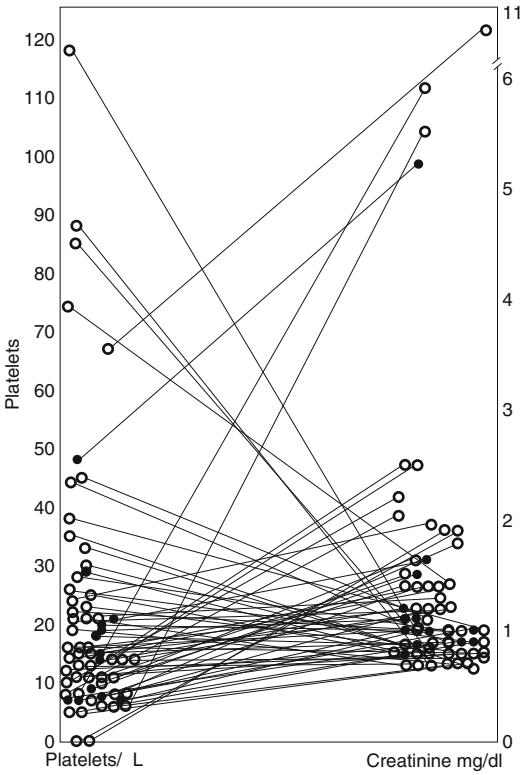
Heterozygotes for the ADAMTS-13 mutations usually have 40–70 % ADAMTS-13 activity and no TTP (Tsai 2010). Patient's homozygous or compound heterozygotes for mutations of ADAMTS-13 protease will manifest TTP.

Monitoring ADAMTS-13 activity level and inhibitor titers is important to long-term management because ADAMTS-13 levels that remain less than 5–10 % after treatment of TTP are associated with a high risk of relapse and poor long-term outcomes (Zheng et al. 2010; Tsai 2010; George 2011).

Kidney Involvement in *Idiopathic* TTP/HUS

Kidney Function. Our review of the literature with regard to *idiopathic* TTP/HUS did not reveal any reports in which all of the key manifestations of kidney injury (hematuria, proteinuria, decreased GFR) were described in detail in individual patients. However, mention is made in general reviews that proteinuria in this condition is moderate (e.g., 24-h proteinuria 1–2 g) and hematuria is usually present. There is, however, a report of individual serum creatinine values in 64 patients with *idiopathic* TTP/HUS and whose ADAMTS-13 level was <5 % of normal. This is displayed in Fig. 1 which shows that at presentation only about 25 % of the patients manifested serum creatinine values >1.3 mg/dl and that severe AKI was uncommon.

Figure 1 is also of interest because the serum creatinine values are shown in relationship to the platelet count in these individual patients, all of whom had severe ADAMTS-13 deficiency (<5 %, open circles) or less severe ADAMTS-13 deficiency (5–10 %, closed circles) (Vesely et al. 2003). As shown, there was no consistent relationship between the presence or absence of



Kidney Involvement in Idiopathic TTP/HUS, Fig. 1 Relationship between platelet count and serum creatinine at presentation in patients deemed to have an *idiopathic* TTP/HUS (Zheng et al. 2010). Each *line* joins the values for platelet count and serum creatinine level for a discrete patient. The data were adapted from Table 1 of Zheng XL (Zheng et al. 2010), with permission of the publisher. The *open circles* are those in which the ADAMTS-13 activity was <5 % of normal. The closed circles are those who had ADAMTS-13 levels that were 5–10 % of normal. As shown, there was no consistent relationship between the degree of thrombocytopenia and the degree of serum creatinine elevation at presentation. In addition, there was no consistent relationship between platelet count and serum creatinine according to whether the ADAMTS-13 activity was <5 % of normal or 5–10 % of normal (see text for further discussion)

severe ADAMTS-13 deficiency and platelet count or serum creatinine level. Figure 1 is further evidence that, although severe ADAMTS-13 deficiency may be highly sensitive and specific for *idiopathic* TTP/HUS, within that category it does not appear to distinguish between those presenting with or without impaired kidney function.

Kidney Biopsy Findings. The published data in this domain are even more limiting. Most of the reported kidney biopsy findings are from an era in which a distinction was made between *idiopathic* TTP and *idiopathic* HUS. This may explain some of the inconsistencies in the published data. For example, although it is stated that *idiopathic* TTP and *idiopathic* HUS can be regarded as variations on the same condition, the interpretation of the kidney biopsies in those deemed to have TTP was different from those deemed to have HUS. For example, the presence of arteriolar platelet thrombi is emphasized in those deemed to have TTP (Lasik and Silva 2007) whereas the presence of fibrin thrombi with platelets is emphasized in those deemed to have HUS (Lasik and Silva 2007). These comparisons likely are further confounded by bias in selecting the patients to be biopsied. The patients deemed to have TTP often had lower platelet counts and better kidney function than those deemed to have HUS. So, likely the "TTP" cohort was less likely to undergo kidney biopsy than the "HUS" patients. Given these limitations, we suggest the following is a reasonable summary of the published evidence regarding the kidney biopsy findings in *idiopathic* TTP/HUS (Lasik and Silva 2007):

(a) The light microscopy shows thrombi in glomeruli and arterioles. These represent patients with disease of recent onset. In patients with more chronic disease, there is conspicuous arteriolar change with intimal hyperplasia and marked narrowing of capillary lumens.
(b) Immunofluorescence microscopy shows that the thrombi are either mainly platelets or mainly fibrin thrombi.
(c) Electron microscopy shows glomerular subendothelial "fluffy" deposits that are thought to represent material derived from fibrin deposits or from cellular debris.

In summary, the kidney manifestations of *idiopathic* TTP/HUS have not been studied in detail and have not been studied with the view of differentiating *idiopathic* HUS/TTP from non-idiopathic forms of TTP. The histologic features described above are not diagnostic of *idiopathic* TTP/HUS but can be seen in other forms of thrombotic microangiopathy, many of which are listed in Table 2.

Despite the relatively tight focus of this work (*idiopathic* TTP/HUS), there are a number of important limitations to this analysis because of the paucity of data in individual patients who meet the diagnostic criteria for *idiopathic* TTP/HUS, as discussed above.

Kupffer Cells in Immune Tolerance

Ian Nicholas Crispe

Kupffer cells: resident liver macrophages

Definition

Kupffer cells are an abundant population of macrophages found mostly in hepatic sinusoids.

Introduction

Kupffer cells are an abundant population of macrophages that reside in the sinusoids of the liver. They are intravascular and, therefore, perfectly located to phagocytose particulates from the blood. The location of the liver in the vascular system results in it receiving both antigenic material and innate immune stimulatory molecules from the intestine, via the hepatic portal vein. Both normal dietary constituents and highly reactive contaminants reach the liver, but in most cases an immune response would serve no useful purpose. For this reason, immune responses in the liver appear to be biased towards immune tolerance. Similarly, the presence of trace amounts of bacterial endotoxin in the portal blood results in a low level of continuous stimulation of innate immune pattern-recognition receptors, such as Toll-like receptor 4. This

influence affects the immunobiology of the liver, resulting in the local expression of adhesion molecules and the constitutive sequestration of activated T cells from the circulation.

The bias of the liver towards immune tolerance is most dramatically illustrated in the case of liver allografts. In mice, in some strain combination of rats and in pigs, an allogeneic liver transplant is frequently accepted. Even in humans, where liver transplantation is typically undertaken in the context of inflammatory disease, there is a bias towards allograft acceptance, and some patients can be weaned off immunosuppression. In addition, several important infections reside in the liver and are subject to ineffective immunity. One interpretation of this is that such pathogens, including hepatitis C virus (HCV), have evolved to take advantage of the liver's tolerogenic bias.

Many different populations of liver cells have been ascribed a role in liver tolerance. These include the hepatocytes, liver sinusoidal endothelial cells, hepatic stellate cells (also termed Ito cells), and the liver's resident and transient dendritic cells. This chapter considers specifically the role of Kupffer cells in inducing immune tolerance. As members of the monocyte-macrophage lineage, Kupffer cells are equipped both to drive inflammatory immunity and to suppress it. In many circumstances, Kupffer cell-mediated immunosuppression is an important element of liver tolerance.

The Origin of Kupffer Cells

Most populations of tissue macrophages are directly derived from circulating monocytes. A subset of macrophages, in particular the microglia of the central nervous system and the Langerhans cells of the skin, have a different origin. These cells arise from fetal precursors, are self-renewing in situ, and do not under normal conditions undergo repopulation from the blood (Hashimoto et al. 2011). Kupffer cells occupy intermediate ground. A subset of Kupffer cells is relatively resistant to ionizing radiation and host-type cells survive in a radiation bone marrow chimera (Kennedy and Abkowitz 1997). Conversely, around half of the liver cells that express mature macrophage markers are in fact bone marrow derived. This same proportion reflects the donor-derived Kupffer cells that persist in a transplanted liver. Therefore, it is likely that the normal liver contains two distinct populations of mature Kupffer cells, one a mainstream tissue macrophage and the other sessile and radioresistant (Klein et al. 2007). It is not yet clear whether these two subsets play different roles in liver immunity and immunopathology.

Immune Suppression Mediated by Cell-Cell Interactions

Kupffer cells express MHC class I and class II molecules, together with co-stimulatory molecules including CD40, CD80, and CD86. They are therefore able to present antigens to both CD4+ and CD8+ T cells. In short-term tissue culture, Kupffer cells activate CD8+ T cells causing their proliferation. They were also capable of cross-presentation of hepatocyte antigens in a coculture (Ebrahimkhani et al. 2011). The expression of MHC class II renders the cells capable of CD4+ T cell activation, but this has not been the topic of extensive study. Stimulation of Kupffer cells via TLR3 increases their expression of both MHC class II and co-stimulatory molecules, suggesting that innate immune activation may modulate their capacity to present antigen (You et al. 2008).

In addition to the capacity to present antigen, Kupffer cells also express a variety of inhibitory ligands that can inactivate or induce apoptosis in T cell that recognize them. One clear example is Fas ligand (CD95L), a tumor necrosis factor (TNF)-like cell surface molecule that engages its counter-receptor Fas (CD95) on activated T cells, leading to caspase-dependent T cell death. In other tissues, the expression of FasL has been linked to immune privilege in the anterior chamber of the eye and to the resistance of immunogenic melanomas to T cell killing (Elzey et al. 2001; Hahne et al. 1996). During

liver transplantation, the induction of tolerance is accompanied by an influx of T cells, followed by apoptotic death of those T cells (Qian et al. 1997). Kupffer cells recovered from such livers express elevated levels of FasL and can kill T cells that recognize them. Furthermore, the adoptive transfer of such Kupffer cells can prolong liver graft survival in a graft rejection model (Sun et al. 2003). Kupffer cells may be paralyzed using an injection of gadolinium chloride, and this treatment reduced the apoptosis of graft-infiltrating T cells and compromised graft survival. This effect was accompanied by loss of NF-kappaB activity and loss of FasL expression by the Kupffer cells and loss of their ability to induce T cell apoptosis (Chen et al. 2008). These and other lines of evidence suggest that FasL on Kupffer cells engages Fas on T cells, promoting T cell death and liver graft survival.

The co-stimulatory molecules CD80 (B7.1) and CD86 (B7.2) belong to a family that also contains an inhibitory molecule, programmed death-ligand 1 (PD-L1, also known as B7-H1). The protein engages a specific counter-receptor PD-1 that is expressed on activated T cells, and this interaction leads to T cell inactivation. Despite the molecule's name, the outcome is often not T cell death, but T cell exhaustion, a functionally compromised but potentially reversible state. Indeed, such PD-1-expressing exhausted T cells can be reinvigorated and can deliver antiviral immunity, simply by blocking the PD-L1/PD-1 interaction (Barber et al. 2006). PD-L1 is expressed on Kupffer cells and appears to mediate tolerance. Thus, Kupffer cells associated with hepatocellular cancers express a high level of PD-L1, and this is correlated with a poor outcome. Such PD-L1 high Kupffer cells were associated with PD-1-high, functionally incapable CD8+ T cells, while the PD-L1 expression was induced by IL-10, secreted by the cancer cells (Wu et al. 2009). The coordinated upregulation of IL-10 and PD-L1 may also be an immunosuppressive strategy adopted by HCV. Thus, the core protein of HCV binds specifically to Toll-like receptor-2 (TLR-2), inducing the secretion of the inflammatory cytokines interleukin-1 beta (IL-1beta) and tumor necrosis factor-alpha (TNF-alpha) but inhibiting others (interferon-alpha and interferon-beta). In parallel, HCV core induces both IL-10 and PD-L1 (Tu et al. 2010). This interaction could therefore compromise antiviral immunity in two ways: suppression of a key antiviral cytokine, IFN-alpha, and the induction of T cell exhaustion by PD-L1. Both mechanisms are supported by clinical observation. Exhausted PD-1 expressing T cells are in fact found in HCV (Radziewicz et al. 2007), while exogenous IFN-alpha is the mainstay of anti-HCV therapy.

Immune Suppression Mediated by Cytokines

Secretion of IL-10 underpins many examples of liver tolerance. Human Kupffer cells exposed to endotoxin secrete IL-10, and this regulates the secretion of inflammatory IL-6 and TNF-alpha by the same cells (Knolle et al. 1995). Kupffer cell-derived IL-10 also acts in trans, negatively regulating the IL-12- and IL-18-dependent activation of liver NK cells (Tu et al. 2008). Kupffer cells may also regulate the severity of virus infections via IL-10. The infection of human Kupffer cells with either wild-type or attenuated yellow fever virus resulted in a cytokine cascade, but in the case of the attenuated virus, more IL-10 was secreted and less of inflammatory cytokines such as TNF-alpha (Woodson et al. 2011). Therefore, a lack of IL-10 may explain the immunopathogenesis associated with wild-type yellow fever virus infection. Similarly, in a mouse model of acute liver injury induced by the injection of the plant lectin, Concanavalin-A, secretion of IL-10 by Kupffer cells, was important in limiting injury (Erhardt et al. 2007). Kupffer cell IL-10 therefore broadly contains liver injury.

In addition to its antagonism of IL-18 and promotion of PD-L1 expression, IL-10 also engages in cross-talk with other immunosuppressive cytokines. Transforming growth factor-beta1 (TGF-beta1) is expressed on apoptotic cell fragments, and such fragments interact with Kupffer cells to induce IL-10 and suppress the

production of inflammatory cytokines including TNF-alpha (Zhang et al. 2011). Just as HCV induces IL-10, so hepatitis B virus (HBV) infects Kupffer cells resulting in the secretion of TGF-beta1 (Li et al. 2012). Thus, Kupffer cells synthesis and response to TGF-beta1, their secretion of IL-10 and their expression of PD-L1 form an interconnected network of immunosuppressive signals, which may both protect the liver from immunopathology and create a window of vulnerability to viral pathogens. Kupffer cells do not simply make IL-10 themselves; they also induce its synthesis by regulatory T cells (Breous et al. 2009), thus participating in active antigen-specific immunosuppression.

Immune Suppression Mediated by Other Mechanisms

In addition to cytokines, Kupffer cells secrete diverse other immunosuppressive molecules. IFN-gamma induces nitric oxide (NO) synthase in Kupffer cells, and this molecule can suppress T cell clonal proliferation (Roland et al. 1994). Kupffer cell activation also results in the upregulation of the enzymes phospholipase A2 and cyclooxygenase A2, which result in synthesis and secretion of the immunosuppressive prostaglandin, PGE2 (Perez et al. 1997).

The enzymatic properties of Kupffer cells further contribute to their immunosuppressive function. The enzyme indoleamine 2,3 dioxygenase (IDO) is implicated in placental tolerance of the fetal allograft, where it acts by creating a tryptophan-deficient local milieu that inhibits T cells activation (Munn et al. 1998). In Kupffer cells, IFN-gamma treatment increases IDO expression and tryptophan depletion, with resulting immunosuppression that could be reversed by the inhibition of IDO (Yan et al. 2010). In another level of regulation, the expression of the enzyme arginase in the liver results in a low L-arginine environment. In an arginine-depleted environment, Kupffer cells secrete increased PGE2, and this causes immunosuppression (Callery et al. 1991).

Conclusion

Kupffer cells exemplify the aspect of macrophage function that deals with homeostasis. Their responses to the inflammatory cytokine IFN-gamma are to secrete TNF-alpha and IL-6, but also to secrete IL-10, and to express NO synthase and IDO, all of which promote immunosuppression. In addition, activated Kupffer cells suppress NK cells, but enhance IL-10 production by regulatory T cells. Similarly, Kupffer cells respond to activation signals by secreting PGE2, which suppresses T cell activation. With all these anti-inflammatory mechanisms, Kupffer cells appear strongly biased towards the containment of injury and the moderation of local immunity. Even the classical "Kupffer cell hyperplasia" described in HCV-infected liver may reflect the containment, rather than the promotion of liver cell injury (Sitia et al. 2011). This bias is likely to be an adaptation to the exposure of Kupffer cells to diverse nonself and pathogen-associated molecules that originate in the intestinal microbiota, but diverse pathogens have evolved mechanisms to exploit Kupffer cells. One of the issues that remains to be addressed is whether Kupffer cell-mediated liver tolerance is sometimes too much of a good thing. The accessibility of Kupffer cells within the circulation renders them potential targets for therapy (Yang et al. 2008), so it will be possible to both enhance and inhibit Kupffer cell-driven immune tolerance for therapeutic benefit.

Cicatricial alopecia; Follicular lichen planus

Definition

Cicatricial or scarring alopecia includes rare disorders that permanently destroy the hair follicle and replace it by scar tissue and cause permanent hair loss. Lichen planopilaris is a primary lymphocytic scarring alopecia, whereas in secondary scarring alopecia, alopecia is a feature of systemic disease as in discoid lupus erythematosus, scleroderma, and dermatomyositis.

Introduction

Lichen planopilaris (LPP) is a variant of lichen planus selectively involving hair follicles with a lymphocytic inflammatory process that eventually destroys the pilosebaceous unit permanently resulting in scarring alopecia. LPP is the most common cause of adult primary scarring alopecia. Frontal fibrosing alopecia and Lasseur-Graham-Little-Piccardi syndrome are considered variants of LPP.

Pathophysiology

Pathogenesis of LPP is poorly understood. The reaction is mediated by T lymphocytes (CD4 and CD8) activated by Langerhans cells that are increased in dermis and epidermis. The target follicular antigens are unknown. In lichen planus, T lymphocytes destroy keratinocytes, which express an unknown antigen on their surface. In LPP, T lymphocytes are located around the upper part of the hair follicle around the infundibulum and isthmus destroying the bulge area, which is a specialized portion of hair follicle marked by the insertion of arrector pili muscle. The bulge area cells are stem cells which generate the new lower anagen hair follicle. Destruction of the hair follicle stem cells in the hair bulge and the sebaceous glands leads to permanent hair loss. In contrast, in alopecia areata, the inflammatory infiltrate is located around the hair bulb and the hair follicle stem cells and sebaceous glands are not affected; hence, the hair loss is always potentially reversible.

The cell-mediated reaction may be triggered by an endogenous or exogenous agent, such as virus, medications, or contact sensitizers, which bind to keratinocytes and follicular epithelium,

I.R. Mackay, N.R. Rose (eds.), *Encyclopedia of Medical Immunology – Autoimmune Diseases*,
DOI 10.1007/978-0-387-84828-0, © Springer Science+Business Media New York 2014

resulting in production of cytokines and chemotactic factors causing inflammation. Contact sensitizers like gold or mercury can act as haptens and evoke inflammation. Certain viruses like hepatitis C virus and human immunodeficiency virus and drugs like beta-blockers, quinidine, and thiazides can cause lichenoid eruptions, which exhibit similar cutaneous and histological findings as lichen planus (Kang et al. 2008). Lichen planus and LPP show similarities in pathogenesis; however, the target antigen in both diseases remains unknown.

The recent work suggests LPP is a lipid metabolic disorder caused by a downregulation of the peroxisome proliferator-activated receptor gamma (PPAR-gamma).

Gene expression profiling studies have shown that the expression of genes required for lipid metabolism and peroxisome biogenesis is decreased in LPP. The expression of PPAR-gamma, a transcription factor that regulates both inflammatory and lipid metabolic genes, has been found dramatically downregulated in LPP (Karnik et al. 2009). This loss of PPAR-gamma function leads to decreased peroxisome biogenesis and lipid homeostasis, causing tissue damage (lipotoxic effects) of the pilosebaceous unit. This tissue damage then triggers chemokine and cytokine expression and activates a lipid-mediated programmed cell death (lipoapoptosis). The combination of genetic and environmental triggers may be leading to this localized and acquired PPAR-gamma dysfunction. Based on this hypothesis, PPAR-gamma agonist therapy has been used in the treatment of LPP (Mirmirani and Karnik 2009).

Clinical Features

LPP is more common in women than in men. The age of onset is frequently between 30 and 60 years. It is unusual in children with incidence of 0.021 % of the total number of new pediatric dermatology outpatient in a hospital in India (Handa and Sahoo 2002). Its incidence rate in the United States ranges from 1.15 % to 7.59 % among all new patients with hair loss (Chiang et al. 2010). The University of British Columbia, Canada, found a lower incidence in the Asian population compared to other ethnic groups (Tan et al. 2004).

The course of the disease is variable. It may evolve slowly with one or more patches of hair loss or diffuse central thinning, with slow progression over the years. In other cases, the course is rapid, and within a few months, patchy hair loss or diffuse thinning spreads over large areas of the scalp. Symptoms of itching, burning, pain, and tenderness are often severe. Few patients are asymptomatic. The scalp lesions may be single or multiple and focal or diffuse and can occur anywhere on the scalp more commonly over the vertex. The center is smooth, devoid of follicular markings, and the margins show perifollicular erythema and perifollicular scale. This is in contrast to DLE where the follicular plugging is in the center of the active patches. A hair pull test may yield anagen hair, when present this is a useful sign of disease activity. Cutaneous, nail, and mucous membrane LP may occur before, during, or after the onset of scalp lesions. The occurrence of associated LP varies in reports from 17 % to 50 % of patients with LPP (Price 2011).

Diagnosis

Scalp biopsy helps to differentiate LPP from other cicatricial alopecias especially discoid lupus erythematosus (DLE). During active disease, biopsy should be taken from the active margin showing perifollicular erythema and scaling.

Histopathology

In early stages, a lichenoid lymphocytic infiltrate affecting the infundibulum and isthmus is observed and sparing the lower portion of hair follicle. Thereafter, interface dermatitis is seen with loss of the basement membrane zone. Sebaceous glands are lost in the early lesions and the root sheath of follicles is destroyed. Mucinous perifollicular fibroplasia with absence of the interfollicular dermal mucin in the upper dermis has been described

in vertical sections. Finally, follicular structure is replaced with extensive perifollicular lamellar fibrosis, especially around the isthmus, and the lichenoid infiltrate "backs away" from the follicle. Direct immunofluorescence may show positive colloid body staining with anti-immunoglobulin M (IgM), anti-IgA, anti-IgG, or C3 at the dermoepidermal junction or around the infundibulum. There is a "shaggy" or linear band of fibrinogen deposition along the basement membrane zone of affected follicles, while the interfollicular epidermis is negative for immunoreactants (Kang et al. 2008; Stefanato 2010).

Treatment

LPP is a very challenging disease to treat. The role of treatment is currently limited to relieve symptoms and to control or slow further progression of disease. Currently available treatments are sometimes of limited efficacy, and there is a demand for novel therapies. Various forms of treatment regimens have been developed based on the severity of disease, age of the patient, and the physician experience. Hair loss is irreversible, and consequently, rapidly progressive disease is treated aggressively.

Corticosteroids

In mild to moderate disease, potent topical corticosteroids with or without intralesional triamcinolone acetonide 10 mg/ml for a total of 2 ml every 4–6 weeks are recommended. Topical steroids like fluocinolone acetonide in an oil formulation (Derma-Smoothe) or clobetasol lotion reduce inflammation and relieve symptoms in most patients. Oral corticosteroids are reserved for rapidly progressing disease. Prednisone 1 mg/kg/day tapered over 2–3 months can be prescribed in severe disease and can be used as a bridge therapy until other agents show effectiveness.

Tetracyclines

Tetracycline antibiotics are commonly used in LPP because of their safety profile; however, there is weak evidence to support its effectiveness (Spencer et al. 2009). Tetracycline is used in a dosage of 1 g/day or doxycycline 100 mg twice a day for a period of 3–6 months (Spencer et al. 2009).

Hydroxychloroquine

Hydroxychloroquine is an antilymphocytic, antimalarial drug that has been widely used in dermatology since the 1950s. It is generally well tolerated. The exact mode of action of hydroxychloroquine is unclear. It possibly interferes with antigen presentation and production of cytokines such as tumor necrosis factor-alpha and interferon-gamma. The efficacy of hydroxychloroquine in decreasing symptoms and signs in LPP was recently reported in an evidence-based study (Chiang et al. 2010). It is significantly effective after 6–12 months of treatment, in decreasing symptoms and signs of LPP.

Mycophenolate Mofetil

Mycophenolate mofetil has been successfully used for the treatment of LLP which is resistant to treatment with hydroxychloroquine. It specifically inhibits activated lymphocytes which play a key role in the inflammatory process underlying LPP. The recommended dosage for LPP is 500 mg twice daily for 4 weeks and then 1 g twice daily for 6 months, some patients may need to continue for up to 1 year (Cho et al. 2010).

Cyclosporin

Cyclosporin has been used in severe, refractory cases of LPP. Its use is limited by its side effects. Cyclosporine is a calcineurin inhibitor that acts by suppressing gene transcription of IL-2, which is required for activation and proliferation of T cells responsible for the T cell-mediated immune response in lichen planus. It is used in a dose of 3–5 mg/kg. It is helpful in rapidly progressive LPP but is associated with a high relapse rate (Mirmirani et al. 2003; Sperling and Nguyen 2010).

Miscellaneous

Various other systemic agents used in the treatment of lichen planus have been used in LPP

with marginal efficacy. Systemic retinoids, griseofulvin, thalidomide, dapsone, topical tacrolimus, and minoxidil have been used with little evidence-based support (Sperling and Nguyen 2010).

Newer Therapies

PPAR-Gamma Agonist

Based on new insight into pathogenesis of LPP, PPAR-gamma agonists have been used in the treatment of LPP. They exert their action by increasing the activity of the nuclear receptor PPAR-gamma. Thiazolidinediones or glitazones are medications used for treatment of type 2 diabetes mellitus. They have been shown to have anti-inflammatory, antiproliferative, and immunomodulatory effects including downregulation of proinflammatory nuclear transcription factors and inflammatory interleukins and other inflammatory molecules. When compared with other oral medications used for treatment of LP, thiazolidinediones have an acceptable adverse effects and safety profile. Pioglitazone hydrochloride 15 mg/day has been used for 8 months with good clinical response (Mirmirani and Karnik 2009). Some side effects limiting use of this drug include body weight gain, congestive heart failure, bone fractures, and possibly bladder cancer which is most likely related to cumulative dose (Cariou et al. 2012; Neumann et al. 2012). The dosage of pioglitazone used in treatment of LPP is relatively smaller and time duration much shorter compared to its use in diabetes mellitus. Another consideration for drug delivery is the topical use due to its concern of adverse effects.

Biological Agents

A recent report has shown efficacy of rituximab in a patient with juvenile arthritis and refractory LPP; however, as with other systemic medications, risk-benefit ratio has to be considered before using newer medications. Rituximab is a chimeric monoclonal antibody directed against CD20 and has been suggested for patients who have autoimmune diseases (Erras et al. 2011).

Laser

Low-dose excimer 308-nm laser has been shown effective in LPP. Twice weekly treatment helped in relieving symptoms and decreased erythema and hyperkeratosis. The probable mode of action is T cell depletion and alteration in cytokine expression (Navarini et al. 2011).

LPP still remains a therapeutic challenge. Early diagnosis and treatment is the key in limiting disease progression. The choice of treatment is based on the extent of disease, symptoms, and progression of hair loss. In general, first-line treatment for active disease includes use of topical and intralesional corticosteroids, topical tacrolimus, oral antibiotics, and hydroxychloroquine sulfate. For more symptomatic, active, and rapidly advancing disease, or disease that is recalcitrant to treatment, medications such as oral prednisone, mycophenolate mofetil, and cyclosporine are used. Lichen Planopilaris Activity Index (LPPAI) score was recently introduced as a numeric summary of symptoms and signs. It allows statistical comparison of disease activity pre- and posttreatment and is helpful in patient follow-up (Chiang et al. 2010).

Synonyms

Lichen planopilaris (LPP); Lichen planus (LP); Oral lichen planus (OLP)

Definition

Lichen planus is an inflammatory disease which can involve hair, skin, nails, and mucosa. Its occurrence may be completely idiopathic and related to medications or hepatitis C (Boyd and Neldner 1991).

Introduction

Lichen planus (LP) is inflammatory in nature and was first described by Hebra as "leichen ruber." Later, in 1869, Erasmus Wilson named the disease lichen planus. Skin, hair, nail, and mucosal surfaces may be affected by LP (Boyd and Neldner 1991).

Epidemiology

Cutaneous LP is believed to affect less than one percent of the population (Boyd and Neldner 1991). Between 1 % and 4 % of the population has been found to have evidence of oral lichen planus (OLP). LP usually presents in the fifth and sixth decades. OLP is diagnosed at a mean age of 52. In some studies, women have been found to be affected by LP more often than men. Up to 75 % of cutaneous LP patients have been found to have oral lesions, while between 10 % and 20 % of OLP patients develop cutaneous LP (Shiohara and Kano 2008).

Pathophysiology/Immunology

All forms of lichen planus are believed to be part of an immune-mediated process. With regard to immunopathogenesis, most data exists on OLP. Multiple mechanisms have been implicated in the immune dysregulation of OLP. These include humoral immunity, autoimmune response, cell-mediated immune response, and nonspecific mechanisms (Roopashree et al. 2010).

The cell-mediated immune response associated with OLP involves auto-cytotoxic CD 8 T cells which set off basal cell apoptosis in the oral epithelium (Lavanya et al. 2011). The initiating event is believed to be keratinocyte antigen expression or antigen unmasking, which may be triggered by medications, allergens, trauma, infection, or another unknown cause (Ismail et al. 2007).

The exact antigen is unknown but is thought to possibly be a self-peptide. Heat shock proteins, which are upregulated in OLP, are thought to possibly be candidates for the role of the antigen in OLP (Roopashree et al. 2010). Subsequently, T cells, primarily CD 8+ cells, enter the epithelium and become activated. Activation may occur through activated CD 4+ lymphocytes or binding of antigen to major histocompatibility complex (MHC-1) located on the keratinocyte (Lavanya et al. 2011). It is believed that Langerhans cells may initiate the local immune response in OLP (Ismail et al. 2007). In lesions of OLP, there are increased Langerhans cells and upregulation of the expression of MHC II. CD 4+ T helper cells are activated through antigen presentation and IL-12. These CD 4+ T helper cells activate CD 8+ T cells with interferon gamma (INF gamma), IL-12, and receptor interaction (Lavanya et al. 2011). Subsequently, basal keratinocytes are killed through tumor necrosis factor (TNF)-alpha-induced, FAS-FAS-L-mediated, or granzyme-B-activated apoptosis (Lavanya et al. 2011).

It has also been proposed that autoimmunity may be responsible for OLP. TGF-B1, which is immunosuppressive, is deficient in OLP. In addition, there is an immune privilege breakdown in OLP in the form of a lack of T cell apoptosis induced by keratinocytes. In OLP, antigen-presenting cells (APCs) are involved in the endocytosis of apoptotic basal keratinocytes. Subsequently, these APCs mature and may activate an autoreactive T cell response against basal keratinocytes. Finally, heat shock proteins, which may serve as self-antigens in OLP, also further the hypothesis that an autoimmune reaction is involved (Roopashree et al. 2010).

The nonspecific immune mechanisms involved in OLP are thought to promote the migration of lymphocytes into the epithelium, enabling the damage of keratinocytes. Factors involved in these nonspecific mechanisms include mast cells, chemokines, matrix metalloproteinases, and the basement membrane of the epithelium (Roopashree et al. 2010).

Although further studies are needed to characterize a humoral response in OLP, in one study circulating autoantibodies against desmoglein 1 and 3 were demonstrated (Roopashree et al. 2010; Lukac et al. 2006).

Presentation

Cutaneous

Classically, the lesions of cutaneous LP have been described as being pruritic, purple, polygonal, and planar papules. A fine white scale, referred to as Wickham's striae, may be present on top of these lesions. Wickham's striae represent an increased granular layer in the epidermis. In cutaneous disease, extremities, particularly wrists and lower legs, are most commonly involved. The neck, trunk, and back may also be involved (Boyd and Neldner 1991). Cutaneous LP is often intensely pruritic. The lesions of LP tend to koebnerize or spread to areas of physical trauma (Shiohara and Kano 2008). There are several variants of cutaneous disease which include hypertrophic, atrophic, linear, vesiculobullous, annular, palmoplantar, actinic, follicular, and lichen planus pemphigoides (Boyd and Neldner 1991).

Cutaneous LP tends to resolve spontaneously within a year (Le Cleach and Chosidow 2012). When lesions of lichen planus clear, they may leave postinflammatory hyperpigmentation, particularly on patients with darker skin types (Usatine and Tinitigan 2011).

Nails

Nail lichen planus often occurs in adults and may be seen with or without other cutaneous or mucosal disease. There is usually nail matrix involvement and nail thinning. Longitudinal ridging, fissuring, and pterygium may be seen. Other symptoms include onycholysis and subungual hyperkeratosis. More rarely, trachyonychia, nail atrophy, nail bed erosions, yellow nail syndrome-like changes, and pigment changes may be seen (Piraccini et al. 2010).

Oral

Lesions in oral lichen planus can vary. Reticular and erosive are the two main types of oral lichen planus (OLP). Reticular OLP is the most common

form and appears as an interwoven network of white lines with surrounding erythema. It appears on the buccal mucosa, the gingiva, mucobuccal fold, lips, palate, and tongue. Reticular OLP is generally asymptomatic. There is a plaque-like variant of reticular OLP often seen on the dorsal tongue. Erosive OLP presents with red and ulcerated lesions with peripheral keratotic striae. Erosive LP may appear in atrophic and bullous forms. Erosive OLP can cause pain and discomfort (Edwards and Kelsch 2002).

Those with OLP have been found to have approximately ten times the risk of developing squamous cell carcinoma compared to the general population. The erosive and atrophic forms are most commonly associated with a higher risk (Edwards and Kelsch 2002).

Other Mucosa

Lichen planus can also affect other mucosal surfaces including conjunctiva, esophagus, and genitalia. Patients with involvement of the penis, vulva, or vagina may present with pruritus, pain, burning, painful intercourse, or sexual dysfunction. Genital LP may result in vulvar scarring, vaginal stenosis, agglutination of labia minora, and phimosis (Le Cleach and Chosidow 2012).

Patients with esophageal involvement may complain of painful or difficulty swallowing. This may result in stricture, redness, and sloughing of the mucosa (Le Cleach and Chosidow 2012).

Lichen Planopilaris

Lichen planopilaris (LPP) is a follicular variant of LP. There is lymphocytic damage of the hair follicle which leads to a cicatricial alopecia. There are three subtypes. Classic disease involves the scalp and may also involve other cutaneous sites. Frontal fibrosing alopecia produces a band-like scarring alopecia along the anterior hairline and is most frequently seen in adult females. Graham-Little-Piccardi-Lassueur syndrome entails scarring hair loss in the scalp, non-scarring alopecia in the pubic area, and axillae and papular follicular involvement of LP in the skin (Kang et al. 2008).

Hepatitis C

There is a statistically significant association between hepatitis C virus (HCV) infection and the development of LP. The geographical location affects the association between HCV and LP (Shengyuan et al. 2009). The strongest association between HCV and lichen planus has been seen in Japanese and Mediterranean populations (Shiohara and Kano 2008). Patients with LP may be screened for HCV using enzyme-linked immunosorbent assay (ELISA) (Le Cleach and Chosidow 2012).

Medications

Drug-induced lichen planus may present similarly to other forms of lichen planus. Implicated medications include beta-blockers, penicillamine, quinidine, quinine, and methyldopa (Thompson and Skaehill 1994). Other medications that may be associated are nonsteroidal anti-inflammatory drugs (NSAIDS), penicillamine, angiotensin-converting enzyme inhibitors, beta-blockers, gold, lithium, and sulfonylurea drugs (Ellgehausen et al. 1998). Other broad categories of causative or exacerbating agents in OLP include antimalarials and antiretrovirals (Ismail et al. 2007). Dental products may also cause or exacerbate OLP. These include metals, composite and resin-based materials, and dental amalgam (Ismail et al. 2007).

Diagnosis

The diagnosis of lichen planus may be made on the basis of patient history and clinical presentation. Skin, hair, or mucosal biopsies of lesions may be done for confirmation.

In cutaneous LP, histology reveals a lichenoid band of lymphocytes located in the papillary dermis in addition to compact hyperkeratosis, hypergranulosis, irregular acanthosis with rete ridges that are sawtoothed, and degeneration of the basal layer. There is also melanin incontinence. On direct immunofluorescence, colloid

bodies stain for immunoglobulin, fibrin, and complement. The immunoglobulin consists mostly of IgM. The histology in OLP reveals more parakeratosis. The histology of LPP consists of plugged follicles surrounded by lichenoid lymphocytes (Rapini 2005).

Differential Diagnosis

The differential diagnosis for cutaneous LP includes other papulosquamous eruptions including secondary syphilis and psoriasis. Other disorders on the differential include lichen nitidus and lupus erythematosus. The differential for OLP is broad and includes leukoplakia, candidiasis, discoid lupus erythematosus, and secondary syphilis. Vaginal LP may mimic the appearance of bullous dermatoses, lichen sclerosus et atrophicus, or atrophic vaginitis (Boyd and Neldner 1991). Histologic studies often help to distinguish these various disorders.

Treatment and Management

Cutaneous Lichen Planus

Spontaneous resolution of cutaneous LP may occur between 1 and 2 years after the onset of disease (Usatine and Tinitigan 2011). Topical corticosteroids are considered to be first-line treatment for cutaneous disease. Specifically, high-potency topical steroids such as clobetasol or halobetasol are applied to individual lesions twice daily. Lesions may also be injected with intralesional kenalog (Usatine and Tinitigan 2011). Oral steroids are another alternative for treatment, particularly when lesions are unresponsive to topical or intralesional therapy (Le Cleach and Chosidow 2012). Oral retinoids are also an option. Oral acitretin may be used. Phototherapy also remains an option for therapy of cutaneous lichen planus. Newer treatments for LP include enoxaparin sodium (low-molecular-weight heparin), sulfasalazine, tetracycline, biologics, metronidazole, and thalidomide (Asch and Goldenberg 2011).

Oral Lichen Planus

Erosive OLP tends to be symptomatic necessitating treatment. As in cutaneous LP, topical corticosteroids are considered first-line therapy in the treatment of OLP. Unresponsive LP may require oral steroids. In addition, topical retinoids have shown efficacy in certain types of OLP (Le Cleach and Chosidow 2012).

Other Mucosa

In anogenital LP, prevention of scarring is the main therapeutic goal. High-potency topical corticosteroids may be helpful. In addition, vaginal dilators and penile foreskin retraction may help to prevent synechiae. Adhesions may require surgical intervention (Le Cleach and Chosidow 2012).

Nail Lichen Planus

Intralesional or systemic steroids are usually the treatment of choice in nail LP (Piraccini et al. 2010).

Lichen Planopilaris

Treatment of LPP is difficult. Generally, treatment serves to decrease pain and pruritus, halt disease progression, and stop development of further hair loss. Generally, hair regrowth of this cicatricial alopecia is not possible, except in early disease (Assouly and Reygagne 2009).

First-line treatment includes topical therapy with ultra-potent corticosteroids and/or intralesional injections with triamcinolone acetonide. Beyond these therapies, patients may be started on courses of oral corticosteroid treatment. Those who are unresponsive to corticosteroids may be started on cyclosporine or mycophenolate mofetil. Other treatments that have been used in patient with LPP include antimalarials, retinoids, thalidomide, tetracycline, griseofulvin, IV methylprednisolone, topical calcineurin inhibitors, and topical minoxidil lotion (Assouly and Reygagne 2009).

Conclusion

Lichen planus is an immune-mediated disease that can affect individuals in different ways.

It may be limited to the skin or it may just affect nails, oral mucosa, or other mucosa. In some, it may involve a combination of these areas. Some may experience spontaneous resolution of the disease. For others, treatment depends on involvement of the disease.

Definition

Linear IgA disease, which is a chronic subepidermal vesicular dermatosis of both children and adults, is defined by IgA autoantibodies to antigens in the BMZ (basement membrane zone). The two subgroups, chronic bullous disease of childhood and adult linear IgA disease, differ only in the age of onset.

While pathogenic IgA autoantibodies are occasionally observed in some of the other

blistering disorders in addition to the strong majority IgG type, IgA predominance is unique to this condition.

Numerous other conditions have been associated with linear IgA disease through varied and limited reports in the literature, which include a variety of other autoimmune disorders, gastrointestinal diseases, malignant conditions, and infections. The incidence of gluten-sensitive enteropathy, which is strongly associated with (immunopathologically similar) dermatitis herpetiformis (DH), ranges from 0 % to 24 % (Vassileva 1998; Labib et al. 1986; Hofmann et al. 2002; Guillaume et al. 1993). The incidence of other gastrointestinal disease is also much lower than that observed with DH. Many drugs have also been implicated in inducing linear IgA disease, most unequivocally vancomycin. This drug produces a toxic epidermal necrolysis-like presentation. The relevance of all these associations has yet to be determined.

Clinical

In children, annular erythema and blisters, which occur predominantly in flexural areas and the lower trunk, thigh, and groin, have been described as resembling a "crown of jewels."

Diagnosis may be difficult as the clinical and immunopathologic pattern may be similar to that of bullous pemphigoid (▶ Subepidermal Blistering Diseases: Bullous Pemphigoid) or dermatitis herpetiformis, with the latter being differentiated by a more granular pattern to BMZ IgA deposition.

The defining feature of this disorder, which is a linear deposition of IgA along the BMZ, is observed through direct IF and histopathologic examination. Inflammatory cells are observed in a subepidermal infiltrate particularly at the tips of dermal papillae that include T cells, eosinophils (but fewer than seen in bullous pemphigoid), and a predominance of neutrophils. Dermal capillary and papillary microabscesses are observed in some blisters, with older lesions showing more nonspecific findings.

Pathophysiology

Linear IgA disease is named for the pathogenic IgA antibodies, mostly monomeric IgA1, that target several different antigens in the adhesion complex at the BMZ (Egan et al. 1999; Leonard et al. 1984; Wojnarowska et al. 1994). Rarely, IgG antibodies are also detected in a small number of patients (Allen and Wojnarowska 2003; Kromminga et al. 2000). The primary target antigen is the 97 kDa shed ectodomain of BP180 (BPAG-2, type XVII collagen, or LAD1). Autoantibodies to other BP180 epitopes, such as the NC16A domain associated with bullous pemphigoid, are observed in some patients, as are antibodies to BP230 and the 285 kDa unique antigen LAD285 (Allen and Wojnarowska 2003; Ghohestani et al. 1997; Marinkovich et al. 1996; Wojnarowska et al. 1991; Zone et al. 1990; Georgi et al. 2001; Zillikens et al. 1999). Rarely, autoantibodies to anchoring fibril component collagen VII are detected but, unlike epidermolysis bullosa acquisita, are almost never associated with friction-induced mechanobullous scarring.

The deposition of IgA attracts other inflammatory cells such as T cells, eosinophils, and neutrophils, which in turn release additional cytokines and proteases that induce vesicle formation. Neutrophils play a prominent role in disease pathogenesis. If papillary microabscesses are present and numerous, the histopathologic findings in linear IgA disease are similar to those observed in dermatitis herpetiformis.

Direct IF shows the linear deposition of IgA along the BMZ and occasionally shows other immunoreactants such as IgG, IgM, and/or C3 (Leonard et al. 1982). Indirect IF detects circulating antibodies in a majority of patients, as opposed to with DH in which they are rarely found.

Linker for Activation of T Cells (LAT)

Sarah Sullivan and Weiguo Zhang
Department of Immunology, Duke University, Durham, NC, USA

LAT

Definition

LAT is a transmembrane adaptor protein vital for TCR-mediated signaling. It is expressed primarily in T cells, but also in mast cells, NK cells, megakaryocytes, and pre-B cells.

Historical Background

Adaptive immune responses to pathogens are primarily mediated by helper T cells, which can stimulate macrophage phagocytosis, B cells class switching, and antibody secretion. Initial T cell activation is dependent on engagement of the T cell receptor (TCR) with the MHC-peptide complex on the surface of an antigen-presenting cell (APC). Upon ligation of the TCR, many proteins become highly tyrosine phosphorylated, including a 36–38-kDa protein that was known to localize in the plasma membrane. Because of the high degree of phosphorylation, it was hypothesized that this protein might play a critical role in linking TCR engagement to downstream signaling events in the cytoplasm. This protein, named *l*inker for *a*ctivation of *T* cells (LAT) was subsequently sequenced, revealing a very short extracellular domain, a transmembrane domain, and a long cytoplasmic tail with nine conserved tyrosine residues. Although LAT has no structural domains, it acts as a scaffolding protein, allowing for the binding of proteins to its multiple tyrosine motifs (Zhang et al. 1998). Deficiency of LAT in a human T cell line illustrated the importance of

LAT for TCR-mediated signaling events, such as ERK activation, calcium mobilization, and activation of the transcription factors AP-1 and NFAT (Finco et al. 1998; Zhang et al. 1999a). Additionally, LAT-deficient mice have a complete block in thymocyte development at the DN3 stage ($CD44^{-}CD25^{+}$), resulting in no mature T cells, thus demonstrating the crucial role of LAT-mediated signaling downstream of the pre-TCR complex (Zhang et al. 1999b). Recently, it was determined that LAT is also indispensible for the transition from DP ($CD4^{+}CD8^{+}$) to SP ($CD4^{+}$ or $CD8^{+}$) thymocytes (Shen et al. 2009).

The Role of LAT in T Cell Receptor Signaling

After TCR ligation with MHC-peptide, Lck, a Src family kinase, is activated and phosphorylates the cytoplasmic domains of TCRζ and CD3 at immunoreceptor tyrosine-based activation motifs (ITAMs). ZAP-70, a tyrosine kinase, can subsequently bind to these phosphorylated ITAMs, is activated by Lck, and then phosphorylates LAT. LAT, in turn, recruits Grb2, Gads, and PLC-γ1, all of which evoke disparate signaling cascades, vital for initiation of gene transcription (Samelson 2002). Among the tyrosine residues in LAT, the distal four are vital for T cell development, proliferation, and activation downstream of TCR engagement since mice with these tyrosine residues mutated resemble LAT-deficient mice (Sommers et al. 2001). In mice, LAT tyrosine 136 binds PLC-γ1, while tyrosines 175, 195, and 235 bind Grb2 and Gads (Zhang et al. 2000). LAT interaction with Grb2 recruits Son of Sevenless (SOS), a Ras guanine nucleotide exchange factor, to the LAT complex. SOS then initiates the Ras-Erk pathway, leading to activation of the transcription factor AP-1. Additionally, LAT recruits Gads, which is constitutively associated with the cytoplasmic adaptor molecule, SLP-76. SLP-76 associates with Vav, the guanine nucleotide exchange factor for Rac/Rho, which allows for actin polymerization and cytoskeleton rearrangement, important for T cell activation and division. Furthermore, Gads aids in PLC-γ1 recruitment and function. In addition to tethering PLC-γ1 to the LAT complex, Gads also indirectly recruits the Tec kinase, Itk, which phosphorylates and activates PLC-γ1. PLC-γ1 then functions to hydrolyze phosphatidylinositol bisphosphate (PIP_2) to inositol triphosphate (IP_3) and diacylglycerol (DAG). IP_3 is essential to drive calcium flux and activation of the transcription factor, NFAT. Simultaneously, DAG mobilizes two downstream pathways. It recruits and allows for subsequent activation of protein kinase C (PKC) and additionally brings RasGRP1 to the plasma membrane. PKC activation ultimately causes NF-κB translocation to the nucleus. RasGRP1, a guanine nucleotide exchange factor similar to SOS, activates the Ras-Erk pathway (Roose et al. 2005). Collectively, these pathways downstream of LAT that are activated upon TCR stimulation are required for proper IL2 upregulation (Samelson 2002).

In addition to its essential role in the positive regulation of T cell activation, LAT can also recruit molecules to the signalosome which dampen signals emanating from the TCR. Gab2, the Grb2-associated binding protein 2, can bind Grb2 and Gads at steady state, and, when brought to the TCR synapse, it is phosphorylated by Zap-70. Gab2 phosphorylation creates a binding site for SHP2, a phosphatase which can dephosphorylate CD3ζ (Yamasaki et al. 2003). Not only does Grb2 recruit the negative regulator Gab2, but it can also bind SHIP-1, the SH2 domain-containing inositol polyphosphate 5-phosphatase-1. Dok-2, downstream of kinase 2, is anchored by SHIP-1 and acts to negatively regulate Zap-70 function (Dong et al. 2006). Therefore, through its binding partners, LAT is integral for proper calcium mobilization and MAPK activation as well as the prevention of prolonged positive signaling.

LAT in CD4 T Cell-Mediated Autoimmunity

LAT clearly plays an indispensable role in the positive regulation of thymocyte development as

LAT-deficient mice lack peripheral T cells. However, the disruption of LAT interaction with its binding partners results in T cell hyperproliferation in the periphery, demonstrating that LAT also plays a role in the negative regulation of T cell homeostasis. LATY136F knock-in mice, in which tyrosine 136 is replaced with a phenylalanine, contain a form of LAT unable to bind PLC-γ1. These mice have a block in thymocyte development; most thymocytes are unable to progress past the DN compartment due to insufficient signaling through the pre-TCR complex. Yet the T cells that do mature in the thymus and escape to the periphery are hyperproliferative, causing a fatal autoimmune-like disease. CD4 T cells dominate peripheral lymphoid organs and infiltrate other tissues, such as the liver, lungs, and kidneys. LATY136F CD4 T cells have an effector memory phenotype ($CD44^{hi}CD62L^{lo}$), express low levels of surface TCR, and secrete large amounts of T helper (Th)2 cytokines, such as IL-4. These mice have increased B cell, macrophage, and eosinophil numbers yet are devoid of CD8 T cells. High levels of serum IgE, IgG1, and IgM are detectable and serum autoantibodies are present in these mice (Aguado et al. 2002; Sommers et al. 2002). However, the autoimmune-like phenotype seen in LATY136F mice is not dependent on Th2 programming. LATY136F mice deficient in STAT6, a master regulator of Th2 development, display a similar CD4 T cell hyperproliferation when compared to LATY136F mice; however, the pathogenic cells are Th1 skewed, producing IFNγ and expressing elevated levels of T-bet (Archambaud et al. 2009).

The autoimmune-like phenotype seen in LATY136F mice suggests that the peripheral T cells could be responding to self-antigen presented on MHC molecules, inducing their proliferation. Indeed, a study uncovered that the thymic selection processes which are meant to prevent self-reactive T cells from entering the periphery are defective in LATY136F mice (Sommers et al. 2005). Furthermore, these mice do not contain T regulatory cells, which are normally critical to control T cell expansion (Koonpaew et al. 2006). Yet, there is also evidence that LATY136F T cell proliferation does not simply result from self-reactivity but from altered intrinsic mechanisms. First, LATY136F T cells are polyclonal and express low levels of surface TCR. Antigen, both self and foreign, is presented to CD4 T cells through MHC class II molecules on the surface of APCs. It was demonstrated that LATY136F T cells proliferate in MHC II-deficient hosts (Wang et al. 2008). Also, an inducible deletion model was developed, by which normal thymic development is allowed to occur through the use of a floxed wild-type LAT allele. This wild-type LAT is then deleted in mature T cells using a Cre-loxP system, allowing for expression of only the recessive mutant allele in peripheral T cells. These mice develop a disease similar to LATY136F mice, indicating that T cell hyperproliferation in the absence of LAT-PLC-γ1 interaction cannot be solely attributed to defective thymic selection (Chuck et al. 2010). Interestingly, mice with LAT inducibly deleted in mature T cells also developed a similar, yet less severe, autoimmune syndrome, characterized by CD4 T cell expansion and enhanced cytokine production (Mingueneau et al. 2009; Shen et al. 2010). Together, these data indicate that LAT functions as a negative regulator of T cell homeostasis and expansion. Specifically, in the absence of the LAT-PLC-γ1 interaction, CD4 T cells expand and produce Th2 cytokines, suggesting a fundamental role for LAT-PLC-γ1 signaling in the repression of this T helper cell commitment.

LAT in γδ T Cell-Mediated Autoimmunity

In addition to the knock-in mouse model with the LAT-PLC-γ1 binding site mutated, mice were generated in which LAT binding to both Gads and Grb2 was inhibited. These mice, LAT3YF mice, harbor mutations at Y175, Y195, and Y235. Whereas LATY136F mice have a partial block in development at the DN3 stage, LAT3YF mice have a complete block in the DN compartment, indicating that signaling through Gads and Grb2 is essential for pre-TCR signaling and thymocyte development of αβ T cells. γδ T cells, on the other hand, rearrange both TCR genes in the

DN compartment. LAT3YF mice contain decreased numbers of thymocytes with both TCR alleles rearranged and expressed on the cell surface; however, these cells are able to populate the periphery. By 6 months of age, the pool of γδ T cells in peripheral lymphoid organs expands, resulting in splenomegaly and lymphadenopathy. The hyperproliferative LAT3YF T cells produce Th2 cytokines, driving elevated serum IgE and IgG1 levels (Nunez-Cruz et al. 2003). These data indicate that LAT-mediated signaling through Gads and Grb2 is required for αβ T cell development and is also necessary to regulate γδ T cell homeostasis.

LAT-Mediated T Cell Proliferation

One aspect that is shared by all forms of LAT-mediated autoimmunity is the hyperproliferative nature of the T cells. Mutation of LAT binding sites results in a block in thymic development; therefore, T cells that do exit the thymus enter a lymphopenic environment. Lymphopenia-driven homeostatic proliferation of CD4 T cells occurs in two forms. The first proliferation is slow, dependent on IL7 and MHC interaction. Homeostatic proliferation can also be rapid, requiring antigen-MHC-driven TCR signaling. T cells with LAT deleted in the periphery fail to undergo rapid homeostatic proliferation (Shen et al. 2010). LATY136F T cells, which are unable to signal through LAT-PLCγ1, also do not undergo rapid proliferation upon transfer into T cell-deficient hosts but rather undergo slow proliferation. These T cells proliferate similar to wild-type T cells in an MHC-deficient environment but do not divide in the absence of IL7 (Wang et al. 2008). This indicates that IL7 plays an important role in T cell expansion in LAT mutant mice and that LAT is critical for the regulation of slow homeostatic proliferation.

Combined, the studies examining the different aspects of the LAT signalosome reveal novel requirements for this adaptor molecule during T cell development, activation, and homeostasis. Understanding both the positive and negative regulation that LAT exerts on T cells will improve our ability to develop potential drug targets to modulate T cell-mediated immune responses.

Immune function of liver sinusoidal endothelial cells

Definition

Liver sinusoidal endothelial cells (LSECs) constitute a unique population of microvascular endothelial cells that line the hepatic sinusoids and posses potent scavenger activity. LSECs maintain a very important role in detecting the presence of pathogen-associated molecular patterns (PAMPs) and initiate inflammation while being able to control deleterious inflammation in response to continuous physiological exposure toward PAMPs contained in portal venous blood. Importantly, LSEC can present and cross-present antigen to both CD8+ as well as CD4+ T cells. T cell priming by antigen-presenting LSEC leads to unresponsiveness or regulatory T cell development. Thus, LSEC appears to contribute to the unique tolerogenic function of the liver that is best exemplified by the propensity of liver grafts to be accepted in the absence of immunosuppression.

Introduction

The liver receives blood through the hepatic artery and the portal vein that is draining the venous nutrient-rich blood from the

gastrointestinal tract. After extensive ramification branches of the hepatic artery and the portal vein merge in the hepatic sinusoids giving rise to a mixed arterio-venous blood supply for the sinusoidal cell populations, i.e., Kupffer cells, liver sinusoidal endothelial cells (LSECs), stellate cells, liver-associated lymphocytes, and hepatocytes (Thomson and Knolle 2010). This results in a low oxygen-tension in the blood flowing through hepatic sinusoids and the absence of typical arterial and venous branches in the hepatic microcirculation (▶ Liver Vasculature and Microvasculature). Due to the sudden increase in the cumulative vascular diameter in the sinusoidal circulation of the liver, there is a drop in perfusion pressure that leads to a slow and chaotic blood flow within hepatic sinusoids. This allows circulating immune cells to establish contact with liver sinusoidal cells without the help of selectins that normally slow down blood-borne immune cells to allow for interaction between adhesion molecules (Wong et al. 1997) (▶ Adaptive Immune Cells in the Liver).

Liver sinusoidal endothelial cells (LSECs) constitute a unique population of microvascular endothelial cells that are very thin (150–200 nm) and line the hepatic sinusoids. Behind LSEC is located another liver-resident cell population, the stellate cells. The space between LSEC/stellate cells and hepatocytes is called the space of Dissé. Liver sinusoids are devoid of a basement membrane, and fenestrae in LSEC with a mean diameter of 50–200 nm allow for diffusion of blood-borne molecules with a size smaller than 30 nm into the space of Dissé (Kempka and Kolb-Bachofen 1988) where they can interact with the microvilli of hepatocytes (▶ Ultrastructure of the Liver Sinusoid). The size of fenestrae in LSEC is dynamically regulated by the actin cytoskeleton and decreases as a consequence of exposure to toxins such as alcohol. Following long-standing toxin exposure, vascular remodeling with loss of fenestrae and development of a basement membrane may occur and is considered an ultrastructural determinant of liver cirrhosis. The size and numbers of fenestrae also decrease with age. The hepatic blood flow is regulated through the contractile activity of the perisinusoidal cells, i.e., stellate cells, that control the sinusoidal diameter. As stellate cells are relatively abundant and ubiquitously present in hepatic sinusoids, their function in regulating hepatic blood flow has been difficult to study.

LSECs have an important function in maintaining sinusoidal blood flow by producing plasminogen activator inhibitor to prevent inadvertent coagulation in liver sinusoids due to the unusual conditions of blood flow. Also, LSEC contributes to liver regeneration and hepatocyte proliferation through the release of hepatocyte growth factor (Ding et al. 2010). Although LSECs are a liver-resident cell population, they can also repopulate from circulating bone-marrow-derived endothelial precursors that produce even larger amounts of hepatocyte growth factor compared to liver-resident LSEC (Wang et al. 2012), thus increasing liver regeneration during situations where substantial losses of liver tissue have occurred.

Thus, LSECs are a highly specialized population of microvascular endothelial cells optimally suited to fit the functional demands of the hepatic microvasculature: They separate circulating immune cells from hepatocytes while allowing for proper execution of the metabolic function of hepatocytes.

Scavenger Function

LSECs are distinct from other microvascular endothelial cells by their extraordinary endocytic function that is conserved in all vertebrates. This scavenger function has for long been underestimated because Kupffer cells were considered to be the principal scavenger cell population of the liver (KC and Tolerance). More sophisticated methods of investigation, however, have revealed that LSECs but not Kupffer cells are responsible for clearance of molecules smaller than 200 nm by receptor-mediated endocytosis from the circulation (Smedsrod 2004). The scavenger function in LSEC is supported by very rapid turnover rates for receptor-mediated endocytosis, delivery of the ligand cargo into an endo(lyso)somal compartment, separation from

the receptor, and receptor reshuttling to the cell surface that all occurs within 15 s (Knolle and Gerken 2000). The molecular mechanisms allowing for this rapid receptor turnover have not been characterized yet. The combination of slow blood flow together with LSEC scavenger function synergizes for most efficient clearance of liver sinusoidal blood from waste products or other molecules.

LSECs employ several receptors for their scavenger function that allow for uptake of a broad range of ligands. These receptors comprise the mannose receptor, the collagen-alpha chain receptor, the scavenger receptor, and the Fc-gamma receptor. The scavenger receptor is involved in most efficient uptake of extracellular matrix molecules such as hyaluronan, chondroitin sulfate, type I and III collagens as well as oxidized LDL, advanced glycation end products, and coagulation products. The mannose receptor similarly supports efficient uptake of denatured collagen but also of lysosomal enzymes for endolysosomal degradation of endocytosed degradation/waste products within LSEC that produce little if any of these lysosomal enzymes themselves (Malovic et al. 2007; Smedsrod 2004). It is of interest to note that LSECs metabolize their endocytosed ligands into acetate and lactate, that in turn serve as metabolites for anaerobic energy generation via glycolysis in other sinusoidal cell populations or hepatocytes (Smedsrod 2004). Therefore, LSEC's scavenger function may operate to provide sufficient fuel for energy production under low oxygen-tension in addition to the obvious clearance function to eliminate waste or degraded molecules from the blood circulation. The scavenger function of LSEC contributes to the well-known first-pass effect of the liver and is a key determinant of hepatic recycling of extracellular matrix molecules.

The physiological scavenger function may be exploited by hepatotropic pathogens that target the liver to exit the blood stream and subsequently infect their target cells, i.e., hepatocytes (Protzer et al. 2012). Duck Hepatitis B Virus, which serves as a experimental model system for Hepatitis B Virus infection, is first taken up by LSEC before hepatocytes presumably following transcytosis (Breiner et al. 2001). Similar observations were made for infection with Hepatitis C Virus (Pohlmann et al. 2003) (► Immune Responses to the Hepatitis C Virus) and for adenovirus (Ganesan et al. 2011). The sinusoidal cells in the liver seem to provide a physical barrier for pathogens even for pathogens that can migrate such as plasmodium sporozoites, because these pathogens target Kupffer cells before eventually infecting hepatocytes (Pradel and Frevert 2001). Thus, LSEC's scavenger function may be exploited by viruses to exit the blood stream and infect their target hepatocytes in a second step following transcytosis.

Innate Immune Function

Expression of immune sensory molecules, such as Toll-like receptors (TLRs), is not restricted to myeloid immune cells but is also found in nonimmune cells (both parenchymal and nonparenchymal cells) in various peripheral organs. In the liver, LSECs are strategically positioned to scavenge gut-derived bacterial degradations products from portal venous blood (van Oosten et al. 2001). They express several immune sensory receptors at the cell surface, in endosomal compartments, and within the cytosol. Agonistic activation through TLR1 to 4, 6, 8, or 9 at the cell surface or in endosomal compartments induces functional activation in LSEC, leading to expression of pro-inflammatory mediators such as IL-6 or TNF (Martin-Armas et al. 2006; Wu et al. 2010). Activation with agonistic ligands to cytosolic sensory receptors such as RIG-I or MDA5 also leads to expression of pro-inflammatory IL-6 (Kern et al. 2010). It is of interest to note that LSECs are most sensitive to TLR stimulation and require only very small concentrations of TLR ligands for induction of pro-inflammatory cytokine expression (Knolle et al. 1997). This sensitivity may be related to the extraordinary endocytic scavenger function of LSEC, because many TLRs are preferentially located in endosomal compartment or only then start their

signaling activity once they reach this compartment. Thus, LSECs combine extraordinary scavenger function with innate immune sensory function, which attributes a particular sentinel function to this cell population in detecting infectious microorganisms or their degradation products.

The preferential infection of LSEC before hepatocytes and the expression of pro-inflammatory mediators are responsible for the rapid induction of the liver acute phase response. Hepatocytes respond to IL-6 that is released from LSEC but also Kupffer cells with expression of acute phase proteins like C-reactive protein and increased expression of coagulation and complement factors (Baumann and Gauldie 1994; Fey and Gauldie 1990). These factors serve to increase the systemic responsiveness of the immune system against infectious microorganisms and also provide the basis for an increased capacity for repair and regeneration of damage inflicted by the immune response.

The sentinel function of LSEC and also Kupffer cells raises the question why the continuous exposure of the liver to gut-derived bacterial degradation products carried out by portal venous blood does not lead to local inflammation in the liver. As scavenger function of LSEC is closely linked to their sentinel function, it is unlikely that LSECs are unresponsive under physiological conditions in the absence of local inflammation. A number of mechanisms have been proposed to limit local inflammation in the liver. Tachyphylaxis and adaptation of LSEC as well as Kupffer cells toward continuous low dose exposure toward pathogen-associated molecular patterns (PAMPs) may limit the expression of pro-inflammatory mediators in these cells while at the same time conserving the responsiveness toward increased concentrations of PAMPs that indicate infection by microorganisms. The sensing of relative increases rather than absolute concentrations of ligands by immune sensory receptors is operative in other sensory systems and provides the most likely explanation for the absence of local inflammation under physiological situations (Knolle et al. 1997). Together with induction of pro-inflammatory mediators, LSECs also show increased expression of anti-inflammatory substances such as prostaglandin that may act in an autocrine negative feedback loop to limit local inflammation (Rieder et al. 1990). Similarly, IL-10 released from Kupffer cells controls expression of pro-inflammatory mediators by LSEC. Thus, cell-intrinsic as well as paracrine mechanisms limit responsiveness of immune sensory receptors in LSEC and thereby seem to prevent induction of hepatic inflammation. It is likely that the high regenerative capacity of the liver conceals the actual extent of immune-mediated damage during inflammation. As expression of hepatocyte growth factor is driven by activation of LSEC, it appears that both immune-mediated damage and repair of injured hepatocytes are orchestrated by liver sinusoidal cells.

Antigen-Presenting Cell Function

The extraordinary scavenger function also forms the basis for another important immune function of LSEC, i.e., antigen presentation. Presentation of peptides derived from endogenous antigens occurs mainly in the context of MHC class I molecules and only to a much lesser extent in the context of MHC class II molecules (Kurts et al. 2010). Peptides associated with MHC class II molecules are mostly derived from proteins that were taken up by receptor-mediated endocytosis or macro-endocytosis. However, peptides derived from exogenous antigens taken up by receptor-mediated endocytosis can also associate with MHC class I molecules in some specialized cell types, a process that has been named cross-presentation (Kurts et al. 2010). Intensive research over the past years has demonstrated that cross-presented antigens are endocytosed through defined receptors and transported into key endosomal compartments competent for executing cross-presentation. Both the mannose receptor and another C-type lectin, DNGR1, have been shown to shuttle antigen for cross-presentation into early recycling

endosomes. These recycling endosomes contain also the necessary molecular machinery required to export antigens into the cytosol where they are degraded by the proteasome, re-import peptides into the endosome, and load these onto MHC class I molecules present in this compartment (Kurts et al. 2010; Osorio and Reis e Sousa 2011). This knowledge on the molecular mechanisms of cross-presentation is crucial for further development of novel vaccine strategies to improve existing prophylactic vaccination schemes and to design more effective therapeutic vaccination protocols.

Cross-Presentation by LSEC to CD8 T cells

Similar to dendritic cells and macrophages, LSECs bear the capacity to cross-present exogenous antigens to CD8 T cells (Limmer et al. 2000). Key to efficient cross-presentation in LSEC is receptor-mediated endocytosis. Direct comparison of cross-presentation following intravenous antigen application revealed that LSECs were faster and more efficient than $CD8^+$ splenic dendritic cells. While dendritic cells retained the antigen for longer time periods resulting in prolonged cross-presentation, LSEC rapidly eliminated endocytosed antigen, leading to shorter lived cross-presentation ability (Schurich et al. 2009). The molecular mechanisms determining cross-presentation in LSEC, however, remain unclear. Antigen routing seems critical for cross-presentation in LSEC as antibody-conjugated antigens endocytosed via the Fc-gamma receptor are not cross-presented on MHC class I molecules (Schurich et al. 2009). In contrast, the mannose receptor, critical for cross-presentation of ovalbumin by dendritic cells, is dispensable for cross-presentation by LSEC (Schurich et al. 2009), indicating that other receptors or other molecular mechanisms awaiting identification facilitate cross-presentation in this liver-resident cell population.

There are fundamental differences between dendritic cells and LSEC in cross-presentation. LSECs do not require a licensing step in order to stimulate naïve CD8 T cells whereas dendritic cells need to be stimulated by CD4 T helper cells or NKT cells (Kurts et al. 2010) (Semmling et al. 2010). This suggests that LSECs employ different means to initiate activation of naïve CD8 T cells compared to professional antigen-presenting cells such as dendritic cells.

It is known that the outcome of stimulation of naïve CD8 T cells by dendritic cells depends on the maturation status of the professional antigen-presenting cell. Activation of dendritic cells by innate immune stimuli or help by CD4 T helper/NKT cells initiates changes in the expression of co-stimulatory molecules that facilitates differentiation of naïve T cells into effector or memory T cells, a process that has been termed cross-priming. In contrast, lack of such stimulation of antigen-presenting dendritic cells results in insufficient stimulation of naïve T cells that eventually leads to their clonal deletion, which has been termed cross-tolerance (Kurts et al. 1997). Cross-presentation by LSEC leads to a third outcome of naïve T cell stimulation that is characterized by initial clonal expansion associated with a lack of responsiveness toward T cell receptor signaling but not clonal deletion. This particular T cell development critically depends on co-inhibitory signaling through B7H1 expressed on LSEC and its ligand PD1 expressed on T cells (Diehl et al. 2008). As T cells only express PD1 upon primary activation and LSECs upregulate B7H1 expression upon cognate MHC-restricted interaction with T cells, the differentiation of T cells by cross-presenting LSEC is a dynamic process occurring over 12–24 h (Schurich et al. 2010). Due to the lack of restimulation by signals delivered through the T cell receptor, $CD8^+$ T cells activated by LSEC failed to kill antigen-expressing tumor cells in the absence of co-stimulatory signals, suggesting that $CD8^+$ T cells became tolerant after antigen-specific stimulation by LSEC (Limmer et al. 2000; Limmer et al. 2005). It is tempting to speculate that the prominent scavenger function of LSEC together with their capacity to cross-present soluble circulating antigen to naïve CD8 T cells skews T cell responses to non-responsiveness toward these antigens, similar to the observation that primary activation of T cells by antigen-expressing hepatocytes (▶ Primary T-Cell Activation in Liver) led to subsequent

lack of T cell activity against the same antigen presented at other sites (Bowen et al. 2004).

Recently, it was found that cross-presentation of hepatocyte-derived antigens elicits a non-canonical effector function of activated $CD8^+$ T cells (▶ Primary T-Cell Activation in Liver). Such LSEC cross-presentation of antigens derived from virus-infected hepatocytes triggered expression of TNF by activated effector $CD8^+$ T cells, which then acted specifically on virus-infected hepatocytes to initiate caspase-dependent apoptotic cell death (Wohlleber et al. 2012). Direct interaction of activated $CD8^+$ T cells with virus-infected hepatocytes accounted only for 50 % of total cytotoxic T cell activity during viral hepatitis, revealing that T cells access hepatocytes even across the sinusoidal barrier (Warren et al. 2006) but is complemented by the non-canonical T cell effector function initiated by cross-presenting LSEC (▶ Ultrastructure of the Liver Sinusoid).

MHC Class II–Restricted Antigen Presentation of LSEC to CD4 T cells

LSEC can also initiate MHC class II–restricted antigen presentation to CD4 T cells. However, MHC class II–restricted presentation requires higher concentrations of antigen compared to cross-presentation on MHC class I molecules (Knolle et al. 1999; Lohse et al. 1996). Interestingly, LSEC can also prime naïve CD4 T cells, indicating that they function as semiprofessional antigen-presenting cells (Knolle et al. 1999). However, the outcome of MHC class II–restricted antigen presentation by LSEC is distinct from that by professional antigen-presenting cells such as dendritic cells. Naïve CD4 T cells primed by LSEC do not differentiate into conventional T helper cells (Knolle et al. 1999) but rather differentiate into T cells with regulatory function (Kruse et al. 2009). Interestingly, regulatory T cells induced by antigen-presenting LSEC express low levels of Foxp3 (Kruse et al. 2009), which re-iterates the notion that T cell priming by LSEC is dominated by molecular mechanisms that are distinct from those acting in immunogenic or tolerogenic dendritic cells. Antigen presentation by LSEC does not promote immunity but rather contributes to suppression of T cells with indirect allo-specificity in a transplantation setting (Banshodani et al. 2013; Tokita et al. 2006), which indicates a potential protective role of LSEC during liver transplantation where only macrovascular endothelial cells but not LSEC are replaced by recipient endothelial cells (Gao et al. 2001).

A close interaction between the gut and the liver has been proposed to exist and to contribute to liver pathology (Adams and Eksteen 2006). It was shown that the chemokine CCL25 produced by LSEC recruits CD4 T cells with the cognate receptor CCR9 that were generated in the gut to the liver (Eksteen et al. 2004). Autoreactive pathogenic $CCR9^+$ $CD4^+$ T cells contribute to inflammatory bowel disease and the same $CCR9^+$ T cells in the liver may cause sclerosing cholangitis (Eksteen et al. 2004), providing a mechanistic explanation for the clinical association of inflammatory bowel disease and primary sclerosing cholangitis. Along this line, it was also demonstrated that antigen-presenting LSEC can generate $CCR9^+$ $CD4^+$ T cells that home to the gut (Neumann et al. 2012), thereby demonstrating the mutual interaction between gut and liver in induction of an enterohepatic circulation of CCR9 expressing T cells (▶ Ultrastructure of the Liver Sinusoid).

CD4 T cells are also actively recruited in an antigen-independent fashion through LSECs that express particular chemokines. As explained above, CCL25 recruits pathogenic CCR9+ T cells to the liver (Eksteen et al. 2004). Furthermore, regulatory T cells adhered in a CCR4-dependent fashion to LSEC and were preferentially recruited to inflamed liver tissue by CXCR3-dependent arrest on inflammatory dendritic cells in the liver (Oo et al. 2010). However, pro-inflammatory Th17 cells were also recruited by LSEC to the inflamed liver by a chemokine-dependent process (Oo et al. 2012). The transmigration of T cells into the parenchyma is also facilitated by chemokines that are transcytosed by LSEC to the apical phase (Schrage et al. 2008) and is modulated by the interaction of LSEC with hepatocytes (Edwards et al. 2005). Thus, there is a complex interaction

of LSEC with circulating CD4 T cells that appears to contribute to development as well as control of local immune responses in the liver.

Sinusoidal Cell Cross-Talk

Beyond antigen-specific interaction, LSECs also interact with other cell populations and influence their functional behavior. Interaction with LSEC inhibits the function of dendritic cells to initiate T cell priming (Schildberg et al. 2008), indicating that dendritic cells fail to function as antigen-presenting cells in vivo as long as they remain in the liver in physical contact with LSEC but regain their function to initiate T cell response upon migration into the draining lymph node (Bertolino 2008). There is also evidence that C-type lectins such as LSECTin and the mannose receptor expressed on LSEC directly influence the effector function of activated $CD4^+$ T cells, thereby attenuating T cell immunity (Tang et al. 2009) and promoting local tumor immune escape in the liver (Arteta et al. 2010). LSEC even inhibits inflammatory $CD4^+$ T cell activity through IL-10-dependent induction of B7H1 and co-inhibitory signaling through PD1 on the T cell side (Carambia et al. 2013). Taken together, LSECs also contribute to local immune regulation of T cell immunity in the liver by antigen-independent interaction with T cells and also dendritic cells.

Conclusion

Liver sinusoidal endothelial cells (LSECs) line the hepatic sinusoids, the microvessels of the liver, and delineate the space of Dissé between hepatocytes and circulating cells in sinusoidal blood. LSECs bear extraordinary scavenger activity to eliminate waste products and degraded extracellular matrix molecules from the sinusoidal blood stream. They also contribute to elimination of bacterial degradation products derived from the gastrointestinal tract. LSECs express pattern recognition receptors and bear sentinel activity to detect the presence of PAMPs and to initiate inflammation, but several mechanisms control deleterious inflammation in response to continuous physiological exposure toward PAMPs contained in portal venous blood. Importantly, LSECs function as organ-resident antigen-presenting cells to stimulate CD8+ as well as CD4+ T cells. The outcome of T cell priming by antigen-presenting LSEC is the development of T cells that rather have regulatory function or are non-responsive to T cell receptor-mediated stimulation. Together with antigen-independent mechanisms that control T cell effector functions, LSECs appear to contribute to the unique tolerogenic function of the liver that is best exemplified by the propensity of liver grafts to be accepted in the absence of immunosuppression.

Antiviral therapy; Hepatitis B; Hepatitis C; Hepatitis E; Liver transplant

Definition

The essay outlines the indications and outcomes of liver transplantation for hepatitis B virus (HBV) and hepatitis C virus (HCV) infection. Prevention strategies for HBV infection of the liver allograft are successful but not for HCV infection where recurrence is universal. Approaches to antiviral therapy for subsequent HCV infection in the allograft are discussed.

Background

Over 350 million people worldwide are chronically infected with hepatitis B and 200 million

with HCV (Maddrey 2000; El-Serag et al. 2003; Lavanchy 2009). Approximately 20 % will develop the complications of cirrhosis or hepatocellular cancer. Hepatocellular cancer (HCC) is the 3rd most common solid cancer worldwide. Both decompensated cirrhosis and HCC due to HBV and/or HCV are well-recognized indications for liver transplantation although it is clear that liver transplantation, due to its limited availability at a cost/technical level as well as at a donor level, is hardly the solution at a population level to these disease burdens. However, when applied to individuals, the outcomes for HBV now are excellent and HBV recurrence post-transplantation can be reduced to very low levels. By contrast outcomes for HCV-related disease remain suboptimal due to universal HCV recurrence.

Indications of Liver Transplantation

Indications for liver transplantation for chronic hepatitis B and hepatitis C are the presence of hepatic decompensation in a patient with cirrhosis or the development of HCC with or without decompensation (Mazzaferro et al. 1996; Wiesner 2003; Merion et al. 2005). The indications for liver transplantation in the setting of HCC include criteria defined by tumor size and number. The most universal accepted criteria are the Milano Criteria (one tumor $< = 5$ cm in diameter or 3 tumors with maximum diameter of 3 cm.

It is generally thought that patients should be listed for liver transplantation for chronic hepatitis B or chronic hepatitis C cirrhosis once there are single clinical features such as uncontrolled ascites, recurrent/persistent encephalopathy, or persistent gastrointestinal bleeding despite therapeutic interventions. Recently, the Model for End Stage Liver Disease (MELD) scoring system has become a much more evidence-based means of listing patients for transplantation. The MELD is a logarithmic derived number based on the levels of serum bilirubin, INR, and creatinine. The benefit of liver transplantation tends to come in with a MELD score of around 15–17.

Antiviral Therapy for HBV Pre-transplant

Drugs that inhibit HBV DNA polymerase activity by binding to its active site form the basis of antiviral therapy in this setting (Zoulim et al. 2008; Woo et al. 2010). The largest treatment experience in patients with advanced liver disease heading toward liver transplant is with lamivudine. This drug is well tolerated in patients with decompensated cirrhosis and results in undetectable viral DNA in approximately 70 % of patients within 2–3 months. Many studies indicate that such therapy improves symptomatology and blood test results. Furthermore there is a decrease in the need for hospital admissions for complications such as ascites, spontaneous bacterial peritonitis, and encephalopathy. Lamivudine can either stabilize patients on the waiting list, allowing them to proceed to transplantation with detectable HBV DNA and thus minimal chance of disease recurrence, or in many cases avoid transplantation altogether. However, there were certain patients who progress despite antiviral efficacy.

Lamivudine however is limited by the emergence of viral resistance due to one or more mutations in the polymerase gene. These are detected in approximately 20–30 % of patients after 1 year of therapy and in up to 70 % of patients with 5 years. The onset of lamivudine resistance in patients with cirrhosis leads to worsening liver disease and can result in flares that are associated with mortality. There is also a cumulative experience of treating patients' pre-liver transplantation with adefovir. In the setting of hepatic decompensation, it is mainly used as an add-on therapy in patients who develop lamivudine resistance. It is not recommended that such patients switch from lamivudine to adefovir as this is associated with adefovir resistance (30 % at 3 years). The combination of lamivudine and adefovir however is associated with minimal adefovir resistance and may control active viral replication even in decompensated patients.

Two newer agents, entecavir and tenofovir, have very potent HBV antiviral activity. They control HBV viral replication in the vast majority of patients with cirrhosis, and both are associated

with little drug resistance in previously untreated patients. There is now evidence that both these drugs may reverse hepatic decompensation in a similar fashion to lamivudine. Entecavir should not be used in patients with previous lamivudine exposure or resistance as resistance to entecavir has been observed in such patients (50 % at 3 years). Thus, patients with lamivudine resistance are best treated with tenofovir. By 2012, entecavir and tenofovir have become the antiviral agents of choice to reverse hepatic failure and to control HBV replication leading up to liver transplantation.

Natural History of HBV Post-transplant without Antiviral Therapy

Before the use of HBV antiviral therapies, liver transplantation was associated with universal HBV recurrence and a significant rate of severe disease including the description of an unusual pattern of recurrence termed fibrosing cholestatic hepatitis (FCH). This form of HBV resulted in death and allograft loss within 9 months in most patients. The inability to prevent HBV recurrence led many centers, particularly in the USA, to stop performing liver transplantation for HBV disease by the early to mid-1990s.

Antiviral Therapy for HBV Post-liver Transplant

There has been an evolution of approaches to the problem of HBV recurrence over the past 20 years (Angus and Patterson 2008). The first regime to suggest that HBV recurrence could be prevented was the administration of high-dose intravenous Hepatitis B Immune Globulin (HBIG). This was particularly effective in HBV DNA negative and e-antigen negative patients. Thus, by the mid-1990s, high-dose HBIG IVI was the "gold standard" for preventing HBV recurrence and was introduced in many centers. However, it was expensive (up to US$ 50 K per annum) and highly inconvenient requiring repetitive dosing to keep anti-HBsAg titers at >100 U/L and sometimes >250 U/L.

Following the introduction of lamivudine, several studies investigated the use of lamivudine monotherapy in the absence of HBIG to prevent viral replication post-transplantation. This regime was moderately successful but reinfection occurred in up to 50 % of patients. Breakthroughs of HBV with lamivudine-resistant mutations were common, and there was significant mortality when this occurred. One of the exceptions to this was the use of lamivudine monoprophylaxis in Asian recipients who received live donors from hepatitis B surface antigen negative but anti-HBs positive donors.

Lamivudine monotherapy was rapidly replaced by a combination of HBIG and lamivudine. Use of intravenous HBIG at very high doses in combination with lamivudine monotherapy showed almost totally eradication of hepatitis B recurrence and rapidly became the standard of care in most liver transplant centers. More recently, similar efficacy has been shown in several studies involving low-dose HBIG protocols in combination with lamivudine monotherapy or lamivudine in combination with adefovir (for lamivudine resistance). The use of high dose HBIG is now considered obsolete by many centers.

Current issues related to HBV recurrence center around withdrawing or eliminating HBIG. It seems that long-term use of HBIG in the setting is unnecessary. One approach to HBIG withdrawal has been to try and vaccinate patients at some stage post-liver transplantation. This does not usually work unless novel adjuvant vaccines are used. The emergence of more potent HBV antivirals such as entecavir or tenofovir has lead to avoidance of HBIG altogether.

Outcomes of Liver Transplantation: HBV

Liver transplantation for hepatitis B has been one of the most successful changing paradigms in liver transplantation medicine and surgery over the last 20 years (http://www.srtr.org/; http://www.eltr.org; http://www.anzltr.org). Before the introduction of direct antiviral agents, liver transplantation was often contraindicated in

many western countries and outcomes were poor. However, now, outcomes for liver transplantation for hepatitis B are probably one of the most successful in all patient subgroups with 5-year survival rates of over 80 %.

Hepatitis Delta Virus (HDV)

Patients with HBV infection may also be co-infected with HDV (Pascarella and Negro 2010). In the pre-transplant setting, therapies against HDV are not useful. In the post-transplant setting, the recurrence of HDV disease does not occur providing there is no HBV recurrence. HBV recurrence is minimal in this setting even in the absence of preventive approaches outlined previously. However optimal prevention of HBV recurrence is required and should be used. The reason for this is that HDV itself may reinfect the allograft but will only become active if HBsAg returns as the HBsAg is required for the production of HDV replicating virions. If HBV reinfection does occur, however, there can be fulminant HDV disease. This is now uncommon and patients with HDV probably have the best outcomes of all HBV infected patients post-transplant.

Antiviral Therapy for HCV Pre-transplantation

Current antivirals for HCV (interferon-ribavirin based) usually exclude patients with cirrhosis and portal hypertension and certainly patients with hepatic decompensation because of side effects and poor efficacy (Terrault 2008). However, there are a number of patients who proceed to liver transplantation with portal hypertension and HCC that may be suitable for antiviral therapy and are candidates for viral eradication in the pre-transplant period. Several studies with small numbers of patients have been modestly successful in viral eradication in such settings. This particularly applies to non-genotype 1 patients where sustained virologic responses can be achieved on the intention to treat basis in up to 20–30 % of patients. However, in genotype 1 patients, this is more likely to be in the 10–15 % range. If sustained virologic responses are obtained in the pre-transplant setting, it is associated with the prevention of HCV recurrence in the post-transplant setting. Successful therapies in this situation have used the so-called Low-Dose Accelerated Regime ("LADR") starting at half doses of pegylated interferon and half doses of ribavirin and increasing over the first 2–4 weeks depending on tolerability re symptoms and cytopenias.

Natural History of HCV Recurrence Post-liver Transplantation without Antiviral Therapy

HCV reinfection of the allograft can occur within 24 h after liver transplantation resulting in levels of viremia similar to pre-transplant levels within days (Ramirez et al. 2008; Gane 2008; McCaughan et al. 2009). Viral recurrence is then associated with peak viremia at about 3 months which is usually at least one log higher than the pre-transplant setting. This is associated with acute hepatitis. A usual variant at this stage is the development of cholestatic HCV in approximately <10 % of patients which results in high levels of allograft failure.

Studies of the immune-viral response to HCV suggest that early events within the first 3 months post-transplant have a significant effect on the outcome. At the 3–4 month mark increased levels of hepatic inflammation levels of viral replication, lack of a specific HCV immune response, and detection of fibrosis markers are associated with increased levels of allograft loss or fibrosis at later time points. Once chronic hepatitis C is present in the allograft, then there may be progression to cirrhosis over a 5–10-year period in up to 30 % of patients.

Levels of immunosuppression may also effect progression of allograft injury. Pulse corticosteroids and OKT3 therapy are detrimental. However there seems no difference in the type of calcineurin inhibitor used. A recent study suggests that inhibitors of the mammalian target of rapamycin (mTOR) may be beneficial. Polymorphisms within the tumor necrosis

factor (TNF) gene have also been associated with increased inflammation in the liver allograft. The occurrence of CMV infection is also a predictor factor for worse outcomes.

Antiviral Therapy Post-liver Transplant

Early use of interferon-based therapies in attempt to minimize viral replication during the early months post-transplant seems not to be beneficial probably related to poor tolerability (Terrault 2008). The use of antiviral therapy in the post-transplant once there is established chronic infection and inflammation in the allograft is considerably lower than in the non-transplant setting. Sustained virologic response rates are only obtained in 15–20 % of genotype 1 patients and 30–40 % of genotype 2/3 patients. However, if a sustained virologic response is obtained then long-term outcomes in such patients are much improved compared to untreated patients or treated patients without a sustained virologic response. Polymorphisms in the IL28 gene locus of both donor and recipient are associated with differing responses to interferon in the post-transplant setting.

Outcomes from Liver Transplantation: Hepatitis C

Unlike hepatitis B infection outcomes for liver transplant for hepatitis C are worse than non-hepatitis C patients over long periods of times (http://www.srtr.org/; http://www.eltr.org; http://www.anzltr.org; McCaughan et al. 2010). Patients with hepatitis C have 5-year survival rates approximately 70 % compared to 80 % for non-hepatitis C patients and at the 10-year mark 50 % versus 70 %.

HCV Prevention of Recurrence: The Future

Direct antivirals against HCV without interferon are on the horizon within 5 years. Proof of concept studies already exist. The successful introduction of such therapies will allow the elimination of HCV and recurrence post-transplantation. Whether such agents can prevent disease progression at an advanced stage pre-transplant and avoid transplantation in a similar fashion to HBV remains to be seen.

Hepatitis E Virus (HEV) and Liver Transplantation

HEV has been associated with chronic hepatitis in the hepatic allograft (Haagsma et al. 2008).

Liver Transplantation Tolerance in Animal Models for Encyclopedia of Medical Immunology

Roy Calne
University of Cambridge, Cambridge, UK
National University of Singapore, Singapore

Definition

This is a short review of the tolerance that can follow experimental liver grafting and the "operational tolerance" that can occur after clinical liver grafting. Although there are many data on the subject that are considered, a full explanation of the mechanisms involved has not yet been clarified.

Liver transplantation in the laboratory and clinic has provided an immunological puzzlement for all those involved, not least the patients. Initially in the early 1960s, the technical details of the surgery required prolonged and consistent perseverance in an understanding of the requirements of the liver being transplanted and the maintenance of a viable physiology of the recipients subjected to the operation. Dr. Starzl in Denver and Dr. Moore in Boston independently worked out successful techniques for transplantation of the liver in the dog. In both cases it was necessary to bypass blood from the lower part of the body and the bowel to the superior vena cava during the anhepatic phase after the recipient's liver had been removed and before the donor liver was revascularized. The standard immunosuppression then available of azathioprine prolonged graft survival modestly in experimental animals successfully transplanted and in one celebrated case of Dr. Starzl, a dog lived for 13 years after immunosuppression was stopped. The technique was then developed in the pig (Cordier et al. 1966) in Paris, in Bristol (Peacock and Terblanche 1967), and in Cambridge (Calne et al. 1967); although the surgery was difficult, success was achieved. In Cambridge Binns (1973) had been studying immunological tolerance in the pig using the classical Medawar intrauterine fetal injection. This was extended to kidney and liver transplants. Although it was possible to demonstrate tolerance with kidney allografts more easily than with skin, liver transplants in the pig sometimes survived long periods without the recipient receiving any immunosuppressive drugs at any stage. In most cases the animals developed rejection confirmed histologically and biochemically, but this subsided spontaneously (Calne et al. 1969).

Although pigs have been bred over hundreds of years to improve the quality of the meat, they are in no sense inbred, as are laboratory murine strains. The porcine liver graft could also protect other tissues from the same donor from rejection,

skin grafts lasted longer but were rejected, while the liver continued to survive. Kidney grafts also had prolonged survival when transplanted together with the liver. These observations were supplemented by many studies in rats where inbred strains were available, and it was shown that between certain strains, irreversible rejection occurred, and between others there was little evidence of rejection. Some rat liver transplants behaved in a similar manner to the pig with rejection and then spontaneous recovery. Reports of these experiments provoked the Lancet to write a leading article entitled "Strange English Pigs" (Anon 1969); however, the phenomenon was not limited to the nationality of the pigs and was repeated in other laboratories (Houssin et al. 1980; Zimmerman et al. 1981; Kamada and Wright 1984; Kamada et al. 1981). An important, detailed, and comprehensive review was published in 2007 (Benseler et al. 2007).

Operational Tolerance in Clinical Liver Grafting

The burden of immunosuppression, apart from its high expense, is a severe impediment to the quality of life of transplant patients. The usual daily dose of pills is unwelcome and unpleasant, not only requiring the swallowing of numerous medications but also the knowledge that each separate drug has side effects, all of which are unpleasant and some extremely unpleasant, for example, the cushingoid facies, stunting of growth and spontaneous fractures in patients taking large doses of steroids, hirsutism, and gum hypertrophy of patients receiving cyclosporine. Both the commonly used calcineurin-inhibiting drugs, cyclosporine and tacrolimus, are nephrotoxic even in therapeutic doses, and they can cause diabetes; azathioprine can inhibit the bone marrow with severe pancytopenia; mycophenolate mofetil can cause gastrointestinal disturbances. Patients know of all these side effects and also the fact that immunosuppression in general renders them susceptible to infection and a variety of malignancies, particularly lymphoproliferative disorders.

It is not surprising then that noncompliance is common in recipients of all organ transplants, but it is a particular cause of graft failure in teenagers and especially in girls. A number of patients transplanted in the Denver/Pittsburgh series of liver transplants stopped taking their drugs after a variety of time intervals from the operation. Some of them rejected their grafts, but others did not suffer from rejection even after many years. These patients were "operationally tolerant" following liver grafting. Other cases in the same series had their immunosuppression stopped by the medical team because of severe viral infections or malignancy. An analysis of this liver transplant-induced "operational tolerance" was undertaken, and a deliberate attempt was made to wean patients who had prolonged survival and good liver function with minimal immunosuppression. Some of these patients did well, exhibiting operational tolerance, but others developed rejection and needed to be returned to immunosuppressive treatment (Mazariegos et al. 1997).

Studies on cell trafficking between the liver and the recipient were published by the Denver/Pittsburgh group whose hypothesis on microchimerism in the blood produced by these cells has been controversial in terms of unravelling cause and effect (Starzl et al. 1993). Undoubtedly the phenomenon of micro-chimaerism occurs but whether it is the cause of specific immunosuppression or an epiphenomenon is still disputed. The protective effect in patients with liver transplantation on grafts or other organs from the same donor was also documented (Rasmussen et al. 1995). Strangely the outcome of liver grafts, unlike that of other organs, does not seem to be beneficially influenced by HLA-matching between donor and recipient.

Liver transplants release large amounts of soluble MHC Class 1 molecules which can have immunosuppressive properties (Zavazava et al. 1996; Geissler et al. 1997). The argument in favor of the immunosuppressive effect of micro-chimerism was discussed by Starzl and colleagues in the Lancet in 1992 (Starzl et al. 1992).

The relevance of micro-chimerism to the fate of organ transplantation and especially liver transplants has been much debated since Starzl's theory was first published. Micro-chimerism can certainly be demonstrated after liver and other solid organ transplants, but there does not seem to be a clear-cut relevance of the presence or absence of micro-chimerism and the immunological fate of the graft (Schlitt et al. 1994). The role of regulatory T cells has also been studied, and experimentally, these Treg cells have been implicated in the acceptance of rat liver grafts (Gassel et al. 1992).

A study by Sriwatanawongsa et al. (1995) compared the tolerogenic potential of leukocytes from the liver compared with liver parenchymal cells in rats. Parenchymal cells were able to induce tolerance, while passenger lymphocytes did not prolong donor skin grafts. Similar findings were reported from other laboratories.

Conclusions

There seems to be a strong body of agreement relating to spontaneous antigen-specific liver transplant tolerance. It has been demonstrated independently in different laboratories in a variety of species, particularly the pig, rat, and mouse, and also "operational tolerance" has been reported in clinical liver transplantation. Some of these observations and suggested explanations have been reviewed in this text, but it must be admitted that although the phenomenon is important practically and theoretically, the mechanisms involved are not fully understood. There seems to be a delicate balance between acceptance and rejection of a liver graft and also evidence of an active immunological engagement between donor and recipient that is relevant to the development of liver-induced tolerance. In the 52 years since the phenomenon was first described experimentally, there is still not a complete picture; however, when robust tolerance occurs, it is an important and striking biological phenomenon that would warrant further study, since harnessing of the mechanisms, if they were understood, might be utilized to induce tolerance, not only to the liver but to other organ and tissue transplants.

Liver Vasculature and Microvasculature

Robert S. McCuskey
Department of Cellular and Molecular Medicine, College of Medicine, University of Arizona, Tucson, AZ, USA

Synonyms

Central vein; Central venule; Fat-storing cell; Hepatic; Ito cell; Liver; Stellate cell; Terminal hepatic vein

Definition

The hepatic vasculature comprises all of the blood vessels that supply blood to and from the liver plus lymphatics which drain lymph from the organ. Within the liver, blood vessels smaller than 300 μm in diameter are classified as the microvasculature. This entry provides an overview of the dynamic structure, function, and regulation of the hepatic vasculature, particularly its microvasculature, in health and some of the basic responses to disease.

Blood Supply to the Liver

The liver has a dual blood supply. Approximately 80 % of the blood entering the liver is poorly oxygenated blood supplied by the portal vein containing venous blood flowing from the intestines, pancreas, spleen, and gall bladder. The remaining 20 % of the blood supply is well oxygenated and delivered by the hepatic artery. Both the hepatic portal vein and hepatic artery enter the liver at the hilus, where efferent bile ducts as well as lymphatics also exit the organ. These vessels then branch to supply the lobes of the liver.

Within each lobe, branches of the hepatic artery, hepatic portal vein, bile duct, and lymphatic vessels travel together in portal tracts through the liver parenchyma. After repeated branching to form the microvasculature, terminal branches of the blood vessels (portal venules and hepatic arterioles) supply blood to the sinusoids which are the exchange vessels in the liver and are organized in an extensive anastomotic network which nourishes the plates of parenchymal cell on several sides. Branches of hepatic arterioles also supply the peribiliary plexus of capillaries nourishing the bile ducts and then drain into sinusoids or occasionally into portal venules. After flowing through the sinusoids, blood is collected in small branches of hepatic veins termed central venules (central veins, terminal hepatic venules). These course independently of the portal tracts and drain via hepatic veins, which leave the liver on the dorsal surface and join the inferior vena cava. Occasionally, branches of hepatic arterioles bypass the sinusoidal bed to supply the walls of hepatic veins.

Lymphatic vessels originate as blind-ending capillaries in the connective tissue spaces of portal tracts. The fluid contained in these lymphatics flows toward the hepatic hilus and eventually into the cisternae chyli.

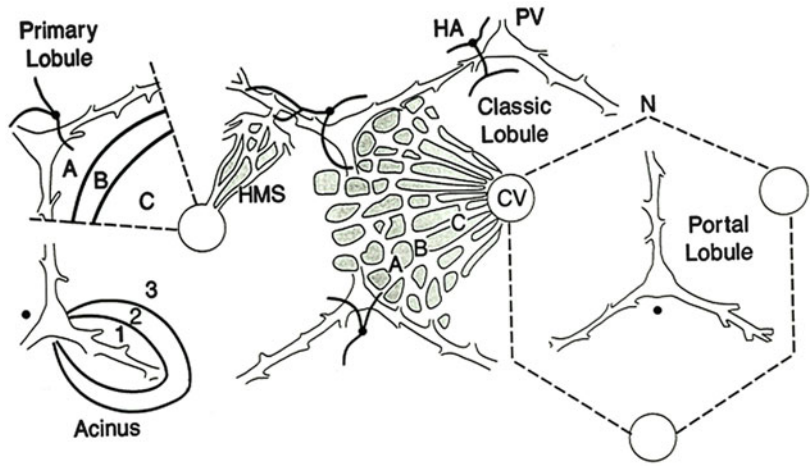
Further details and references concerning the blood supply to the liver are reviewed in McCuskey (2012).

Microvascular Functional Units

The organization of each liver lobe into structural or functional units related to function and/or disease has been the subject of considerable debate during the past century. Several models, none of which are mutually exclusive, have been proposed as follows and illustrated in Fig. 1.

The classic hepatic lobule is a polygonal structure having as its central axis a central venule, with portal tracts distributed along its peripheral boundary. The peripheral boundaries of these lobules are poorly defined in most species, including man. In some species, e.g., the pig, there is considerably more connective tissue present in the liver, and the connective tissue is distributed along the peripheral boundary of classic lobules thus making them very distinct. Considerable sinusoidal anastomoses occur between adjacent lobules, and thus the blood collected by each central venule is supplied by several portal venules. For these reasons, and because of intralobular regional differences in oxygenation, metabolic functions, and responses to some disease, an acinar concept was proposed to define the hepatic functional unit.

The hepatic acinus is a unit having no distinct morphologic boundaries. Its axis is a portal tract, and its peripheral boundary is circumscribed by an imaginary line connecting the neighboring terminal hepatic venules (central hepatic venules of the classic lobule), which collect blood from sinusoids. Contained within the acinus are three zones, each having different levels of oxygenation and metabolic function. Although the acinar concept has been widely accepted, it fails to account for those mammalian species (e.g., pig, seal) that have connective tissue boundaries circumscribing the classic lobule.



Liver Vasculature and Microvasculature, Fig. 1 Contiguous hepatic lobules illustrating the interconnecting network of sinusoids derived from two portal venules (PV). Note that the sinusoids become more parallel as they course toward the central venule (CV), which forms the axis of the classic lobule. Hepatic arterioles (HA) supply blood to sinusoids near the periphery of the lobule, usually by terminating in inlet venules or terminal portal venules. As a result, three zones (*1*, *2*, *3*) of differing oxygenation and metabolism have been postulated to compose a hepatic acinus, with its axis being the portal tract (*lower left*). Several acini would compose the portal lobule (*lower right*). Each classic lobule contains several cone-shaped subunits having convex surfaces fed by portal and arterial blood at the periphery and its apex at the central venule (*upper left*). *A*, *B*, and *C* represent hemodynamically equipotential lines in a "primary lobule." Recently, a modification further subdivides lobules into conical hepatic microcirculatory subunits (HMS), each being supplied by a single inlet venule (McCuskey 2008)

Additional inconsistencies increasingly have been identified in three-dimensional studies of metabolic heterogeneity and microvascular structure.

In yet another model of hepatic organization, the unit is defined by bile drainage. The so-called portal lobules have at their center a portal tract, with central veins present around the periphery of each lobule. This concept has received little support.

Currently, the concept of subunits of the classic lobule forming functional units is the most consistent with existing evidence. In this model, each "classic" lobule consists of several "primary lobules." Each primary lobule is cone shaped, having its convex surface at the periphery of the classic lobule supplied by terminal branches of portal venules and hepatic arterioles and its apex at the center of the classic lobule drained by a central (terminal hepatic) venule. These "primary lobules" were renamed as "hepatic microvascular subunits (HMS)" and were demonstrated to consist of a group of sinusoids supplied by a single inlet venule and its associated termination of a branch of the hepatic arteriole from the adjacent portal space. Further confirmation of this HMS concept was obtained studying their development in neonatal livers. Accompanying the HMS are hepatic parenchymal cells and the associated cholangioles and canaliculi. Hepatocellular metabolic gradients also have been demonstrated to conform to this proposed functional-unit concept.

Studies using three-dimensional reconstruction of sectioned livers, scanning electron microscopic examination of corrosion casts, and in vivo microscopy of several species support the concept of the functional unit being a conical microvascular subunit of the classic lobule. These "primary lobules" were renamed "hepatic microvascular subunits (HMS)" and were demonstrated to consist of a group of sinusoids supplied by a single inlet venule and its associated termination of a branch of the hepatic arteriole (AST) from the adjacent portal space.

Further details and references concerning microvascular functional units are reviewed in Ekataksin et al. (1997) and McCuskey (2012).

Hepatic Microvascular System

The hepatic microvascular system comprises all blood and lymphatic vessels immediately involved in the delivery and removal of fluids to and from the hepatic parenchyma, namely, portal venules, hepatic arterioles, sinusoids, central venules, and lymphatics. Figure 2 is a diagram illustrating the microvascular connections that supply and drain the sinusoids within a single hepatic lobule.

Most blood enters the sinusoids from portal venules. These inlets are reported to be guarded by sphincters composed of sinusoidal lining cells termed the afferent or inlet sphincters. Arterial blood enters some of the sinusoids, principally through branches of the hepatic arterioles. These vessels, arterio-sinus twigs, terminate in sinusoids near their origins from portal venules. In addition, occasional direct connections (arterioportal anastomoses, APA) have been observed with the terminal portal venules. The frequency of these APAs appears to be species dependent. Because all of these structures are independently contractile, the sinusoids receive a varying mixture of portal venous and hepatic arterial blood. Finally, some evidence suggests that the fraction of blood delivered to the sinusoids by the hepatic artery differs between the hilus and periphery of hepatic lobes. Within the network of sinusoids, blood flow is reportedly regulated by contractile sinusoidal lining cells which control not only the velocity of flow but also its distribution within the network. Blood leaves the sinusoids by flowing into central (terminal hepatic) venules reportedly by passing through outlet or efferent sphincters composed of sinusoidal lining cells.

Further details and references concerning the hepatic microvascular system are reviewed in McCuskey (2000, 2008, 2012).

Structure and Function of Hepatic Sinusoids

Structure. The sinusoids are unique exchange vessels composed of specialized non-parenchymal

Liver Vasculature and Microvasculature, Fig. 3 Sinusoid and contiguous hepatic parenchymal cells (HC). E endothelium, KC Kupffer cell, SD space of Disse, SP sieve plate composed of endothelial fenestrae, SC stellate cell, BC bile canaliculus (McCuskey 2008)

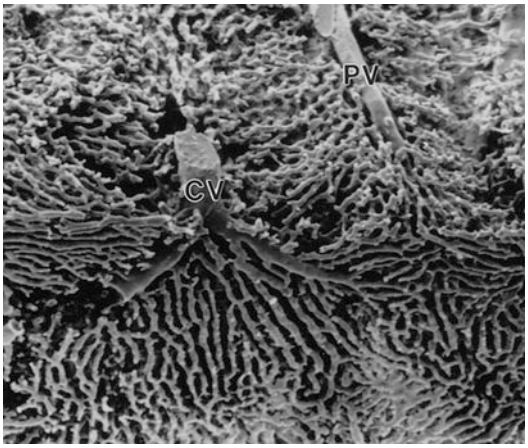
cells that exhibit structural and functional heterogeneity. The structure of the sinusoid is illustrated in Fig. 3.

The liver sinusoidal endothelial cells (LSEC) are highly fenestrated and lack a supporting basal lamina. The fenestrae are organized in clusters known as sieve plates. As a result, there is continuity between the plasma in the sinusoid lumen and the perisinusoidal space (of Disse). The sinusoidal endothelial cells contain numerous endosomes and scavenge a number of substances including breakdown products of connective tissue. They also are the source of several cytokines, eicosanoids, nitric oxide, and endothelins.

Stellate cells (fat-storing cells of Ito) lie external to the endothelium in the space of Disse. They are pericytes which frequently contain lipid droplets that are a storage site for vitamin A. Multiple cytoplasmic projections of these cells surround and embrace the abluminal surfaces of the endothelial cells. When activated, these cells produce collagen and become contractile. As a result, they are thought to play a role in the regulation of sinusoidal blood flow.

Kupffer cells are attached to the luminal surfaces of the endothelium. These are highly phagocytic, specialized fixed macrophages of the liver and contain numerous lysosomes and phagosomes. Kupffer cells are involved in a number of host defense mechanisms and immune functions and are the source of a number of cytokines, eicosanoids, free radicals, and nitric oxide.

Further details and references concerning the structure of hepatic sinusoids are reviewed in Wisse et al. (1996) and McCuskey (2012).



Liver Vasculature and Microvasculature, Fig. 4 Vascular cast of the hepatic microvasculature illustrating the tortuous, anastomotic sinusoids adjacent to the portal venule (PV) and the more parallel and larger sinusoids near the central venule (CV) (McCuskey 2008)

Heterogeneity. The organization of the sinusoid network exhibits heterogeneity. Near portal venules and hepatic arterioles, sinusoids are arranged in interconnecting polygonal networks; farther away from the portal venules, the sinusoids become organized as parallel vessels that terminate in central venules (terminal hepatic venules). Short inter-sinusoidal sinusoids connect adjacent parallel sinusoids. Figure 4 is a microvascular cast illustrating these regional differences.

In the periportal area, the volume of liver occupied by sinusoids is greater than that surrounding central venules. However, because of the smaller size and anastomotic nature of the periportal sinusoids, the surface available for exchange in this area (surface/volume ratio) is greater than in centrilobular sinusoids. The size and pattern of distribution of endothelial fenestrae differs along the length of the sinusoid. At the portal end, the fenestrae are larger but comprise less of the endothelial surface area than they do in the pericentral region. The functional significance of these regional differences is unclear but relates to the functional metabolic heterogeneity that has been demonstrated for hepatocytes in different regions of the lobule. This, in turn, may depend on the recognized portal-to-central intralobular oxygen gradient and the unique microcirculation in the liver.

Further details and references concerning heterogeneity are reviewed in McCuskey (2008) and (2012).

Morphologic sites for regulating the hepatic microcirculation. There are several potential morphological sites for regulating blood flow through the sinusoids. These include the various segments of the afferent portal venules and hepatic arterioles, the sinusoids themselves, as well as central and hepatic venules. These vessels contain several potentially contractile cells – smooth muscle cells in arterioles and venules – and in sinusoids, endothelial, stellate, and Kupffer cells.

Portal venules and central venules contain limited amounts of smooth muscle in their walls relative to their luminal size but nevertheless are contractile and respond to pharmacologic agents. Hepatic arterioles are more responsive because of a complete investment of smooth muscle and relatively small lumens. The principal site of regulation of blood flow through the sinusoids, however, is thought to reside in the sinusoid itself, where the major blood pressure drop occurs in the liver.

The sinusoidal lining cells are responsive to a wide variety of pharmacodynamic substances. By contracting (or swelling), they may selectively reduce the patency of the sinusoid lumen, thereby altering the rate and distribution of blood flow. The relative roles of Kupffer versus endothelial cells in this process are not yet resolved, but both appear to be involved. The participation of perisinusoidal, stellate cells (fat-storing, Ito cells) in regulating sinusoidal diameter also has been reported. All three cell types contain filaments, tubules, and contractile proteins suggestive of contractile activity.

Because of these structures, blood flow through individual sinusoids is variable. At sites where the lumen is narrowed by the bulging, nuclear regions of sinusoidal lining cells, flow may be impeded by leukocytes that transiently plug the vessel and obstruct flow. Transient leukocyte plugging is more frequent in the periportal sinusoids, which are narrower and more tortuous

than those in the centrilobular region. The more plastic erythrocytes usually flow easily through such sites unless the lumen is reduced to near zero. Some sinusoids, however, may act as thoroughfare channels and have relative constant rates of blood flow, while others have more intermittent flow. This may depend on not only the distribution of intra-sinusoidal sphincter cells but also on the distribution of arterio-sinus twigs (AST) and the contribution of arterial blood flowing to individual sinusoids. For example, arterial blood flowing into an individual sinusoid through a dilated AST may increase the rate of sinusoidal blood flow. Because of the delivery of arterial blood at higher pressure, some arterial blood may even reverse the entry of portal blood into the sinusoids. As a result, the AST in concert with the initial segment of the sinusoid in which it terminates may form a "functional" arterioportal anastomosis so that arterial blood is delivered into the portal venules. In the anesthetized, healthy animal, however, terminal branches of the hepatic arteriole containing flow are seen infrequently so that most blood delivered to the sinusoids is derived from the portal venules. Consistent with this is the in vivo microscopic observation that the velocity of flow in sinusoids and portal and central venules located near the capsule of the liver is not significantly altered by hepatic artery occlusion in healthy anesthetized rats. However, arterial inflow to the sinusoids may be more significant in regions near the hepatic hilum.

The frequency distribution of the wide variations in blood flow in the sinusoids exhibits a polymodal pattern composed of several Gaussian distributions. These wide variations in flow are due to the structural features previously described for sinusoids and also are due to intermittent arterial inflow into the sinusoids. Blood pressures in portal and central venules have been measured to be about 6–7 cm H_2O and 1.5–3.0 cm H_2O, respectively. Arterial blood enters the sinusoid at pressures ranging from 12 cm to 25 cm H_2O.

Further details and references concerning regulation of sinusoidal blood flow are reviewed in Clemens and Zhang (1999), Vollmar and Menger (2009), and McCuskey (2000, 2012).

Pathophysiology of the Hepatic Microcirculation

Significant interactive roles for endotoxin, cytokines, chemokines, reactive-free radicals, nitric oxide (NO), endothelin (ET-1), carbon monoxide (CO), sinusoidal lining cells, leukocytes, and platelets have been demonstrated in the pathophysiology of hepatic microvascular disturbances and parenchymal injury resulting from infection, toxicants, and ischemia/reperfusion following hemorrhage or liver transplantation. The responses of the hepatic microvasculature are of two basic types: (a) an inflammatory response involving paracrine activation of the LSEC by mediators released from adjacent Kupffer cells and/or hepatic parenchymal cells following stimulation by toxicants leading to the upregulation of adhesion molecules and the subsequent adhesion of leukocytes to the LSEC as well as swelling of the LSEC both of which restrict sinusoidal blood flow and (b) direct injury of the LSEC resulting in loss of fenestrae, formation of gaps, penetration of the sinusoidal lining by blood cells, destruction of LSEC, and obstruction of the sinusoid by SEC debris. The inflammatory response results from endotoxemia, sepsis, ischemia/reperfusion injury, and acute alcohol ingestion, while direct injury is elicited by acetaminophen (APAP) or during hepatic venoocclusive disease by pyrrolizidine alkaloids. Both types of injury may occur together or sequentially as is seen when ethanol sensitizes sinusoidal lining cells to other toxicants such as APAP or endotoxin which exacerbates the extent of injury. In should be noted that due to the highly anastomotic nature of the hepatic sinusoid bed, plugging of single or scattered segments of sinusoids results in redirection of blood flow into adjacent unplugged vessels. However, unless the injury is highly localized, these latter vessels eventually become plugged and results in microcirculatory failure.

Further details and references concerning pathophysiology of the hepatic microcirculation are reviewed in Clemens and Zhang (1999), Vollmar and Menger (2009), and McCuskey (2008, 2012).

Pathogenesis of cutaneous lupus erythematosus

Definition

Cutaneous lupus erythematosus (CLE) is an inflammatory skin condition in which a characteristic inflammatory infiltrate of primarily lymphocytes damages the interface between the top layer of the skin (epidermis) and the dermis. CLE is important as it may be manifestation of systemic lupus erythematosus, is often an unwanted reaction to ultraviolet light exposure of the skin, and can cause permanent scarring and disfigurement.

Introduction

Although cutaneous lupus erythematosus (CLE) is the second most frequent manifestation of systemic lupus erythematosus (SLE), it may present as an organ-specific (e.g., skin limited) disease. CLE may present with acute, subacute, or chronic lesions that each have distinct clinical and pathological characteristics but are thought to have a similar pathogenesis (Obermoser et al. 2010; Wenzel et al. 2010). The immunepathogenesis of CLE is still not completely understood. However, due to the accessibility of the skin for study, much has been learned about the inflammatory response in CLE. In general, environmental stimulation is thought to initiate an inflammatory response with subsequent recruitment of inflammatory cells into the skin. Two phases of an inflammatory response, initiation of inflammation followed by induction of tissue injury, participate in the formation of skin lesions in CLE. Herein, published information pertinent to each of these proposed phases of lesion induction is reviewed.

Initiation of Inflammation in CLE

Environmental factors trigger an immune response in genetically predisposed individuals. Ultraviolet (UV) light is considered the most common environmental trigger for SLE and CLE. Other factors associated with the onset of CLE include viruses, drugs, trauma, chemicals,

cigarette smoking, psychological stress, and hormones. These factors may induce local alterations in epidermal KCs or resident cells that, in turn, induce immune mediators and cytokines to recruit inflammatory cells.

UV Light as Initiator of CLE Lesions and SLE

The most consistent environmental trigger factor for SLE is UV light, and this has been the most extensively studied environmental initiator of disease. One of the hallmarks of patients with SLE is the development of cutaneous lesions upon exposure to sunlight. Up to 70 % of patients with SLE report photosensitivity, and abnormal photoreactivity is regularly noted in patients with either SLE or CLE (Kuhn et al. 2010). In murine models of lupus, repeated UV exposure can accelerate the spontaneous onset of SLE in lupus mouse models (Ghoreishi and Dutz 2010). How does this occur?

UV-Mediated Induction of Cell Death

Sunlight can induce or exacerbate skin lesions in SLE patients by inducing skin cell (keratinocyte – KC) death through either apoptosis or necrosis. Apoptotic cells are increased in LE skin lesions suggesting that these cells may not be cleared appropriately or may be more susceptible to cell death. Abnormalities in dead cell clearance have been noted in SLE patients (Gaipl et al. 2007) and may predispose to inflammation (Shao and Cohen 2011). UV irradiation of patients with SLE does not reproducibly induce more skin cell death than in unaffected individuals (therefore it is unlikely that skin in SLE is simply more susceptible to cell death), but it does induce an inflammatory environment (Bijl et al. 2007).

In addition to direct cytotoxic effects, UV light induces other mediators of cell death that promote KC death. Tumor necrosis factor-related apoptosis-inducing ligand (TRAIL), a potent inducer of apoptosis, and the TRAIL receptor R1 are expressed in lesions of CLE by KCs and infiltrating immune cells (Zahn et al. 2011). The UV-induced cytokine milieu and specifically type 1 interferons (IFNs) promote the expression of these molecules. TRAIL, in addition to inducing apoptosis, has a pro-inflammatory property such as the induction of IL-8 and intercellular adhesion molecules (such as ICAM-1). Likewise, overexpression of IL-18 receptor is noted in CLE KC in response to UV-induced cytokines TNF-α and IFN-γ. IL-18 signaling then promotes KC death (Wang et al. 2008).

In addition to KC death, increased neutrophil infiltration and death is noted in CLE (Villanueva et al. 2011). Neutrophil extracellular traps (NETs) are released by dying neutrophils and contain chromatin structures loaded with antimicrobial peptides (AMPs). These DNA-AMP complexes serve as B-cell auto-antigens promoting the generation of DNA- and RNA-specific autoantibodies that are characteristic of SLE. DNA-AMP complexes also stimulate plasmacytoid DC (pDC) to produce type 1 IFN through Toll-like receptor ligation (Craft 2011; Knight and Kaplan 2012). UV-induced IFN-α further primes local neutrophils for NETosis initiating a positive feedback loop. Reduced CD44 expression on neutrophils and the presence of DNAse inhibitors and anti-DNAse antibodies are possible explanations for the impaired clearance of dying neutrophils (Craft 2011).

UV-Mediated Promotion of Inflammation

UV stimulates KC to release multiple cytokines resulting in an inflammatory environment. UV light promotes KC to release TNF-α, IL-1 family (IL-1α, IL-1β, IL-18, IL-33), IL-8, IL-6, IFN-γ, granulocyte colony-stimulating factor (G-CSF), and, critically, type 1 interferons (IFN, mainly IFN-α) (Reefman et al. 2008).

Type 1 IFNs play a key role in innate immune responses and prime the immune system for adaptive immune responses. Type 1 IFNs modulate autoimmunity by promoting DC maturation, T-cell survival, B-cell differentiation, immunoglobulin class switching, and antibody production. Plasmacytoid DCs, which are the primary source for this cytokine, are detected in the skin of lupus patients but not in normal skin. The type 1 IFN-inducible protein MxA is abundant in CLE skin, suggesting local overproduction of this type 1 IFN. The overexpression of type 1 IFN-related

genes in the clinically normal skin of patients with SLE is consistent with a genetically determined activation of the pathway in these patients (Obermoser and Pascual 2010). Type III IFNs share many functions with type I IFN but are primarily expressed by and act upon epithelial cells. Expression of both type III IFN and type III INF receptors is enhanced in CLE (Zahn et al. 2011). Increased expression of epithelial-derived interferon may be an initial step in the initiation of the immune response on CLE.

UV irradiation induces IL-1 and TNF-α production by KCs. Further, in CLE PBMCs, TNF-α production is significantly elevated and correlates with disease activity (Nabatian et al. 2012). IL-1 stimulates the activation of a network of cytokines including chemokines and adhesion molecule upregulation. Finally, UV-induced IL-6 stimulates B-cell differentiation and immunoglobulin secretion and thus promotes autoantibody formation.

UV light also induces release of chaperonins like HMGB-1 from the cell nucleus to the extracellular milieu. In the extracellular milieu, HMGB-1 regulates cell migration and inflammatory responses and cytokine production such as type 1 IFN, TNF-α, and IL-1β. High expression of HMGB-1 has been shown in photo-provoked skin lesions in patients with CLE after UV irradiation, which coincided with CLE lesion induction (Barkauskaite et al. 2007). Finally, AMPs such as LL37 contribute to human skin defense, but these molecules may also participate in increased local release of type 1 IFN, promoting inflammation. AMPs are induced by UV and are expressed in CLE lesions (Kreuter et al. 2011).

Genetic Determinants of CLE

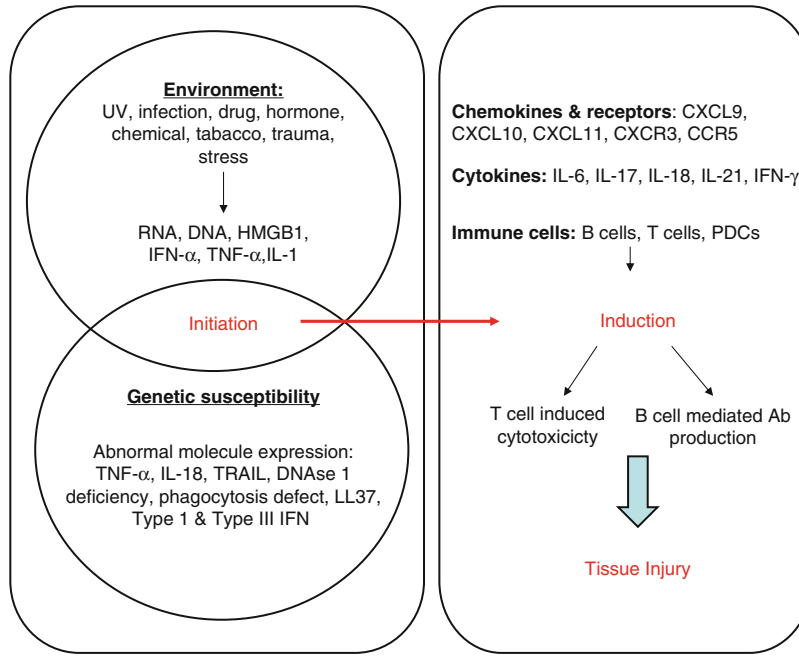
Subacute cutaneous lupus erythematosus (SCLE) is a distinct subtype of CLE that is characterized by exquisite photosensitivity and the development of polycyclic and annular lesions. This form of CLE is associated with antibodies to Ro/SSA and is linked to the HLA1, HLA-B8, DR-3, DRw52, and C4 null haplotypes in Caucasians. Other genes associated with CLE in large genome-wide studies include polymorphisms in ITGAM, IRF5, TYK2, and FCGR2A (reviewed in (Zhang 2012)). These genes are involved in type 1 IFN signaling and dead cell clearance.

Induction of Skin Injury in CLE

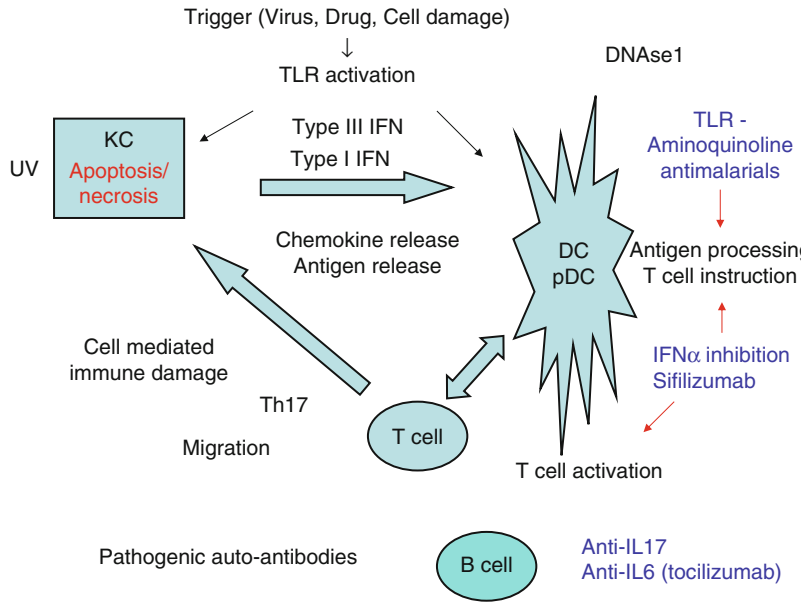
Activation and infiltration of inflammatory cells including T cells and B cells, DCs, pDC, and macrophages occurs in CLE skin, resulting in further damage to the skin. Thus, the pathology of CLE is a "lichenoid tissue reaction" where basal KCs are targeted by inflammatory cells, including granzyme-positive cytotoxic $CD8^+$ T cells and $CD4^+$ T cells (Dutz 2009; Sontheimer 2009). This tissue reaction depends upon the appropriate expression of immune homing molecules or chemokines resulting in the attraction and retention of damaging T cells (Meller et al. 2009). Upregulation of inflammatory CXCR3 ligands, CXCL9, CXCL10, and CXCL11, is associated with the recruitment of both effector cytotoxic T cells and pDC and is characteristic in CLE (Wenzel et al. 2009). Importantly, type 1 IFN signaling promotes a Th1-biased and Th17-biased inflammation. The Th1-associated chemokine receptor 5 (CCR5) is highly expressed by circulating T cell in patients with active CLE (Freutel et al. 2011). Elevated levels of Th17-type cytokine IL-17 are noted in the skin and serum of patients with CLE and SLE (Tanasescu et al. 2010). IL-21, a cytokine produced by activated CD4 T cells and NK cells, affects B and T cells, NK T cells, DCs, monocytes, and macrophages and generally promotes cytotoxicity. IL-21 is also elevated in lesional CLE (Costanzo et al. 2010).

Summary

In CLE, genetic susceptibilities promote the release, dislocation, or overexpression of molecules including DNA, RNA, HMGB1, TRAIL, and AMPs and the production of cytokines or chemokines including IL-1, IL-6, IL-10, IL-18, and TNF-α. Environmental factors such as



Lupus Erythematosus, Skin, Fig. 1 Summary depicting the proposed interaction between genetic predisposing factors and environment in the development of cutaneous lupus erythematosus lesions



Lupus Erythematosus, Skin, Fig. 2 Model of the pathogenesis of cutaneous lupus erythematosus. Skin cell (keratinocyte) damage is proposed to be the primary initiating event. The *thin red arrows* indicate potential novel therapeutic targets

UV are required to trigger lesion induction in susceptible individuals through the generation of inflammatory cells that induce immune-mediated damage at the initial trigger site. These interactions are depicted in Fig. 1.

Current therapies for CLE involve the use of topical anti-inflammatory drugs such as corticosteroids and calcineurin inhibitors. Aminoquinolone antimalarials are an effective treatment, possibly due to the inhibition of Toll-like receptor signaling (Kuhn et al. 2010). New therapies to "prevent" skin lesions formation should focus on targeting abnormally expressed or released molecules or should replace deficient

molecules combined with blocking the environmental triggering factor. Once lesions are developed, novel therapies should target aberrant immune response including targeting immune cells, autoantibodies, or cytokines to ameliorate the tissue damage. The potential points of therapy are depicted in Fig. 2.

Definition

Lupus nephritis (LN) is a common and often severe complication of Systemic Lupus Erythematosus (SLE). LN is defined as a manifestation of a systemic autoimmune disease characterized by loss of self-tolerance which results in immune complex accumulation in the kidney glomeruli. Despite extensive investigation, the pathogenesis of LN remains incompletely understood. In fact, LN is thought to be a heterogeneous disorder involving several pathogenic mechanisms. This entry will review the current understanding of the pathogenesis of LN and discuss novel therapeutic targets for treatment.

Introduction

SLE is an autoimmune, multisystem disease. It is characterized by the production of autoantibodies directed against nuclear and cellular antigens and the formation of pathogenic immune complexes. The exact pathogenesis of LN remains elusive. Multiple abnormalities of innate and adaptive immunity have been described, and immunologic dysfunction may precede clinical manifestations by several years. SLE and LN occur when there is a loss of tolerance to self-antigens with production of autoantibodies to these self-antigens. Normally, up to 75 % of newly formed and 40 % of mature B cells recognize self-antigens (Foster 2007). These produce natural IgM autoantibodies that are generally of low affinity for self-antigens. In SLE, however, autoantibodies undergo somatic mutation, class switching (IgM to IgG), and become high affinity and are directed against diverse epitopes on autoantigens (Foster 2007). The binding of autoantibodies to self-antigen creates immune complexes which can accumulate in the kidney activating inflammatory mediators such as complement, T cells, and macrophages which promote intrarenal inflammation leading to the development of LN. Hyper-reactive B and T cells, abnormal antigen presentation and increased levels of autoantigens, and defective clearance of apoptotic debris enhance production of pathogenic autoantibodies (Stuart and Hughes 2002).

Autoantibodies and LN

A necessary feature of the kidney biopsy in patients with LN is the presence of immuno globulins (pathologic features of LN on kidney biopsy can be found in the entry on

Lupus Nephritis and Novel Therapies, Pathogenesis, Table 1 Autoantibodies with pathogenic activity in lupus nephritis

Autoantibodies	Prevalence	Location
Anti-nucleosome	60–90 %	GBM, mesangial cells, endothelial cells, epithelial cells
Anti-dsDNA	70–96 %	GBM, mesangial cells, endothelial cells, epithelial cells, PTCs
Anti-Smith	10–60 %	GBM
Anti-Ro	25–44 %	GBM
Anti-C1Q	40–97 %	GBM, mesangial cells, TBM
Anti-ribosomal P protein	75 %	Glomerulus, mesangial cells
Anti-alpha-actinin	20 %	Glomerulus, mesangium, podocytes
Anti-Annexin II	32–65 %	Glomerulus, mesangium

GBM glomerular basement membrane, *PTC* peritubular capillaries, *TBM* tubular basement membrane

▶ Lupus Nephritis, Diagnosis and Treatment). Patients with active disease often demonstrate high-serum levels of circulating antinuclear and anti-double stranded (ds)DNA antibodies, the autoantibodies most associated with SLE. However, over 100 additional self-antigens have been identified in SLE as targets for autoantibodies (Kyttaris 2010), and several autoantibodies associated with LN are listed in Table 1. Autoantibodies to dsDNA and complement component C1q maybe particularly important in LN.

High-titer anti-dsDNA antibodies have been found to be associated with active LN (Tsao et al. 1992; Vlahakos et al. 1992). Anti-dsDNA antibodies are predominantly IgG subclasses 1 and 3 which are the most proinflammatory IgG subclasses due to their ability to activate complement and engage Fc receptors for IgG (Manolova et al. 2002). The classical view of LN pathogenesis is that circulating immune complexes deposit in the kidney and initiate an intrarenal inflammatory process through these mechanisms. Experimental work suggests that anti-dsDNA antibodies directly cross-react with glomerular antigens such as mesangial cell membranes, laminin, α-actinin, and exposed chromatin fragments on glomerular basement membranes (Madaio et al. 1987). Glomerular antigens may be exposed due to defective clearance of apoptotic debris. As an example, DNase 1 may be deficient in SLE exposing chromatin for binding to anti-dsDNA antibodies (Mortensen and Rekvig 2009). Furthermore, defective clearance of apoptotic debris such as chromatin can activate intrarenal dendritic cells, enhance T-B cell interaction, and increase production of anti-chromatin antibodies (Mortensen and Rekvig 2009). Supporting this theory is the identification of nucleosome specific T cells and induction of anti-nucleosome, anti-dsDNA, and anti-histone antibodies through Th cells (van der Vlag and Berden 2011). These antibodies have been detected in both lupus mice and in patients with SLE.

C1q antibodies have been strongly correlated to lupus nephritis (Sinico et al. 2005; Meyer et al. 2009). C1q is thought to be a crucial participant in macrophage-mediated clearance of apoptotic material which is important in regulating the development of autoreactive B cells. Both mice and humans with C1q deficiency are characterized by an autoimmune phenotype similar to SLE (Stoll and Gavalchin 2000). Thus, C1q has an important role in maintaining self-tolerance. Additionally, anti-C1q antibodies trigger classical complement pathway amplification enhancing renal tissue damage. Patients with active LN demonstrate high levels of circulating anti-C1q antibodies as well as deposition in the renal biopsy tissue. The absence of anti-C1q antibodies has a high negative predictive value for active LN (Mok et al. 2010), while its presence may be a potential marker for disease activity (Tsirogianni et al. 2009).

Genetics in LN

Genetics also play a role in LN. Using genome-wide and candidate gene studies, over 30 genes

have been identified that appear to be involved in the pathogenesis of SLE in general (Tsao 2004). These include immune-complex clearance genes, immune response genes, and IFN-α signaling and response genes. The specific genetics of human LN are less clear. Studies in LN suggest significant heterogeneity in different racial/ethnic groups and are therefore challenging. Genes that seem to play a role in LN include those for Fc receptors for IgG, the cytokines monocyte chemotactic protein-1 (MCP-1) and interleukin (IL)-18, signal transducer and activator of transcription-4 (STAT4), and the HLA DR3 allele (DRB1 *0301) (Vuong et al. 2010).

The Fc receptor is of particular importance in the pathogenesis of LN as Fc receptors for IgG (known as Fcγ receptors, or FcγR) are engaged by immune complexes and mediate either protection or injury. Protection is facilitated by FcγR-induced phagocytosis and clearance of the immune complexes. Inflammation is facilitated because the FcγR engaged by immune complexes activate their leukocytes to secrete proinflammatory molecules such as oxygen free radicals and proteolytic enzymes (Waldman and Madaio 2005). FcγR with a genetically determined lower affinity for immune complexes have been associated with SLE and particularly with LN. This suggests that forms of FcγR that bind more efficiently promote immune complex clearance, and lower affinity FcγR promote activation of proinflammatory leukocytes (Clatworthy et al. 2007) (Foster 2007).

Complement and LN

The role of complement in LN is related to its affinity for immune complexes. The complement cascade ideally removes circulating immune complexes before they can mediate injury. The complement system is activated by circulating immune complexes and either solubilizes immune complexes so they are less likely to become trapped in tissue or opsonises them through complement activation products C4b and C3b/bi for direct clearance. Additionally, complement functions to remove apoptotic debris through opsonization by complement component C1q. However, once immune complexes have deposited in tissue, complement can drive tissue inflammation and can directly injure cells via the membrane attack complex or indirectly through activation of proinflammatory cytokines and toxic mediators (Bao and Quigg 2007). For further detail, please see the entry ▶ Complement Regulation in the Kidney located elsewhere in the Encyclopedia.

T and B cells in LN

Kidney-infiltrating T cells play several roles in LN. These include T cells providing help to B cells, production of autoantibodies through T cell effector functions, generation of cytokines, and direct infiltration into renal tissue triggering inflammation through recruitment of proinflammatory leukocytes, including macrophages.

Abnormalities in both Th1 and Th2 cytokines occur in LN; however, intrarenal production of Th1 cytokines, specifically IL-12, IFN-γ, and IL-18, appears to exceed Th2 cytokines in proliferative LN and correlates with histologic activity (Masutani et al. 2001). Th1 responses are associated with activated macrophages and with the production of immunoglobulin isotypes capable of activating complement and FcγR pathways. The Th1 dominance displayed in LN patients, both locally in the kidney and systemically in the circulation, suggests that this may be an important prerequisite for developing LN.

MRL/lpr mice spontaneously develop a severe autoimmune syndrome closely resembling human SLE and have been shown to develop severe nephritis due to polyclonal expansion of $CD4^+$ T cells suggesting a pathogenic role in promoting nephritis (Okamoto et al. 2012). $CD4^+$ T cells have been implicated in the development of nephritis in experimental lupus models with several co-stimulatory interactions playing important roles. Interruption of co-stimulatory pathways, including CD28/B7 and CD40/CD40L, attenuates renal injury in animal models (Peng 2004).

IFN-γ is also thought to be pathogenic in murine LN models. Lupus-prone BWF1 mice develop nephritis after administration of IFN-γ,

while renal disease was prevented in murine LN models after the administration of neutralizing antibodies and in those deficient in the IFN-γ receptor (Foster 2007). Several other cytokines including IL-6, IL-12, IL-23, IL-27, and TGF-beta have been shown to affect the kidney through various mechanisms in murine models of SLE (Mishra et al. 2003; Kelley and Wuthrich 1999).

Human regulatory T cells, characterized as $CD4^+CD25^+$, inhibit immune responses through effects on T and B cells, and particularly autoantibody production. Patients with SLE have normal and reduced number of regulatory T cells that are functionally defective during disease activity. Additionally, regulatory T cells have a protective effect in lupus-prone mice, and mice depleted of regulatory T cells develop accelerated autoimmune features (Foster 2007; Tucci et al. 2010).

Like T cells, B Cells are also heavily involved in the pathogenesis of LN. Abnormalities in B cell tolerance allows for the development of autoantibodies and eventual immune complex deposition in the kidney. In the MRL/lpr model, B cell-deficient mice are protected from disease, whereas those mice with nonsecretory plasma cells still develop autoimmunity, suggesting B cell involvement beyond antibody production (Foster 1999). In SLE, there is impaired removal of autoreactive B cells. B cells are also efficient antigen-presenting cells (APC) that can process and present antigens to T cells via MHC Class I and MHC Class II. Dysregulation of apoptotic cell clearance results in exposed nuclear antigens on cells surfaces and results in the activation of autoreactive B cells and presentation of antigens to autoreactive T cells. This may directly contribute to intrarenal inflammation. Additionally, chemoattractants secreted from B cells can influence the chemotaxis of other immune cells such as T cells and monocyte-derived dendritic cells (Chang et al. 2011).

Toll-Like Receptors and LN

Toll-like receptors (TLR) are present on cell membranes (TLR2 with TLR1 or 6, TLR4, TLR5, TLR11) and endosomal membranes (TLR3, TLR7/TLR8, TLR9, TLR10) in various cell types. Several types of TLRs have been identified in humans. They are able to recognize bacterial, viral, and fungal antigens as well as endogenous ligands. Ligand binding to TLRs activate Type I IFN production and/or proinflammatory cytokine production (Conti et al. 2011).

TLRs have been demonstrated to have a role in LN in both human and animal studies. Mice overexpressing TLR7 have premature mortality with the increased production of proinflammatory cytokines. TLR7 has a role in the activation of autoreactive B cells which are directed against RNA-associated autoantigens. In the MRL/lpr animal model, the presence of TLR7 ligands increased the development of glomerulonephritis, while a lack of TLR7 decreased the severity of renal involvement (Santiago-Raber et al. 2009).

In lupus-prone animal models, deletion of TLR9 decreases the production of anti-nucleosome/histone antibodies in one model and the production of anti-DNA autoantibodies in another model. Experiments with transgenic mice have shown that the TLR9 signaling pathway is crucial in the generation of pathogenic anti-DNA/polyreactive antibodies. However, there have been reports that in TLR9-/- lupus-prone mice (MRL-, $B6\text{-}Fas^{lpr}$), nephritis still developed despite the absence of anti-dsDNA antibodies (Santiago-Raber et al. 2009). This suggests that reactivity of autoantibodies to DNA or chromatin may not be necessary, but instead the ability of autoantibody to react with antigen on renal parenchymal cells could drive disease (Christensen et al. 2005).

Immune complexes containing DNA and RNA are endogenous ligands for both TLR7 and TLR9, and activation of these intracellular TLRs induces plasmacytoid dendritic cell IFN-α production. IFN-α is an important cytokine in SLE and LN, with the serum level of INF-α as well as expression of IFN-α-dependant genes in monocytes correlating with disease activity (Anders et al. 2010). The effects of IFN-α on the immune response include promoting maturation of conventional dendritic cells into potent antigen-presenting cells, inducing B cell differentiation to plasma cells, and contributing to the development of CD4 helper and CD8 memory T cells.

Neutrophils and Neutrophil Extracellular Traps (NETs)

Neutrophils are also now being recognized as important participants in the pathogenesis of SLE. Lupus neutrophils are thought to be of lower density, with decreased phagocytic and lysosomal activity compared to normal neutrophils. These Low-Density Granulocytes (LDGs) are proinflammatory and cause direct tissue damage. Peptides released from LDGs are toxic to glomerular structures, and in experimental models, depletion of neutrophils protects against antibody-mediated glomerulonephritis (Knight and Kaplan 2012). NETosis is a form of neutrophil cell death. NETs are chromatin structures that bind foreign material including microbes and in SLE, autoantigens. In SLE, aberrant NETosis leads to the potent release of NETs from LDGs stimulating IFN-α secretion by dendritic cells and causing direct tissue damage through toxic mediators. This occurs through a complex interaction between DNA, anti-DNA autoantibodies, and neutrophil-derived peptide LL37. The role of LL37 is not entirely clear; however, it is thought to stabilize NETs and prevent degradation by DNase1. This perpetuates a cycle of continuous autoreactivity driven by IFN-α and continuous tissue injury by NETs (Garcia-Romo et al. 2011; Lande et al. 2011; Knight and Kaplan 2012).

Biomarkers for LN

There is considerable interest in identifying biomarkers that reflect impending LN flare, disease severity and that can predict response to therapy and disease progression. Several urine biomarker candidates have been identified, but to date none have been validated for clinical use in a large, prospectively followed lupus cohort. The rationale for developing LN biomarkers is to improve real-time disease management and achieve more complete renal remissions. A few potential biomarkers are described below.

Monocyte chemoattractant protein 1 (MCP-1) has been shown to be involved in the pathogenesis of lupus nephritis in both animal and human studies. Urine MCP-1 levels are higher in active renal disease than healthy controls or those with nonrenal SLE or inactive LN. Levels are also higher in proliferative LN compared to non-proliferative LN. However, urinary MCP-1 is also elevated in several other glomerulonephritides and is not specific for LN (Rovin and Zhang 2009).

Another biomarker of interest is neutrophil gelatinase-associated lipocalin (NGAL). NGAL is involved in cellular iron transport and is constitutively expressed within the kidney. An increase in urinary NGAL is predictive of acute kidney injury with both serum and urine levels correlate better to glomerular filtration rate than more conventional analytes such as serum creatinine. NGAL has been shown to be sensitive and specific for active LN in children, with levels increasing prior to clinical flare. However, similar to MCP-1, elevated levels of urine NGAL are also seen in other types of renal injury (Han et al. 2009).

Novel Therapies for Lupus Nephritis

Cytotoxic therapies have improved outcomes in LN; however, current standard therapies such as cyclophosphamide are nonspecific and associated with significant adverse effects. The need for new approaches for the treatment of LN is also highlighted by the low complete and modest overall remission rate with current approaches. As more is understood regarding the immunopathology of LN, drugs with more targeted mechanisms of action can be developed. Several targeted LN therapies are currently being evaluated in clinical trials.

Rituximab is a chimeric mouse/human monoclonal antibody targeted against CD20. CD20 is present on B cells from the pre-lymphocyte stage to more mature lymphocytes. As described above, B cells play an important role in the pathogenesis of lupus, and rituximab is able to deplete B cells through complement-mediated cell lysis and Fc receptor-mediated cellular cytotoxicity and by inducing apoptosis (Maloney et al. 2002).

Fcγ-RIIIa genotype may help predict the level of B cell depletion to rituximab therapy. Specific variants of the Fcγ-RIIIa gene, described above, can limit rituximab efficacy in SLE and may be an important tool to guide clinicians in the future (Anolik et al. 2003). Additional effects of rituximab include increasing regulatory T cells, decreasing the T cell co-stimulatory molecule CD40 ligand, and decreasing other important co-stimulatory molecules (Vigna-Perez et al. 2006). A potential complication associated with rituximab use is autoantibody formation against rituximab. Formation of these human anti-chimeric antibodies (HACA) is thought to be more prevalent in SLE than in other diseases treated by rituximab. The effect of HACA is reduced rituximab-mediated B cell depletion, loss of rituximab, and serum sickness. Premedication with intravenous steroids reduces the incidence of antibody development (Saito et al. 2005).

Epratuzumab is a humanized monoclonal antibody directed against CD22, which is expressed on the surface of mature B cells. The mechanism of action is through the B cell receptor and modulation of B cell responses. Epratuzumab has been shown to be effective in moderate to severe SLE but has not yet been evaluated in human LN.

B-lymphocyte stimulator protein (BLyS) is a member of the TNF superfamily and is an important cytokine in the development and survival of B cells through interaction with 3 different receptors. Elevated BLyS levels have been demonstrated in patients with SLE and are associated with disease activity. Belimumab is a fully humanized monoclonal antibody specific for BLyS and inhibits its activity. A recent phase III trial demonstrated safety and efficacy of Belimumab in treatment of SLE, although active LN patients were specifically excluded (Navarra et al. 2011).

The interaction and signaling between B cell and T cells is crucial in the pathogenesis of lupus, and these co-stimulatory molecules have become targets for immunotherapy. CD28 is expressed on resting T cells and once T cells have been activated CTLA4 is expressed. These molecules are able to bind to receptors, CD80(B7.1)/CD86(B7.2), which are on antigen-presenting cells. CTLA4, once bound to these receptors, inhibits the T cell response and therefore limits T cell proliferation. Abatacept is a fusion protein between the extracellular domain of CTLA4 and the Fc portion of IgG (CTLA4-Ig) that is able to function as a receptor for B7, and this inhibits T cell activation. In murine LN, CTLA4-Ig was able to decrease proteinuria, autoantibody production, and mortality. There is now a clinical trial underway investigating the use of abatacept as adjunct therapy in treatment of LN.

Another cytokine being targeted in LN is IL6. High levels of IL6 have been demonstrated in patients with SLE, and the administration of a monoclonal antibody against IL6 in LN mice resulted in decreased proteinuria and increased survival (Cordeiro and Isenberg 2008; Karim et al. 2009). Currently, a study evaluating the safety and effectiveness of an anti-IL-6 antibody in LN is underway.

Finally, TNF-like weak inducer of apoptosis (TWEAK) is a member of the TNF superfamily and regulates cell proliferation, cell death, and inflammation through interaction with the fibroblast growth factor-inducible 14 receptor (fn14). Current evidence suggests TWEAK may be a target in renal and vascular injury. In SLE, urinary TWEAK levels are elevated during acute LN flares and the TWEAK-fn14 pathway may be involved in the pathogenesis of LN (Schwartz et al. 2009). A randomized clinical trial is underway to assess the efficacy of anti-TWEAK as an adjunct therapy for LN.

Summary

The exact pathogenesis of LN remains unclear and significant efforts are being made to identify the multiple mechanisms involved in this heterogenous disorder. LN occurs due to a loss of self-tolerance leading to autoantibody formation and immune complex accumulation in the kidney, triggering a multifaceted immune reaction that involves activation of complement, T cells, B cells, and macrophages. Intra-renal

inflammation follows and leads to the development of LN. As more is learned about the pathogenesis of LN, biomarkers to identify early and severe disease will be developed. Current approaches to treatment are suboptimal and new therapeutic approaches are being evaluated to provide more targeted therapy and improve outcomes while limiting side effects. A more clear understanding of the pathogenesis of SLE and LN is necessary to achieve these therapeutic goals.

Definition

The kidney is one of the major target organs affected by systemic lupus erythematosus (SLE). Lupus nephritis (LN) is the most common form of kidney disease in SLE, and occurs as a result of immune complex accumulation in the renal glomeruli. Depending on their location within glomeruli, immune complexes can trigger renal cell proliferation, matrix formation, or inflammation. Clinically, intra-renal immune complexes can manifest as hematuria, proteinuria, or kidney insufficiency. Although there are other types of kidney injury in SLE, this essay will focus on LN.

Introduction

Kidney involvement in SLE is common and often severe. Approximately 40 % of adults and 80 % of children with SLE develop clinically significant kidney disease, and kidney disease significantly increases the morbidity and mortality of SLE (Contreras et al. 2006; Saxena et al. 2011). Younger age (<33 years old), male sex, and non-European ancestry are thought to

be risk factors for development of LN (Saxena et al. 2011). Death attributable to renal disease occurs in 5–25 % of patients with proliferative LN within 5 years (Franco et al. 2010). The incidence of LN and progressive kidney failure is higher in Black, Hispanic, and Asian populations (Seligman et al. 2002). In fact, the progression to ESRD has been reported as high as nine times greater in Black patients (Korbet et al. 2007).

The diagnosis and prognosis of LN is confirmed by kidney biopsy and the histopathologic classification based on biopsy findings guides treatment. Current strategies for LN treatment use intense, nonspecific immunosuppressive therapy that carries considerable risk and often suboptimal results.

Diagnosis of Lupus Nephritis

Most patients with LN lack overt signs of kidney disease, but rather have abnormalities of serum creatinine and/or the urine sediment. Assessment of serum creatinine, urine dipstick and sediment, and quantification of proteinuria are important screening tools. While many patients will have findings of LN at initial diagnosis of SLE, all patients with SLE should undergo testing for LN at regular intervals because preservation of kidney function is best achieved by early diagnosis and treatment.

The urine dipstick is commonly used to screen for LN, and a dipstick positive for blood and protein is suggestive, but there is a high false-negative rate (Woolhandler et al. 1989). Microscopic examination of the urine sediment after centrifugation is thus essential to look for evidence of glomerular bleeding (dysmorphic red blood cells, acanthocytes, red blood cell casts) or renal inflammation (white blood cells, white blood cell casts in the absence of infection) (Image 1). The evaluate of urine sediment is discussed in detail elsewhere in this Encyclopedia, in the entry on "Urinalysis."

Proteinuria is the hallmark of LN, and in a comprehensive review 100 % of LN patients presented with proteinuria (Cameron 1999). Proteinuria is a biomarker for LN activity and is used to assess relapse, remission, and effect of treatment. Proteinuria is not simply a marker of disease but is also toxic to the kidney, and can cause progressive renal damage. The ideal method to quantify proteinuria is a 24-h urine collection for protein and creatinine (Parikh et al. 2011). An intended 24-h collection that is at least 50 % complete is also accurate. Measurement of the protein to creatinine ratio on the intended 24 h urine removes errors that may occur with under- or over-collections (Birmingham et al. 2007).

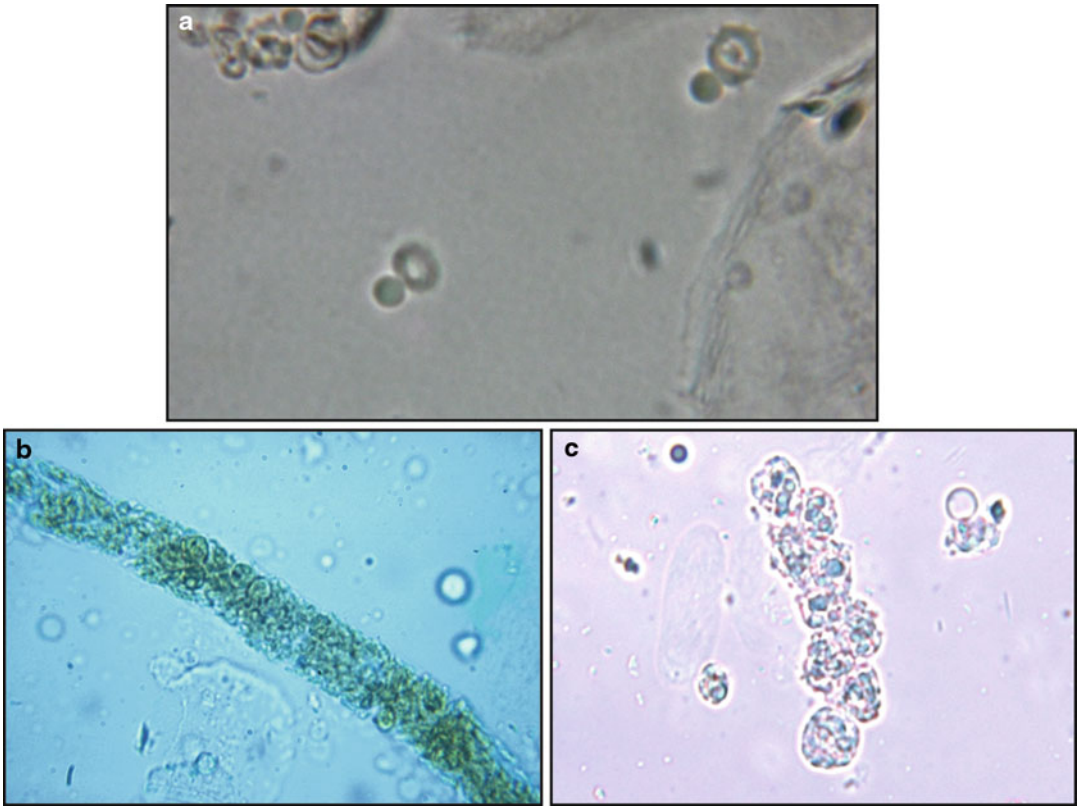
A kidney biopsy is the gold standard for diagnosis and classification of LN. A biopsy may not be necessary if the only clinical abnormalities suggesting LN are isolated hematuria, or minor proteinuria (<500 mg/day) in the absence of hematuria. A biopsy should be considered when proteinuria is over 500 mg/day, because this degree of proteinuria can be associated with significant kidney injury (Ardoin et al. 2011).

The Pathology of Lupus Nephritis

LN is currently classified by the 2003 International Society of Nephrology and the Renal Pathology Society (ISN/RPS) criteria (Table 1). These criteria define six classes of LN, and categorize renal lesions as active (A), chronic (C), or both, and whether they affect less than (segmental) or more than (global) 50 % of the glomerular surface area (Markowitz and D'Agati 2007).

Light microscopy describes active glomerular lesions as mesangial and endocapillary hypercellularity with associated capillary lumina occlusion and possible rupture of the capillary basement membranes leading to extracapillary cell proliferation and leukocyte infiltration (crescent formation). Chronic glomerular lesions include glomerular sclerosis and scarring (fibrosis). LN is classified as focal if <50 % of all glomeruli are injured, or diffuse if ≥50 % of all glomeruli are injured.

Immunofluorescence microscopy classically shows a "full house" pattern, which refers to the presence of IgG, IgA, IgM, C1q, C3, and kappa and lambda light chains all together in glomeruli. C1q deposition is often prominent and is specific



Lupus Nephritis, Diagnosis and Treatment, Image 1 *Urine sediment*: Urine microscopic examination demonstrating: (**a**) Acanthocytes – ring-shaped red cells with vesicle shaped protrusions or blebs that are indicative of glomerular bleeding. (**b**) Red blood cell (RBC) cast – urinary cast composed of a matrix containing RBCs and indicative of glomerular bleeding. (**c**) White blood cell (WBC) cast – urinary cast composed of matrix with WBCs and indicative of renal inflammation. For more detail, refer to entry on "Urinalysis"

for LN (Trendelenburg et al. 2006). It is uncommon to see full house pattern in other types of glomerulonephritis.

Ultrastructural evaluation of kidney biopsies by electron microscopy always shows mesangial electron-dense deposits, which are immune complexes. Outside the mesangium, immune deposits are variable in location. Subendothelial deposits appear between the glomerular capillary endothelial cells and the glomerular basement membrane, and are usually seen in proliferative LN. Subepithelial deposits are found between glomerular epithelial cells (podocytes) and the outer layer of the glomerular basement membrane, and are found in non-proliferative, membranous LN. Electron microscopy also often shows tubuloreticular structures in renal endothelial cells which are thought to be induced by interferon in lupus patients (Venkataseshan et al. 1991).

The specific classes of LN are:

Mesangial Lupus Nephritis (Class I and II)

Class I LN has normal glomeruli by light microscopy, but immunofluorescence and electron microscopy show mesangial immune complexes, a finding in all classes of LN. Class I LN typically has no overt clinical kidney abnormalities, so it is rarely diagnosed.

Class II, or mesangial proliferative LN, demonstrates pure mesangial hypercellularity and mesangial matrix expansion by light microscopy (Image 2), with mesangial immune deposits

Lupus Nephritis, Diagnosis and Treatment, Table 1 Lupus nephritis 2003 ISN/RPS classification

LN Class	Pathologic description	Treatment recommendations
Class I	Normal glomeruli by LM[a], mesangial immune complexes on IF[b]or EM[c]	IS[d] to treat extra-renal disease only
Class II	Pure mesangial hypercellularity with mesangial immune deposits. Mesangial matrix expansion seen by LM	IS to treat extra-renal disease only
		Renoprotective measures[e]
Class III	Active: segmental or global endo- and/or extracapillary proliferation in <50 % of glomeruli; subendothelial immune deposits	Active or active+chronic lesions – induction[f] and maintenance[g] IS
	Chronic: segmental or global glomerulosclerosis in <50 % of glomeruli	Chronic lesions only – renoprotective measures; IS to treat extra-renal disease
Class IV	Active: segmental or global endo- and/or extracapillary proliferation in ≥50 % of glomeruli; subendothelial immune deposits	Active or active+chronic lesions – induction[f] and maintenance[g] IS
	Chronic: segmental or global glomerulosclerosis in <50 % of glomeruli	Chronic lesions only – renoprotective measures; IS to treat extra-renal disease
Class V	Thickening of the glomerular basement membrane with global or segmental subepithelial immune deposits. May occur in combination of Class III or IV	Subnephrotic proteinuria – renoprotective measures. IS to treat extra-renal disease
		Nephrotic or abnormal renal function – treat with IS
Class VI	Advanced sclerosis ≥90 % of glomeruli are sclerosed	Renoprotective measures only

[a]LM – Light microscopy
[b]IF – Immunofluorescence
[c]EM – Electron microscopy
[d]IS – immunosuppression
[e]Renoprotective measures – Used for all patients with any form of LN. Includes anti-proteinuric therapy with blockade of renin-angiotensin-aldosterone system, blood pressure control, sodium restriction, protein restriction, and correction of metabolic abnormalities
[f]Induction therapy – IV or Oral cyclophosphamide or Mycophenolate mofetil for 3–6 months
[g]Maintenance therapy – Azathioprine or Mycophenolate mofetil after induction therapy to achieve and maintain remission; generally continued for at least 1 year after complete remission or indefinitely in partial remission

by immunofluorescence and electron microscopy. Clinically Class II LN shows microscopic hematuria and low-grade proteinuria, but kidney function is usually normal.

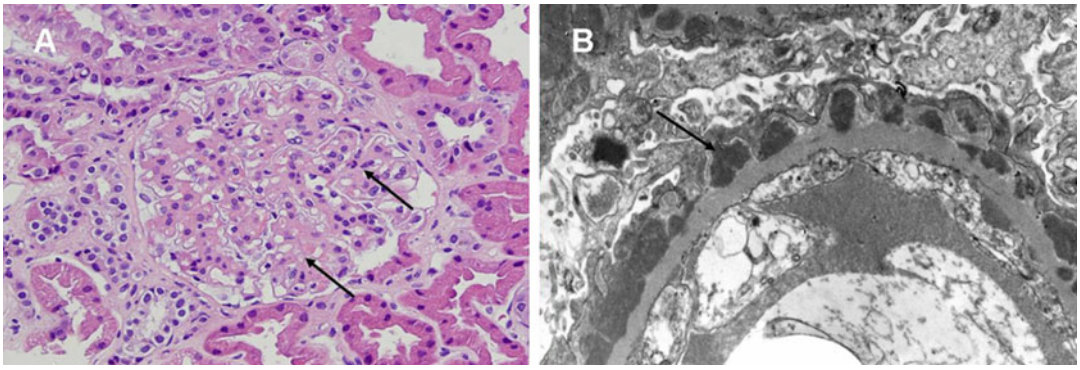
Proliferative Lupus Nephritis (Class III and IV)

Class III LN, also called focal proliferative LN, is characterized by endocapillary proliferation, crescents (Image 3), or both in fewer than 50 % of glomeruli, generally in a segmental distribution. Immunofluorescence and electron microscopy reveal mesangial and glomerular capillary immune complexes that localize to the subendothelial space. Lesions are further characterized as active, chronic, or having both chronic and active elements. Clinical evaluation reveals hematuria, proteinuria that may be in the nephrotic range (over 3.5 g/day), and normal or impaired kidney function.

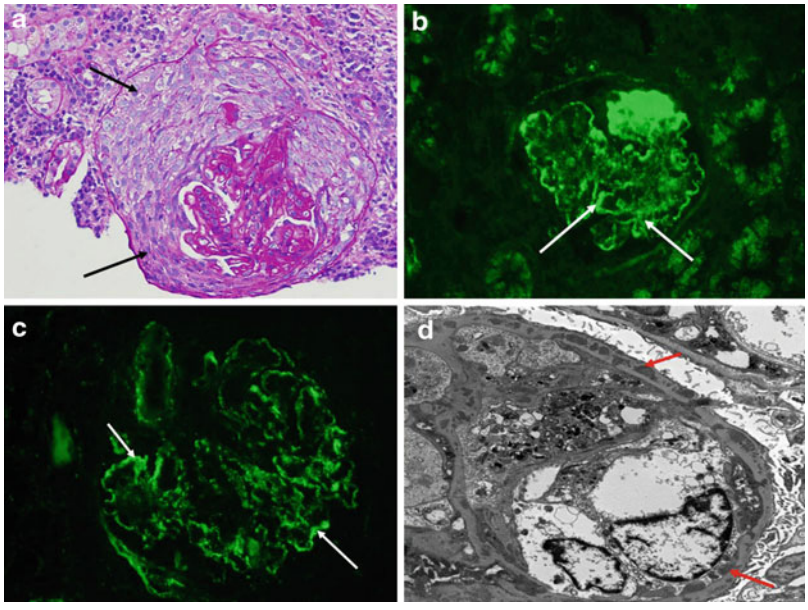
Class IV LN or diffuse proliferative LN is characterized by involvement of more than 50 % of glomeruli, can be global or segmental, and active, chronic, or both. Immunofluorescence and electron microscopy show mesangial and capillary loop immune complex deposits (Image 3). Capillary loop deposits are often large and localize to the subendothelial space. Clinically Class IV LN presents with hematuria, proteinuria that may be in the nephrotic range, and often impaired kidney function.

Membranous LN (Class V)

Pure Class V LN has immune complexes that localize to the mesangium and subepithelial side of the glomerular basement membrane (Image 2). There is no endocapillary hypercellularity. However, Class V LN may occur in combination with Class II, III, or IV LN, and



Lupus Nephritis, Diagnosis and Treatment, Image 2 *Non-proliferative lupus nephritis*: (**a**) Light microscopic image of Class II LN with hematoxylin and eosin stain demonstrating mesangial hypercellularity (*top arrow*) and mesangial matrix expansion (*bottom arrow*). This may also be seen in Class V LN. (**b**) Electron micrograph image of Class V LN with only subepithelial deposits (*arrow*) with classic "humps"



Lupus Nephritis, Diagnosis and Treatment, Image 3 *Proliferative lupus nephritis*: (**a**) Light microscopic image demonstrating cellular crescents (*arrows*). (**b**) Immunofluorescence with IgG staining in mesangium (*right arrow*) and along the basement membrane (*left arrow*). (**c**) Immunofluorescence with C1Q along the basement membrane (*arrows*). (**d**) Electron microscopy with immune complex deposition in the subendothelial space (*bottom arrow*). Intramembranous deposits are also present (*top arrow*)

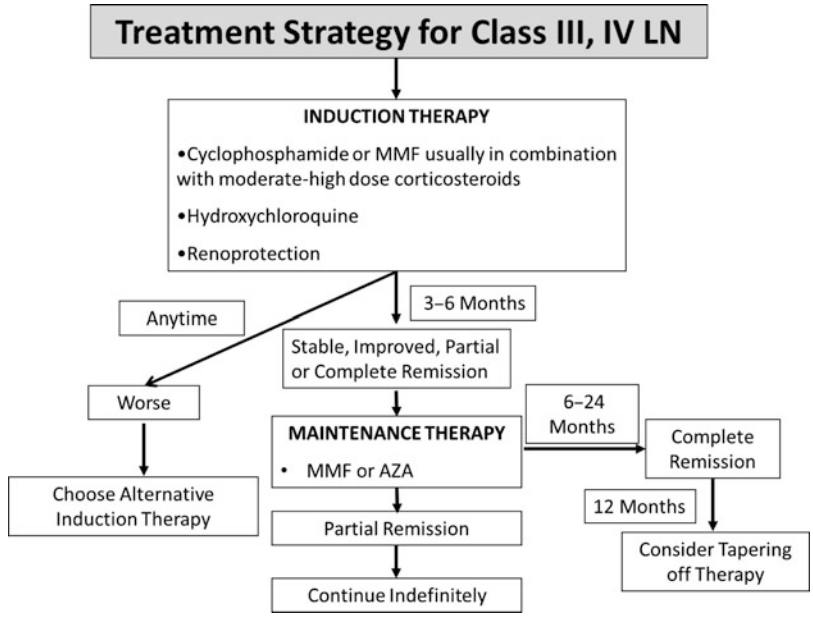
proliferative changes may become the dominant lesions. Clinically Class V demonstrates high-grade proteinuria that is often in nephrotic range, but usually does not present with impaired kidney function, unless associated with one of the proliferative forms of LN.

Advanced Sclerosing LN (Class VI)

Class VI LN is an end-stage category in which over 90 % of glomeruli are globally sclerosed without residual activity. Immunofluorescence and electron microscopy may still show glomerular immune complexes in non-sclerotic glomeruli. These patients typically have advanced chronic kidney disease and ultimately develop end-stage renal disease.

Tubulointerstitial Changes in LN

The presence of tubulointerstitial inflammation is common in LN and typically occurs with



Lupus Nephritis, Diagnosis and Treatment, Fig. 1 Treatment strategy for proliferative lupus nephritis. *MMF* mycophenolate mofetil, *AZA* azathioprine

glomerular disease. The severity of tubulointerstitial involvement is the best marker of renal prognosis (Yu et al. 2010). Interstitial inflammatory cell infiltrates are most common in proliferative forms of LN. If tubular injury progresses, then tubular atrophy and interstitial fibrosis will occur and progressive chronic injury will ensue.

Treatment of Lupus Nephritis

The treatment of LN depends on the type of injury found on kidney biopsy. Classes I and II are typically managed conservatively with emphasis on treating extra-renal symptoms with corticosteroids and/or immunosuppression as indicted. Classes III and IV are often active and aggressive, and are treated with therapies that are designed to quickly "turn off" the disordered immunologic milieu associated with LN. In contrast, if only chronic changes are found on biopsy (e.g., Class VI), the treatment strategy shifts from aggressive immunosuppression to kidney protective measures that will delay progression of kidney disease toward end-stage. These renoprotective therapies are discussed in detail elsewhere in this Encyclopedia, in the entry on "▶ Proteinuric Kidney Diseases: Importance of Blood Pressure Control." Additionally, all LN patients should receive the anti-malarial hydroxychloroquine unless contraindicated. Hydroxychloroquine may protect against vascular thrombosis, chronic kidney disease, renal flares, ESRD, and has a favorable impact on lipid profiles (Tang et al. 2012).

Proliferative LN

Proliferative LN (Class III or IV) is typically an aggressive disease that requires aggressive therapy. The current strategy for treatment is shown in Fig. 1. Treatment is divided into an induction phase and a maintenance phase. During induction, patients are usually treated with one of several cyclophosphamide-based regimens, or a cyclophosphamide-free regimen using mycophenolate mofetil (MMF). Corticosteroids are used with both cyclophosphamide and MMF, most often starting at moderate to high dose, with a taper over several weeks to months. In very severe cases, high-dose intravenous corticosteroids can be used briefly at the beginning of therapy. The duration of induction is typically

6 months for MMF and traditional monthly intravenous pulse cyclophosphamide, 2–4 months for oral cyclophosphamide, or 3 months for low-dose intravenous cyclophosphamide. While induction implies remission, LN does not usually completely remit within 6 months. Thus, treatment for proliferative LN is continued in a maintenance phase, during which the intensity of immunosuppression is reduced to limit toxicity. The two most commonly used medications for maintenance are MMF (in a lower dose than for induction) and azathioprine (AZA).

Cyclophosphamide is a cytotoxic agent that nonspecifically depletes all bone marrow cell lines. MMF and AZA are antimetabolites that prevent B and T cell proliferation. The major complications associated with cyclophosphamide are infertility, future malignancy, and infection. To reduce malignancy risk, the cumulative life time exposure to cyclophosphamide should be <36 g (Faurschou et al. 2008). The most common complications associated with MMF include infection and gastrointestinal complaints such as abdominal pain, nausea, and diarrhea. AZA may also induce bone marrow suppression.

The evolution of the treatment of proliferative LN is beyond the scope of this entry, but demonstrates an evidence-based approach using a foundation of data obtained from experimental models (Austin et al. 1986; Boumpas et al. 1992; Gourley et al. 1996; Contreras et al. 2004; Faurschou et al. 2008; Appel et al. 2009; Grootscholten et al. 2006; Houssiau et al. 2010; Dooley et al. 2011). The goal of treatment was initially to improve mortality of LN, followed by prevention of end-stage kidney disease requiring renal replacement therapy, and more recently, the goal has been to achieve these results with fewer adverse effects. This has prompted the newer low-dose cyclophosphamide and cyclophosphamide-free regimens. The evolution of treatment is not over, and the development and testing of biologic agents that are less toxic and more specifically target immune mediators involved in the pathogenesis of LN are active areas of research.

Membranous LN

Membranous LN (Class V) is a non-proliferative glomerulopathy found in 8–20 % of LN patients (Donadio et al. 1977). It is slowly progressive, but 20 % of patients develop chronic kidney disease, and 8–12 % reach end-stage kidney disease over several years (Sloan et al. 1996). Class V LN with heavy proteinuria therefore requires immunosuppressive treatment, and the general approach to therapy is outlined in Fig. 2 (Austin et al. 2009; Appel et al. 2009).

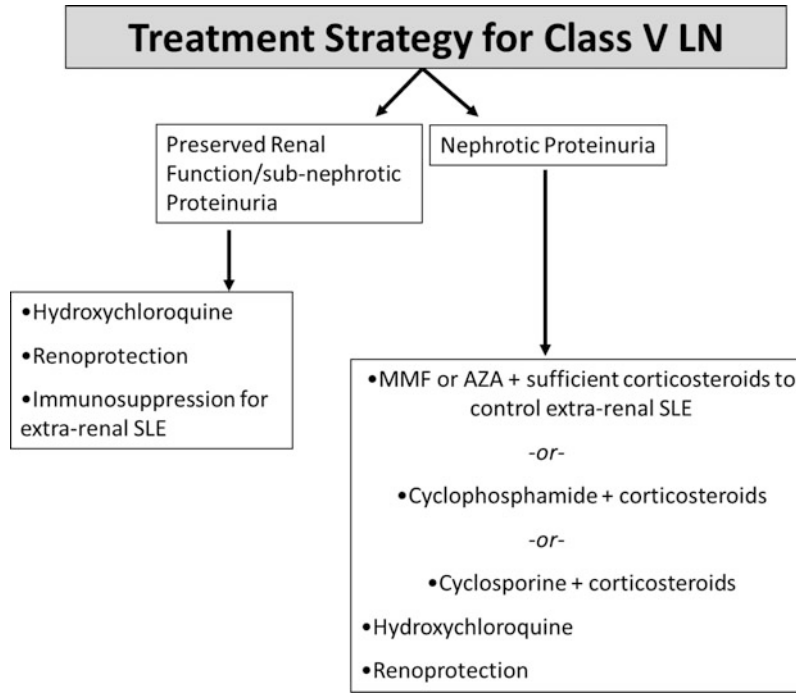
Renal Relapse and Resistant Therapy

LN is a relapsing disease. Almost half of the patients who achieve remission (complete or partial) will experience a renal flare. Flare occurs within a median of 36 months in complete remitters and 18 months in partial remitters (Illei et al. 2002). Renal flare is commonly defined as increase in serum creatinine by ≥25 % and/or an increase in proteinuria above 1 g/day in patients who have completely responded, or a doubling of proteinuria in partial responders. Non-LN causes of an increase in creatinine (medications, infection, dehydration) or proteinuria (excessive salt intake) must be excluded.

There is no consensus definition for resistant LN, but the diagnosis should be considered in patients who have not responded to traditional induction therapy. If one induction regimen fails, an alternative induction agent is typically tried (Fig. 1). If this also fails, a diagnosis of resistant LN can be made. A repeat biopsy may be beneficial to confirm ongoing active disease. Rescue therapies such as rituximab and calcineurin inhibitors have shown some success in small, retrospective trials and may be considered for resistant disease (Vigna-Perez et al. 2006; Cortes-Hernandez et al. 2010).

Anti-phospholipid Syndrome (APS) in SLE

APS is the most common clotting disorder affecting the kidneys in SLE. The incidence of APS in SLE is 30 % and often occurs in



Lupus Nephritis, Diagnosis and Treatment, Fig. 2 Treatment strategy for class V lupus nephritis

conjunction with LN. Lupus anticoagulant is present in 30–50 % of cases and anti-cardiolipin antibodies in 72–95 % of patients, but up to 15 % had neither (Love and Santoro 1990; Daugas et al. 2002). APS describes renal injury due to thrombotic microangiopathy confirmed by renal biopsy. APS is treated with chronic anticoagulation plus hydroxychloroquine. It is non-inflammatory, so immunosuppressive agents are not indicated. Diagnosis of renal APS is imperative as it may lead to CKD/ESRD if not recognized and treated.

Conclusion

LN is a major complication of SLE and is associated with poor outcomes if not recognized early and treated aggressively. Histologic classification is based on ISN/RPS 2003 criteria and proliferative forms of LN require aggressive immunosuppression. Induction therapy with cyclophosphamide or MMF should be followed by maintenance therapy to prevent relapse and progression of CKD. LN relapse rates remain high and current therapies, while effective, are suboptimal, nonspecific, and have significant toxicity. New, more specifically targeted therapies are currently being evaluated to improve response rates and long-term outcomes in LN.

Lymphocytes in Atherosclerosis

Daniel F. J. Ketelhuth and Göran K. Hansson
Department of Medicine, Experimental Cardiovascular Research Unit, Center for Molecular Medicine, Karolinska University Hospital, Stockholm, Sweden

Synonyms

Atherosclerosis; Atherothrombosis; B lymphocytes; Cardiovascular disease; Coronary artery disease; Lymphocytes; Stroke; T lymphocytes

Definition

Atherosclerosis is a chronic inflammatory disease characterized by the formation of an atherosclerotic plaque or lesion (also called atheroma) in the intima of the artery wall (Crawford et al. 2010). The atheroma is a complex tissue composed of lipids and lipoproteins, infiltrating macrophages and T cells and areas of necrosis and fibrosis. T cells as well as macrophages are found in all stages of disease. Less common B lymphocytes can also be found in the vessel wall and are prevalent in the connective tissue surrounding advanced atheroma, where tertiary lymphoid organs may form. Together, T and B lymphocytes, as the representatives of the adaptive immune system, have been proposed as key modulators of different immunopathogenetic mechanisms on atherosclerosis, e.g., the development of an unstable versus a stable plaque phenotype.

The pathogenic role of these cells has largely been studied in mouse models of human disease. In fact, gene-targeted mice carrying defects in cholesterol metabolism not only develop hypercholesterolemia but also atherosclerosis that is rather similar to the human disease. This has permitted detailed studies of disease mechanisms. Findings made in such models systems obviously require validation in human biobanks, clinical studies, cell culture, and epidemiological investigations (Libby et al. 2011).

Lymphocytes in the Atherosclerotic Lesion

In the advanced human plaque, T cells constitute approximately 10 % of all cells. Around 70 % of these T lymphocytes are $CD4^+$; the remaining ones being largely $CD8^+$ cells, $CD4^+$ lymphocytes can often be found in clusters, suggesting clonal expansion (Jonasson et al. 1986).

Most $CD4^+$ T lymphocytes in the atheroma are of the T helper (Th) 1 subtype and constitute a major source of the pro-atherogenic cytokines interferon gamma (IFNγ) and tumor necrosis factor (TNF), both which have multiple proinflammatory and metabolic actions. However, Th2 cells and/or their signature cytokines have also been identified in the plaque. To a lesser extent, other T lymphocytes are present in the atheroma, including the regulatory T cells (Treg), Th17 cells, and their associated cytokine IL-17, TCR$\gamma\delta^+$ T lymphocytes, and NKT cells (Ketelhuth and Hansson 2011).

Although the immune-mediated reactions in the plaque have been considered to be primarily mediated by macrophages and T lymphocytes, B lymphocytes are also found in human and animal vessel walls, and they accumulate in the periadventitial connective tissue surrounding the atherosclerotic artery. At this site, tertiary lymphoid organs may form, with germinal centers containing B cells in different stages of differentiation to plasma cells, follicular dendritic cells, T cells, macrophages, and conventional dendritic cells (Grabner et al. 2009).

Impact of the Lack of Lymphocytes in Atherosclerosis

The role of lymphocytes in atherosclerosis has been experimentally addressed using immunodeficient mice lacking T and B cells that also

suffered from hypercholesterolemia due to targeted deletions in the *ApoE* or *Ldlr* gene (Daugherty et al. 1997; Song et al. 2001). Such studies showed that lack of adaptive immunity, with an absence of mature T and B cells, led to substantially reduced formation of atherosclerotic lesions. For instance, lesions were reduced by 70 % in *Scid/Scid* x *ApoE*$^{-/-}$ mice (Reardon et al. 2001). Altogether, these data established that although small lesions can develop in the absence of adaptive immunity, T and B lymphocytes play an important role in plaque formation.

Role of Different T Lymphocytes Subsets in Atherosclerosis

The advanced human atherosclerotic plaque contains T cells producing IL-2, IFNγ, and TGF-β (Frostegard et al. 1999). Although TCR (T cell receptor) $\alpha\beta^{+}CD4^{+}$ cells are by far the most frequent ones, $TCR\gamma\delta^{+}$ cells, $CD8^{+}$ T cells, and NKT cells (natural killer T cells) are also detected. Lack of all $CD4^{+}$ T lymphocytes in mice substantially reduces atheroma formation (Zhou et al. 2005). Consequently, adoptive transfer of purified $CD4^{+}$ T lymphocytes from atherosclerotic mice to immunodeficient mice (*ApoE*$^{-/-}$, *scid/scid*) accelerates lesion progression mirrored by increased secretion of IFNγ (Zhou et al. 2000).

The role of Th1 lymphocytes in atheroma formation has been extensively studied. For instance, deletion of the Th1 transcription factor T-bet or deficiency in the Th1 signature cytokine IFNγ leads to reduced plaque size in hypercholesterolemic mice. Abrogation of the action of the anti-inflammatory cytokine TGF-β on T lymphocytes in *ApoE*$^{-/-}$ mice exacerbates Th1 responses, leading to a substantial increase in disease. The role of Th2 lymphocytes in atheroma is not yet very clear. Considered first to be protective against atherosclerosis, the role of Th2 lymphocytes in disease development is controversial. Deficiency in IL-4, the signature Th2 cytokine, leads to less severe disease, implying a pro-atherogenic role of these cells. However, when another Th2 cytokine, IL-5, was targeted in *Ldlr*$^{-/-}$ mice, a protective function was suggested (Hansson and Hermansson 2011; Ketelhuth and Hansson 2011).

Considered to be an effector cell in the context of different autoimmune diseases, i.e., multiple sclerosis, Th17 lymphocytes have been recently evaluated in the context of atherosclerosis. While lack of the Th17 signature cytokine IL-17A or its receptor has been shown to confer protection against atherosclerosis, administration of a recombinant IL-17 limited early lesion development in Ldlr$^{-/-}$ mice. Thus, as for Th2 lymphocytes, further investigations will be necessary to elucidate the role of the Th17 cell subset in atherosclerosis (Ketelhuth and Hansson 2011).

Analysis of T lymphocyte subsets in peripheral blood of patients suffering from atherosclerotic cardiovascular disease showed the expansion of an unusual subset of T lymphocyte, characterized by the lack of CD28 and therefore named $CD4^{+}CD28^{null}$ T lymphocytes. Similarly to Th1 lymphocytes, these cells are characterized by the secretion of high levels of IFNγ and TNF and have been therefore suggested to participate in atheroma development and plaque instability. $CD4^{+}CD28^{null}$ T lymphocytes are expanded in patients with unstable angina and uncommon in patients with stable angina, suggesting also a role in the pathophysiology of atherothrombosis. Unfortunately, $CD4^{+}CD28^{null}$ lymphocytes do not exist in mice limiting research options (Ketelhuth and Hansson 2011).

While in general the response of T lymphocytes is considered pro-atherogenic, the regulatory subsets, i.e., Tregs, are suggested to limit inflammation and plaque formation. Different studies have shown that different subpopulations of Tregs can exert anti-inflammatory functions through the secretion of the cytokines TGF-β and IL-10. In bone marrow transplantation experiments, immunodeficient mice reconstituted with bone marrow deficient in Treg developed significantly increased plaque size (Ait-Oufella et al. 2006). In line with this, defective TGF-β or IL-10 signaling led to

substantially accelerated atherosclerosis (Andersson et al. 2010; Ketelhuth and Hansson 2011).

The role of $CD8^+$ T lymphocytes or CTLs (cytotoxic T lymphocytes) has been in part addressed in the context of atherosclerosis. $CD8^{-/-}$ x $ApoE^{-/-}$ double knockout mice show no major consequences on atheroma development (Elhage et al. 2004). However, the concomitant increase in lesion size and number of $CD8^+$ T lymphocytes in plaques after stimulation with a $CD8^+$ T lymphocyte agonist antibody (Olofsson et al. 2008), anti-CD137, suggests that these cells may be involved in the pathogenesis of this disease.

Role of B Cells in Atherosclerosis

As well as for T lymphocytes, the role of B lymphocytes in atherosclerosis has been studied using different animal models. Reconstitution of irradiated $Ldlr^{-/-}$ using B lymphocyte-deficient bone marrow leads to plaque size increase. Similarly, elimination of a large B lymphocyte population by splenectomy of $ApoE^{-/-}$ mice aggravates atherosclerosis. Interestingly, the latter phenotype can be rescued by adoptive transfer of B lymphocytes (Caligiuri et al. 2002). In this context, B1a lymphocytes have been implicated as the atheroprotective B lymphocyte population. Data suggest that natural IgM secreted by these lymphocytes offers protection by depositing IgM in atherosclerotic lesions, which reduces the necrotic cores of lesions (Kyaw et al. 2011a). Together, these observations suggest a protective role for these cells. However, this concept has been challenged recently. In 2010, two independent studies showed that the depletion of B2 lymphocytes using antibodies to CD20, a glycosylated phosphoprotein expressed on the surface of all B lymphocytes, protected $ApoE^{-/-}$and $Ldlr^{-/-}$ animals against atherosclerosis (Kyaw et al. 2011b).

B lymphocytes can differentiate into plasma cells and secrete antibodies. Antibodies, both IgM and IgG, are also present within atherosclerotic plaques at all stages of lesions development (van Leeuwen et al. 2009). However, if antibodies play a pro- or anti-atherosclerotic role or if they are simply biomarkers of different stages of disease remains unclear.

Proteins Secreted by Lymphocytes Influencing Atherosclerosis

Soluble mediators such as cytokines and antibodies are common soluble factors released by T and B lymphocytes which can modulate atherosclerotic plaque formation, development, and stability. Table 1 illustrates some of the main soluble factors, target cells in the vessel wall, and their potential effects in atherosclerosis.

Antigens Recognized by Lymphocytes in Atherosclerosis

Several autoantigens as well as microbial molecules have been proposed to activate T and B lymphocytes in the atherosclerotic plaque and/or lymphoid organs. LDL is considered to be the major self-antigen implicated in atherogenesis, and it has been suggested that oxidation of the LDL particle breaks immunological tolerance. Human and animal's atherosclerotic plaques present high concentrations of LDL particles. However, T lymphocytes can recognize motifs on native LDL particles, and antibodies are formed to epitopes on native as well as oxidized LDL (Andersson et al. 2010; Ketelhuth and Hansson 2011). Several immunization studies employing LDL preparations have shown atheroprotective effects that have encouraged further research aimed at developing anti-atherosclerotic vaccines. Irrespective of the controversial role of oxidation, recognition of LDL appears to play an important role in the autoimmune process of atherosclerosis.

Also extensively studied, a family of proteins found in mammals and microbes, the heat shock proteins (HSP), has been implicated in atherogenesis. Studies have shown that adaptive immune responses to HSP60 can affect

Lymphocytes in Atherosclerosis, Table 1 Soluble factors released by T and B lymphocytes acting in the plaque

For more detailed information about the different T cell subsets involved in atherosclerosis, read the following references: (Song et al. 2001; van Leeuwen et al. 2009; Andersson et al. 2010; Crawford et al. 2010; Hansson and Hermansson 2011; Ketelhuth and Hansson 2011; Kyaw et al. 2011b; Libby et al. 2011).

atherosclerosis (Hansson and Hermansson 2011). Further, other antigens found in the plaque, e.g., beta-2 glycoprotein I (β2GPI), extracellular matrix-derived antigens, and glycation end products (AGE), have been suggested to trigger lymphocyte responses.

Conclusion

Substantial advance has been made in the understanding of the adaptive immune response in atherosclerosis with the discovery of the critical roles of T and B lymphocytes and the complex interactions between these and other immune cell populations.

During the course of plaque formation, the recognition of specific epitopes by lymphocytes in the plaque or in the periphery can critically modulate inflammation in the vessel wall, i.e., pro-atherogenic effects, stimulate (1) endothelial cells to overexpress adhesion molecules, (2) macrophages to release inflammatory cytokines and metalloproteases, and (3) destabilization of the fibrous cup, or anti-atherogenic effects, (1) secretion of anti-inflammatory cytokines, (2) generation of protective antibodies, and (3) thickening of the fibrous cap. Hence, an increasing body of evidence indicates that cellular immunity mediated in special by Th1, Th17, and NKT lymphocytes have pro-atherogenic roles that are counteracted by the protective responses of Tregs and potentially some classes of B cells, e.g., B-1 cells.

Future therapies should aim at reducing the response of pro-atherogenic lymphocytes and favor the expansion of the anti-atherogenic types. Because of the specificity of T and B lymphocytes to their antigens, targeting these cells or their recognizable epitopes may lead to the development of new classes of therapies. Indeed, very promising results arise from the experimental researches. Future work should address whether such responses in human atherosclerosis are similar to that of experimental models and whether similar immunomodulatory strategies for the treatment or prevention of pro-atherosclerotic responses will affect cardiovascular events in humans.

Atherosclerosis and macrophages

Definition

Vascular inflammation and oxidative stress mediated by macrophages play a key role in the development and progression of atherosclerotic disease. Both of these processes accentuate a proinflammatory milieu which propagates atherosclerosis.

Introduction

Atherosclerotic vascular disease is the leading cause of cardiovascular disease (CVD) and stroke, the two major causes of death in the United States. In response to physiologic stimuli, the vasculature responds dynamically to regulate arterial vascular tone and maintains endothelial integrity and dynamics by producing vasodilators and vasoconstrictors. Risk factors such as diabetes, smoking, hypercholesterolemia, autoimmune disease, and hypertension interfere with this response, promoting macrophage activation, endothelial dysfunction, and atherosclerosis. Recent evidence suggests a central role for vascular inflammation mediated by macrophages and resultant oxidative stress in atherosclerosis and endothelial dysfunction. These studies support the hypothesis that unique oxidants generated in microvasculature and inflammatory cells promote atherosclerosis by lipoprotein oxidation and impairment of macrophage function. Therapies interrupting these oxidative pathways in vascular tissue might help prevent cardiovascular disease.

According to the recent report by the National Vital Statistics, in 2008 over 616,000 people died of heart disease, which translates to roughly 1 in 4 Americans (Minino et al. 2011). CVD remains the leading cause of death for both men and women. In 2008, 405,309 people died from coronary heart disease (CHD). The costs due to health-care services, medications, and loss of productivity for CHD alone have ballooned to an estimated $108.9 billion in 2010 and expected to grow in the future (Heidenreich et al. 2011). Additional manifestations of atherosclerosis include peripheral vascular disease and cerebrovascular events which further increase morbidity, mortality, and economic impact of this process. Therefore, understanding molecular mechanisms of initiation and progression of atherosclerosis has been a prime focus of research of several investigators.

Some conditions like obesity, diabetes, autoimmune diseases, and kidney disease magnify the burden of atherosclerotic disease by accentuating oxidant stress. In this review, the pivotal role of macrophages and oxidative stress in atherosclerosis and the link between the two processes will be discussed. The potential relationship of lipoproteins and reactive carbonyls to macrophage-derived oxidant-generating pathways and the rationale for therapies aimed at decreasing oxidative stress are emphasized. Identifying specific pathways of reactive oxidant generation in vascular tissue will ultimately lead to design of drugs to interrupt this process and prevent atherosclerotic complications.

Role of Macrophages in Atherosclerosis

Atherosclerosis is a chronic inflammatory disease characterized by infiltration of lipids and inflammatory cells, such as monocyte-derived macrophages and T-lymphocytes into the artery wall (Ross 1999). Macrophages were the first inflammatory cells to be associated with atherosclerosis. Macrophages produce proinflammatory cytokines, participate in lipid retention and vascular cell remodeling, and express pattern-recognition receptors (PRR), including scavenger receptors (SR) and toll-like receptors (TLRs) that connect the innate and adaptive immune response during atherosclerosis. Macrophages are linked to all stages of atherosclerosis including lesion initiation, propagation of atheroma, and rupture and acute myocardial events (Moore and Tabas 2011). Macrophages can produce reactive oxidants that can damage proteins and lipids and accentuate atherosclerosis (Fig. 1).

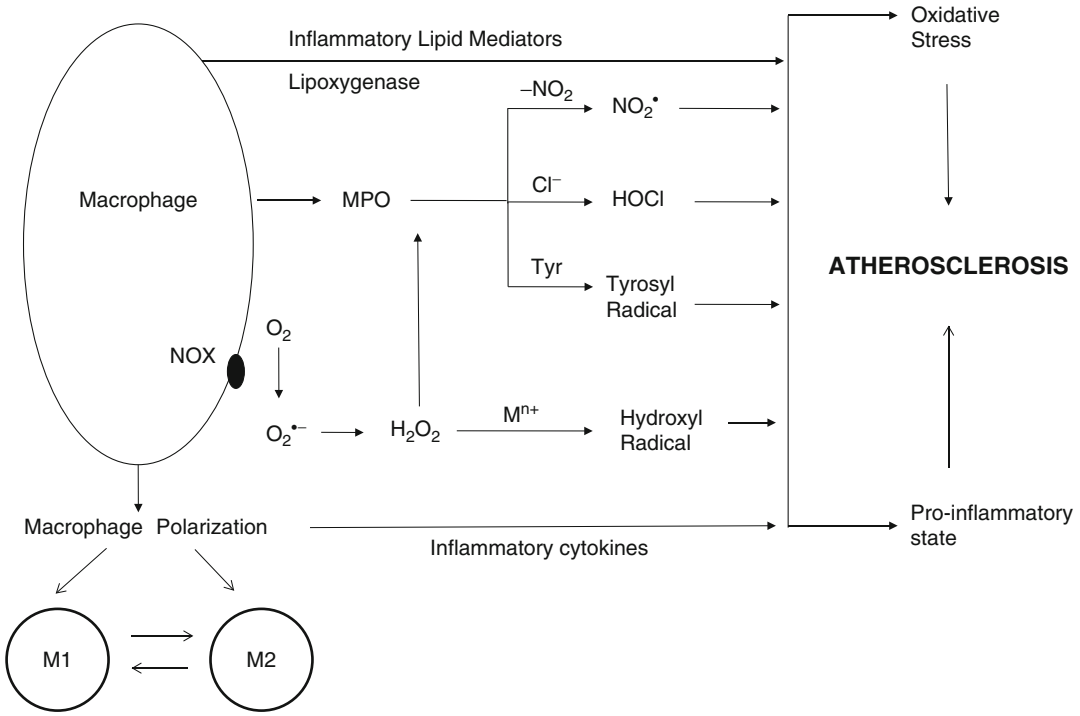
Macrophage Polarization in Atheroma

Mac-1+ cells are the resident macrophages in the arterial wall and express CD11b, CD68, and F4/80. *Classically activated M1* macrophages, driven by *Th1* cytokines (interferon gamma (IFN-γ) and tumor necrosis factor (TNF)) or by lipopolysaccharide (LPS), produce high levels of interleukins 12 and 23 (IL-12 and IL-23) and low levels of interleukin-10 (IL-10) and secrete proinflammatory cytokines. *The alternatively activated protective M2* macrophages are driven by *Th2* cytokines. M1 and M2 macrophages play complimentary but opposing roles during inflammation restraining the process. Indeed, both are present in atherosclerotic lesions, and the balance between the two types determines the degree of vascular inflammation. Flow cytometric analysis of the aortic lesions of low-density lipoprotein (LDL) receptor-deficient mice fed an atherogenic diet for 30 weeks revealed that 39 % of the aortic macrophages express M1 marker CD86, 21 % expressed M2 marker CD206, 45 % expressed Mox marker heme oxygenase 2, and 10 % co-expressed CD86 (Kadl et al. 2010). Upon entry in to the subendothelial space, the macrophages express high levels of scavenger receptor A (SR-A), lipoxygenase 1 (LOX1), chemokine (C-X-C motif) ligand 16 (CXCL16), and CD36.

Endoplasmic reticulum (ER) stress is a key regulator to the macrophage differentiation and cholesterol deposition. When macrophages from diabetics were exposed to oxidized LDL (OxLDL) after either alternative activation into M2 or classic activation into M1, the M2 macrophages formed more foam cells and expressed the scavenger receptors CD36 and SR-A1. ER stress was necessary to generate M2 macrophages through c-Jun N-terminal kinases (JNK) activation and increased peroxisome proliferator-activated receptor (PPAR γ) expression. Absence of SR signaling decreased ER stress and prevented M2 macrophage formation. Furthermore, suppression of ER stress decreased M2 formation and foam cell formation by increasing the high-density lipoprotein (HDL) and Apo lipoprotein A1 (Apo A1)-mediated efflux (Oh et al. 2012).

Oxidized LDL and Atherosclerosis

Although it is well known that elevated levels of LDL greatly increase the risk for atherosclerosis, in vitro studies suggest that LDL by itself is not atherogenic but needs to be modified to initiate atherosclerotic disease. This conclusion led to the "oxidation hypothesis," which proposed that LDL must be oxidatively modified to become



Macrophages, Oxidative Stress, and Atherosclerosis, Fig. 1 *Macrophages-derived oxidants and inflammatory stimuli promote atherosclerosis*. Pathologic conditions result in increased superoxide ($O_2^{\bullet -}$) by macrophages through NADPH oxidase (NOX). $O_2^{\bullet -}$ can dismutate to yield hydrogen peroxide (H_2O_2). H_2O_2 can react with redox-active metal ions (M^{n+}) to form hydroxyl radical or with phagocyte-derived myeloperoxidase (MPO) to nitrate (nitrogen dioxide; $NO_2^{\bullet}$), chlorinate (hypochlorous acid; HOCl), or cross-link (tyrosyl radical) proteins. Macrophages can also promote a proinflammatory milieu by generation of a multitude of cytokines which can overwhelm endogenous anti-inflammatory antioxidant defenses resulting in atherosclerosis

atherogenic. Many lines of evidence support this hypothesis. OxLDL is taken up by SR-A and CD 36 of macrophages, which then become lipid-laden foam cells, the pathologic hallmark of early atherosclerotic lesions. OxLDL has been isolated from human and animal atherosclerotic tissue, and immunohistochemical studies have detected oxidized lipids in atherosclerotic lesions. All major cell types involved in atherosclerosis – smooth muscle cells, endothelial cells, and macrophages – produce reactive oxidants that can oxidize LDL in vitro. Moreover, OxLDL attracts mononuclear cells and stimulates the production of monocyte chemoattractant protein-1 (MCP-1) and other inflammatory cytokines such as macrophage colony-stimulating factor (M-CSF), leading to the conversion of fatty streaks to more advanced complex lesions as smooth muscle cells migrate from the media into the subendothelial space. OxLDL may also stimulate smooth cells to synthesize extracellular matrix and activate a signaling cascade by interacting with the lectin-like OxLDL receptor. Finally, several structurally unrelated lipid-soluble antioxidants that inhibit LDL oxidation in vitro also inhibit atherosclerosis in hypercholesterolemic animals (reviewed in Vivekanadan-Giri et al. 2008).

There is some controversy about the function of scavenger receptors in atherogenesis. Early studies showed that SR plays a pro-atherogenic role in atherosclerosis. Crossing $CD36^{-/-}$ null mice on apolipoprotein E (ApoE)-deficient background showed protection from atherosclerosis (Febbraio et al. 2000). In a separate study, $ApoE^{-/-}$ mice lacking SR-A or CD36 showed

increased aortic sinus lesion areas with abundant foam cells, suggesting alternative lipid uptake mechanisms and a possible athero-protective role for SR-A and CD36 (Moore et al. 2005). $ApoE^{-/-}$ mice with a combined deficiency of CD36 and SR-A I/II showed no further reduction of atherosclerosis compared with $Cd36^{-/-}ApoE^{-/-}$ mice (Kuchibhotla et al. 2008).

High-Density Lipoproteins and Reverse Cholesterol Transport

HDL, a lipid-protein complex, has long been recognized for its inverse association with CVD, largely attributed to its ability to remove excess cholesterol from arterial wall macrophages, a process known as reverse cholesterol transport (RCT; Tall et al. 2008). Once internalized, free cholesterol trafficking to the cell membrane may play a role in lesion regression, and deficiency in this pathway in certain macrophages might be the reason for lesion progression. Once at the membrane, the ABCA1 (ATP-binding cassette protein A1)- and ABCG1 (ATP-binding cassette G1)-mediated transfer to Apo A1 and HDL respectively occurs (Tall et al. 2008). Passive diffusion occurs as well.

Along with its important role in mediating RCT, HDL has multiple endothelial actions that also afford cardiovascular protection, including antioxidative, anti-inflammatory, antiapoptotic, and antithrombotic activities. Further, HDL activates endothelial nitric oxide (NO) synthase (Besler et al. 2011), enhances endothelial progenitor cell-mediated endothelium repair, and stimulates endothelial cell proliferation and migration. Additionally, increasing the levels of HDL by drugs, gene therapy, or direct infusion has been shown to improve outcomes in animal models and in patients with CVD.

Role of Macrophages in Thinning of Fibrous Cap/Plaque Rupture

The older and mature plaques rupture and ulcerate at the shoulder regions enriched with macrophages and macrophage-derived foam cells. Macrophages trigger smooth muscle cell apoptosis by activating apoptotic pathways and by secreting TNF-α and NO (Boyle et al. 2003). Macrophages also decrease transforming growth factor (TGF) β production causing decrease in collagen production (Fadok et al. 1998). With prolonged ER stress, the unfolded protein response (UPR) effector C/EBP homologous protein (CHOP) can trigger UPR. Macrophages secrete metalloproteinases (MMP) which can lead to thinning of the fibrous cap due to their protease activity and may predispose to the unstable plaque and rupture (Tabas 2010).

Macrophages produce tissue plasminogen activator (TPA) and plasminogen activator inhibitor type 1(PAI-1) for control of local fibrinolysis. PAI-1 and alpha 2-antiplasmin are elevated in atherosclerotic plaques while TPA is low, which may favor thrombosis and predispose to acute MI (Schwartz et al. 1988).

Diabetes Promotes Inflammatory Macrophage Phenotype

Recent evidence points out to direct effects of diabetes on atherosclerotic lesion cells, such as macrophages, which play an additional important role in accounting for increased atherosclerotic risk in diabetes. Thus, the increased macrophage expression of inflammatory mediators associated with diabetes can be mimicked by elevated glucose concentrations in vitro (Wen et al. 2006). In addition, fatty acids exert inflammatory effects in macrophages, which could contribute to inflammation in the setting of diabetes-accelerated atherosclerosis and possibly other complications (Hummasti and Hotamisligil 2010). After entering the cell, fatty acids are thio-esterified into their acyl-CoA derivatives catalyzed by long-chain acyl-CoA synthetases (ACSLs). Kanter et al. (2012) demonstrated that monocytes from humans and mice with type 1 diabetes also exhibit increased ACSL1. Furthermore, myeloid-selective deletion of ACSL1 protected monocytes and macrophages from the inflammatory effects of diabetes. Strikingly, myeloid-selective deletion of ACSL1 also prevents accelerated atherosclerosis in diabetic

mice without affecting lesions in nondiabetic mice (Kanter et al. 2012). These observations indicate that ACSL1 plays a critical role by promoting the inflammatory phenotype of macrophages associated with diabetes.

Macrophage Sterol Regulation and Atherosclerosis

Sterol-regulated transcriptional factors liver X receptors (LXR α and β) appear to be anti-atherogenic as mice lacking LXR's have advanced atherosclerosis and LXR agonists decrease atherosclerosis. Transplanting aortic arches from atherosclerotic ApoE-deficient mice with LXR α and LXR β deficiency into wild-type mice resulted in marked regression of atherosclerotic lesions (Feig et al. 2010). The salutary effects of LXR's in part are thought to be due to upregulation of RCT due to increased ABCA1 and ABCG1 activity in macrophages. Activation of PPAR γ can inhibit foam cell formation with and without help from the ABCA1 pathways. PPAR γ activation reduces cholesterol esterification and induces ABCG1 expression. Becker et al. showed that the peritoneal macrophages from chow- versus high-fat-fed LDL receptor-deficient mice differentially expressed cytoskeleton, lipid trafficking, and lipid-binding proteins utilizing mass spectrometry (MS)-based proteomic techniques (Becker et al. 2010). Their analysis revealed a sterol-responsive network that is highly enriched in proteins with known physical interactions and established roles in vesicular transport associated with atherosclerotic phenotypes in mice. Pharmacologic intervention with a statin or rosiglitazone and use of mice deficient in LDL receptor or ApoE implicated the network in atherosclerosis. Biochemical fractionation revealed that most of the sterol-responsive proteins resided in microvesicles, providing a physical basis for the network's functional and biochemical properties. These observations identify a highly integrated network of macrophage proteins whose expression is influenced by environmental, genetic, and pharmacological factors implicated in atherogenesis.

Role of Oxidative Stress in Atherosclerosis

Although oxidative stress has a well-established role in atherosclerosis, its origins and magnitude remain poorly understood. Moreover, it is not known whether oxidative stress is a primary event that occurs early in the disease or whether it represents a secondary phenomenon that merely reflects end-stage tissue damage. This distinction has important clinical relevance. If oxidative stress simply reflects tissue damage, interventions that reduce it may fail to affect the disease process. If oxidative stress promotes tissue injury, therapies that interrupt oxidative pathways early in the disease may prevent complications, and those that act later may slow disease progression.

Pathways for Generating Oxidants

Many pathways oxidize proteins in vitro. However, the specific pathways that promote oxidative stress in atherosclerosis have not been conclusively identified. One reason is that oxidizing intermediates are difficult to detect in vivo because they are short lived and generated at low levels.

Macrophage-Derived Oxidants

(a) *The NADPH pathway*. The major pathway through which macrophages and other phagocytic cells of the innate immune system generate oxidants begins with the cell membrane-bound NADPH oxidase (NOX), which produces superoxide. Superoxide dismutates into hydrogen peroxide which can be used as a substrate for propagating oxidative reactions by free metal ions (hydroxyl radical) or used as substrate by myeloperoxidase (MPO). Superoxide can also react with NO to form the potent oxidant peroxynitrite. Several NOX isoforms are present in the endothelium, and smooth muscle cells are selectively upregulated by pathologic stimuli, which can augment macrophage-derived oxidants. Potential factors

include angiotensin II, endothelin-1, hypercholesterolemia, shear stress, nonesterified fatty acids, hyperglycemia, and growth factors. Angiotensin II may represent a pathophysiologically relevant pathway for stimulating the production of reactive intermediates by artery wall cells because inhibitors of this pathway lower the risk for cardiovascular events. In humans, NOX activity correlates inversely with endothelial function, even after other major risk factors for atherosclerosis, including diabetes and hypercholesterolemia, are taken into account (Guzik et al. 2006).

(b) *The MPO pathway*. The peroxide generated by NOX can be used by another phagocyte enzyme, MPO, to convert chloride ion to hypochlorous acid (HOCl). Oxidation of NO with oxygen yields nitrite (NO_2^-), which MPO converts to nitrogen dioxide radical ($NO_2^{\bullet}$), a potent nitrating intermediate (Gaut et al. 2002). Reactive nitrogen species, including peroxynitrite and $NO_2^{\bullet}$, might contribute to the inflammatory process by nitrating lipoproteins and other biomolecules. Hyperglycemia can activate protein kinase C (PKC) (Ishii et al. 1998), which leads to phagocyte activation, secretion of MPO, and oxidant generation. Nonesterified fatty acids (NEFA) that commonly are overabundant in diabetes can also activate phagocytes in vitro. These changes might enhance the production of superoxide and hydrogen peroxide, which myeloperoxidase converts into more potent cytotoxic oxidants, such as HOCl and $NO_2^{\bullet}$.

MPO is a major source of reactive oxidants in the human vasculature and has been widely implicated in the development of human atherosclerotic lesions. In large epidemiological studies, the level of plasma MPO is a strong independent predictor of CVD (Brennan et al. 2003). Further, MPO has been localized to atherosclerotic plaques, and oxidants produced by MPO activate protease cascades and plaque rupture (Fu et al. 2001). Lipoproteins that have been modified by MPO and HOCl have also been detected in human atherosclerotic lesions (Vivekanadan-Giri et al. 2008). For example, MPO has been linked to LDL oxidation, which triggers the formation of lipid-laden foam cells. Oxidants produced by MPO also activate protease cascades that weaken atherosclerotic plaques, increasing the likelihood of rupture (Fu et al. 2001). Moreover by consuming the NO that relaxes blood vessel walls, MPO may cause vasoconstriction and endothelial dysfunction and reduce anti-inflammatory function (Baldus et al. 2006). MPO is also a source of reactive nitrogen species because it generates nitrotyrosine in vitro and in vivo (Gaut et al. 2002). Expression of human MPO in macrophages accelerated atherosclerosis in mice (McMillen et al. 2005), strongly supporting the hypothesis that the enzyme's ability to produce reactive intermediates promotes vascular disease. Consistent with this potential pro-atherogenic role, certain MPO polymorphisms associate with cardiovascular risk. Vita and colleagues (Vita et al. 2004) examined the relationship between serum MPO levels and endothelial function (measured with flow-mediated and nitroglycerin-mediated dilation of the brachial artery) in 298 subjects with or without CVD. Correlates of vasodilator function included established CVD risk factors, such as age and HDL level, as well as serum MPO level. When the data were stratified into quartiles, MPO levels predicted endothelial dysfunction even after multivariate adjustment.

MPO binds to glycosaminoglycans in vessel walls, where it has been proposed to oxidize endothelium-derived NO and impair endothelial function. Baldus et al. (2006) demonstrated that heparin mobilizes MPO from vascular compartments in humans with and without CVD. Thus, administration of heparin increased plasma levels of MPO. Heparin treatment also improved endothelial NO bioavailability, as monitored by flow-mediated dilation and acetylcholine-induced changes in forearm blood flow. Improved endothelial function correlated with the

extent of heparin-induced MPO release. These observations suggest that MPO represents a mechanism for heparin's anti-inflammatory effects and that it affects vascular NO bioavailability.

(c) *The reactive nitrogen pathway*. Another pathway for generating oxidants involves nitric oxide (NO). NO is produced during inflammation by macrophages, which are early components of atherosclerotic lesions from inducible nitric oxide synthase (iNOS). NO reacts with superoxide ($O_2^{\bullet -}$) to generate peroxynitrite, a potent oxidant that converts tyrosine residues to 3-nitrotyrosine. Thus, 3-nitrotyrosine is a marker for the reactive nitrogen pathway. It has been detected in low-density and high-density lipoproteins (LDL and HDL) isolated from human diabetic atherosclerotic lesions (Pennathur et al. 2004), and plasma nitrotyrosine levels are elevated in patients with CHD (Shishehbor et al. 2003). Because acute hyperglycemia promotes vasodilation in humans, glucose might directly or indirectly enhance NO release and oxidant generation.

Other Oxidant Pathways That Promote Oxidative Stress in the Vascular Wall

There are several sources of non-macrophage-derived oxidants in the artery wall that can propagate oxidative stress in the vascular wall. These include the glycoxidation pathway, which involves glucose-derived oxidants which generate advanced glycosylation end products (AGEs), the mitochondrial electron transport chain, uncoupled endothelial nitric oxide synthase, xanthine oxidase, and non-phagocytic NOX enzymes. These pathways can accentuate oxidative damage in a pro-atherogenic milieu.

Experimental Studies Identifying Pathways of Oxidation in Atherosclerosis

Mass spectrometry (MS) is a powerful approach for detecting biomarkers of oxidative stress in vivo. Antibody-based assays and dihydroethidium fluorescence have been extensively used to study oxidation-specific epitopes and oxidant production in atherosclerosis. These techniques are highly sensitive, and the ability of immunochemical studies to provide anatomical data can localize oxidative events. However, they are nonspecific and, at best, only semiquantitative. In contrast, MS offers a powerful set of analytical tools for quantifying and identifying biomolecules. Isotope dilution gas or liquid chromatography (GC and LC)/MS is a highly sensitive and specific method that is used to quantify oxidation of specific amino acid markers (reviewed in Vivekanandan-Giri et al. 2011). Biomolecules such as oxidized amino acids derived from plasma or tissue are separated by GC or LC and ionized. The *mass-to-charge* ratios of ions derived by fragmenting the ionized, parent compound are determined by MS. Such a spectrum can unequivocally identify a target biomolecule because each compound has a unique fragmentation pattern. The analyte is quantified by adding a stable, isotopically labeled internal standard, which is identical to the target analyte except for the heavy isotope. With certain ionization processes, such as electron capture negative-ion chemical ionization, it is possible to detect and quantify sub-femtomole levels of biomolecules.

Oxidized Amino Acids Serve as Molecular Fingerprints for Specific Oxidation Pathways

To understand the molecular mechanisms that promote oxidative stress in vivo, a chemical approach to define the patterns of oxidation products that are formed by well- characterized oxidant-generating systems in vitro has been employed. Similar patterns in tissue and plasma were identified. Focus was on proteins because aromatic amino acids constituting proteins retain the initial footprint of the reactive intermediate that initiates oxidative damage. In contrast, lipid peroxidation products readily undergo subsequent chain-propagating reactions, which mask the products formed early in the pathway. Moreover, many different oxidizing intermediates give the same spectrum of oxidized lipids, making it difficult to identify specific pathways that trigger lipid oxidation.

Oxidizing intermediates are difficult to detect in vivo because they are short lived and generated

at low levels. To sidestep this problem, acid-stable products of protein oxidation were identified and monitored, both in vitro and in vivo (Bhattacharjee et al. 2001; Pennathur et al. 2001, 2004, 2005). The overall approach is to use isotope dilution MS to accurately identify oxidized amino acids isolated from tissue proteins. These markers, which include *ortho*-tyrosine, *meta*-tyrosine, dityrosine, 3-nitrotyrosine, and 3-chlorotyrosine indicate which biochemical pathway has damaged a protein (reviewed in Vivekanadan-Giri et al. 2008, 2011).

MS Quantitation of Oxidized Amino Acids in Aortic Proteins of Diabetic *Cynomolgus* Monkeys Reveals Localized Oxidative Damage by Hydroxyl Radical in the Artery Wall

To investigate the potential role of localized oxidative stress in diabetic macrovascular disease, *cynomolgus* monkeys that had been hyperglycemic for 6 months due to streptozotocin-induced diabetes were used (Pennathur et al. 2001). Samples from seven controls and eight diabetic *cynomolgus* monkeys were analyzed, sampling three different areas from the thoracic aorta of each animal. Compared with the control samples, the aortic wall proteins from the diabetic animals showed a significant (40 %) increase in *ortho*-tyrosine and a similar (60 %) increase in *meta*-tyrosine. This pattern of oxidized amino acids suggests that a hydroxyl radical-like oxidant promotes aortic damage in this animal model of diabetic vascular disease. To determine whether glucose promotes protein oxidation in vivo, we assessed the relationship between level of glycemic control (measured as serum glycated hemoglobin) and levels of amino acid oxidation products in aortic tissue in control and diabetic *cynomolgus* monkeys. Linear regression analysis demonstrated a strong correlation between levels of both *ortho*-tyrosine and *meta*-tyrosine and glycated hemoglobin ($r^2 = 0.9$ and 0.8, respectively; both $p < 0.001$). Levels of *o*,*o*′-dityrosine and glycated hemoglobin correlated less strongly ($r^2 = 0.3$; $p = 0.07$). In contrast, there was no correlation between levels of 3-nitrotyrosine and glycated hemoglobin. These observations support the hypothesis that glucose promotes the formation of *ortho*-tyrosine and *meta*-tyrosine in the artery wall and suggest that both glucose and other pathways contribute to the generation of *o*,*o*′-dityrosine (Pennathur et al. 2001).

Plasma and Urinary Levels of Oxidized Amino Acids Are Potential Markers for Assessing Oxidative Stress In Vivo

There is increasing evidence that oxidized amino acids in plasma and urine can serve as markers for noninvasive assessment of oxidative stress in vivo. Plasma and urinary levels of these markers are likely to be proportional to the rate of generation and thus can serve as indices of chronic oxidative stress in vivo (Bhattacharjee et al. 2001; Bergt et al. 2004). These observations may be relevant to human pathophysiology. For example, a case–control study demonstrated that systemic levels of protein-bound nitrotyrosine were significantly higher in patients with CVD than in controls with healthy arteries. Moreover, statin therapy lowered levels of oxidation markers in plasma, raising the possibility that these drugs can potentially be antioxidants. Therefore, these markers might serve not only to assess oxidative stress but also to monitor the efficacy of therapy.

HDL Oxidation and Altered HDL Proteome in Atherosclerosis

Oxidized amino acids in plasma lipoproteins are markers of lipoprotein oxidation which are implicated in atherogenesis. Preliminary studies demonstrated that HDL, but not LDL, isolated from plasma of subjects with established CVD contained high levels of 3-chlorotyrosine, a highly specific marker for the myeloperoxidase pathway. The level of 3-chlorotyrosine was 13-fold higher in HDL isolated from plasma of subjects with established CVD than in HDL from plasma of healthy subjects (Bergt et al. 2004). Levels of 3-nitrotyrosine were twice as high in

HDL from plasma of patients with established CVD (Pennathur et al. 2004). Circulating HDL from patients with known CVD has impaired reverse cholesterol transport (Bergt et al. 2004; Pennathur et al. 2004; Shao et al. 2012). HDL isolated from atherosclerotic plaques is bound to MPO and enriched in MPO-derived oxidation products, supporting an important role of MPO in the development of dysfunctional HDL. Proteomic approaches were applied to the composition of HDL isolated from healthy subjects and subjects with CVD. Multiple complement regulatory proteins and a diverse array of distinct serpins with serine-type endopeptidase inhibitor activity were identified. Many acute-phase response proteins were also detected, supporting the proposal that HDL is of central importance in inflammation. MS and biochemical analyses demonstrated that HDL3 from subjects with CVD was selectively enriched in ApoE, raising the possibility that HDL carries a unique cargo of proteins in humans with clinically significant CVD. HDL protein cargo plays a role in regulating the complement system and protecting tissue from proteolysis and contributes to its anti-inflammatory and anti-atherogenic properties (Vaisar et al. 2007). These observations raise the exciting possibility that oxidized HDL and HDL proteome might be a novel marker for clinically significant CVD. Furthermore, it highlights the importance of MPO as a mechanistic cause of atherosclerosis.

Lipoxidation and Atherosclerosis

Lipoxygenases

The LOX enzymes are present in macrophages and are implicated in human atherosclerosis. They are named for the numbered carbon where they oxygenate their polyunsaturated fatty acid (PUFA) substrates (e.g., 12-LOX and 5-LOX). The human LOX enzymes include 5-LOX (which produces leucotrienes), 12-LOX (with platelet-type and leukocyte-type forms), and 15-LOX (which is further separated into the reticulocyte or leukocyte-type, 15-LOX-1). The human leukocyte-type 12-LOX and the human reticulocyte-type 15-LOX-1 can form similar products from common substrates and are often referred to in the literature as 12/15-LOXs (Dobrian et al. 2011).

In humans, 12/15-LOXs act upon arachidonic acid to form a number of important lipid mediators including 12- and 15-hydroperoxyeicosatetraenoic acids (HPETEs), 12- and 15-hydroxyeicosatetraenoic acids (HETEs), and hydroxyoctadecadienoic acids (HODEs) from linoleic acid. These lipid products in addition to oxidizing LDL can have a myriad of proinflammatory functions that can propagate atherosclerosis. While the pro-atherogenic role of the 5-LOX pathway is generally better established in animal models and human studies, the role of the 12- and 15-LOX pathways is not yet clear. Indeed, some 15-LOX metabolites are known to be anti-inflammatory and promote a more anti-inflammatory macrophage phenotype in the vessel wall.

Hyperlipidemia in Concert with Hyperglycemia Stimulates the Proliferation of Macrophages in Atherosclerotic Lesions: Potential Role of Glucose-Oxidized LDL

Macrophage proliferation has been implicated in the progression of atherosclerosis. Recent studies have investigated the effects of hyperglycemia and hyperlipidemia on macrophage proliferation in murine atherosclerotic lesions and isolated primary macrophages (Lamharzi et al. 2004). Glucose promoted lipid and protein oxidation of LDL in vitro (Pennathur et al. 2005). Oxidation of LDL with glucose resulted in a selective increase in protein-bound *ortho*-tyrosine and *meta*-tyrosine. Moreover, glucose-oxidized LDL – but not elevated levels of glucose alone – stimulated proliferation of isolated macrophages. These observations may be pertinent to diabetic vascular disease because macrophage proliferation in atherosclerotic lesions was observed in LDL receptor-deficient mice that were both hypercholesterolemic and hyperglycemic but not in mice that were only hyperglycemic (Lamharzi et al. 2004).

Conclusion and Perspectives

Many lines of evidence implicate macrophages and oxidative stress in atherosclerosis. Macrophages play a critical determinant in initiation and progression of atherosclerosis, and its effect, is in part mediated by oxidative stress. Measuring levels of specific oxidized biomolecules by MS show promise for evaluating the role of oxidative stress in the pathogenesis of vascular disease and determine therapeutic efficacy of agents that promote diminished vascular inflammation. Our observations also suggest that chlorinated and/or nitrated HDL might serve as a marker – and perhaps a mechanism – of active cardiovascular disease in humans. If oxidation of HDL by MPO converts the cardioprotective lipoprotein into a dysfunctional form, the enzyme might be a suitable therapeutic target for preventing vascular disease. Additionally agents that improve HDL function and ability to perform RCT would potentially have a major therapeutic role. These include LXR agonists, creating oxidant resistant forms of HDL, peptide, or small molecule HDL mimetics. Additionally, agents that would alter macrophage phenotype to anti-inflammatory state would also be beneficial in preventing CVD.

Mammalian Target of Rapamycin (mTOR)

Christopher J. Gamper and Jonathan D. Powell
Department of Oncology, Johns Hopkins University, School of Medicine, Baltimore, MD, USA

Synonyms

FK506 binding protein 12-rapamycin associated protein 1 (FRAP1); Mammalian target of rapamycin (mTOR); Rapamycin and FK506 binding protein 12 targets 1 (RAFT1)

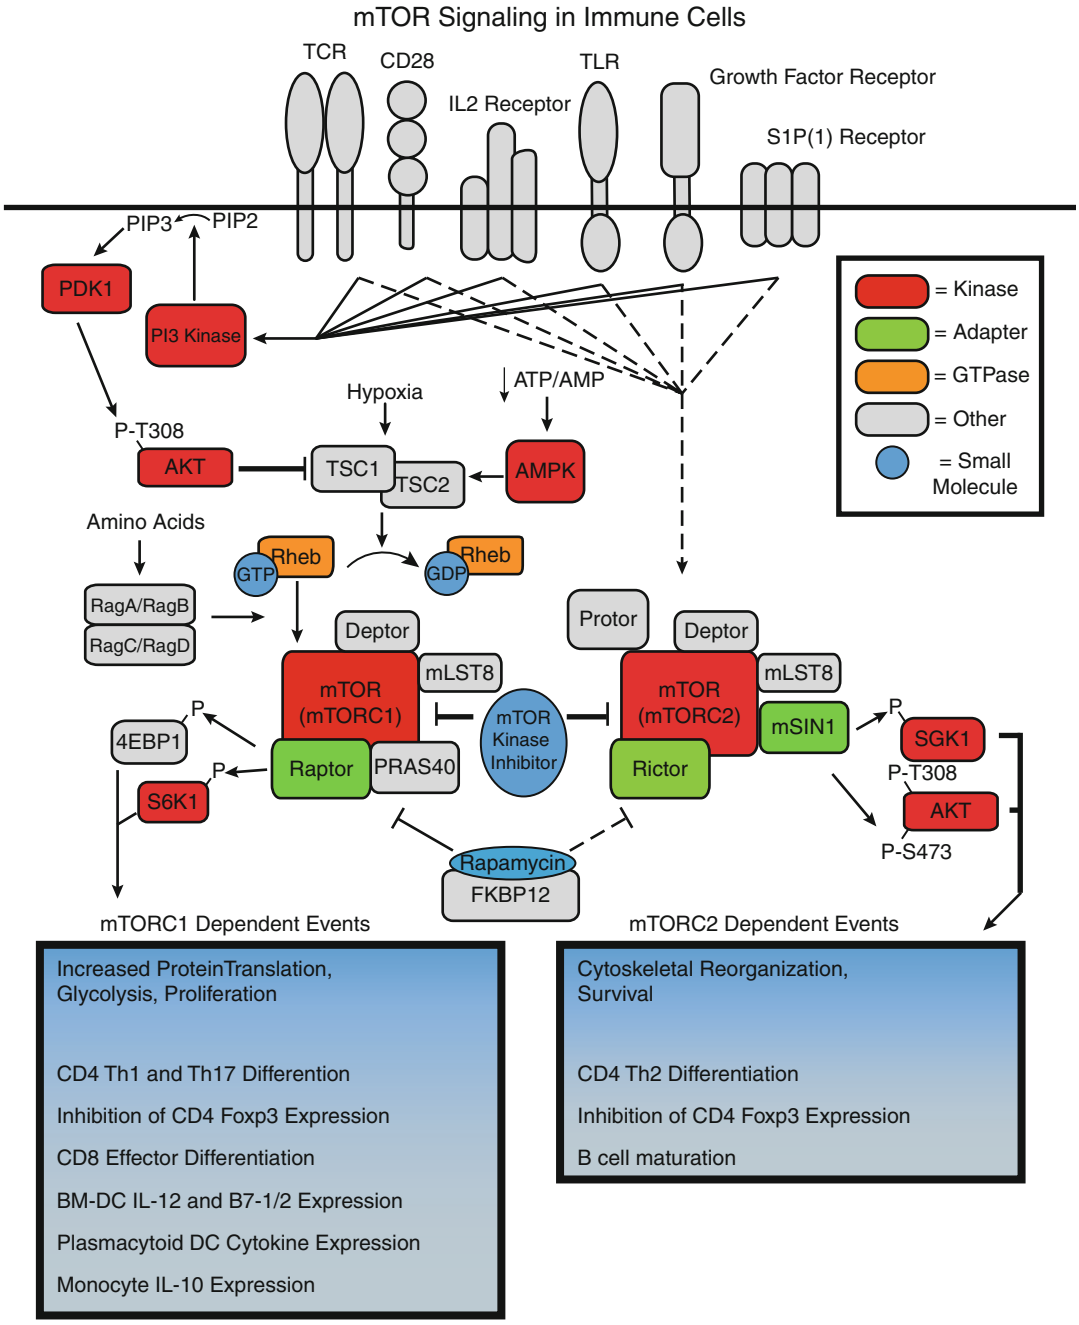
Definition

mTOR is a 289-kD evolutionarily conserved protein with homology to phosphoinositide 3 (PI3)-kinase. Unlike PI3-kinase, mTOR possesses serine-threonine kinase activity sensitive to inhibition by the macrolide antibiotic rapamycin isolated from *Streptomyces hygroscopicus* collected on *Rapa nui* (Easter Island) (reviewed in (Dennis et al. 1999)). The rapamycin-dependent inhibition of kinase activity was used to identify both yeast and mammalian TOR proteins. Rapamycin was quickly noted to have profound immunosuppressive effects, but an understanding of the mechanisms by which mTOR inhibition mediates immunologic tolerance has only recently been more clearly understood.

Yeast have two separate genes, TOR1 which regulates protein translation and TOR2 which regulates cytoskeletal reorganization, while mammalian cells utilize the mTOR protein encoded by the single *Frap1* gene to form two distinct multi-protein complexes termed mTORC1 and mTORC2. Each complex has different inputs for activation and unique downstream substrates and functions (reviewed in (Laplante and Sabatini 2009)). A schematic view of mTOR signaling is depicted in Fig. 1. mTORC1 consists of mTOR, the regulatory-associated protein of mTOR (raptor), the mammalian lethal with Sec13 protein 8 (mLST8), the proline-rich Akt substrate 40 kDa (PRAS40), and the DEP-domain-containing mTOR-interacting protein (Deptor). mTORC2 consists of mTOR, the raptor-independent companion of TOR (rictor), mLST8, the mitogen-activated protein kinase-associated protein 1 (MAPKAP1 also called mSIN1), and the protein observed with rictor (Protor). Inputs that activate mTORC1 include growth factor signaling such as insulin, the presence of adequate cellular energy stores via inhibition of the AMP-activated protein kinase (AMPK) pathway, the presence of sufficient amino acids, the presence of normoxia, and in T cells, activation of CD28 costimulatory molecules and signaling via the interleukin-2 receptor (IL-2R) (reviewed in (Thomson et al. 2009)). Pathways linking several of these inputs to mTORC1 activation include protein kinase B (also called AKT)-dependent phosphorylation of the tuberous sclerosis 1 and 2 protein complex (TSC1/TSC2). The TSC1/2 complex functions as a GTPase-activating protein (GAP) for the GTPase Ras-homolog enriched in brain (Rheb). Phosphorylation of TSC1/2 inhibits GAP activity, increasing Rheb-GTP levels resulting in mTORC1 activation (Laplante and Sabatini 2009). Inputs that activate mTORC2 are less well understood, but like mTORC1, mTORC2 is strongly activated in T cells in the presence of costimulation and cytokine exposure (reviewed in (Cantrell 2002)). mTORC1 is exquisitely sensitive to inhibition by the complex of rapamycin with FKBP12, resulting in loss of phosphorylation of the eukaryotic initiation factor 4E-binding protein 1 (4E-BP1) and the p70 ribosomal S6 kinase 1 (S6K1) and subsequent inhibition of protein translation (Laplante and Sabatini 2009). Measurement of 4E-BP1 and S6K1 phosphorylation is utilized to monitor the activation status of mTORC1. mTORC2 activity is insensitive to low doses of rapamycin in vitro; however, upon incubation of cells with higher rapamycin doses or following prolonged exposure to rapamycin, loss of mTORC2-dependent AKT S473 phosphorylation is detected (Delgoffe et al. 2011). More recently, small molecules that directly inhibit the kinase activity of mTOR have been developed. These interfere with both mTORC1- and mTORC2-dependent phosphorylation events (Thoreen et al. 2009). Consequences of pharmacologic and genetic blockade of mTOR signaling in various immune cell types are explored below and summarized in Table 1.

mTOR Function in T Cells

Normal T cell activation is dependent on simultaneous recognition of antigen in the form of peptide bound to major histocompatibility complex (MHC) on the antigen-presenting cell (APC) surface by cognate TCR (Signal 1) with concurrent activation of T cell costimulatory molecules including CD28 by APC-expressed B7-1 or B7-2 surface proteins (Signal 2). Such activation leads to T cell interleukin (IL)-2 secretion, autocrine IL-2 stimulation, and proliferation resulting in clonal expansion of the peptide-specific T cell. Biochemically, signals resulting from costimulation, cytokine receptors, and the local nutrient supply are integrated via mTOR signaling in T cells. mTOR activation results in increased expression of metabolic enzymes to permit cell growth and division, as well as acquisition of effector functions such as cytokine expression. Following TCR stimulation in the absence of costimulation (Signal 1 alone), mTOR is not activated, and a T cell is rendered unresponsive to subsequent full stimulation (Signal 1 + 2) in vitro, a condition termed anergy (reviewed in (Powell 2006)). Full stimulation (Signal 1 + 2) in the presence of 2-deoxyglucose



Mammalian Target of Rapamycin (mTOR), Fig. 1 mTOR activation by environmental stimuli: an overview of the mTOR signaling cascade

(2DG) or 5-aminoimidazole-4-carboxamide ribonucleoside (AICAR) mimicking energy depletion, N-acetyl-leucine (NALA) mimicking amino acid deprivation, and rapamycin all inhibit normal mTOR activation and result in anergy upon restimulation of the T cell in the absence of the inhibitory drug (Zheng et al. 2009). Importantly, induction of anergy depends on

Mammalian Target of Rapamycin (mTOR), Table 1 Summary of mTOR-dependent signaling in immune cells

Cell type	Experimental manipulation of mTOR	Effect
CD4 T cell	Proximal blockade of mTOR activation (costimulatory blockade, 2-DG, AICAR, NALA)[a], rapamycin, or mTOR kinase inhibitor during T cell activation	Decreased proliferation and cytokine secretion upon restimulation (anergy)
Naïve CD4 T cell	Initial T cell activation in the presence of rapamycin or after genetic inactivation of mTOR	Enhanced expression of FoxP3 and generation of Treg; inhibition of HIF-1α-dependent Th17 differentiation by rapamycin
Naïve CD4 T cell	Thymopoiesis of T cells overexpressing S1P(1) with hyperactivation of mTOR after TCR/CD28 signaling	Inhibition of FoxP3 expression, enhanced Th1 differentiation, spontaneous autoimmunity
Naïve CD4 T cell	Initial T cell activation after genetic inactivation of mTORC1 (via deletion of Rheb)	Inhibition of Th1 and Th17 differentiation with preservation of Th2 differentiation
Naïve CD4 T cell	Initial T cell activation after genetic inactivation of mTORC2 (via deletion of rictor)	Inhibition of Th2 differentiation with preservation of Th17 and preservation or decrease of Th1 and differentiation
Naïve CD8 T cell	Initial T cell activation after genetic inactivation of mTORC1 (via deletion of Rheb)	Decreased CD8 effector gene expression
Naïve CD8 T cell	Initial T cell activation after blockade of mTOR with rapamycin	Enhanced frequency of antigen-specific memory CD8 T cells
Bone marrow-derived dendritic cell	LPS and IL-4 stimulation during blockade of mTOR with rapamycin	Inhibition of costimulatory molecule surface expression and IL-12 secretion (generation of "tolerogenic" DC)
Plasmacytoid dendritic cell	CpG oligonucleotide stimulation during blockade of mTOR with rapamycin	Inhibition of IFN-α, IFN-β, TNF-α, and IL-6 secretion
Monocyte, macrophage, mature dendritic cell	LPS stimulation during blockade of mTOR with rapamycin	Inhibition of IL-10 and enhancement of IL-12 secretion
B cell	Partial blockade of mTOR in hypomorphic knock-in mouse	Partial block in B cell maturation in the bone marrow and reduced numbers of transitional, marginal zone, and follicular B cells in the spleen; decreased T-independent antibody production
B cell	Selective disruption of mTORC2 by deletion of mSin1	Reduction of mature IgM + B cells
B cell	Constitutive activation of mTOR via conditional deletion of TSC1	Decreased B cell maturation and a reduction in marginal zone B cells in the spleen; decreased T-dependent and loss of T-independent antibody production

[a]Abbreviations: *2-DG* 2-deoxyglucose, *AICAR* 5-aminoimidazole-4-carboxamide ribonucleoside, *NALA* N-acetyl leucine

TCR-mediated, calcium-dependent activation of nuclear factor of activated T cells (NF-AT), as demonstrated by the fact that the immunosuppressive drugs cyclosporine or FK506 that block calcium-dependent NF-AT activation actually prevent the induction of anergy by Signal 1 alone or by Signal 1 + 2 in the presence of rapamycin (Powell 2006). Clinical implications of this difference in mechanism of immune modulation between rapamycin and calcineurin inhibitors are discussed below.

Following activation, naïve CD4 T cells acquire specialized effector function in response to the particular cytokine and costimulatory milieu present at the time of activation. Different effector fates are associated with induction of specific master transcriptional regulators and restricted patterns of cytokine expression,

for example, Th1 cells express T-box expressed in T cells (Tbet) and secrete interferon (IFN)-γ, Th2 cells express GATA3 and secrete IL-4, Th17 cells express retinoic acid receptor-related orphan receptor γ (RORγT) and express IL-17A/F, and a subset of CD4 T cells termed Tregs acquires suppressive regulatory function dependent on Forkhead-box-P-3 (Foxp3) transcription factor expression (reviewed in (Weaver et al. 2006)). mTOR plays a critical role in CD4 effector differentiation. Activation of T cells in the presence of rapamycin in vitro increases the frequency of cells expressing Foxp3 that have suppressor function (Battaglia et al. 2005). Genetic blockade of mTOR signaling by conditional deletion of mTOR in T cells using CD4-Cre transgenic mice does not interfere with generation of naïve T cells. However, following activation, mTOR-deficient CD4 T cells upregulate FoxP3 expression, fail to express effector cytokines, and become functional suppressor cells (Delgoffe et al. 2009). Reciprocally, excessive activation of mTOR in mice bearing T cells transgenic for the sphingosine 1-phosphate receptor S1P(1) suppressed generation of normal FoxP3+ Tregs and promoted Th1 effector cytokine expression resulting in spontaneous autoimmunity (Liu et al. 2009). Inhibition of FoxP3 expression downstream of mTOR signaling has been demonstrated to partly result from the induction of hypoxia-induced factor-1 alpha (HIF-1α) expression which enhances Th17 cell generation by cooperating with RORγT to promote IL-17 expression and simultaneously direct proteolytic degradation of FoxP3 protein (Dang et al. 2011).

Somewhat unexpectedly, the enhanced FoxP3 expression in the absence of mTOR is dependent on complete loss of both mTORC1 and mTORC2 signals, as selective deletion of mTORC1 alone via T cell conditional deletion of Rheb results in selective inhibition of Th1 and Th17 cell generation but permits Th2 cells (Delgoffe et al. 2011). Conversely, selective deletion of mTORC2 alone via T cell conditional deletion of rictor results in inhibition of Th2 cells but permits Th17 effectors and has variable effects on Th1 cells in two reports (Delgoffe et al. 2011; Lee et al. 2010). The complete mechanism by which loss of either mTORC1 or mTORC2 selectively impairs cytokine responses of naïve T cells remains under investigation, but mTORC1 null T cells demonstrate decreased Signal Transducers and Activators of Transcription(STAT)4 phosphorylation after stimulation with IL-12 and STAT3 phosphorylation after stimulation with IL-6 (Delgoffe et al. 2011). Variable effects of mTORC2 deletion on cytokine signaling in T cells have been reported, with impaired STAT6 activation after stimulation with IL-4 in rictor-floxed mice on a CD4-Cre background (Delgoffe et al. 2011) but normal IL-4 induced STAT6 phosphorylation with abnormal TCR-induced proximal AKT and distal PKC-θ activation in rictor-floxed mice on the dLck-iCre background (Lee et al. 2010). In summary, while selective loss of mTORC1 or mTORC2 impairs a subset of CD4 effector fates, complete loss of mTOR signaling results in generation of Tregs instead of effector cells.

mTOR has also been shown to participate in generation of effector CD8 T cells. TCR stimulation, IFN-γ signaling, and IL-12 signaling in naïve CD8 cells lead to strong mTORC1 activation and resulting upregulation of Tbet, promoting proliferation and expression of effector genes such as perforin and granzyme B (Rao et al. 2010). CD8 T cells lacking mTORC1 due to deletion of Rheb or with constitutively activated mTORC1 due to deletion of TSC2 have impaired and enhanced CD8 effector function, respectively, consistent with necessity of mTORC1 in activation of the CD8 effector program (Pollizi, K.P. and Powel, J.D., manuscript in preparation). Following control of an acute infection, the number of antigen-specific CD8 T cells declines, and the cells downregulate expression of Tbet and increase expression of a homologous transcription factor eomesodermin (Eomes) along with the IL-7 receptor, CD127, and the IL-2/IL-15 receptor beta chain, CD122, in order to persist as a smaller population of long-lived memory CD8 cells. Somewhat unexpectedly, blockade of mTOR with low-dose rapamycin during acute infection of mice with lymphocyte choriomeningitis virus (LCMV) does not impair the antiviral response; rather, it enhances the

frequency and persistence of virus-specific CD8 T cells (Araki et al. 2009). Furthermore, mTOR inhibition during vaccination has also been shown to enhance antitumor immune responses (Rao et al. 2010). Mechanistically, this appears to be due to effects of rapamycin on promoting Eomes expression at the expense of Tbet, thereby increasing the frequency of memory CD8 cells.

mTOR Function in Antigen-Presenting Cells

Antigen-presenting cells (APCs) are critical bridges between innate immune recognition of infectious pathogens and the adaptive immune response. The cytokines produced by APCs following activation with pathogen-associated molecular patterns (PAMPs) such as bacterial lipopolysaccharide, viral ribonucleic acid, and fungal cell wall components initiate the inflammatory response and recruit adaptive immune cells to fight infection. Following activation, APCs upregulate cell-surface expression of costimulatory molecules including B7-1 and B7-2, resulting in full activation of T cells that recognize antigenic peptides taken up and presented by the APC. Effector differentiation of the activated T cells is then influenced by the local cytokines secreted from the APC. mTOR signaling within the APC regulates many of these critical steps in a manner that is cell type- and activation state-specific.

Resting bone marrow-derived dendritic cells (DCs) are poor stimulators of T cells but acquire potent immune-stimulatory capacity when "matured" following LPS stimulation and culture with IL-4 or CD40 cross-linking as a consequence of IL-12 secretion and induction of surface B7-1/B7-2 expression. Maturation in the presence of rapamycin inhibits both IL-12 and costimulatory molecule expression, rendering the rapamycin-treated DC tolerogenic rather than stimulatory in a manner at least partly dependent on an enhanced ability to induce CD4 T cells to become FoxP3+ Treg (Turnquist et al. 2007). In plasmacytoid dendritic cells, CpG oligonucleotides which mimic viral infection elicit robust secretion of IFN-α, IFN-β, tumor necrosis factor (TNF)-α, and IL-6 in a manner sensitive to inhibition by rapamycin (Cao et al. 2008). In contrast, in monocytes in peripheral blood, macrophages, and mature DCs, mTOR signaling appears to limit secretion of Th1-promoting IL-12 by enhancing secretion of the immunosuppressive cytokine IL-10. Thus, stimulation of these cell types with LPS in the presence of rapamycin has the paradoxical effect of inhibiting IL-10 with resulting enhanced IL-12 secretion and stronger Th1 immune responses in some systems (Weichhart et al. 2008). Which of these two opposing effects of mTOR inhibition on APC function are dominant in vivo appears to depend on the type of inflammatory stimulus and the dose and timing of mTOR inhibition used. For example, rapamycin treatment protects susceptible Balb/C mice from Listeria infection and augments LCMV immunity but impairs immunity to yellow fever vaccine (Araki et al. 2009; Cao et al. 2008; Weichhart et al. 2008).

mTOR Function in B Cells

The PI3-kinase/mTOR axis is activated in B cells following surface immunoglobulin (Ig) cross-linking, LPS stimulation, and CD40 ligation and resulting proliferation and antibody secretion that is inhibited by rapamycin (reviewed in (Thomson et al. 2009)). Several genetic models have very recently been utilized to examine the mechanism for these effects. An mTOR hypomorphic mouse generated by insertion of a neo-cassette within the Frap1 gene was found to have lymphopenia and reduced numbers of both T and B cells, with a partial block in B cell maturation in the bone marrow and reduced numbers of transitional, marginal zone, and follicular B cells in the spleen. These mice make poor responses to the T-independent antigen nitrophenol-LPS (Zhang et al. 2011). Selective disruption of mTORC2 by deletion of mSin1 resulted in a reduction of mature IgM + B cells in irradiated mice reconstituted with mSin1-deficient fetal liver cells. This was due to a partial arrest at the pro-B cell stage associated with persistent Rag1

gene expression and enhanced IL-7 receptor expression. Mechanistically, this was found to be due to enhanced nuclear translocation of the Forkhead family transcription factor FoxO1 as a consequence of reduced mTORC2-dependent FoxO1 phosphorylation that retains FoxO1 in the cytoplasm (Lazorchak et al. 2010). Unlike in T cells, constitutive activation of mTOR via conditional deletion of TSC1 using CD19-Cre did not produce a reciprocal phenotype to the mTOR hypomorph or mTORC2 null mice reported above. Instead, mice with constitutively active mTOR in B cells also have decreased B cell maturation and a reduction in marginal zone B cells in the spleen. This effect was partially rescued by rapamycin treatment. Such mice make poor responses to T-dependent antigen and fail to make a response to a T-independent antigen (Benhamron and Tirosh 2011). While more details regarding the targets of mTOR-dependent signaling in B cells remain to be identified, these early data are consistent with mTOR-dependent signaling being necessary for normal generation of naïve B cells and for regulation of mature B cell proliferation/activation. They also suggest that physiologic limitation of the duration or intensity of mTOR signaling during B cell terminal differentiation may be necessary for to permit normal antibody production during an immune response.

mTOR Inhibition as Clinical Immunosuppressant

Given the pleiotropic effects of mTOR signaling on cells involved in both innate and adaptive immunity, it is not surprising that rapamycin and related compounds have found clinical utility in the fields of solid organ and hematopoietic stem cell transplantation. Numerous examples of both animal models and human systems are reported, but due to space limitations, only a few are highlighted that help to illustrate important differences between tolerogenic mTOR inhibition and conventional calcineurin-based immunosuppression that may interfere with generation of long-term tolerance.

In a murine model of cardiac allograft rejection, DCs were matured in vitro in the presence of rapamycin and infused into cardiac allograft recipients who received a short course of systemic rapamycin. This resulted in long-term allograft survival off immunosuppression, increased allograft infiltration by Foxp3+ Tregs, and the ability to adoptively transfer tolerance to secondary recipients by infusion of CD4 T cells isolated from tolerant graft recipients (Turnquist et al. 2007). Several groups have isolated human Tregs for expansion in vitro, relying on culture with rapamycin to promote sustained Foxp3 expression, with the goal of applying these to treat autoimmune disease or prevent graft versus host disease (GVHD). This technology has been applied in a phase I clinical trial of Treg infusion following unrelated umbilical cord blood transplantation and demonstrated safety and lower rates of GVHD compared to historical controls from the same institution (Brunstein et al. 2011).

Systemic treatment with rapamycin is also used to promote tolerance. The longer clinical experience with calcineurin-based GVHD prophylaxis in hematopoietic stem cell transplant has resulted in most trials adding rapamycin to regimens containing cyclosporine or tacrolimus. Despite the mechanistic antagonism, there is encouraging evidence of a favorable incidence of acute GVHD, as low as 20.5 % Grade II–IV acute GVHD following myeloablative transplant with tacrolimus- and sirolimus-based GVHD prophylaxis (Cutler et al. 2007). However, based on the potential inhibition of rapamycin-induced tolerance by calcineurin inhibitors and preclinical work demonstrating that treatment with low-dose total body irradiation (TBI) and rapamycin alone permitted stable mixed donor chimerism in a murine model of non-myeloablative haploidentical bone marrow transplant, a human clinical trial was opened for the treatment of severe sickle cell anemia with matched sibling donor peripheral blood stem cell transplant using a regimen of alemtuzumab, low-dose TBI, and post-transplant rapamycin. This study achieved stable mixed donor chimerism in 9 of 10 treated patients, no patients experienced acute or chronic GVHD, all had

resolution of sickle cell-related symptoms, and two patients who discontinued rapamycin have remained stable mixed chimeras off of immunosuppression (Hsieh et al. 2009).

In summary, mTOR signaling plays an essential role in integration and transmission of signals in multiple immune cell types leading to cellular activation, proliferation, and effector differentiation. Thoughtful blockade of mTOR signaling appears to offer significant promise as a means to achieve immunologic tolerance in the setting of organ and hematopoietic stem cell transplantation while preserving the ability to make protective immune responses against viruses, bacteria, and tumors.

mTORC1 consists of mTOR, raptor, mLST8, PRAS40, and Deptor. mTORC2 consists of mTOR, rictor, mLST8, Deptor, MAPKAP1 (also called mSIN1), and Protor. In the figure, straight arrows indicate activating signals, and lines ending in a bar indicate inhibitory signals. Curved arrows indicate chemical reactions catalyzed by the indicated enzymes. "P" indicates select sites of protein phosphorylation. Inputs that activate mTORC1 include growth factor signaling such as insulin, the presence of adequate cellular energy stores via activation of the AMP-activated protein kinase (AMPK) pathway, the presence of sufficient amino acids via the Rag (RagA/B/C/D) family of GTPases that promote Rheb colocalization with mTORC1, the presence of normoxia via regulated in development and DNA damage responses 1 (REDD1), and in T cells activation of TCR, CD28 and other costimulatory molecules, sphingosine 1-phosphate receptor 1 (S1P(1) receptor), and signaling via the interleukin-2 receptor (IL-2R). Pathways linking several of these inputs to mTORC1 activation include protein kinase B (also called AKT)-dependent phosphorylation of the tuberous sclerosis 1 and 2 protein complex (TSC1/TSC2). The TSC1/2 complex functions as a GTPase-activating protein (GAP) for the GTPase Ras-homolog enriched in brain (Rheb). Phosphorylation of TSC1/2 inhibits GAP activity, increasing Rheb-GTP levels resulting in mTORC1 activation. Inputs that activate mTORC2 are less well understood, but like mTORC1, mTORC2 is activated in T cells by costimulation and cytokine exposure. mTORC1 is inhibited by the complex of rapamycin with FKBP12, resulting in loss of phosphorylation of the eukaryotic initiation factor 4E-binding protein 1 (4E-BP1) and the p70 ribosomal S6 kinase 1 (S6K1) and subsequent inhibition of protein translation. Measurement of 4E-BP1 and S6K1 phosphorylation is utilized to monitor the activation status of mTORC1. mTORC2 activity is insensitive to low doses of rapamycin in vitro; however, upon incubation of cells with higher rapamycin doses or following prolonged exposure to rapamycin, loss of mTORC2-dependent AKT S473 phosphorylation is detected. Phosphorylation of both mTORC1 and mTORC2 substrates is blocked by small molecule inhibitors of mTOR kinase activity. Boxes at the bottom catalogue cellular responses known to be downstream of mTORC1 or mTORC2. Global functions ascribed to each pathway are listed at the top in shaded areas, and the growing list of functions defined in immune cells is listed at the bottom.

Synonyms

$CD27^+$ IgM^+ IgD^+ B cells; IgM memory B cells

Definition

Marginal zone (MZ) B cells are a subpopulation of B lymphocytes that localize at the border of the red and white pulp in the spleen where they are positioned to sample blood-borne antigens. Accordingly, MZ B cells mount rapid and T cell–independent antibody responses to blood-borne pathogens that display repetitive epitopes such as the polysaccharides found on

encapsulated bacteria and viral coat proteins. They are derived as a separate lineage from naïve follicular B cells and express a unique phenotype. The antibodies produced by MZ B cells bear little-to-no mutation but often display polyreactive and auto-reactive specificities.

Introduction

Antibodies are a critical component of adaptive immunity and their production is a cooperative effort between different B cell subpopulations (Swanson et al. 2013). MZ B cells contribute to humoral immunity upon pathogen infection by rapidly producing pathogen-specific antibodies that limit and contain infection and during the time needed for the generation of somatically mutated high affinity antibodies of appropriate subclass that are produced by naïve follicular B cells (Cerutti et al. 2013; Martin and Kearney 2002; Pillai et al. 2005; Weill et al. 2009). MZ B cell antibody responses are typically comprised of IgM and limited IgG subclass (IgG2 in humans and IgG3 in mice) antibodies that harbor little-to-no mutations and thus are of relatively weak affinity. However, these pathogen-specific antibodies are effective due to the avidity provided by the pentameric IgM and because the MZ B cell–derived antibodies often display polyreactive specificities that include determinants common to many microbial pathogens.

Much of our understanding about the development and function of MZ B cells comes from rodent studies performed over the last several decades (Martin and Kearney 2002; Pillai et al. 2005). However, human and murine MZ B cells are analogous populations that share many similar features that include phenotype, localization in lymphoid organs and ability to respond to pathogenic encapsulated bacteria in a T cell–independent manner (Cerutti et al. 2013; Weill et al. 2009).

Phenotype

The MZ B cells in both humans and mice express a very similar pattern and level of receptors defined as IgM^{hi} IgD^{lo} $CD21^{hi}$ $CD1^{hi}$ $CD23^{lo}$, presumably reflecting a similar function in both species. Human MZ B cells additionally express CD27, a surface antigen previously considered to be a marker of memory B cells (Klein et al. 1998). In contrast to murine MZ B cells, whose antibodies are germline encoded, human MZ B cells harbor (relatively few) somatic mutations in their immunoglobulin (Ig) genes (Cerutti et al. 2013; Weill et al. 2009). These features led to their initial consideration as "IgM memory" B cells (Klein et al. 1998). However, introduction of somatic mutations and production of memory B cells occurs in germinal centers, and mutated IgM^{+} IgD^{+} $CD27^{+}$ human B cells are nevertheless present in individuals with mutations that preclude germinal center formation (Weill et al. 2009). Furthermore, IgM^{+} IgD^{+} $CD27^{+}$ human B cells function analogously to murine MZ B cells (Kruetzmann et al. 2003; Weller et al. 2004). Thus, $CD27^{+}$ human MZ B cells are functionally analogous to murine MZ B cells and are not germinal-center experienced conventional memory B cells.

Human and mouse MZ B cells are larger cells compared to naïve follicular B cells. In the mouse, these large MZ B cells are considered "pre-activated" as they display elevated levels of activation antigens such as CD86 and have a lower threshold of activation by either specific antigen or toll-like receptor ligands (Capolunghi et al. 2008; Snapper et al. 1993). The antibody repertoire expressed by both mouse and human MZ B cells also shares a number of features and differs from the major follicular B cell population. Notably, the murine MZ B cell antibody repertoire is known to harbor polyreactive specificities that include weak reactivity to autoantigens and that are important in promoting the development of the MZ B cell population (Martin and Kearney 2002; Pillai et al. 2005). Consistent with this, MZ B cell antibodies from humans and mice also harbor relatively short complementary determining region 3 (CDR3) Ig heavy chain sequences (Briney et al. 2012; Schelonka et al. 2007) that are also a common feature of antibodies with polyreactive specificities (Chen et al. 1991). Finally, human MZ

B cells recirculate and, thus, are present in blood and other lymphoid organs where they reside in microenvironments among macrophages similar to those present in the marginal zone of the spleen. Murine MZ B cells do not recirculate and are restricted to the spleen. However, they are not restricted to the marginal zone as they continuously shuttle antigen into the B cell follicle to deliver it to follicular dendritic cells (Cyster and Schwab 2012).

Development

MZ B cells in the mouse develop from bone marrow–derived transitional B cells as a separate lineage from the major follicular B cell population in a process that is influenced by both antigen specificity and signaling ability of the B cell antigen receptor (BCR) (Martin and Kearney 2002; Pillai et al. 2005). The precise signals that dictate development of immature B cells into FO or MZ B cells are unknown, but certain specificities provided by Ig transgenes promote or discourage MZ B cell development in mouse models. In addition, a number of studies have suggested that a weak BCR signaling leads to MZ B cell preferential development, as shown in mice with deficient BCR signaling components that include the Btk tyrosine kinase and surface CD19 antigen (Martin and Kearney 2002; Pillai et al. 2005). In addition, both Notch- and Pyk2-deficient mice have suggested that both these signaling molecules are important for MZ B cell development. Whether human MZ B cells also develop as a separate lineage from immature bone marrow B cells similar to their mouse counterparts is not established but their development appears to depend on TLR signaling (Weller et al. 2012). Furthermore, in contrast to mouse MZ B cells, human MZ B cells harbor somatic mutations within their Ig genes that are present even in the absence of germinal center formation. It has been postulated that human MZ B cells introduce somatic mutations during their development independent of antigen and in a mechanism that diversifies the MZ B cell antibody repertoire similar to other species (Weill et al. 2009).

Finally, the development and maintenance of both mouse and human MZ B cells is dependent on the spleen. B cells with a mature MZ B cell phenotype are not present in the spleen of children until approximately 2 years of age or mice until approximately 3–4 weeks of age (Cerutti et al. 2013; Weill et al. 2009). This neonatal lack of MZ B cells is thought to account for the poor antibody responses to encapsulated bacteria by children and neonatal mice.

Localization

In both humans and rodents, MZ B cells reside within the marginal zone that lies at the border between the red and white pulp. In mice, the marginal zone is separated from the white pulp by a marginal sinus into which arterial blood empties, promoting MZ B cell sampling of blood-borne antigens (Mebius and Kraal 2005). In humans, the marginal sinus within the marginal zone appears to be replaced by a plexus of capillaries that terminate in the perifollicular region surrounding the marginal zone (Steiniger et al. 2011). However, the juxtaposition of the marginal zone to this region presumably allows human MZ B cells to similarly sample blood antigens. Importantly, as the marginal zone is juxtaposed to the site where arterial blood empties into the spleen, the marginal zone also harbors post-germinal center memory B cells.

Studies in the mouse have demonstrated that MZ B cell localization in the marginal zone is a result of a signaling balance between chemokine and sphingosine-1-phosphate G-protein coupled receptors (GPCR) and that the $\alpha L\beta 2$ and $\alpha 4\beta 1$ integrins mediate MZ B cell adhesion to their respective ICAM and VCAM ligands expressed by cells within the marginal zone (Cyster and Schwab 2012).

Participation in the Immune Response

MZ B cells are best characterized to mount rapid antibody responses independent of T cells and directed against repetitive surface epitopes on

blood-borne pathogens referred to as T cell–independent type 2 (TI-2) antigens. Physiological TI-2 antigens to which MZ B cells are known to respond include the polysaccharide capsules of pathogenic bacteria such as *Streptococcus pneumoniae*, *Hemophilus influenzae*, and *Neisseria meningitides* (Kruetzmann et al. 2003; Martin and Kearney 2002) and the viral coat proteins of polyoma virus, vesicular stomatitis virus, and foot and mouth disease virus (Gatto and Bachmann 2005). The ability of MZ B cells to rapidly respond to these pathogens is, in large part, due to their location in the spleen within the marginal zone, an area close to the interface between the red and white pulp and where arterial blood is emptied and where in collaboration with specific macrophages, its contents are efficiently sampled. In contrast to germinal center–derived antibody responses, which take time to develop but are somatically mutated and highly specific, MZ B cell antibody responses are rapid and display relatively weak antigen affinity and can be polyreactive.

A notable feature of human MZ B cells is the presence of somatic mutations in Ig genes, and these mutations are introduced during development and independent of germinal centers (Weill et al. 2009). Accordingly, the anti-polysaccharide antibodies produced by human MZ B cells are typically mutated (Zhou et al. 2002). In contrast, abundant evidence from mouse studies suggests that the MZ B cell antibody response to TI-2 antigens is devoid of mutations and, consequently, it is presumed that MZ B cells do not initiate germinal centers. However, it is now clear that the model antigens used to define the MZ B cell antibody response in rodents (typically hapten-coupled polysaccharides) would not be able to engage $CD4^+$ T cells nor facilitate germinal center formation. Thus, the ability of MZ B cells to mount a mutated antibody response to *bona fide* TI-2 antigens, such as those associated with microbial pathogens, may be underappreciated. Indeed, when directly tested mouse MZ B cells are able to contribute to the antibody response against T cell–dependent (TD) protein antigens by seeding germinal centers and undergoing somatic hypermutation (Song and Cerny 2003).

CD21 is expressed at relatively high levels by both human and mouse MZ B cells, and serves not only as a costimulatory molecule but also as a receptor for complement components, thus allowing for the capture of complement-bound antigen. MZ B cells also express nonclassical major histocompatibility complexes (MHC) such as CD1d in rodents and CD1c in humans that allow these cells to interact with a wider range of T cells, including iNKT cells. Finally, MZ B cells can affect more long-term responses by shuttling antigen into the follicle for delivery to follicular dendritic cells (FDCs), which mediate selection during germinal center reactions (Cyster and Schwab 2012).

Conclusion

MZ B cells fill an important niche in humoral immunity by their ability to rapidly produce antibodies against blood-borne pathogen and independent of T lymphocytes. This antibody response contributes to limiting infection during the time needed for highly specific antibodies of appropriate subclass to be generated in germinal centers. A number of features contribute to the expedited MZ B cell antibody response including their localization in the marginal zone of the spleen that facilitates blood sampling, their expressed antibody repertoire that often is capable of recognizing common microbial determinants, and the decreased threshold necessary to be activated.

Synonyms

Endothelial cell activation; Endothelial dysfunction; Vascular endothelium

Definition

The vascular endothelium is a multifunctional organ that actively participates in the maintenance of vascular homeostasis. Proper endothelial function is critical for vascular health, and endothelial dysfunction causes or contributes to numerous diseases. *Endothelial activation* is a type of endothelial dysfunction that describes the process by which blood-borne and environmental stimuli cause endothelial cells to undergo dramatic functional changes.

Introduction

The vascular endothelium is a monolayer of cells that lines the entire luminal surface of the vasculature and forms a regulatory interface between circulating blood components and underlying tissue compartments. The vascular endothelium covers a network of blood vessels that exceeds 100,000 km in aggregate length, with a surface area of approximately 5,000 m^2 (De Caterina et al. 2007). Its massive size and distribution into all organs and tissues gives the endothelium the capacity to monitor physiological perturbations throughout the entire body. By virtue of its juxtaposition with circulating blood components, the endothelium is critically situated to sense and respond to blood-borne stimuli on a systemic scale, making it the body's largest homeostatic organ (DiCorleto and Fox 2005).

Although it was originally considered a passive barrier, modern research has uncovered numerous mechanisms by which the endothelium actively maintains vascular homeostasis. Under physiological conditions, the endothelium prevents vasospasm, resists leukocyte adhesion, inhibits smooth muscle cell proliferation, and acts as a non-thrombogenic surface for the entire circulatory system. In addition, the endothelium acts as a selective physical barrier by actively regulating the passage of macromolecules and leukocytes into and out of the bloodstream (Pober and Sessa 2007). These physiological roles are influenced by environmental stimuli that can cause the endothelial phenotype to fluctuate between antagonistic functions of vascular homeostasis. At different times or locations, the endothelium can be nonadhesive or hyperadhesive to leukocytes, can be procoagulatory or anticoagulatory, and act as a vasoconstrictor or vasodilator (DiCorleto and Fox 2005). In this way, the endothelium displays a remarkable phenotypic plasticity to adapt to environmental changes. These phenotypic changes are usually normal, adaptive responses to the changing vascular environment, and are an essential contribution to vascular homeostasis.

Localized, nonadaptive changes to endothelial physiology can also alter its phenotype to induce changes in vessel tone, leukocyte adhesiveness, coagulation, and the production of autocrine and paracrine factors, including vasorelaxants and vasospastic substances. These aberrant alterations are collectively referred to as *endothelial dysfunction*, and are involved in the initiation and progression of numerous cardiovascular diseases. *Endothelial activation*, a type of endothelial dysfunction, is a distinct term that describes the process by which blood-borne and environmental stimuli cause endothelial cells to undergo dramatic functional changes and acquire new physiological properties (De Caterina et al. 2007).

Proper endothelial function is critical for maintaining vascular health, and endothelial dysfunction may cause or contribute to numerous vascular diseases. This entry will provide a brief overview of normal endothelial physiology that will serve as a foundation for an in-depth explanation of the molecular mechanisms underlying endothelial cell activation as well as the contribution of endothelial cell activation to the genesis and progression of vascular diseases.

Normal Vascular Endothelium

Morphology and Barrier Function

As a continuous monolayer of cells, the vascular endothelium forms an extensive regulatory interface between the bloodstream and underlying tissues with cells that are elongated in the direction of blood flow (Chiu and Chien 2011).

Abundant intercellular junctions including tight junctions, gap junctions, and adherens junctions allow the endothelium to act as an active physical barrier. The relative abundance of these junctions varies between anatomic locations and confers site-specific specialization of endothelial permeability (Pober and Sessa 2007). Arteries and blood vessels of the brain contain more tight junctions, which restrict macromolecular flux between intravascular and extravascular compartments. Gap junctions, which consist of connexin proteins, link the cytoplasm of neighboring endothelial cells and likely play roles in intercellular communication. Adherens junctions, which consist of cadherin proteins, are important for endothelial cell organization, growth, and migration (De Caterina et al. 2007).

The modulation of intercellular junctions via posttranslational modifications of junction proteins plays a role in the regulation of vascular permeability. The mechanisms vary according to stimuli, but permeability is usually increased by phosphorylation of junction proteins, actin-myosin-dependent morphological changes, and an increased number of intercellular gaps in the endothelial monolayer (Pober and Sessa 2007). Under physiological conditions, these changes are controlled and reversible, representing adaptive control of macromolecular flux between the bloodstream and tissues.

Regulation of Vascular Tone

The endothelium acts as a regulator of vascular tone by synthesizing and secreting vasodilatory or vasoconstrictive substances that act on underlying smooth muscle cells. The most important endothelial-derived vasorelaxing factor is nitric oxide (NO), which is synthesized by endothelial nitric oxide synthase (eNOS) and inducible nitric oxide synthase (iNOS). NO exerts a local vasorelaxing effect by diffusing into the smooth muscle cell and activating guanylate cyclase, thereby increasing levels of cyclic guanosine monophosphate (cGMP). Higher levels of cGMP inhibit calcium entry into the smooth muscle cell, resulting in decreased vasoconstriction (Kinlay and Ganz 2007; Lüscher et al. 2005). Endothelial cells are also capable of synthesizing vasoactive metabolites of arachidonic acid called eicosanoids. The most important eicosanoid for maintaining physiological vessel tone is the vasorelaxant prostacyclin. Endothelial cells express the enzymes cyclooxygenase-1,2 (COX-1, COX-2) which synthesize prostaglandin H2 (PGH2) from arachidonic acid (Lüscher et al. 2005). PGH2 can then be converted to a number of vasoactive metabolites, but endothelial cells express significant levels of the enzyme prostacyclin synthase, thus favoring the formation of prostacyclin. Prostacyclin is secreted by endothelial cells and is a potent vasodilatory substance which acts on smooth muscle cells to decrease vascular tone (DiCorleto and Fox 2005).

NO and prostacyclin antagonize a number of endothelial-derived vasoconstrictive substances. These substances, which include angiotensin II, endothelin-1 (ET-1), and platelet-derived growth factor (PDGF), act as agonists of smooth muscle cell contraction (DiCorleto and Fox 2005; Kinlay and Ganz 2007). All three of these molecules are expressed as propeptides by normal endothelial cells until appropriate stimuli trigger their activation by proteolytic cleavage. So, whereas the expression of vasorelaxing substances NO and prostacyclin is normally constitutive, the activation of endothelial-derived vasoconstrictive substances is rapidly inducible, allowing the endothelium to quickly and reversibly regulate vascular tone (De Caterina et al. 2007).

Regulation of Hemostasis

Under normal conditions, the endothelium actively participates in the prevention of blood clot formation. This non-thrombogenic property is maintained by the production of several endothelial-derived factors that act on platelets and enzymes of the coagulation cascade. Endothelial cells synthesize thrombomodulin which binds to thrombin and inactivates thrombin's procoagulant activity (DiCorleto and Fox 2005). Additionally, endothelial cells synthesize the arachidonic acid metabolite prostacyclin, which was previously discussed in terms of its role as a vasodilator. Prostacyclin is a particularly potent inhibitor of platelet aggregation and

platelet adherence to the endothelium. Under physiological conditions, endothelial-derived prostacyclin activates the prostacyclin receptor IP_1 on platelets to inhibit aggregation and adhesion (DiCorleto and Fox 2005).

Endothelial production of prostacyclin, thrombomodulin, and other anticoagulant factors appears to be constitutive under normal conditions, necessitating the rapid production of the procoagulant factors when clotting is required. The endothelium synthesizes numerous thrombotic factors including tissue factor (TF), platelet-activating factor (PAF), and von Willebrand factor (vWF) (DiCorleto and Fox 2005). TF is particularly important for the transformation of the vessel wall into a thrombogenic surface because it promotes the activation of factors X and IX of the coagulation cascade (De Caterina et al. 2007). Healthy vessels maintain a strict balance between thrombotic and antithrombotic factors, favoring the expression of antithrombotic factors under physiological conditions and rapidly producing TF and other coagulant factors following exposure to thrombotic stimuli.

Transduction of Biomechanical Forces

The endothelium is situated in direct contact with circulating blood. As a result, endothelial cells are constantly exposed to a variety of hemodynamic forces including shear stress, hydrostatic pressure, and cyclic strain. Shear stress is particularly significant because it is transduced by endothelial cell-surface proteins to activate signaling pathways that regulate changes in cell morphology, growth, and gene expression (Hahn and Schwartz 2009). The endothelial response to shear stress depends on the type and rate of flow. For example, exposure of endothelial cells to steady laminar flow may induce cell-cycle arrest in G_0 or G_1, whereas exposure to disturbed blood flow exhibits pro-proliferative effects (Chiu and Chien 2011). Additionally, laminar flow causes endothelial cells to become aligned and elongated in the direction of flow, while disturbed flow causes endothelial cells to adopt a more polygonal shape without a clear orientation (Chiu and Chien 2011). Rearrangement of intercellular junctions and cytoskeletal proteins underlies the morphological changes of endothelial cells in response to both types of flow.

Fluid shear stress can also modulate endothelial gene expression. Shear stress response elements (SSRE) have been discovered in the promoters of many genes and act as critical *cis*-acting elements for shear stress-regulated gene expression (DiCorleto and Fox 2005). Mechanotransducers at the endothelial cell surface respond to shear forces to activate signaling pathways and transcription factors that regulate gene induction. The exact mechanisms by which endothelial cell-surface proteins transduce mechanical forces are not known, but cytoskeletal proteins, receptor tyrosine kinases (RTKs), G-protein-coupled receptors (GPCRs), and ion channels all play a role (Hahn and Schwartz 2009). The ability of endothelial cells to react to specific types of biomechanical forces emphasizes its role as a type of organism-wide sensory organ, capable of detecting and responding to a variety of hemodynamic forces depending on both the type and magnitude of the force.

Mechanisms of Endothelial Activation

The original models of the endothelium's role in disease progression were largely based on the response-to-injury hypothesis. This hypothesis stated that the endothelium was a protective, passive barrier whose absence following injury led to abnormal contact between circulating platelets and thrombogenic basement membrane. However, after researchers observed that the endothelium could interact with circulating monocytes, oxidize low-density lipoprotein, and synthesize growth factors and cytokines, it was suggested that the endothelium may play an active role in the development of atherosclerosis and other vascular diseases (DiCorleto and Chisolm 1986). After decades of research, it is well accepted that endothelial activation is associated with a number of vascular diseases including atherosclerosis.

Inflammatory and pro-thrombotic substances transition the endothelium to an activated state

characterized by increased intimal permeability, expression of leukocyte adhesion factors, and shifts in protein secretion. Alterations in the secretion profile affect the balance of pro- and antithrombotic factors, pro- and anti-inflammatory cytokines, growth factors and inhibitors, and vasodilatory and constrictive substances. Endothelial reactions to stimulation are largely coordinated by a central signaling pathway, NF-κB. Stimulation of this pathway results in the induction of hundreds of genes associated with the activated phenotype. The results of endothelial activation are manifested as altered interactions between the endothelium, other cells of the vascular wall, and components of the blood.

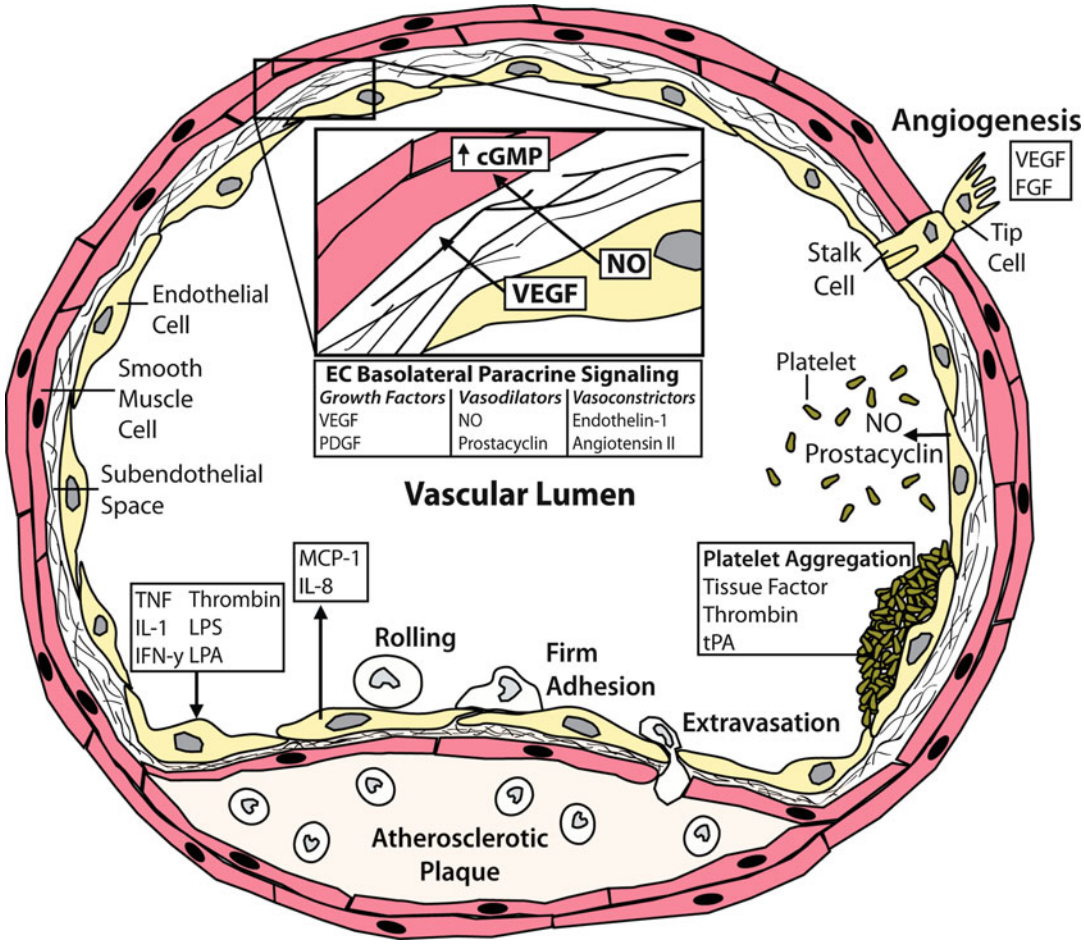
NF-κB as a Central Regulator of Endothelial Cell Activation

The endothelium responds to inflammatory agonists primarily by inducing genes not transcribed in the resting state. Signals for a variety of activating agonists, such as TNF, IL-1, LPS, or oxidized LDL, converge on the NF-κB signaling pathway to activate transcription of target genes (De Caterina et al. 2007). The NF-κB family includes five transcription factors, RelA (p65), RelB, c-Rel, NF-κB1 (p50), and NF-κB2 (p52), and their inhibitors, the IκB subunits, all of which are ubiquitously expressed in mammalian cells. Characteristic of NF-κB family members is a common domain essential for dimerization and DNA binding, the Rel homology domain. At rest, the transcription factors are sequestered by their inhibitory partners in the cytosol. These inhibitors are phosphorylated, usually by the IκB kinase complex (IKK), ubiquitinated, and targeted for proteasomal degradation upon stimulation. Newly liberated NF-κB factors dimerize and translocate to the nucleus, where they bind the κB sequence in the promoter of target genes. The transcriptional activity of NF-κB members is further regulated through associations with coactivators and through a variety of posttranslational modifications (Oeckinghaus et al. 2011). The NF-κB binding site is a remarkably loose, decameric sequence written as GGGRNNTYCC (R = G or A, Y = C or T, N = any nucleotide) (Baltimore 2011). Genes important in the inflammatory program often are induced under the control of NF-kB. These include the adhesion molecules E-selectin, VCAM-1 and ICAM-1, as well as IL-1, IL-6, IL-8, MCP-1, TF, PAI-1, COX-2, and iNOS (De Caterina et al. 2007).

Expression of Leukocyte Adhesion Molecules, Cytokines, and Chemokines

Leukocytes do not interact with healthy, unstimulated endothelial cells, but following exposure to an activating agent, adhesion molecules are expressed on the luminal surface and chemokines are secreted into the blood to interact with and recruit leukocytes (Fig. 1, bottom). Initial interactions between endothelial cells and leukocytes involve the immune cell rolling along the endothelium, followed by arrest, focal adhesion, spreading, and emigration of the leukocyte from the lumen across the endothelial barrier.

Leukocyte rolling on the endothelial surface is a relatively weak interaction governed by the selectin family of proteins, P-, E-, and L-selectin. P-selectin is present in platelet secretory granules, as well as the Weibel-Palade bodies of endothelial cells, and is therefore rapidly displayed on the endothelial cell surface within minutes of agonist exposure (De Caterina et al. 2007; Pober and Sessa 2007). L-selectin is expressed on leukocyte populations and has affinity for ligands expressed on endothelial cells and other leukocytes. E-selectin is only expressed in activated endothelial cells. Stronger interactions mediated by the immunoglobulin superfamily tether the rolling leukocyte to the endothelium. These adhesion molecules include ICAM-1, ICAM-2, and ICAM-3, VCAM-1, and PECAM-1. While low levels of ICAM-1 are constitutively expressed by endothelial cells, this gene and other members of the immunoglobulin family are induced upon activation. Migration of the tethered leukocyte through the intima is promoted by cell-type-specific chemoattractants secreted by endothelial cells, smooth muscle cells, and leukocytes (DiCorleto and Fox 2005). Chemokines also play a role in sustaining inflammation and are often expressed under the control of NF-κB. Chemokines of particular importance



Mechanisms of Endothelial Activation, Fig. 1 *Mechanisms of endothelial activation*. Clockwise from the *left*: Blood vessels are lined by a single-cell-thick layer of endothelial cells surrounded by extracellular matrix proteins and concentric layers of smooth muscle cells. Endothelial cells synthesize and secrete a variety of growth factors and vasoactive substances (*top*) to regulate smooth muscle cell growth, motility, and vessel tone. Endothelial cells also respond to growth factors to create angiogenic sprouts to form new blood vessels (*top right*). Endothelial cells actively regulate the hemostatic/thrombotic balance of circulating blood by modulating production of procoagulant and anticoagulant factors (*right*). Inflammatory activation of endothelial cells (*bottom*) is caused by a wide variety of factors and is implicated in numerous disease states, including atherosclerosis. Inflammatory factors such as TNF induce expression of leukocyte adhesion molecules and chemokines which recruit leukocytes to sites of inflammation, permit leukocyte rolling and firm adhesion to endothelial cells, and facilitate the extravasation of leukocytes into the subendothelial space. The accumulation of monocytes in the subendothelial space, and the activation of monocytes by oxidized lipoproteins and endothelial-derived factors, are critical events in the initiation of atherosclerosis

in atherosclerosis include IL-6, IL-8, and monocyte chemotactic protein 1 (MCP-1) (De Caterina et al. 2007).

Recent research has discovered that NF-κB signaling also regulates the formation and release of endothelial-derived microparticles. Microparticles are membrane vesicles less than 1 μm in diameter that are released from the cell in response to various stimuli. These microparticles can be generated by the same agents that induce adhesion molecule and cytokine expression (e.g., TNF and thrombin) and are functionally heterogenous (Rabelink et al. 2010). Depending on their lipid and protein compositions,

these NF-κB-regulated microparticles can be procoagulant and chemotactic or promote leukocyte adhesion to the endothelium (Rautou et al. 2011). Circulating levels of endothelial-derived microparticles increase at early stages in atherosclerosis and may contribute to disease progression, in part, by reducing eNOS phosphorylation and the bioavailability of NO (Rautou et al. 2011). The overall contribution of microparticles to vascular disease progression remains uncertain. However, as a functionally heterogenous group of bioactive substances, microparticles may represent an additional target of pathophysiologically relevant factors regulated by NF-κB transcription factors.

Altered Permeability of the Activated Endothelium

LDL, in a pathway common to many cells, normally enters endothelial cells through an LDL receptor-mediated endocytic route, leading to the hydrolysis of cholesteryl ester and reesterification of free cholesterol. This pathway is usually downregulated in hypercholesterolemic animals. Experiments have shown enhanced endothelial permeability to plasma lipoproteins in hypercholesterolemic animals, leading to plasma-derived buildup of LDL and VLDL particles in the subendothelial space (De Caterina et al. 2007). This accumulation of relatively large lipoproteins and lipids results from changes in vessel wall permeability in response to blood-borne inflammatory molecules in the local environment. Agonists such as histamine transiently open intercellular junctional proteins, allowing plasma-derived lipids and lipoproteins to become trapped in the subendothelial space (DiCorleto and Fox 2005). Once there, these lipoproteins can become oxidized by free radicals released by endothelial cells and leukocytes located within the lesion. Conversion of LDL to oxidized forms allows the particles to be recognized and taken up by various scavenger receptors, including CD36. Further, other products of lipid and lipoprotein oxidation function to induce changes in endothelial behavior. Cell culture experiments show that atherogenic concentrations of both oxidized LDL and unmodified LDL trigger the binding of monocytes to endothelial cells by activating transcription of the adhesion molecules VCAM-1 and ICAM-1 (DiCorleto and Fox 2005). Other functional changes, such as alterations in motility, and the expression of growth factors and cytokines have also been reported.

Thrombogenicity and Vasospasm

The healthy endothelium actively inhibits coagulation. Endothelial synthesis of prostacyclin and other antithrombotic factors inhibit platelet aggregation and adherence to the endothelium. During endothelial dysfunction, however, localized alterations in the balance of hemostatic factors may render the endothelial surface thrombogenic (Fig. 1, right). Endothelial expression of the pro-thrombotic tissue factor can be induced by a variety of agonists including thrombin, TNF, shear stress, and oxidized lipoproteins (Chiu and Chien 2011; DiCorleto and Fox 2005). Additionally, changes in the relative expression of tissue plasminogen activator (tPA) and plasminogen activator inhibitor-1 (PAI-1) contribute to increased thrombogenicity of the activated endothelium. Under normal conditions, the expression of these enzymes is tightly regulated to maintain a hemostatic/thrombotic balance. Activated endothelial cells tend to express higher levels of PAI-1, which can be induced by oxidized lipoproteins and shear stress, and lower levels of tPA (DiCorleto and Fox 2005). Together, these changes reduce the rate of fibrinolysis at localized sites of endothelial cell activation, creating a more thrombogenic environment.

The vasorelaxants NO and prostacyclin are key mediators of vascular tone. Availability of NO is curtailed in a number of vascular pathologies, including atherosclerosis and coronary artery disease, and is considered characteristic of vascular disease (De Caterina et al. 2007). Reductions in NO availability occur though multiple mechanisms, including decreased NO production, stabilization, or inactivation by ROS. A number of endothelial-derived vasoconstrictive substances antagonize the actions of NO and prostacyclin to induce smooth muscle cell

contraction (Fig. 1, top). ET-1 is the most potent and perhaps the most pathophysiologically important vasoconstrictor reported to date. It is expressed as a propeptide by endothelial cells and is activated by proteolytic cleavage mediated by ET-converting enzyme. Endothelial cells secrete most of the protein basolaterally, where the active form interacts with endothelin receptors on smooth muscle cells to induce vasoconstriction. Multiple atherogenic factors induce ET-1, including lipoproteins, interferon-γ, IL-1β, thrombin, and shear stress. Aberrant expression of endothelial-derived ET-1 may function in a number of vascular diseases, including atherosclerosis, where it is expressed in atherosclerotic vessels and contributes to pathophysiological vasoconstriction (Lüscher et al. 2005; De Caterina et al. 2007).

Biomechanical Forces and Endothelial Activation

As previously discussed, the location of the endothelium exposes it to a variety of biomechanical forces, which regulate cell shape, growth, and gene expression. Mechanotransduction of laminar flow and high shear stress is normally adaptive and atheroprotective, but low-level shear stress or disturbed flow is atherogenic. Atherosclerotic lesions form at sites of disturbed blood flow in arterial vessels, suggesting that changes in shear stress may alter patterns of atheroprotective or atherogenic gene expression (Chiu and Chien 2011). While the mechanisms by which disturbed blood flow contributes to lesion formation are not completely understood, some differences in the activation of signaling pathways between laminar and disturbed flow have been observed. Both types of flow activate intracellular signaling kinases and transcription factors including NF-κB, early growth response 1 (EGR1), activator protein 1 (AP1), and JUN N-terminal kinase (JNK) (Hahn and Schwartz 2009). Under laminar flow, the activation of these molecules is transient, increasing over several hours and then returning to basal levels. In contrast, endothelial cells exposed to disturbed flow show sustained activation of kinases and transcription factors, including NF-κB and JNK, which coincides with increased expression of inflammatory genes, such as ICAM-1, VCAM-1, E-selectin, MCP-1, ET-1, and PDGF (Chiu and Chien 2011; Hahn and Schwartz 2009). These differences in the kinetics of pathway activation and gene expression between laminar and disturbed flow may represent a potential basis for the nonrandom formation of atherosclerotic lesions at vessel bifurcations where blood flow is disturbed or slowed.

Growth Factor Activation of the Endothelium and Angiogenesis

Normally quiescent under physiological conditions, endothelial cells can be activated by growth factors to acquire proliferative, migratory, and invasive properties. Important stimulators of endothelial cell proliferation include fibroblast growth factor (FGF), vascular endothelial growth factor (VEGF), PDGF, and epidermal growth factor (EGF) (Manka et al. 2005). These substances also induce angiogenesis, the formation of new blood vessels from the preexisting vasculature.

The primary event governing the initiation of angiogenesis is the formation of an endothelial cell sprout from a preexisting endothelial cell monolayer (Potente et al. 2011). Environmental cues, primarily in the form of growth factors such as VEGF, cause normally quiescent endothelial cells to become activated and acquire a migratory and invasive phenotype (Herbert and Stainier 2011; Potente et al. 2011). This phenotypic change coincides with a reduction in cell-to-cell contacts and a corresponding increase in vascular permeability (Herbert and Stainier 2011). Based on relative amounts of VEGF receptor-2 (VEGFR-2), a "tip cell" (TC, high VEGFR-2 expression) is selected to lead an endothelial cell sprout to form a new vessel. The TC leads migration by following chemoattractant guidance cues and degrading extracellular matrix (ECM) proteins. Other activated endothelial cells, termed "stalk cells," (SC) follow behind TCs, maintain a proliferative phenotype, and form a rudimentary new vessel lumen (Fig. 1, top right). Together, TCs and SCs constitute the

endothelial cell sprouts that continue to migrate until an adjacent sprout is reached. Sprouts then fuse together in a process called anastomosis. Following anastomosis, the motile and proliferative phenotypes of TCs and SCs are gradually lost, and cell-to-cell junctions are reestablished to form a proper lumen and allow for blood flow. The endothelium plays an additional role in forming a mature neovasculature by synthesizing and depositing ECM proteins as well as synthesizing growth factors such as PDGF which recruit pericytes to support the new vessel (Potente et al. 2011).

Clinical Definitions of Endothelial Dysfunction

The results from many studies using in vitro systems and animal models have led to the currently accepted definition of endothelial dysfunction. An unresolved challenge in vascular research is to create a reliable method for the clinical diagnosis of endothelial dysfunction, and various plasma biomarkers have been proposed and investigated for this purpose. In particular, plasma levels of von Willebrand factor (vWF) may be useful as a prognostic factor for cardiovascular diseases. Other potential biomarkers include ET-1, soluble adhesion molecules, angiotensin II, PDGF, asymmetric dimethylarginine ADMA, and NO (Freestone et al. 2010).

Importantly, some studies have shown that NO bioavailability is reduced in early atherosclerotic lesions (Chiu and Chien 2011). Additionally, it has long been known that ADMA is an endogenous inhibitor of NO synthesis, and ADMA levels are elevated in patients with various vascular diseases including coronary artery disease, hypertension, hypercholesterolemia, and atherosclerosis (Freestone et al. 2010; Leone et al. 1992). It has therefore been suggested that ADMA may be a plasma marker for early-stage endothelial dysfunction.

More recently, endothelial-derived microparticles in the plasma have been proposed as a diagnostic indicator of endothelial dysfunction. As previously mentioned, endothelial microparticles are known to be generated by a variety of atherogenic cytokines. Additionally, increased levels of microparticles generated from the endothelium have been observed in a variety of disease states including atherosclerosis, coronary artery disease, pulmonary hypertension, and end-stage renal failure (Rautou et al. 2011).

As the body's largest homeostatic organ, the vascular endothelium forms a marvelous non-thrombogenic surface lining every vessel in the body. Its function is critical for maintaining vascular health, and its dysfunction is associated with the genesis and progression of various vascular diseases. As a dynamic biological interface, the endothelium has the capacity to sense environmental changes, synthesize vasoactive substances, interact with other cell types, regulate vascular permeability, and form collateral vessels from the preexisting vasculature. Dysregulation of these processes is present in many vascular diseases, and endothelial dysfunction often precedes atherosclerosis and associated conditions, suggesting that endothelial activation may play a causative role in serious vascular illnesses. However, while the endothelium is known to participate in the genesis and progression of vascular diseases, the specific triggering events of endothelial activation, which distinguish pathophysiological dysfunction from physiological adaptation, are still incompletely characterized. Therefore, a more thorough understanding of endothelial dysfunction may lead to descriptions of causative events underlying endothelial dysfunction for distinct disease states. Such knowledge may allow for better risk stratification of patients before major adverse events as well as the identification of novel opportunities for therapeutic intervention to prevent or treat vascular diseases.

Micro-RNA in Autoimmunity

To-Ha Thai
Division of Rheumatology, Department of Medicine, Beth Israel Deaconess Medical Center, Harvard Medical School, Boston, MA, USA

Synonyms

Micro-ribonucleoprotein (miRNP); Micro-RNA (miRNA, miR); RNA polymerase II (pol II); RNA-induced silencing complex (RISC); Systemic lupus erythematosus (SLE)

Definition

Micro-RNAs are small, ∼21- to 22-nucleotide (−nt) long, noncoding regulatory RNAs that contribute to the regulation of coding gene expression.

Introduction

In vivo gain- and loss-of-function studies in mouse models demonstrate without a doubt that micro-RNAs (miRNAs), alongside with coding genes, control the mammalian immune system. The regulation of miRNA expression is tightly controlled, and often the same rules and regulations that govern coding gene expression apply also to miRNAs. Similar to coding genes, altering the levels and the temporal expression of a specific miRNA clearly affects the proper development and function of the tissue where it is expressed. Therefore, it is reasonable to argue that the dysregulated control of miRNA expression would affect immune functions and development as has been well established for coding genes. Along the same line of reasoning, there is an impetus to use miRNAs as diagnostic biomarkers and to develop therapeutic agents to target miRNAs for the treatment of various diseases such as autoimmune diseases.

Micro-RNAs are small, ~21 to 22 nucleotide (nt) long, noncoding regulatory RNAs, first discovered in *Caenorhabditis elegans* (*C. elegans*) for its role in regulating the expression of coding genes. Most mammalian miRNAs are transcribed by RNA polymerase II (pol II), the same polymerase that directs the transcription of coding genes. MiRNA genes are encoded in intergenic regions, in sense or antisense orientation within introns of specific genes, or by noncoding transcripts (Pillai et al. 2007). In the nucleus, miRNAs are derived from larger precursors called primary (pri)-miRNAs that are processed into 75-nt-long precursor (pre)-miRNA hairpins by the RNAse III enzyme Drosha. The hairpins are exported into the cytoplasm by exportin 5. In the cytoplasm, Dicer, an RNAse III-like enzyme, processes the pre-miRNA hairpins to generate small RNA duplexes. One and sometimes both of the strands will be incorporated into the RNA-induced silencing complex (RISC) or micro-ribonucleoprotein (miRNP) complex containing Argonaute 2 (Ago 2), among other proteins. The RISC/miRNP complex executes miRNA functions, and miRNAs perform their functions by forming a duplex with the target gene(s) in the 3′ untranslated (UTR) region of its messenger RNA (mRNA). Depending on the degree of complementarity between the miRNA: mRNA duplex, this interaction usually leads to the downregulation of protein expression by translational repression, mRNA cleavage, or promotion of mRNA decay (Fabian et al. 2010). Interestingly, the interaction between mRNAs and miRNAs not only affects the translation of the target mRNA, but also the miRNA stability, and this reciprocal relationship depends on the extent of base pairing between the two molecules (Ameres and Fukunaga 2010).

To date, hundreds of miRNAs have been identified in species including viruses, plants, nematodes, mice, and humans, and the number is still increasing (miRBase, http://www.mirbase.org/). Most human miRNAs are conserved in the mouse, and about one-third of *C. elegans* miRNAs have vertebrate homologues, suggesting that a large fraction of miRNAs play evolutionary conserved developmental and/or functional roles.

Effects of Global Reduction of miRNA Expression

The first hint that miRNAs play an important role in the immune system came from mouse studies in which the *dicer-1* or *Ago2* gene is conditionally deleted. The ablation of *dicer* leads to a global reduction of miRNAs and other small RNAs, and it is clear that inactivation of Dicer activity, thus the expression of most if not all miRNAs, impacts the development and differentiation of T and B lymphocytes (Thai et al. 2010). Additionally, B-cell-specific deletion of *dicer* in female mice leads to the development of autoimmunity characterized by the presence of high titers serum autoreactive B-cells. It is noteworthy that not all miRNAs are equally ablated. It is also evident that not all T-cell lineage commitment programs are subjected to Dicer control. Irrespective of the cell type examined, Dicer activity is required for cell survival and proliferation, suggesting that the defects in lymphoid development may be partially due to the reduction of a group of miRNAs controlling cell survival and proliferation. Could all these phenotypes be ascribed to miRNAs, if so, which subsets of miRNAs are involved in each cell type and at which stage of lineage commitment? The answer awaits further studies.

Although Dicer and Ago2 are among the major factors involved in miRNA biogenesis and function, they are also involved in small interfering RNA (siRNA) and other small RNA biology. Therefore, the defects observed in the above mutant mice may not be solely due to the loss of miRNAs.

Lymphocyte Development

Through several seminal genetic studies, it is apparent by 2004 that individual miRNAs exert control on the immune system. First, mice reconstituted with bone marrow cells overexpressing the thymus-enriched miRNA, miR-181, whose expression is dynamically regulated during T-cell development, have a higher and lower percentage of B- and T-cells in the

periphery, respectively. MiR-181a is also over-represented in tolerized and re-tolerized $CD8^+$ T-cells (Schietinger et al. 2012). The generation and analysis of miR-181 loss-of-function mice would be valuable to provide a more physiological flavor to these observations.

Subsequently, work from two different groups demonstrates the important role of miRNAs in B-cell development (Xiao et al. 2007; Zhou et al. 2007). Loss- and gain-of-function studies show that miR-150, a mature lymphocyte-specific miRNA, regulates B-cell differentiation by controlling the transcription factor c-myb in a dose-dependent manner (Xiao et al. 2007). Therefore, miR-150 may act as a dimmer rather than an on/off switch in the modulation of B-cell development, and it achieves this delicate balance by fine-tuning the expression levels of its targets, such as c-myb, in B-cells. Although c-myb plays an important role in both T- and B-cell development, ectopic expression or deletion of miR-150 has a stronger effect on B- than T-cell development. Thus, other miR-150 targets may be more crucial to T-cell development.

The developmental programs in B- and T-cells are controlled by many transcription factors, among which some are lineage- and stage-specifically expressed and some are more ubiquitously expressed. It is not surprising that it is the case with miRNAs such as the miR-17∼92 cluster, and mature miRNAs from this cluster are broadly but differentially expressed in various mouse tissues. Mice overexpressing the miR-17-92 cluster suffer from lymphoproliferative and autoimmune manifestations with no obvious defects in B-cell development (Xiao et al. 2008). By contrast, miR-17-$92^{-/-}$ mice have a profound impairment of both fetal and adult B-cell development while their peripheral B-cell effector function appears to remain intact (Ventura et al. 2008). These results suggest that miR-17-92 overexpression and miR-17-92 deficiency affect overlapping but not identical targets. It would be interesting to determine whether miR-17-92 deficiency would alleviate autoimmunity.

Adaptive Immunity

Many miRNAs seem to participate in both hematopoiesis and immune responses, and the same mechanisms may be employed in both processes. In addition to the dysregulated B-cell development observed, miR-$150^{-/-}$ mice (discussed above) also displayed augmented steady state levels of serum immunoglobulin (Ig) A, IgG1, IgG2b, and IgM, as well as an enhanced T-dependent immune response, perhaps due to the increased c-myb levels. It has been shown that c-myb promotes lymphocyte survival by controlling the pro-survival factor Bcl2 (Taylor et al. 1996). The data suggests that miR-150 also regulates the immune response; doing so whether through c-myb or other targets remains to be determined.

One miRNA that participates in both innate and adaptive immunity is miR-155. It does not regulate lymphocyte development. MiR-155 expression is transiently induced upon activation. Dysregulated miR-155 expression results in impaired immune responses due in part to defects in germinal center (GC) formation (Rodriguez et al. 2007; Thai et al. 2007). In addition, results from many groups clearly showed that miR-155 plays an essential role in both T- and B-cell effector function (Thai et al. 2010).

One might wonder how does miR-155 regulate B- and T-cell effector functions? Does it do so by controlling the expression of a yet to be identified master regulator or by modulating different targets? Another plausible scenario would be that miR-155 controls a pathway(s) downstream of receptor activation, which might modulate genetic/epigenetic modifications in lymphoid effector genes.

Innate Immunity

The importance of miRNAs in innate immunity is also underscored by work demonstrating that miR-223, a myeloid-specific miRNA encoded in the X chromosome, negatively regulates granulocyte lineage specification and inflammatory

response (Johnnidis et al. 2008). In the absence of miR-223 (miR-223$^{-/y}$), granulocytes are hypermature, hypersensitive to stimuli and they display enhanced fungicidal activity. As a result, miR-223$^{-/y}$ mice develop spontaneous inflammatory lung pathology and exhibit an exaggerated tissue destruction following endotoxin challenge. The mutant mice display an expanded granulocytic compartment as a result of progenitor hyperproliferation. Ablation of *Mef2c*, a transcription factor that promotes progenitor proliferation and a miR-223 target predicted with the highest confidence in miR-223$^{-/y}$ mice, does not rectify the functional defects, while the progenitor proliferation and granulocyte differentiation defects are rescued. These results suggest that miR-223 is a negative regulator of progenitor proliferation, and granulocyte differentiation and activation. In addition, the data imply that miR-223 may regulate distinct targets during granulocyte development and function.

Similar to miR-155, miR-146a is induced in human monocytes after in vitro activation by LPS, suggesting that this miRNA may be involved in mammalian microbial infection. In a recent publication, the same group demonstrates that miR-146a null mice manifest an exaggerated inflammatory response to endotoxin challenge (Boldin et al. 2011). In addition, old miR-146a$^{-/-}$ mice develop spontaneous autoimmune symptoms characterized by splenomegaly, lymphadenopathy, and multi-organ inflammation that ultimately leads to premature death. MiR-146a also regulates immunological tolerance by controlling the IFN-γ signaling pathway in Treg cells (Lu et al. 2010). Thus, miR-155 and miR-146a appear to govern both the innate and adaptive immune responses to foreign and endogenous antigens. The dysregulated expression of either miRNA will lead to the breakdown of immune regulation and tolerance in mice. Because of their inducible nature, miR-155 and miR-146a would be excellent targets for the treatment of inflammatory and autoimmune diseases without interfering with normal immune responses.

Autoimmunity

Data from animal studies highlighted above clearly demonstrate that the dysregulated expression of a subset of miRNAs involved in normal lymphoid development and functions leads to some form of autoimmunity. MiR-17-92 cluster controls targets that may contribute to autoimmunity. By contrast, miR-146 and miR-223 targets appear to suppress autoimmunity. Although overexpression of miR-155 in mice does not appear to contribute to autoimmunity, its deficiency clearly alleviates inflammatory and autoimmune manifestations.

It is suggested that miR-101 might be involved in the pathogenesis of lupus-like diseases in the *sanroque* mouse; however, there is no direct genetic evidence to support this observation (Yu et al. 2007). While the observations are intriguing, the final proof implicating miR-101 in lupus pathogenesis awaits the generation of a miR-101 mutant mouse models.

The paucity of available miRNA mouse models for the study of autoimmune diseases such as systemic lupus erythematosus (SLE) is not due to a lack of interest in linking miRNAs to autoimmune diseases. Indeed, many groups have identified miRNAs that are differentially expressed in lupus patients by miRNA array assays using mostly peripheral blood mononuclear cells (PBMCs) (Thai et al. 2010). The type of miRNAs, and their putative targets, identified in these studies ranges from those associated with innate immunity to inflammation and DNA methylation. Suggestions from the data are tantalizing, yet again the final proof requires the generation and in-depth analysis of animal models for each of these miRNAs.

Micro-RNAs as Potential Drug Targets

Due to their small size and potential roles in disease processes, miRNAs have been intensively exploited as potential drug targets by both academic institutions and biopharmaceutical companies.

Several studies have demonstrated that the introduction of a small inhibitory nucleic acid

molecule, either RNA or DNA, into animal models of disease abrogates molecular pathology and, in some cases, the disease itself. To date, only three miRNAs have been effectively targeted in vivo, miR-122, miR-155, and miR-21. The injection of an anti-miRNA modified oligonucleotide (locked nucleic acids, LNA) against the liver-specific miR-122 into mice and non-human primates selectively and effectively lowers the level of this miRNA in the liver, reduces serum cholesterol, and resolves *Hepatitis C* infection, and the effects are long-lasting (Lanford et al. 2010). The US Food and Drug Administration (FDA) approves a Clinical Phase 2a trial to assess the efficacy and tolerability of the anti-miR-122 LNA (miravirsen-SPC3649) in treatment-naïve patients with chronic *Hepatitis C* infection. This represents the first miRNA-targeted drug to enter clinical trials. At this point, no data is available to indicate if miravirsen-SPC3649 is efficacious in humans. As discussed above, the dysregulated expression of miR-155 and miR-146a has been implicated in inflammation and cancer in mice. However, to date, no targeted drugs for these miRNAs have moved into in vivo animal models or clinical trials. One group though demonstrated that it is possible to inhibit miR-155 in vivo (Zhang et al. 2012). Recently, miR-21 was effectively targeted in vivo in the lupus-prone mouse model B6-*sle123* with miR-21 LNA (Garchow et al. 2011). Since miR-21 is ubiquitously and constitutively expressed, it is not clear how targeting miR-21 would ameliorate lupus-like symptoms in their study. In addition, there is no mouse or human genetic data to support the results.

In vivo miRNA replacement therapy has not been fully explored. However, one group is successful in inhibiting cancer cell proliferation, inducing tumor-specific apoptosis and providing protection from disease progression by systemically administering miR-26a into a hepatocellular carcinoma (HCC) mouse model (Kota et al. 2009). The replacement protocol described here requires the use of adeno-associated virus to express miR-26a in vivo. It might be more advantageous to develop means to introduce miRNA mimics, thus avoiding unwanted adjuvant effects inherent in adenovirus vector.

Although results in animal models proved promising, many hurdles must be overcome before anti-miRNAs or miRNA replacement therapy could be routinely used as therapeutic agents in humans: first, the mode of delivery to achieve specificity in vivo; second, the bioavailability of theses reagents; third, the potential off-target effects of these RNA molecules; and finally the cost-effectiveness of developing large-scale RNA agents.

Perspective

One can conclude without any doubt that miRNAs participate, along with coding genes, in the regulation of complex biological processes in mammalian hematopoietic/immune system. However, there is a dearth of genetic studies in human to implicate the dysregulation of miRNA expression in the pathogenesis of human diseases. To date only one study in which targeted deletion of a miRNA region faithfully recapitulates a disease state: deletion of the *LEU2/miR-15a/16-1* region results in the onset of a form of CLL manifested by a subset of patients. What accounts for the paucity of human genetic evidence to implicate miRNAs in human diseases? Is it because most miRNAs do not act as master regulators of gene expression, but rather as modifiers of gene levels? Or most miRNAs reside in more stable genomic regions that are protected from agents that induce genetic instability? Or perhaps the direction of research carried out by miRNA biologists precludes the identification of genetic evidence implicating miRNAs in human diseases? The answer is probably all of the above. While the first two issues are beyond scientists' ability to address since the nature of biology could not be modified, the miRNA biology community could focus its creativity and resources on in-depth genetic and in vivo functional studies such as the one described for the *DLEU2/miR15a/16-1* in CLL, to definitively draw a connection between miRNA expression/function and autoimmunity.

Microscopic Polyangiitis

Atul Khasnis and Leonard H. Calabrese
Department of Rheumatic and Immunologic Diseases, Section of Clinical Immunology, Cleveland Clinic Foundation, Cleveland, OH, USA

Definition

A systemic inflammatory disease characterized by necrotizing small and medium vessel vasculitis.

History

Microscopic polyangiitis (MPA) was first described as a microscopic variant of polyarteritis nodosa (Wohlwill. 1923). It was classified as a small and medium vessel vasculitis under the Chapel Hill Consensus Conference (Jennette et al. 1994). In 1950, Wainwright and Davson used the term "microscopic polyarteritis" to describe this illness (Wainwright and Davson 1950).

Epidemiology

The annual incidence of MPA has been reported to be 2–17 per million in various populations (Gibelin et al. 2011). There is no gender or age predilection for MPA, but the incidence has been reported to peak in the sixth to seventh decade.

Etiology and Pathogenesis

The etiology of MPA is unknown. The disease is characterized by necrotizing inflammation of arterioles and venules with infiltration of neutrophils and lymphocytes, often with leukocytoclasis and fibrinoid necrosis. The pathogenesis of MPA is incompletely understood but has been proposed to involve the formation of antineutrophil cytoplasmic antibodies (ANCAs) (Jennette et al. 2011). The mechanisms that lead to ANCA production are unclear. ANCAs are, however, neither absolutely necessary nor sufficient to cause histologic or clinical manifestations of MPA. The initial event in MPA may involve the priming of neutrophils with cytokines such as tumor necrosis factor alpha (TNF-α) which could be triggered by environmental factors, such as infection. Neutrophil priming results in translocation of normally intracellular neutrophil granule contents to its surface. One of the proteins translocated in this way is myeloperoxidase (MPO), an enzyme that forms the antigenic target for the perinuclear ANCA (pANCA). The binding of ANCA to MPO results in neutrophil activation, degranulation, and demise by multiple pathways that include apoptosis, necrosis, and neutrophil extracellular traps. Although this has been well documented in some preclinical models, it has been inconsistently demonstrated in clinical studies. Although there appears to be an important antigen-antibody interaction in the pathogenesis of this illness, immune complexes are not observed in tissues on biopsy. Abnormal host immune responses undoubtedly participate in the onset and maintenance of vascular injury.

Clinical Features

MPA tends to involve predominantly small and medium sized blood vessels in multiple visceral organs. In one study of patients with MPA (Guillevin et al. 1999), the mean age was 56.8 years and major manifestations included renal disease (78.8 %), weight loss (72.9 %), rash (62.4 %), fever (55.3 %), mononeuritis multiplex (57.6 %), arthralgias (50.6 %), myalgias (48.2 %), hypertension (34.1 %), lung involvement (24.7 %), alveolar hemorrhage (11.8 %), and cardiac failure (17.6 %). Patients with MPA tend not to have ear, nose, and throat (ENT) involvement or lung nodules and they lack granulomatous inflammation. These features, along with the ANCA pattern and specificity (see below), help to distinguish it from granulomatous polyangiitis (Wegener's) (GPA).

Diagnosis

The diagnosis of MPA is based on a compatible clinical presentation accompanied by laboratory test results (including a positive ANCA serology) and/or imaging studies. The clinical presentation of systemic inflammation is often accompanied by concordant laboratory tests. These include a normochromic normocytic anemia, leukocytosis, thrombocytosis, low serum albumin, abnormal urinalysis (microscopic hematuria, proteinuria, and/or red blood cell casts), and elevated acute phase reactants such as erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP).

Positive ANCAs are present in 75–80 % patients with a predominant pANCA pattern on immunofluorescence and antibodies directed at myeloperoxidase (MPO) by Enzyme Linked ImmunoSorbent Assay (ELISA) testing.

Chest imaging with CT scan without radiographic contrast can be used to evaluate pulmonary involvement in the form of capillaritis/alveolitis/diffuse alveolar hemorrhage which typically shows a "ground glass appearance," In patients with multiple episodes of previous diffuse alveolar hemorrhage or capillaritis, pulmonary fibrosis in the form of "honeycombing" may be seen. Renal biopsy in indicated cases classically demonstrates a pauci-immune (relative lack of immune complexes on immunofluorescence and electron microscopy) crescentic glomerulonephritis.

Treatment

The treatment of MPA is guided by the severity of disease. The treatment paradigm for MPA has been extrapolated from treatment of related small vessel vasculitides such as GPA. The treatment is based on the classification of MPA as severe (organ-threatening or life-threatening) or non-severe. With either type, glucocorticoids form the cornerstone of treatment. The choice of a second immunosuppressive medication is driven by the severity of disease. In 1996, the French Vasculitis Study Group devised a five-factor score (FFS) (Guillevin et al. 1996) based on patients with polyarteritis nodosa, MPA, and Churg Strauss syndrome (CSS) which included proteinuria >1 g/dL, renal insufficiency (stabilized peak creatinine >1.4 mg/dL), cardiomyopathy, severe gastrointestinal manifestations, and CNS involvement. The revised FFS (Guillevin et al. 2011) based on patients with PAN, MPA, CSS, and GPA found that age >65 years, cardiac symptoms, gastrointestinal involvement, and renal insufficiency (stabilized peak creatinine >1.69 mg/dL) were associated with a high 5-year mortality. The presence of each was assigned 1 point. ENT symptoms (most commonly affecting patients with GPA and CSS) were associated with a lower risk of death, and therefore, their absence was also assigned 1 point. For patients with non-severe disease (FFS = 0), glucocorticoids alone may be sufficient as they have been shown to result in survival rates comparable to those of patients who received glucocorticoids and cyclophosphamide. For severe disease (FFS ≥ 1), the typical treatment regimen involves high-dose glucocorticoids (often intravenous followed by oral) and either oral cyclophosphamide (2 mg/kg/day) or rituximab.

In a study that compared cyclophosphamide to rituximab for remission induction in patients with new onset or relapsing GPA or MPA, rituximab was found to be non-inferior to cyclophosphamide (Stone et al. 2010). At 3–6 months, upon achievement of remission, the cyclophosphamide may be replaced with a maintenance immunosuppression medication such as methotrexate, azathioprine, or mycophenolate mofetil (Pagnoux et al. 2008) with continued taper of glucocorticoids. The choice of the maintenance immunosuppressant should be individualized based on patient preference, comorbidities, and other factors such as thiopurine methyltransferase (TPMT) genotype status for patients being considered for azathioprine. In patients who receive rituximab as induction therapy, whether to add a maintenance immunosuppression medication or continue the glucocorticoid taper alone is controversial. In patients with non-severe disease, methotrexate along with high-dose glucocorticoids can be used to induce remission provided renal insufficiency does not contraindicate the use of methotrexate. Informed decision making by the patient in terms of risk and benefit is imperative in the selection of immunosuppression and close clinical and laboratory monitoring is warranted. Plasma exchange has been shown to be effective as adjunctive therapy to conventional immunosuppression in patients with advanced renal failure in the setting of MPA (Jayne et al. 2007).

Prognosis

The FFS was also used to derive prognostic information in patients with MPA based on the

severity of illness. Based on the original FFS of 0, 1, and > =2 were associated with 5-year mortality rates of 12 %, 26 %, and 46 %, respectively. According to the revised FFS, 5-year mortality rates for scores of 0, 1, and > =2 were 9 %, 21 %, and 40 %, respectively. For 13 patients with MPA who died during the first year, older age, renal involvement, central nervous system involvement, and possibly cardiomyopathy seemed to confer the greatest risk of death. Treatment confers a good prognosis in patients with MPA. Even in patients with a FFS = 0, with a good overall 5-year survival, glucocorticoids achieved and maintained remission in only about half of the patients (40 % patients required additional immunosuppressive therapy) (Ribi et al. 2010). ANCA-associated vasculitides (GPA, MPA, CSS, and renal limited vasculitis) can result in end-stage renal disease and account for 1–2 % of patients on renal replacement therapy (Stegeman CA. 2012); however, separate data on the contribution of MPA is unavailable.

Conclusion

MPA is a systemic small and medium vessel vasculitis that merits prompt recognition and treatment. The choice of immunosuppression is guided by the severity of illness and mandates close monitoring. The introduction of newer therapeutic agents such as rituximab and the controlled duration of use of agents such as oral cyclophosphamide with change to maintenance immunosuppression after securing disease remission have made the treatment of this illness safer and more effective.

Mixed Connective Tissue Disease (MCTD)

Eric L. Greidinger
Division of Rheumatology, Miami VAMC and University of Miami Miller School of Medicine, Miami, FL, USA

Synonyms

Mixed connective tissue disease; Sharp's syndrome

Definition

MCTD is an autoimmune syndrome in which high-titer autoantibodies to the U1 small nuclear ribonucleoprotein (anti-RNP) are present along with overlapping clinical manifestations of lupus, scleroderma, and/or inflammatory myositis. Several classification criteria for MCTD have been published that perform similarly in identifying patients with MCTD (Alarcón-Segovia and Cardiel 1989). The criteria set of Alarcon-Segovia and colleagues is particularly concise and easy to apply in clinical settings (Table 1). However, it may be less likely to identify patients with primarily pulmonary manifestations as having MCTD compared to more complex schemes (Gunnarsson et al. 2012). Clinical overlap syndromes in the absence of anti-RNP antibodies exist and are distinct from MCTD. Patients with other well-defined rheumatic diseases (especially lupus and scleroderma) may have anti-RNP antibodies without having MCTD. Among lupus patients, anti-RNP is a marker of more severe disease including an increased risk of nephritis (Kirou et al. 2005). In contrast, MCTD often follows a mild and benign clinical course, though a significant risk of lung diseases emerges in some MCTD patients later in the course of their disease (Burdt et al. 1999).

Mixed Connective Tissue Disease (MCTD), Table 1 The Alarcon-Segovia classification criteria for MCTD

1. High-titer RNP+
2. Swollen hands
3. Synovitis
4. Myositis
5. Raynaud's
6. Acrosclerosis

To be classified with MCTD, patients must have criterion 1, plus at least 3 of the remaining 5 criteria

Historical Background

MCTD was first described by Gordon Sharp and colleagues, working initially at Stanford and then at the University of Missouri-Columbia in the late 1960s and early 1970s (Sharp 2002). It was the first rheumatic syndrome to be defined in part by the presence of a specific set of autoantibodies (anti-RNP).

Controversy has surrounded MCTD regarding the extent to which it was or was not distinct from lupus and other rheumatic diseases. Reports showing that, compared to lupus, MCTD has different Class II MHC disease associations, different autoantibody epitope targeting, and can be clinically distinguished by machine learning approaches have muted these concerns to some extent (Hoffman and Greidinger 2012). Concerns remain that the name "Mixed Connective Tissue Disease" may connote too general a sense of an overlap syndrome despite its acceptance as a clearly defined clinical entity (Swanton and Isenberg 2005).

Clinical Features

The most common manifestations of MCTD include Raynaud's Phenomenon, swollen hands, arthritis, sicca complaints, and esophageal disease (Table 2). Other typical manifestations include lupus-like and/or scleroderma-like skin changes, myositis, serositis, and the potential for lung disease. The manifestations of MCTD are

Mixed Connective Tissue Disease (MCTD), Table 2 Clinical manifestations present in >50 % of MCTD patients in multiple cohorts

Raynaud's Phenomenon	>85 %
Hand swelling	>75 %
Synovitis	>75 %
Dry eyes and/or mouth	>56 %
Gastroesophageal reflux	>51 %

generally consistent across geographical and ethnic boundaries (Maldonado et al. 2008).

A nationwide retrospective study in Norway estimated the point prevalence of MCTD in adults to be 3.8/100,000, with an incidence of 2.1/1,000,000, and a 3.3:1 female predominance (Gunnarsson et al. 2011). These values are similar to those observed elsewhere.

Since the initial reports by Sharp and others, MCTD has been recognized to be a generally more mild form of rheumatic disease that tends not to be associated with the most serious complications of lupus, scleroderma, or myositis. Diffuse proliferative glomerulonephritis, scleroderma renal crisis, and acute respiratory failure due to profound muscle weakness are all rare in MCTD. There is, however one exception: at least one third of MCTD patients develop serious lung disease manifestations including pulmonary hypertension, interstitial pneumonitis, or pulmonary fibrosis. Lung disease is the predominant mechanism of death attributable to MCTD, and it tends to emerge later in the evolution of the condition.

Although MCTD may be less likely to lead to major organ complications than SLE, disease activity can be substantial and impact the ability of patients to perform their activities of daily living. Most MCTD patients typically require some level of ongoing treatment. Among patients who escape the major organ complications of MCTD, some may ultimately lose their anti-RNP antibodies and enter sustained clinical remission.

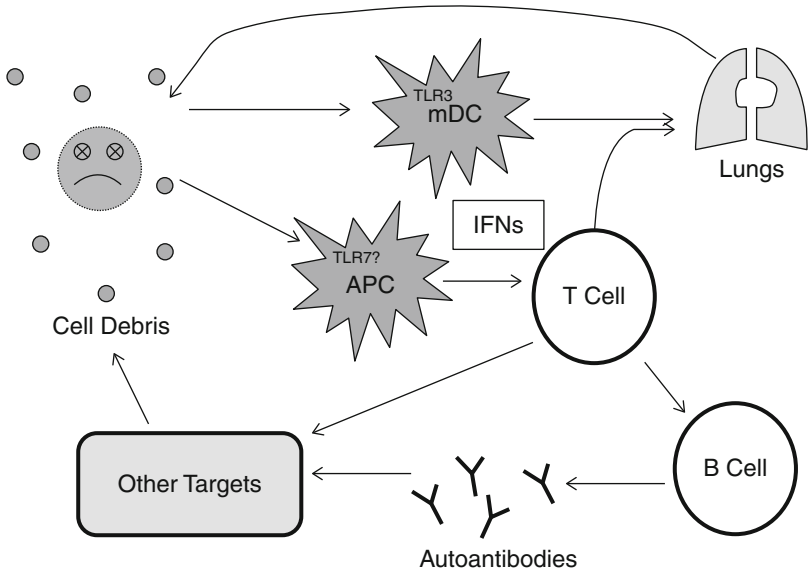
Given the potential for lung involvement in MCTD, active surveillance for evidence of lung disease with pulmonary function testing and echocardiography to assess right heart pressures is commonly performed, though these tests may miss some patients with evolving disease. Right heart catheterization to assess for pulmonary hypertension and/or high-resolution chest CT to assess for interstitial lung disease can be helpful when clinical suspicion is high. Investigators are seeking safer, less invasive tests with higher diagnostic yield to improve future disease management.

Treatment

In contrast to scleroderma lung disease in which immunosuppressive therapy has yielded minimal clinical benefit, lung disease in MCTD may be highly responsive to aggressive immunosuppression, including approximately 50 % of cases with pulmonary hypertension (Jais et al. 2008). No validated prediction rule has yet emerged to distinguish MCTD lung disease patients who will respond to immunosuppression from those who will not. The relative effectiveness of other immunosuppressive therapies (such as mycophenolate or calcineurin inhibitors) for MCTD lung disease compared to cyclophosphamide remains to be established.

There are scant treatment trials published regarding MCTD patients. The accrued evidence and anecdotal reports supports the use antimalarials, corticosteroids, disease modifyingantirheumatic drugs (DMARDs), and immunosuppressives for the treatment of MCTD activity. Treatments for organ-specific manifestations of MCTD, such as vasodilators for Raynaud's Phenomenon, proton pump inhibitors for gastroesophageal reflux disease, and topical steroids for inflammatory rashes, appear to be similarly helpful as in other rheumatic diseases.

Biologic antirheumatic therapies have not been systematically tested in MCTD. Progress in understanding the pathogenesis of MCTD may offer more opportunities to develop biologic drugs for use in this disease. Potential targets may include T cell response modifiers, anti-B cell therapies, Toll-like receptor antagonists, Type I Interferon antagonists, and IL-17 axis antagonists. Some promise exists that



Mixed Connective Tissue Disease (MCTD), Fig. 1 Putative pathogenesis of MCTD: Dead cell debris functions as a source of autoantigenic and autoinflammatory stimuli. Taken up by myeloid dendritic cells (mDC) or other antigen presenting cells (APC), the U1-RNA and other pro-inflammatory components of this cellular debris activate TLR3 and potentially TLR7 and other innate immune sensors to induce pro-inflammatory responses including elaboration of type I interferons and presentation of autoantigens to autoreactive T cells. A subset of TLR3-expressing mDC traffic to the lungs and induce the influx of autoreactivce T cells to the lungs leading to interstitial lung disease and pulmonary hypertension. Under the influence of other APC, T cells traffic to other target organs and support the development of antigen-driven autoantibody responses that also induce end organ pathology in target tissues. Target tissue injury induces additional cell debris that can cause perpetuation and amplification of the autoimmune process

antigen-targeted tolerogenic therapies may also be effective in anti-RNP autoimmunity, based on animal models and studies in SLE (Page et al. 2009; Trivedi et al. 2010).

Pathogenesis

Autoantigen-specific T cells and immunoglobulin have been identified in MCTD patients (Greidinger and Hoffman 2005). Patterns of epitope spreading in MCTD patients over time implicate immune responses against U1 snRNP macromolecules. Early recognition of apoptosis-specific RNP epitopes in some patients suggests that, as has been hypothesized in lupus, apoptotic cell debris may constitute a significant source of antigenic stimulus in MCTD. RNP antigens targeted in MCTD are also susceptible to other forms of posttranslational modification that have been hypothesized to have relevance to autoimmune disease pathogenesis, including metal-catalyzed oxidation, granzyme B cleavage, phosphorylation, and RNA conjugation (Hof et al. 2005). The RNA backbone of the U1 snRNP has been found to be a potent agonist of Toll-like receptors 3 and 7 (Greidinger et al. 2007).

A murine model of MCTD induced by immunization with an RNP peptide and U1-RNA has supported the model of MCTD as an antigen-driven immune process dependent on TLR activation (Greidinger et al. 2006). Oligoclonal anti-RNP T cell responses are seen in the mice that are homologous to those seen in human patients (Greidinger et al. 2008). Adoptive transfer studies have shown the importance of myeloid dendritic cells for the development of MCTD-like lung disease (Greidinger et al. 2009). A figure integrating the established data regarding MCTD pathogenesis (Fig. 1) must be regarded as largely speculative.

Mucous Membrane Pemphigoid

Bryan D. Sofen and Nicholas A. Soter
The Ronald O. Perelman Department of Dermatology, New York University School of Medicine, New York, NY, USA

Synonym

Cicatricial pemphigoid

Definition

Mucous membrane pemphigoid (MMP), previously known as "cicatricial pemphigoid," (Chan et al. 2002) is a chronic, autoimmune, subepithelial blistering disorder characterized by involvement of predominantly mucosal surfaces and a tendency for scarring.

HLA type DQB1*0301(DQ7) is common amongst patients with both MMP and classic bullous pemphigoid.

Clinical

A chronic and progressive disease, MMP may be associated with substantive morbidity due to the tendency for scarring and fibrosis. When present on the conjunctivae, these effects may lead to blindness.

The histopathologic presentation of MMP is similar to that observed in classic bullous pemphigoid but with fewer eosinophils and more plasma cells being present in the lymphohistiocytic infiltrate that surrounds the subepidermal blisters. Mast cells and other mononuclear leukocytes are also found. Later stages also show granulation tissue in the submucosa and the characteristic fibrosis in the upper dermis.

Pathophysiology

The heterogenous nature of this condition is reflected in the variety of antigenic targets that are associated with mucous membrane pemphigoid. The principal antigens for pathogenic autoantibodies, which are all in the basement membrane zone, are the hemidesmosomal bullous pemphigoid antigen 180 (BP180, BPAG2, or type XVII collagen) and laminin 5 (laminin 332), which is a component of the anchoring filaments outside the hemidesmosomal plaque. Several other pathogenic target antigens have been suggested, which include the α_6 (predominant in oral pemphigoid) and β_4 (predominant in ocular pemphigoid) subunits of the transmembrane and hemidesmosomal $\alpha_6\beta_4$ integrins (Bhol et al. 2000, 2001; Rashid et al. 2006), the major ligand for which is laminin 5. Collagen VII and BP230 have also been implicated in some cases (Chan et al. 2002). Autoantibodies are mostly IgG1 and IgG4 isotypes, with IgA1 antibodies present in a minority of cases (Bernard et al. 1991).

Despite the similarity of target antigens with bullous pemphigoid and other bullous diseases in many cases of MMP, the specific mechanisms and reasons for the mucosal predilection, chronicity, and tendency for scarring are not well understood.

For BP180, the carboxy terminal is the immunodominant epitope in oral pemphigoid, with the shed ectodomain (LABD97) autoreactive in other forms of MMP (Calabresi et al. 2007; Kromminga et al. 2002; Leverkus et al. 2001; Schmidt et al. 2001; Schumann et al. 2000). The α_3 subunit of laminin 5 is the principal autoreactive epitope in patients with laryngeal involvement; less frequently the β_3 and/or γ_2 subunits are involved (Chan et al. 2002; Seo et al. 2001).

NC16A domain-specific T cells are present in a minority of patients, which contributes to blister formation along with released TNF-α and IFN-γ. Complement is not required (Lazarova et al. 2000). Increased expression of TGF-β1 and collagen-binding heat shock protein 47 likely contributes to conjunctival scarring in ocular disease (Black et al. 2004).

Perilesional biopsy specimens for direct IF are often difficult to obtain owing to the mucosal site, but if obtained, most patients display a fine, linear deposition along the epithelial

BMZ of IgG and/or C3. Less commonly, IgA and/or IgM may be observed (Bean et al. 1972). Circulating antibodies are observed by indirect IF in only a few cases.

Myositis, Pathogenesis

Marinos C. Dalakas
Department of Pathophysiology, Neuroimmunology Unit, National University of Athens Medical School, Athens, Greece
Thomas Jefferson University, Philadelphia, PA, USA

Synonyms

Dermatomyositis; Inclusion body myositis; Inflammatory myopathies; Necrotizing myositis; Polymyositis

Definition

Myositis refers to a group of inflammatory myopathies (IM) that constitute a heterogeneous group of subacute, chronic, or sometimes acute acquired muscle diseases, which have in common the presence of muscle weakness and inflammation on muscle biopsy. Based on distinct clinical, histological, and immunopathological criteria, as well as different degrees of response to therapies, the most common types of myositis seen in practice can be separated into four distinct subsets: *polymyositis (PM), dermatomyositis (DM), necrotizing autoimmune myositis (NAM), and inclusion body myositis (IBM)* (Dalakas 1991, 2010a, 2011; Dalakas and Hohlfeld 2003).

PM was first recorded by Wagner in 1863 but became a recognized clinical entity 75 years later when Walton and Adams published a remarkable monograph entitled Polymyositis. The first definitive description of dermatomyositis was reported by Unverricht in 1891. Inclusion body myositis (IBM) was first recognized as a separate entity between 1967 and 1971 based on distinct

microtubular filamentous inclusions by electron microscopy in the muscle biopsies of some patients. The term "inclusion body myositis" was coined by Yunis and Samaha in 1971 to stress the uniqueness of the disease and to separate it from polymyositis. NAM has been known for some time but it has been always included within the group of PM, until the last 10 years when it has been increasingly recognized as a distinct entity attracting considerable attention for diagnosis and therapy (Dalakas 2010a, 2011).

Main Clinical Features

All forms have in common a myopathy characterized by muscle weakness which develops subacutely (weeks to months, as in PM and DM); acutely, even in days, as in some cases of NAM; or insidiously over years, as in IBM, simulating the tempo of a limb-girdle muscular dystrophy leading eventually to wheelchair confinement (Dalakas 1991, 2010a, 2011; Dalakas and Hohlfeld 2003).

DM affects both children and adults, and females more often than males, whereas PM is seen after the second decade of life and very rarely in childhood. IBM is more frequent in men than women and more likely to affect persons over the age of 50 years comprising the most commonly acquired myopathy in this age group (Dalakas 1991, 2010a, 2011; Dalakas and Hohlfeld 2003; Mastaglia et al. 2003; Engel et al. 2008); in contrast, PM is the least common while DM is the most frequent inflammatory myopathy in children.

Patients with these inflammatory myopathies have difficulty performing tasks requiring the use of proximal muscles, such as getting up from a chair, climbing steps, or lifting objects; IBM patients however may experience early difficulties with distal muscles such as inability to hold certain objects, turning keys, shaking hands, or buttoning a shirt. Falling is common among IBM patients because of early involvement of the quadriceps muscle that causes buckling of the knees and weakness of foot extensors (Dalakas 1991).

All forms of myositis can be seen with increased frequency in patients with other systemic autoimmune, viral, or connective tissue diseases. Up to 10 % of patients have interstitial lung disease and anti-Jo-1 antibodies, directed against histidyl-transfer RNA synthetase; the presence of anti-Jo-1 antibodies denotes a high probability of having or developing interstitial lung disease (Dalakas 1991, 2011; Dalakas and Hohlfeld 2003; Mastaglia et al. 2003).

Polymyositis has no unique clinical features, and its diagnosis is one of exclusion, best defined as an inflammatory myopathy of subacute onset (weeks to months) and steady progression occurring in adults that do not have the following: rash; involvement of eye and facial muscles; family history of a neuromuscular disease; endocrinopathy; history of exposure to myotoxic drugs or toxins; any neurogenic, dystrophic, or metabolic myopathy; and no signs of inclusion body myositis (Dalakas 1991, 2010a; Dalakas and Hohlfeld 2003). Unlike dermatomyositis, in which the rash secures early recognition, the actual onset of polymyositis cannot be easily determined, and the disease may exist for several months before the patient seeks medical advice.

Dermatomyositis is a distinct clinical entity identified by a rash, which accompanies or, more often, precedes the muscle weakness. The typical skin changes include a heliotrope (blue-purple discoloration) on the upper eyelids with edema; a flat red rash on the face and upper trunk, anterior chest (often in a V sign), or shoulders (shawl sign); and erythema of the knuckles with a raised violaceous scaly eruption (Gottron rash) (Dalakas 1991, 2010a, 2011; Dalakas and Hohlfeld 2003; Mastaglia et al. 2003; Engel et al. 2008).

Dermatomyositis usually occurs alone, but it may overlap with systemic sclerosis and mixed connective tissue disease. An increased incidence of malignancies is seen in patients with DM (particularly over 50 years of age), but not in PM or IBM, requiring frequent malignancy work-up and vigilance at least for the first 3 years (Dalakas 1991, 2011; Dalakas and Hohlfeld 2003). Ovarian cancer is most frequent, followed by breast, lung, and liver cancer. In Asian populations, nasopharyngeal cancer is more common.

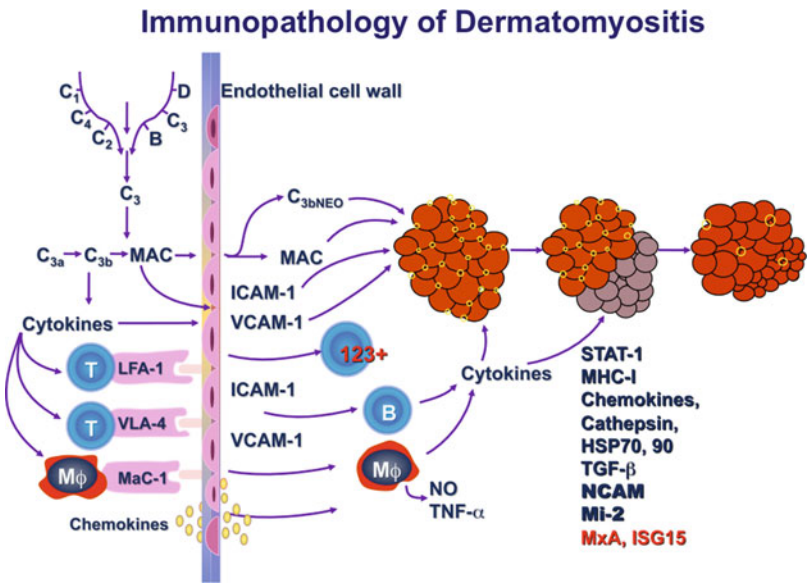
Necrotizing autoimmune myositis (NAM) has been an overlooked entity, misdiagnosed as polymyositis for many years. NAM may in fact be more common than polymyositis based on the number of cases increasingly recognized in large clinics. The patients present with very high CK, in the thousands, and moderate to severe muscle weakness of acute or subacute onset. The cause of NAM is multifactorial. Some patients have cancer or an active viral infection (i.e., HIV); others have been exposed to statins, which can induce both a toxic and an autoimmune necrotizing myositis that responds to immunotherapy; others may have a smoldering underlying autoimmune process; and still others have no other disease or apparent exposure to exogenous agents (Dalakas 2010a, 2011). The muscle biopsy shows only necrotic fibers and macrophages necessitating the absolute need to exclude dystrophic or toxic processes (Dalakas 2009), especially when the disease has subacute onset.

Inclusion body myositis has a distinct presentation with the earliest and most frequent symptom falling and tripping due to weakness and atrophy of the quadriceps muscle and foot extensors (Dalakas 1991, 2010a; Mastaglia et al. 2003). In other patients, the disease may begin with weakness of the distal muscles of the hands leading to a weak grip. Inclusion body myositis is, therefore, a proximal and distal myopathy. Weakness is asymmetrical in one third of patients (Engel et al. 2008), progresses slowly over years, and is always associated with worsening atrophy. Dysphagia and facial muscle weakness are also common.

Diagnosis

The diagnosis of DM is relatively easy when the typical skin changes are apparent. The diagnosis of PM or NAM is one of exclusion and based on finding a steadily progressive myopathy of acute or subacute onset in adults who do not have a family history of a neuromuscular disease, history of exposure to myotoxic drugs or toxins, endocrinopathy, neurogenic disease, dystrophy, or IBM (Dalakas 1991). The diagnosis of IBM should be considered in an adult who has slow-onset disease that involves distal muscles, especially foot extensors and deep finger flexors, and should be always suspected when a patient with presumed polymyositis did not respond to therapy (Dalakas 1991, 2010a; Dalakas and Hohlfeld 2003). The diagnosis is established or confirmed by elevated levels of serum muscle enzymes, electromyographic findings of an active myopathy, and, definitively, by the muscle biopsy. The serum CK, in the presence of active disease, can be elevated by as much as 50 times above normal and usually parallels disease activity; it can be however normal in active DM and IBM. In NAM, the CK is very high, usually around 8,000–15,000 IU/L.

The muscle biopsy shows distinct changes in each subset. In DM the inflammation is perivascular or at the periphery of the fascicle and is often associated with perifascicular atrophy (Dalakas 1991; Engel et al. 2008). The presence of perifascicular atrophy even in the absence of inflammation should raise the suspicion of DM. In NAM, there are necrotic fibers invaded by macrophages; T cells are characteristically absent and MHC-I is not upregulated (except in necrotic fibers). In PM and IBM, the inflammation is in multiple foci within the endomysial parenchyma and consists predominantly of CD8+ T cells that invade healthy muscle fibers expressing the MHC-I antigen which is ubiquitously upregulated on the surface of most fibers. The MHC/DC8 complex is characteristic of PM and IBM, as discussed later. In IBM, in addition to inflammation, there are rimmed vacuoles and tiny amyloid deposits in a variable number of fibers, usually in or near the vacuoles, identified with Congo-red or crystal violet stains or with Texas-red fluorescent optics. The vacuoles contain 12–16 nμ filamentous masses, reported to be identical to the paired helical filaments found in the brains of Alzheimer's disease. Ragged-red fibers with mitochondrial excess as well as cytochrome oxidase-negative fibers are frequent (Engel et al. 2008; Dalakas 2011). A number of degeneration-associated and stressor molecules accumulate within the myofibers of IBM muscles, including beta-amyloid and a series of amyloid-related proteins including phosphorylated



Myositis, Pathogenesis, Fig. 1 Immunopathogenesis of dermatomyositis. Activation of complement, possibly by autoantibodies (Y), against endothelial cells and formation of C3 via the classic or alternative pathway. Activated C3 leads to formation of C3b, C3bNEO, and membrane attack complexes (*MAC*), which are deposited in and around the endothelial cell wall of the endomysial capillaries. Deposition of MAC leads to destruction of capillaries, ischemia, or microinfarcts most prominent in the periphery of the fascicles and perifascicular atrophy. B cells, CD4 T cells, and macrophages traffic from the circulation to the muscle. Endothelial expression of vascular cell adhesion molecule (*VCAM*) and intercellular adhesion molecule (*ICAM*) is induced by cytokines released by the mononuclear cells. Integrins, specifically very late activation antigen (*VLA*)-4 and leukocyte function-associated antigen (*LFA*)-1, bind VCAM and ICAM and promote T cell and macrophage infiltration of muscle through the endothelial cell wall

tau, best detected with antibodies to transporter protein p62/SQSTMI, ubiquitin, and others (Dalakas 2010a, 2011). Currently, there is no unique molecule that serves as a specific IBM biomarker of diagnostic value.

Immunopathogenesis

Dermatomyositis

The primary antigenic target in DM is the vascular endothelium of the endomysial blood vessels (Dalakas 1991; Hohlfeld and Dornmair 2007; Engel et al. 2008). The disease begins when putative antibodies directed against endothelial cells activate complement C3 that subsequently forms C3b and C4b fragments and leads to the formation of C5b-9 (MAC), the lytic component of the complement pathway that leads to osmotic lysis of the endothelial cells and necrosis of the capillaries. This results in marked reduction in the number of capillaries per muscle fiber and dilatation of the remaining capillaries in an effort to compensate for impaired perfusion (Dalakas 1991; Engel et al. 2008). Larger intramuscular blood vessels are also affected in the same pattern, leading to muscle fiber destruction (often resembling microinfarcts) and inflammation. The perifascicular atrophy often seen in more chronic stages is a reflection of the endofascicular hypoperfusion that is prominent distally (Dalakas 2011). Membranolytic attack complex and the early complement components C3b and C4b can be detected in the serum, correlate with disease activity, and are deposited on the capillaries before inflammatory or structural changes are seen in the muscle (Engel et al. 2008; Dalakas 2010a) (Fig. 1). The endomysial infiltrates, consisting of CD4+ cells, macrophages, B cells, CD8+ cells, and plasmacytoid dendritic cells, are prominent in the perimysial, perivascular, and perifascicular regions.

The release of cytokines and chemokines related to complement activation upregulates VCAM-I and ICAM-I on the endothelial cells and facilitates the exit of lymphoid cells through the blood vessel wall to the perimysial and endomysial spaces (Fig. 1). After successful therapy, these abnormalities are no longer prominent in the repeat biopsies (Dalakas 2010a, 2011). The perifascicular regions of DM contain many regenerating or degenerating fibers and they are in a stage of continuous remodeling. As a result, they stain with alkaline phosphatase, desmin, and NCAM, with the autoantibody against chromatin remodeler Mi-2 and with a variety of antibodies against immune or stressor molecules, including TGF-β, MHC-I, αB-crystallin, cathepsins, amyloid precursor protein, STAT-1 (triggered by interferon-γ), or myxovirus-resistance MxA protein (triggered by α/β-interferon) (Dalakas 2010a, 2011). The theory that the perifascicular myofibers may be primarily injured by chronic overproduction of α/β-interferon-inducible proteins because they stain with MxA lacks specificity for DM and does not explain the aforementioned sequence of events.

Immunopathology of Polymyositis and IBM

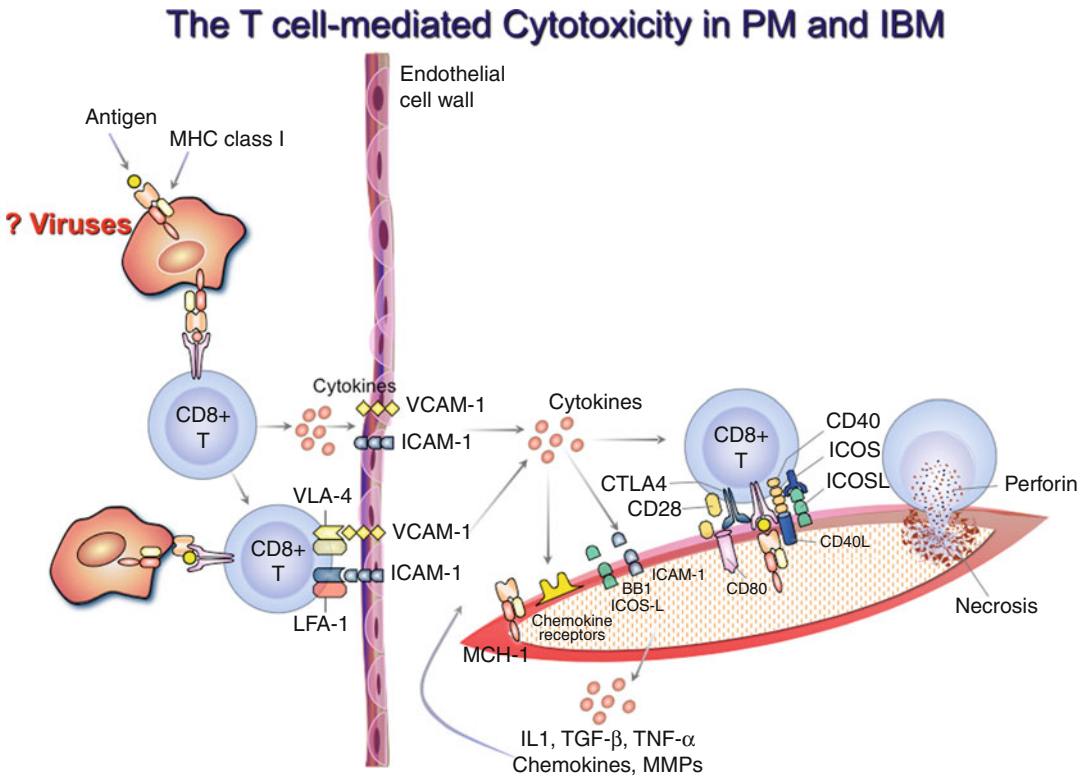
In PM and IBM, there is evidence of a T cell-mediated and MHC-1-restricted cytotoxicity process directed against heretofore unidentified muscle antigens (Engel and Arahata 1986; Emslie-Smith et al. 1989; Dalakas 1991, 2010a, 2011; Dalakas and Hohlfeld 2003; Mastaglia et al. 2003; Engel et al. 2008). The immune components associated with this process are identical in both PM and IBM, in spite of poor response to immunotherapies of the latter, and include the following (Fig. 2).

Activated, Cytotoxic CD8+ T Cells that Invade Healthy-Appearing Muscle Fibers Overexpressing MHC-I Antigen

In PM and IBM, the CD8+ T cells invading muscle fibers are activated and cytotoxic. They express ICAM-I, MHC-I, CD45RO, and inducible co-stimulator (ICOS) on their surface; send spikelike processes into nonnecrotic muscle fibers, which traverse the basal lamina and focally displace the fibers; contain perforin and granzyme granules, which are vectorially directed towards the surface of the muscle fiber inducing necrosis upon release; and are cytotoxic in vitro when exposed to autologous myotubes. An early event in PM and IBM is the widespread overexpression of MHC-I, even in areas remote from the inflammation (Engel and Arahata 1986; Emslie-Smith et al. 1989), probably induced by cytokines and chemokines such as IFN-γ or TNF-α which are found increased in the muscle fibers. The presence of perforin-positive CD8 + T cells that surround and invade MHC-I-class-expressing, nonnecrotic muscle fibers (the CD8/MHC-I lesion) is characteristic of IBM and PM and helpful to distinguish them from nonimmune myopathies (Dalakas and Hohlfeld 2003; Dalakas 2010a, 2011). In other chronic myopathies including the inflammatory dystrophies, the muscle fibers do not express the MHC-I antigen in a ubiquitous and consistent pattern as in PM and IBM, and the few T cells found in the proximity to the muscle fibers do not release cytotoxic granules.

Rearrangement of the TCR Genes of the Endomysial T Cells and Formation of Immunological Synapses Between the MHC-I-Expressing Muscle Fibers and Autoinvasive CD8+ T Cells

T cells recognize an antigen via the CDR3 region of the T cell receptors (TCR), a heterodimer of two α- and β-chains, encoded by specific genes. In patients with PM and IBM, but not in those with DM or dystrophies, only certain T cells of specific TCRα and TCRβ families are recruited to the muscle from the circulation. Cloning and sequencing of the amplified endomysial or autoinvasive TCR gene families has demonstrated a restricted use of certain gene families with conserved amino acid sequence in the CDR3 region, indicating that these cells are specifically selected and clonally expanded in situ probably driven by local antigen(s). This has been further confirmed by combining spectratyping with



Myositis, Pathogenesis, Fig. 2 Cell-mediated mechanisms of muscle damage in polymyositis (PM) and inclusion body myositis (IBM). Antigen-specific CD8 cells are expanded in the periphery, cross the endothelial barrier, and bind directly to muscle fibers via T cell receptor (TCR) molecules that recognize aberrantly expressed MHC-I. Engagement of co-stimulatory molecules (BB1 and ICOS-L) with their ligands (CD28, CTLA-4, and ICOS) along with ICAM-1/LFA-1 stabilizes the CD8–muscle fiber interaction between MHC-I and TCR (immunological synapse). Muscle fiber necrosis occurs via perforin granules released by the autoaggressive T cells. The stimulated muscle fiber also secrets myocytotoxic cytokines such as interferon (IFN)-γ, interleukin (IL)-1, or tumor necrosis factor (TNF)-α, which stimulate further the production of cytokines in an auto-amplificatory mechanism that may perpetuates disease chronicity. Death of the muscle fiber is mediated by necrosis

molecular laser-assisted microdissection and by demonstrating that the clonally expanded TCR families persist over time even in different muscles (Engel and Arahata 1986; Hofbauer et al. 2003; Salajegheh et al. 2007; Engel et al. 2008). In an important case of PM, a single clone of γ/δ T cells was the primary cytotoxic effectors that recognized genuine muscle antigens. Myeloid dendritic cells (DC), potent cells in antigen presentation, as well as large numbers of plasma cells and clonally expanded B cells are also found within the endomysial infiltrates of all inflammatory myopathies including PM, DM, and IBM (Bradshaw et al. 2007). The presence of these cells, frequently noted in the targeted tissues in several autoimmune disorders, denotes that different effector mechanisms may concurrently play an active role in the autoimmune process and contribute to muscle fiber injury.

Cytokines, Chemokines, and Adhesion Molecules

The muscle fibers and their autoinvasive CD8+ T cells coexpress co-stimulatory molecules (B7-1, B7-2, BB1, CD40, or ICOS-L) and the respective counter-receptors CD28, CTLA-4 (cytotoxic T lymphocyte antigen 4), CD40L, or ICOS (Dalakas 2011). Cytokines, chemokines,

and various adhesion and extracellular matrix molecules, such as VCAM, ICAM, thrombospondins, and metalloproteinases MMP-9 and MMP-2, are also upregulated in the tissues of patients with PM and IBM and may enhance T cell adhesion, transmigration, and cytotoxicity. Of interest, the muscle has the potential to secrete proinflammatory cytokines upon cytokine stimulation, such as INF-γ, in an auto-amplificatory mechanism that may facilitate the self-sustaining nature of endomysial inflammation and disease chronicity (Fig. 2).

Immunopathology of NAM

Although poorly studied, emerging data indicate that in NAM the main effector cell associated with muscle fiber necrosis is the macrophage. Histologically, there are a large number of necrotic fibers invaded by macrophages, but no T cell infiltrates or MHC-I expression as seen in polymyositis and inclusion body myositis (Dalakas 2010a, 2011). In a number of patients, there is deposition of complement on blood vessels (Christofer-Stine et al. 2010). It is likely that NAM is an antibody-mediated disease, as suggested by the presence of antibodies against signal recognition particles (SRP) or against a 100-kd protein corresponding to 3-hydroxy-3-methylglutaryl-coenzyme A reductase (HMGCR) (Christofer-Stine et al. 2010; Mammen et al. 2011). The recruitment of macrophages is probably consistent with an antibody-dependent cell-mediated cytotoxicity (ADCC) process (Dalakas 2010a, 2011). Because statins upregulate the expression of HMGCR in cultured cells, the major target of autoantibodies in statin-associated NAM is probably the HMGCR (Mammen et al. 2011). These autoantibodies were found in 6 % of patients with myopathies but in 92.3 % of those taking statins and aged 50 years and older.

Autoantibodies

Various autoantibodies against nuclear antigens (antinuclear antibodies) or cytoplasmic antigens are found in as many as 20 % of patients with inflammatory myopathies. These antibodies are directed against ribonucleoproteins involved in translation and protein synthesis and include various synthetases and translation factors, including Jo-1, PL-7, PL-12, OJ, EJ, PMS1, and PMS2. Of those, the antibody directed against the histidyl-transfer RNA synthetase, called anti-Jo-1, accounts for 75 % of all the antisynthetases and is clinically useful because up to 80 % of patients with Jo-1 antibodies develop interstitial lung disease. In general, the role of these antibodies in the pathogenesis of inflammatory myopathies is unclear because they are directed against ubiquitous cytoplasmic antigens with undefined function. Further, they are present in less than 15 % of the patients, and with the exception of Jo-1, they do not define an immunopathologically distinct myositis subset. Among the autoantibodies, the ones of pathogenic significance and of diagnostic value are those against SRP and HMGCR which are being evolved as specific markers of necrotizing myositis, as mentioned above.

Viral Triggers

Although several viruses have been implicated in chronic and acute myositis, sensitive PCR studies have repeatedly failed to confirm the presence of such viruses in patients' muscle biopsies. The best evidence of a viral connection is with the retroviruses. Monkeys infected with the simian immunodeficiency virus and humans infected with HIV and human T cell lymphotropic virus (HTLV-1) develop PM or IBM with typical clinical and immunopathological features as the HIV-negative myositis (Dalakas and Hohlfeld 2003; Dalakas 2010a, 2011). Viral antigens are not, however, detected within the muscle fibers but only in occasional endomysial macrophages. Molecular immunology studies using tetramers have shown that among the autoinvasive T cells, there are retrovirally specific CD8+ cells that clonally expand in situ (Dalakas et al. 2007). It is likely that the chronic infection triggers a persistent, in situ inflammatory response, which, via infected macrophages and viral-specific T cells, changes the local milieu leading to myositis.

Degenerative Pathomechanisms in IBM and Interrelationship with Inflammation

IBM is a complex disorder because in addition to the immunopathogenic events described above, there is an equally strong degenerative process as evidenced by the presence of rimmed vacuoles (almost always in fibers not invaded by T cells) and intracellular deposition of congophilic amyloid and degeneration-associated or stressor molecules, including beta-amyloid and its precursor protein, alpha-chymotrypsin, phosphorylated tau, ubiquitin, apolipoprotein E, prion protein, and others (Dalakas 2010a, 2011). One line of evidence suggests that the proteasome machinery is malfunctioning or overloaded with aberrant proteins, which may explain why these proteins accumulate in the cytoplasm of muscle fibers. The β-secretase, a major enzyme relevant for processing of amyloid precursor protein (APP), has been overexpressed in sIBM muscle fibers and may explain why processing of APP may be shifted towards the generation of β-amyloid. The aforementioned accumulations, although extensively studied in sIBM, do not seem to be unique to this disease, because they are also observed in other vacuolar myopathies. What appears unique to IBM, however, compared to other chronic vacuolar myopathies, is the concomitant accumulation of these molecules with a strong primary inflammatory response and the overexpression of proinflammatory mediators and MHC-I on all fibers, vacuolated or not. The T cell invasion appears to occur early and in higher frequency than the Congo-red-positive fibers, suggesting that inflammation precedes the accumulation of amyloid and stressor molecules. Regardless of whether the primary event in IBM is an inflammatory or protein dysregulation process, the unique coexistence of the two processes and co-localization of APP with cytokines has provided evidence that there is an interrelationship between inflammation and degeneration and that inflammatory mediators affect or increase the accumulation of degenerative molecules (Dalakas 2008, 2010a, 2011; Schmidt et al. 2008).

Therapeutic Strategies

As the specific target antigens in DM, PM, and IBM are unknown, current therapies are not selectively targeting either the autoreactive T cells or the complement-mediated process on intramuscular blood vessels. Instead, they induce nonspecific immunosuppression or immunomodulation. Furthermore, many of these therapies are empirical. Based on experience, but not controlled studies, the majority of patients with PM and DM respond to corticosteroids to some degree and for a period of time (Dalakas 2006, 2010b). Intravenous immunoglobulin (IVIg), as tested in a controlled study, is effective in DM as a second, and at times, first-line therapy (Dalakas et al. 1993). IVIg also appears to be effective in PM and NAM. Immunosuppressants are used as steroid-sparing agents but their efficacy remains unclear. New agents in the form of monoclonal antibodies or fusion proteins that target cytokines, adhesion molecules, T cell transduction or transmigration molecules, and B cells or their activation factors are emerging as promising immunotherapeutic drugs. Among them, rituximab, a B cell-depleting agent, has been helpful in some cases of DM and NAM but a controlled study – although with a problematic design – did not show efficacy (Oddis et al. 2013).

In contrast to PM and DM, there is currently no effective treatment for IBM. Prednisone, cyclosporine, azathioprine, methotrexate, total body irradiation, and IFN-β have generally failed justifying the contention that the condition could be more of a degenerative disease rather than an autoimmune condition. A number of patients with IBM however may respond to common immunotherapeutic agents early on to some degree and for a period of time; up to 25 % of patients in a controlled study have also responded transiently to IVIg. These benefits are arguably limited and short-lived; IBM remains a steadily progressive disease that, over time, is uniformly resistant to all therapies. Although transient therapeutic responses are also seen in other autoimmune diseases with poor response to immunotherapies, such as

primary progressive multiple sclerosis, the lack of treatment efficacy remains of concern and a reason for tilting the pathogenetic theories towards a primary degenerative process rather than autoimmune. It should be noted, however, that in IBM, therapy is typically initiated late when the degenerative cascade has already begun or is too advanced, due to insidious onset and very slow disease progression. This is supported by the observations that IBM patients, even with minimal clinical weakness, already exhibit significant muscle atrophy and extensive histopathologic changes.

Myositis: Polymyositis, Dermatomyositis, Inclusion Body Myositis, and Myositis Autoantibodies

Ritu Valiyil
Division of Rheumatology, Beth Israel Deaconess Medical Center, Harvard Medical School, Boston, MA, USA

Synonyms

DM (dermatomyositis); IBM (inclusion body myositis); Idiopathic inflammatory myopathies (IIM); Inflammatory myopathies; Myositis; PM (polymyositis)

Definition

The idiopathic inflammatory myopathies are a group of connective tissue diseases manifested by chronic inflammation of the striated muscle, characteristic cutaneous features (dermatomyositis), and a variety of systemic complications.

History

In 1886, Wagner first coined the term "polymyositis" to describe a woman presenting with muscle weakness, diffuse muscle and joint pain, swelling of the extremities, and erythema of the forearms (Oddis and Medsger 2004). In 1891, Unverricht described a 39-year-old pregnant woman with facial erythema and swollen, erythematous legs and thighs who subsequently developed myalgias with muscle weakness and atrophy. Unverricht then coined the term "dermatomyositis" to describe her condition. Inclusion body myositis was not named until more recently in 1967 when the pathology of inclusion bodies was described (Levine 2003). Criteria for the diagnosis of polymyositis and dermatomyositis were later created by Bohan and Peter in 1975 and these are still used today.

Epidemiology

The reported incidence of idiopathic inflammatory myopathy ranges from 2 to 10 new cases per million persons at risk per year (Oddis and Medsger 2004). Dermatomyositis has a bimodal incidence with a peak incidence at childhood and then again between the ages of 50 and 70. Polymyositis, in contrast, rarely occurs in childhood. The overall female to male incidence is 2.5:1, although this ratio is lower (1:1) in childhood disease and with malignancies and is much higher (10:1) when myositis occurs with a coexisting connective tissue disease. Disease onset is more frequent in the winter and spring months, especially in childhood cases of inflammatory myositis (Becezny 1935).

Classification Criteria of PM and DM

Many classification systems have been proposed for polymyositis and dermatomyositis, but the 1975 Bohan & Peter criteria are still most frequently used for defining patient groups for clinical research and to aid in diagnosing individual patients. These criteria are shown in Fig. 1. The essential elements of the criteria include proximal muscle weakness on physical examination, increased serum muscle enzymes, abnormal electromyogram (EMG), muscle biopsy consistent with myositis, and the characteristic rash of dermatomyositis. Inclusion body myositis (IBM) and amyopathic dermatomyositis (in which patients have the rash of dermatomyositis but no overt muscle weakness) are not included in the

Myositis: Polymyositis, Dermatomyositis, Inclusion Body Myositis, and Myositis Autoantibodies, Fig. 1 Bohan & Peter criteria for diagnosis of polymyositis and dermatomyositis. The Bohan and Peter classification criteria are shown

1. Symmetrical proximal muscle weakness
2. Muscle biopsy evidence of myositis (degeneration/regeneration, perifascicular atrophy, necrosis, phagocytosis, fiber size variation, mononuclear inflammatory infiltrate)
3. Increase in serum skeletal muscle enzymes
4. Characteristic electromyographic pattern (polyphasic, short small motor unit potentials; fibrillations; positive sharp waves; insertional irritability; high frequency repetitive discharges)
5. Typical rash of dermatomyositis (Gottron's sign, Gottron's papules, heliotrope rash)

Diagnostic Criteria:

Polymyositis:

Definite: all of 1–4

Probable: any 3 of 1–4

Possible: any 2 of 1–4

Dermatomyositis:

Definite: 5 plus any 3 of 1–4

Probable: 5 plus any 2 of 1–4

Possible: 5 plus any 1 of 1–4

Bohan and Peter classification criteria. Most experts have agreed that the Bohan and Peter criteria should be updated and such efforts are currently underway. Myositis-specific serum autoantibodies and magnetic resonance imaging (MRI) have been proposed to be added to the new criteria.

Clinical Features of PM and DM

Skeletal Muscle Weakness

The most frequent presenting symptom is insidious, progressive, painless symmetrical proximal muscle weakness that is subacute in onset occurring over weeks to months. In polymyositis and dermatomyositis, the hip flexors or pelvic girdle is often affected initially and patients often complain of difficulty walking up steps or arising from a chair. Upper extremity or shoulder girdle symptoms usually follow with patients experiencing difficulty raising their arms overhead or difficulty washing and combing their hair. Dysphagia can occur with nasal regurgitation of liquids or difficulty swallowing, indicating pharyngeal striated muscle involvement. Ocular or facial weakness is very uncommon in PM and DM and should prompt consideration of other neuromuscular diagnoses.

Skin Manifestations

Dermatomyositis has characteristic skin manifestations which may precede, develop simultaneously with, or follow muscle symptoms. Pathognomonic cutaneous features of dermatomyositis include Gottron's papules and the heliotrope rash. Gottron's papules are scaly, erythematous, or violaceous papules located over the dorsal aspect of the metacarpophalangeal and proximal and distal interphalangeal joints of the hands. Gottron's sign is a macular erythematous rash that occurs over extensor areas such as elbows, knees, and ankles (Sontheimer and Provost 2004). Sixty to eighty percent of dermatomyositis patients demonstrate either Gottron's papules or sign. The heliotrope rash is a characteristic erythematous or violaceous rash seen over the eyelids and periorbital area and is seen in fewer than 50 % of patients with dermatomyositis. A "V" sign with erythema over the anterior chest can be seen as well as the "shawl" sign with a macular erythema over the nape of the neck, upper back, and across both shoulders. The facial rash of dermatomyositis can appear similar to the malar rash of lupus but can involve the nasolabial folds and forehead which is atypical for lupus, and pruritus is a common and underrecognized complaint in dermatomyositis especially in the scalp (Shirani 2004).

Another characteristic rash is "mechanics hands" which is hyperkeratosis, scaling, and cracking/fissuring of the palms and lateral fingers, and is most frequently seen in patients with anti-synthetase myositis autoantibodies. Other common skin findings include cuticular hypertrophy, periungual erythema, nailfold telangiectasias, infarcts, and capillary dilation. These findings can be seen in both dermatomyositis and myositis in overlap with other connective tissue diseases.

Calcinosis

Soft tissue calcifications can occur in dermatomyositis, and is more common in the juvenile form of dermatomyositis (30–70 %) than in adult-onset disease (10 %) (Dalakas and Holhfeld 2003). Typically, calcinosis is associated with increased disease activity and duration. Calcinosis may be intracutaneous, subcutaneous, fascial, or intramuscular in location and is typically located at sites of compression.

Joints

Arthralgias and arthritis can occur early in the disease course. Typically, symptoms are mild; however, the arthropathy associated with anti-Jo1 antibody can be erosive and deforming.

Lung

The lung is the most common extramuscular organ affected in polymyositis and dermatomyositis and is a major cause of morbidity and mortality. Pulmonary complications of PM and DM can be due to hypoventilation from respiratory muscle weakness, aspiration pneumonias, and interstitial lung disease. Interstitial lung disease (ILD) has been reported to occur in 26–64 %, of patients with PM or DM, and can occur before, concomitantly, or after the onset of skin and muscle disease (Khan and Christopher-Stine 2011). The strongest predictors of poor outcomes in a large retrospective cohort study of PM/DM and ILD included older age, symptomatic ILD, low diffusion capacity (DLCO) and decreased forced vital capacity (FVC) at diagnosis, and usual interstitial pattern on chest computed tomography (CT) scan (Marie et al. 2011). Myositis-specific anti-synthetase autoantibodies such as anti-Jo1 were the strongest predictive marker for ILD.

Heart

Cardiac manifestations are quite common in PM and DM but are usually asymptomatic and thus under-recognized. In a long-term follow-up study of PM and DM patients, cardiovascular involvement was the most common cause of death in patients with myositis (Danko et al. 2004). Cardiac abnormalities can include arrhythmias, conduction abnormalities, cardiac arrest, congestive heart failure, myocarditis, pericarditis, angina, and fibrosis.

Gastrointestinal

Because pharyngeal muscle is striated and can also become inflamed in myositis, patients can exhibit dysphonia and swallowing dysfunction with difficulty initiating swallow and nasal regurgitation of liquids. Cricopharyngeal muscle dysfunction can also occur, resulting in dysphagia with a "blocking" or "sticking" sensation with swallowing.

Peripheral Vascular System

Raynaud's phenomenon can occur in all idiopathic inflammatory myopathies. Systemic vasculitis can occur commonly in childhood dermatomyositis, but it does not occur frequently in adults. The vascular lesions of dermatomyositis can include dermal or subcutaneous nodules, periungual infarcts, and digital ulcerations (Oddis and Medsger 2004).

Differential Diagnosis

The differential diagnosis of adult polymyositis and dermatomyositis is broad and can include numerous conditions affecting skeletal muscle. Inherited or genetic causes of muscle disease include the muscular dystrophies, metabolic myopathies, glycogen storage disorders, and mitochondrial myopathies. These can be

differentiated from acquired myopathies, because they are more slowly progressive and can involve a family history of myopathy. While the idiopathic inflammatory myopathies are considered acquired myopathies, other acquired myopathies can also present with skeletal muscle weakness including toxic (or drug-induced) myopathies, endocrinopathy (especially hypothyroidism), or myopathies triggered by infections such as viruses. History, physical examination, differences in laboratory tests, and muscle biopsies are essential in differentiating among these conditions.

Association with Malignancy

Epidemiologic studies have shown an association between dermatomyositis and polymyositis and a higher risk of cancer. National registries and population-based cohort studies of biopsy proven cases have found that the risk of malignancy is highest in patients with dermatomyositis. In a pooled analysis of all cases of dermatomyositis and polymyositis in Sweden, Denmark, and Finland, 618 cases of dermatomyositis were identified (Hill et al. 2001). Thirty-two percent of the DM cases had cancer, suggesting that patients with DM had a three-fold increased risk of developing cancer. The same study identified a lower but still statistically significant increased risk of cancer associated with polymyositis with a standardized incidence ratio (SIR) of 1.3. The overall risk of cancer is greatest in the first 3 years after the diagnosis of myositis. In dermatomyositis, the strongest associations are with ovarian, lung, pancreatic, breast, and colorectal cancers. Lung, bladder cancer, and non-Hodgkin's lymphoma are more strongly associated with polymyositis.

Diagnosis of PM and DM

Physical Examination

The examining physician should assess for objective signs of weakness and impaired muscle function through manual muscle strength testing which involves testing a patient's proximal and distal muscle groups against resistance and grading the strength on a 0–5 scale.

Serum Muscle Enzymes

Enzymes that leak from injured skeletal muscle into the serum are valuable in detecting muscle injury. The serum creatine kinase (CK) can be quite elevated in myositis (over 1,000 to several thousands) and is the most sensitive marker of ongoing muscle injury. Other enzymes that can also be elevated in decreasing order of sensitivity include aldolase, aspartate and alanine aminotransferases (AST and ALT), and lactate dehydrogenase (LDH) (Oddis and Medsger 2004).

Electromyography

Electromyography (or EMG) evaluates the electrical activity of muscle fibers and is a sensitive but nonspecific method of evaluating muscle inflammation. The electrical activity is recorded via surface electrodes during needle insertion, rest, and voluntary muscle contractions. Typical EMG findings in inflammatory myopathies include irritability of myofibrils on needle insertion and at rest (fibrillation potentials, complex repetitive discharges, positive sharp waves) and short duration, low amplitude complex (polyphasic) potentials on contraction. More than 90 % of patients with active myositis will have an abnormal EMG.

Muscle Biopsy

Muscle biopsy is the gold standard for confirmation of the diagnosis of inflammatory myopathy, and open surgical biopsy tends to provide more definitive pathology compared with percutaneous needle muscle biopsy. Degeneration and regeneration of myofibrils occurs in 90 % of cases. Chronic inflammatory cells in the perivascular and interstitial areas surrounding myofibrils are present in 80 % of cases and lymphocytic invasion of non-necrotic fibers is considered pathognomonic of polymyositis (Lundberg 2004). In dermatomyositis, B cells, CD4+ T cells, and the late component of complement (C5-C9, membrane attack complex) predominate in the perivascular area. Perifascicular myofibril

atrophy and endothelial cell hyperplasia of blood vessels are also noted. In contrast, polymyositis features cytotoxic T cell (mostly CD8+) invasion of myofibrils with sparing of the vasculature.

Muscle biopsies in inclusion body myositis can also demonstrate inflammatory infiltrate primarily of cytotoxic T cells, although inflammation is usually mild. The notable finding on muscle biopsy in inclusion body myositis is rimmed vacuoles representing abnormal filaments.

MRI

Magnetic resonance imaging (MRI) can be a useful, noninvasive tool for evaluating myositis (Scott and Kingsley 2004). The T1-weighted images provide anatomic detail, and normal tissue appears homogenously dark with a low signal, whereas fat appears bright. Inflammation is bright on both T1 and T2 images, but adding fat suppression to the T2 technique, in the form of short tau inversion recovery (STIR) sequences, improves the detection of muscle inflammation by enhancing the bright signal of inflammation and decreasing the fat signal (dark). Thus, T1-MRI demonstrates damage and chronicity of disease, while STIR-MRI demonstrates inflammatory disease activity.

Pathophysiology of PM and DM

The true pathogenesis of the inflammatory myopathies is unknown. The presence of T lymphocytes in muscle tissue in a majority of patients with myositis as well as serum autoantibodies suggests that immune mechanisms are involved in the pathogenesis, and both T and B cells may play a pathogenic role in these diseases. Mechanisms that have been proposed for the development of muscle inflammation include possible direct cytotoxic effects of infiltrating leukocytes such as T cells and macrophages on muscle cells, indirect effects of pro-inflammatory cytokines on muscle function, or microvessel involvement and disturbed circulation which could lead to reduced muscle function (Lundberg 2004).

Immunohistochemistry analysis of muscle tissue from myositis patients has revealed that lymphocytes such as CD8+ T lymphocytes in polymyositis and CD4+ T lymphocytes in dermatomyositis appear to invade muscle fibers, and different lymphocytes tend to aggregate in different areas of the muscle (Engel and Arahata 1986). Inflamed muscle also expresses MHC class I and II molecules in muscle fibers, which normally do not express these antigens. Although MHC class I molecules are expressed on most nucleated cells in the body, mature muscle fibers lose class I MHC expression during their differentiation from immature fibers. In myositis patients, MHC class I antigen expression is not only found in a majority of patients' muscle but can also be found distant from sites of inflammation (Karpati et al. 1988). The exact role of induced MHC expression on muscle fibers is not known. In terms of other possible cytotoxic mechanisms, perforins and granzymes have also been suggested as possible mechanisms of disease. Perforin-containing granules within CD8+ T cells have been found oriented toward adjacent muscle fibers (Goebels et al. 1996). It has been suggested that perforin may mediate the transfer of granzymes into the target cell, which may then activate caspases, leading to cell lysis and nuclear damage. Many of the myositis autoantigens are cleaved by granzyme B, and this process may play a role in creating proteins that are immunogenic and resulting in autoimmunity.

Several cytokines and chemokines have been detected in muscle tissue from patients with myositis, and it has been hypothesized that these cytokines may cause direct toxicity to muscle fibers or indirectly affect muscle fiber metabolism and contractility. The most frequently reported cytokines are pro-inflammatory cytokines IL-1α, IL-1β, and TNF-α (Lundberg 2004).

With respect to dermatomyositis, perifascicular atrophy is a unique feature of this subset of myositis, and some have speculated that this may provide a clue into the pathogenesis of DM. In muscle fibers of DM patients, capillary density tends to be highest in the middle of the fiber and lowest in the periphery of the fiber,

or the perifascicular region. Histopathologic analysis has also demonstrated that in early DM patients, there seems to be localization of the late components of complement (C5-C9) in the areas with fewer capillaries. There is also complement deposition seen on endothelial cells and dropout of endothelial cells in the perifascicular region. It is unclear if this complement deposition and possible injury to the vasculature precedes the infiltration of inflammatory cells, leading to muscle fiber damage. It has also been hypothesized that perifascicular atrophy may be the result of microvessel involvement and metabolic disturbance, leading to localized hypoxia in the perifascicular region.

A combination of immune-mediated mechanisms and different molecular pathways may ultimately contribute to the muscle pathology seen in polymyositis and dermatomyositis. The key pathways, however, are still unclear and require further research.

Myositis Autoantibodies

Serum autoantibodies can be found in up to 50 % of patients with polymyositis and dermatomyositis and can be useful in defining subsets of patients with certain distinguishing clinical features and unique phenotypes. The role of autoantibodies is unclear as it is not well understood whether they are involved in pathogenesis of myositis or just an epiphenomenon. The autoantibodies are typically classified into myositis-specific autoantibodies (MSAs) and myositis-associated autoantibodies (MAAs).

Myositis-specific autoantibodies are specific for autoimmune disease as they are not associated with other neuromuscular diseases characterized by inflammation. The myositis-specific autoantibodies are classified into anti-synthetase antibodies directed against aminoacyl tRNA synthetase antigens and non-synthetase antibodies. The most frequent myositis-specific antibodies are those directed against aminoacyl-tRNA synthetase. There are 20 different aminoacyl-tRNA synthetases, and seven of them have been found to be autoantigens in myositis. Anti-synthetase antibodies are generally found in 16–26 % of patients with inflammatory myopathies. There are several well-known anti-synthetase antibodies (Fig. 2).

Anti-synthetase Myositis-Specific Antibodies

Anti-Jo1 antibodies are directed against histidyl-tRNA synthetase and are the most common MSAs since they are found in 20 % of patients with myositis (Khan and Christopher-Stine 2011). The clinical associations of the anti-synthetase antibodies are similar and have been collectively described as the "anti-synthetase syndrome." Classically, patients with anti-Jo1 autoantibodies and other anti-synthetase antibodies experience symptoms of myositis with recurrent fevers, nonerosive arthritis, mechanic's hands, Raynaud's phenomenon, and interstitial lung disease. The myositis and interstitial lung disease in this syndrome can be quite severe with multiple exacerbations, often requiring combination therapy with corticosteroids and immunosuppressive agents. It is not clear whether anti-Jo1 has a pathogenic role in myositis, but anti-Jo1 titers have also been correlated with disease activity. Longitudinal analysis of 11 patients showed modest correlation of anti-Jo1 titers and CK levels, myositis, lung, and joint disease activity (Stone et al. 2007). In three of these patients, anti-Jo1 antibody became negative when their disease was inactive.

Non-synthetase Myositis-Specific Antibodies

Non-synthetase MSAs are also associated with unique clinical phenotypes (Fig. 3). Anti-MI2 autoantibodies are directed against MI-2, a multiunit protein complex participating in transcription regulation at the chromosome level. Anti-MI2 antibodies are found in 10–30 % of adult dermatomyositis patients and are strongly associated with dermatomyositis. Anti-MI2 myopathy is characterized by severe skin manifestations of DM but has excellent response to immunosuppressive therapy. Anti-p155 is an autoantibody directed against a 155/140-kd doublet and has been found to be significantly associated with cancer in adult dermatomyositis. A more recent meta-analysis of six cohort studies involving 312 DM patients found

Antibody	Antigen	Frequency	Clinical Manifestations
Anti-Jo1	Histidyl-tRNA synthetase	18–20%	PM, DM + ILD
Anti-PL7	Threonyl-tRNA synthetase	≤3%	DM, PM + ILD
Anti-PL12	Alanyl-tRNA synthetase	≤3%	ILD > PM, DM
Anti-EJ	Glycyl-tRNA synthetase	≤2%	PM>DM + ILD
Anti-OJ	Isoleucine-tRNA synthetase	≤1%	ILD + DM, PM
Anti-KS	Asparaginyl-tRNA synthetase	≤1%	ILD > DM, PM
Anti-Zo	Phenylalanyl-tRNA synthetase	≤1%	ILD + DM, PM
Anti-Ha	Tyrosyl-tRNA synthetase	≤1%	ILD + DM, PM

Myositis: Polymyositis, Dermatomyositis, Inclusion Body Myositis, and Myositis Autoantibodies, Fig. 2 Myositis-specific autoantibodies: anti-synthetase antibodies. The myositis-specific anti-synthetase autoantibodies are shown. *PM* polymyositis, *DM* dermatomyositis, *ILD* interstitial lung disease, ≤ less than or equal to, > more often than (Adapted with permission from Khan and Christopher-Stine (2011))

Antibody	Antigen	Clinical Manifestations
Anti-SRP	Signal recognition particle	Severe, resistant necrotizing myopathy
Anti-MI2	Chromatin remodeling enzyme	DM with rash > muscle symptoms
Anti-SAE	Small ubiquitin-like modifier activating enzyme	DM with severe skin symptoms and rapidly progressive ILD
Anti-HMGCR	HMG-CoA Reductase	Necrotizing myopathy associated with statin
Anti-MDA5	MDA5	DM with rapidly progressive ILD, Cancer associated myositis
Anti-155/140	Transcriptional intermediary factor 1Y	Cancer associated myositis
Anti-140	Nuclear matrix protein (NXP-2)	Juvenile DM

Myositis: Polymyositis, Dermatomyositis, Inclusion Body Myositis, and Myositis Autoantibodies, Fig. 3 Myositis-specific autoantibodies: non-synthetase antibodies. The myositis-specific non-synthetase autoantibodies are shown. *DM* dermatomyositis, *ILD* interstitial lung disease, *HMGCR* HMG-CoA reductase, *MDA5* melanoma differentiation-associated gene 5, *SAE* small ubiquitin-like modifier-activating enzyme, > more often than (Adapted with permission from Khan and Christopher-Stine (2011))

pooled sensitivity of anti-P155 for cancer-associated myositis of 78 % and specificity of 89 % (Trallero-Araguas et al. 2012). This study found that patients with anti-P155 antibodies have 27-fold higher odds of having cancer-associated myositis than patients without the autoantibody.

Anti-SRP is an autoantibody directed against the signal recognition particle (SRP), a ribonucleoprotein involved in protein translocation across the endoplasmic reticulum. The prevalence of anti-SRP antibodies is estimated to be 5 % of myositis cases. Patients with anti-SRP myopathy present with a unique clinical syndrome with markedly elevated CK levels and rapidly progressive severe proximal muscle weakness that leads to significant disability. Patients often demonstrate early muscle atrophy and dysphagia is quite common in the later stages of the disease. Muscle biopsy specimens in anti-SRP myopathy are often distinct because they demonstrate necrosis with often scant or no inflammatory infiltrate. Staining also shows vigorous regeneration and deposition of the terminal components of the complement (C5b-9 or membrane attack complex) in the endomysial capillaries and the sarcolemma. The myopathy is also difficult to treat as it is poorly responsive to corticosteroid monotherapy.

An autoantibody directed against 3-hydroxy-3-methylglutaryl-coenzyme A reductase (HMG-CoA reductase) has also been described and is

Antibody	Antigen	Clinical Manifestation
PM-Scl	Unidentified	PM/SSc overlap
U1RNP	U1 small RNP	MCTD, overlap syndrome
Non-U1 snRNPs	U2, U4/6, U5, U3 snRNPs	PM or DM/SSc or SSc overlap
Ku	DNA-binding proteins	Myositis/SSc/SLE overlap
Ro (SS-A) includes Ro60 and Ro52	RNA protein	Myositis often with SS or SLE, Ro52 with ILD
56 kDa	RNP particle	Myositis, often with Jo-1
KJ	Unidentified translation factor	PM, ILD, RP
Fer	Elongation factor 1α	Myositis
Mas	$tRNA^{ser}$-related antigen	Myositis, rhabdomyolysis, chronic hepatitis
MJ	Unidentified nuclear pore	Juvenile DM
hPMS1	Protein related to DNA repair	Myositis

associated with an autoimmune necrotizing myopathy and statin medication use. The initial study described 16 patients with necrotizing myopathy on muscle biopsy with serum that precipitated a 200/100 kd antibody (Christopher-Stine et al. 2010). In 12 of these patients over the age of 50, 83 % had been exposed to statin medications prior to the onset of weakness which was higher than age-matched DM and PM controls. Discontinuation of the statin medication did not lead to clinical improvement in these patients, and the myopathy responded well to immunosuppression. A subsequent study demonstrated that specifically regenerating muscle fibers from patients with the anti-HMGCR myopathy expressed high levels of HMG-CoA reductase (Mammen et al. 2011).

Myositis-Associated Autoantibodies

There are multiple myositis-associated autoantibodies (MAAs) which are found in patients with myositis but can also be found in other connective tissue diseases. Although these antibodies may not occur exclusively in patients with inflammatory myopathies, they can also have unique clinical phenotypes (Fig. 4). Anti-PM Scl is an antinucleolar antibody that identifies a subset of patients with myositis and features of systemic sclerosis. Anti-U1 RNP antibodies can occur in patients with "mixed connective tissue disease" and can have clinical findings of Raynaud's disease, systemic lupus erythematosus, polymyositis, dermatomyositis, or systemic sclerosis, or a combination of these diseases.

Inclusion Body Myositis

Inclusion body myositis (IBM) is included among the idiopathic inflammatory myopathies, but there is still debate whether IBM should be regarded as an inflammatory myopathy or as a degenerative myopathy with secondary inflammation. Symptoms of muscle weakness begin insidiously and progress slowly. IBM primarily affects individuals over the age of 50, and is more common in males. Although patients can manifest proximal muscle weakness, distal weakness is common and is often asymmetric.

Treatment of the Inflammatory Myopathies

Because of the rarity of the inflammatory myopathies, randomized controlled studies are lacking and treatment of these diseases remains empiric

based on case series. The mainstay of treatment is with daily oral corticosteroids initially dosed 1–2 mg/kg/day. Combination therapy with cytotoxic drugs is commonly prescribed to reduce corticosteroid side effects and to treat more aggressive therapy. A variety of cytotoxic drugs have been recommended including methotrexate, azathioprine, cyclosporine, mycophenylate mofetil, intravenous immunoglobulin (IVIg), rituximab, and cyclophosphamide.

The response to treatment of IBM has been considered so poor that most have recommended not treating the disease with immunosuppressive medications. Although several controlled trials have investigated the use of IVIg (Dalakas et al. 1997), these have shown variable responses. In many cases, weakness appears to progress despite immunosuppressive treatment.

Definition

Nephritogenic autoantibodies are autoantibodies present in patients with SLE and in mouse models of the disease (spontaneous or induced) that contribute to the pathogenesis of kidney disease in lupus.

Lupus Nephritis: Overview

Systemic lupus erythematosus (SLE), a systemic autoimmune disease, is characterized by the presence of a myriad of autoantibodies (autoAbs) to self-antigens. Clinically, SLE may affect most organs, including the kidneys, brain, skin, and blood cells, and its course is one of flares and remissions. Lupus nephritis (LN) is a leading cause of morbidity and mortality in SLE, and is reported in 40 % or more of SLE patients (Rovin and Stillman 2011). LN manifests as hematuria and/or proteinuria, diminished renal function, and eventually end-stage renal disease (ESRD). LN is more prevalent in non-Caucasian populations, which also have a greater propensity to advance to ESRD. It has been reported that non-Caucasian SLE patients have a 50 % or greater incidence of LN; while about 62 % of black LN patients progress to ESRD, only 19 % of Caucasians follow a similar course (Rovin and Stillman 2011). Histologically, LN has been classified by the International Society of Nephrology/Renal Pathology Society (ISN/RPS) into six classes, based on the morphology of the lesion, the antibody deposition site within the glomerulus, the extent of the glomeruli involved, and the distinction between active and chronic lesions. Briefly, classes I and II reflect mesangial involvement; classes III and IV are focal and diffuse proliferative glomerulonephritis, respectively, with glomerular immune deposits; class V describes a membranous pathology; and class VI is irreversible glomerulosclerosis (Weening et al. 2004). Of note, over 90 % of SLE patients have histological changes in their kidneys, although a smaller fraction develop overt kidney disease (Rovin and Stillman 2011).

I.R. Mackay, N.R. Rose (eds.), *Encyclopedia of Medical Immunology – Autoimmune Diseases*,
DOI 10.1007/978-0-387-84828-0, © Springer Science+Business Media New York 2014

The pathogenesis of LN is now thought to involve two steps. In early nephritis, immune complex deposition is seen in subendothelial and mesangial areas, while in late nephritis, immune deposits are seen in subepithelial and intramembranous areas (Tsokos 2011). One recent explanation advanced for the transformation from the early to the late stage is that of changes in DNase I enzyme activity in the kidney. Decreased DNase I activity can slow the rate of chromatin clearance and promote the release of metalloproteinases that degrade the glomerular basement membrane (GBM), allowing for the accumulation of immune complexes at that site (Rekvig et al. 2011).

The occurrence of numerous autoAbs in SLE has long been recognized; indeed, the presence of autoAbs comprises 2 of the 11 American College of Rheumatology criteria for the diagnosis (Tan et al. 1982). Nevertheless, their specific pathogenic role is far less understood. Clearly, some autoAbs are a diagnostic marker for lupus, but do not actually participate in tissue damage. In this entry, the focus will be on the role of SLE-associated antibodies in the pathogenesis of renal disease. Among the proposed mechanism of kidney damage mediated by SLE autoAbs are in situ immune complex deposition, leading to local inflammation via complement activation and by direct activation of inflammatory cells through Fc receptor engagement; binding directly to cell surfaces causing cytotoxicity; penetration into living cells; and binding to cross-reactive kidney antigens (Putterman 2004; Rekvig et al. 2011). While multiple autoAbs have been implicated in the pathogenesis of LN, discussed below are relatively well-established examples of nephritogenic antibodies, embodying the different types of mechanisms thought to be involved in the nephritic process.

Anti-Double-Stranded DNA Antibodies

Approximately 70 % of SLE patients are positive for anti-double-stranded DNA antibodies (anti-dsDNA Abs) which are relatively lupus specific (97 %), rendering them useful in diagnosis. Over the last few years, it has become clear that anti-dsDNA Abs have important systemic effects related to the engagement of toll-like receptor 9 (TLR 9) in dendritic cells (DCs) following internalization of dsDNA–anti-dsDNA Ab complexes. In turn, the DC become activated and secrete B-cell-activating factor (BAFF) and other pro-inflammatory cytokines, including interferon-α (IFNα). Overexpression of IFNα-inducible genes characterizes SLE patients, and IFNα expression has been shown to correlate with disease activity. IFNα overexpression then leads to a vicious cycle in which IFNα induces monocytes to differentiate into DC that themselves become activated. The activated DC then prime naive T cells to promote activation and expansion of autoreactive T and B cells, while at the same time releasing BAFF due to the TLR9 activation. In turn, more IFNα is secreted, and autoreactivity is perpetuated (Aranow et al. 2011). An analogous mechanism is thought to be relevant to RNA-binding Abs and TLR7.

Currently, there are three popular methods utilized by clinical laboratories to measure anti-dsDNA Abs levels. The Farr assay is based on the precipitation of DNA–anti DNA antibody complexes in high salt concentrations. It detects high-avidity anti-dsDNA Abs, and antibody levels measured by this method closely correlate with SLE flares, particularly nephritic ones. The sensitivity and specificity of the Farr assay for measuring anti-dsDNA Abs levels in the diagnosis of SLE are 42–85 % and 95–99 %, respectively. The Farr assay, however, is not routinely performed, as it requires the use of a radiolabeled antigen. The *Crithidia luciliae* assay is an indirect immunofluorescence assay based on the fact that the kinetoplast of this particular hemoflagellate is rich in dsDNA. *Crithidia* detects medium- to high-avidity antibodies, and shows somewhat improved specificity (98–100 %), while maintaining good sensitivity (47–55 %). Quantitation of antibody levels using *Crithidia* requires serum titration, and so it is not routinely employed to serially measure Abs levels over the course of the disease. The third, and most widely used method, is enzyme-linked immunosorbent assay (ELISA).

In this technique, serum anti-dsDNA Abs adhere to dsDNA that is fixed to a plastic well, and then detected using a secondary anti-human IgG antibody conjugated to a detector enzyme. The ELISA detects both high- and low-avidity anti-dsDNA Abs, and so is the most sensitive (56–67 %), but not as specific (91–96 %) as the two previously described methods. ELISA is technically relatively easy and usually automated. However, changes in Abs levels detected by ELISA do not always reliably reflect or predict fluctuations in disease activity (Ghirardello et al. 2007). Another relatively new, and increasingly used, method for measuring anti-dsDNA Abs (and other autoantibodies) is the multiplexed immunoassay which utilizes magnetic beads, allowing for the quantitative detection of over 10 antibodies simultaneously. This method is clearly efficient and time conserving, but its relative reliability remains to be determined.

Anti-dsDNA Abs titers have been found to correlate with SLE disease activity, and in particular with LN activity (Aranow et al. 2011). Support for the pathogenic role of anti-dsDNA Abs in LN comes from the finding of a relative enrichment of anti-dsDNA Abs in IgG eluted from LN patients' kidneys. In addition, both ex vivo and in vivo experiments in murine models have shown that anti-dsDNA Abs can promote LN: For example, perfusion of a rat kidney with monoclonal mouse and polyclonal human IgG anti-dsDNA Abs leads to proteinuria and decreased renal function, and injection of specific subsets of anti-dsDNA Abs into non-autoimmune mice produces nephritis (Putterman 2004).

While over two-thirds of SLE patients harbor anti-dsDNA Abs, many do not develop nephritis. Consequently, it was assumed, and later experimentally demonstrated in murine models, that not all of these Abs are pathogenic. It is the high-avidity, somatically mutated, cationic subsets that are particularly nephritogenic (Aranow et al. 2011). The differential pathogenic potential of specific subsets of anti-dsDNA Abs led to the following, not mutually exclusive, hypotheses as to the mechanism of anti-dsDNA Abs-mediated nephritis in SLE: the "planted" antigen hypothesis, and the cross-reactivity theory.

"Planted" Antigen

The concept of preformed circulating immune complexes that become sequestered in the glomeruli promoting an immune reaction is not currently considered valid (Aranow et al. 2011). Rather it is thought that LN is triggered by in situ formation of immune complexes, generated by recognition of exposed chromatin on the surface of apoptotic glomerular cells by circulating anti-dsDNA Abs. The "planted" immune complex then promotes mesangial proliferation through Fcγ receptors on the mesangial cells, and local activation of the immune system (Rekvig et al. 2011). Support for this theory comes from electron microscopy evidence of immune complex deposition in the GBM, and the specific recognition of GBM nucleosomes by the nephritogenic antibodies (Kalaaji et al. 2006).

Cross-Reactivity with Renal Antigen

It is important to note, however, that there are SLE patients with biopsy-proven LN, without detectable levels of anti-dsDNA Abs (Hanrotel-Saliou et al. 2011). Moreover, monoclonal anti-dsDNA Abs and human SLE serum can bind glomeruli even after eliminating nuclear material. Therefore, another hypothesis is that anti-dsDNA Abs cross-react directly with glomerular antigens, leading to local complement fixation and activation of inflammatory pathways. Accordingly, a common feature reported in many nephritogenic anti-dsDNA Abs is their ability to cross-react with an array of cell-surface and matrix components, including among others α-actinin, annexin II, laminin, and fibronectin. This hypothesis is especially pertinent as analysis of kidney-eluted IgG revealed that only about 10 % of the total IgG were Abs binding to dsDNA (Hanrotel-Saliou et al. 2011).

Since injection of some anti-dsDNA Abs to mice fails to induce glomerular injury, it is assumed for such Abs that a separate event is necessary to incite the inflammatory process and cause initial apoptosis of the glomerular cells in order to expose the chromatin to the environment. These two proposed mechanisms, DNA-mediated and cross-reactivity with renal

antigens, may then possibly work sequentially in order to trigger and amplify glomerulonephritis. In other words, circulating anti-dsDNA Abs may cross-react with resident glomerular antigens causing local inflammation, bringing about cellular apoptosis which exposes chromatin that is itself recognized by anti-dsDNA Abs – thus further intensifying the inflammatory process (Krishnan et al. 2012). Support for this sequential concept can be found in the report that anti-glomerular Abs are detected earlier than anti-nuclear Abs in kidneys of lupus-prone mice (Hanrotel-Saliou et al. 2011).

Anti α-Actinin Antibodies

α-actinin belongs to a family of actin-binding proteins, and has been described in four forms in humans: 1 and 4 are the non-muscle forms, and 2 and 3 are striated muscle forms. In the kidney, α-actinin 1, 2, and 4 are expressed by podocytes and mesangial cells. α-actinin 4 is crucial for normal kidney physiology, as α-actinin-4-deficient mice present with severe glomerular disease, while humans with point mutations in the α-actinin 4 actin-binding site develop familial focal and segmental glomerulosclerosis (Renaudineau et al. 2007).

Anti-dsDNA Abs cross-reacting with α-actinin are increased in patients with LN compared with SLE patients without LN, and track with lupus nephritis activity. Furthermore, the presence of serum α-actinin Abs is associated with a 2.5-fold increase in prevalence of LN (Youinou and Putterman 2009). In a longitudinal follow-up of LN patients, α-actinin Abs could be detected before evidence of renal disease, and the titer of the autoAbs dropped significantly following the initialization of treatment. This close association between LN activity and anti-dsDNA/α-actinin Abs implies that the cross-reactivity with α-actinin is what enables the anti-dsDNA Abs to become pathogenic (Renaudineau et al. 2007).

In concert with the human data, in murine experimental models, anti-dsDNA Abs that bound α-actinin were found to be pathogenic, while closely related anti-dsDNA Abs that differed only with regard to cross-reactivity with α-actinin were not pathogenic (Mostoslavsky et al. 2001; Deocharan et al. 2002). Moreover, polymorphisms in the *ACTN* gene were found in lupus-prone mice, leading to differential α-actinin expression (Youinou and Putterman 2009). Increased α-actinin expression may contribute to renal susceptibility to the anti-dsDNA/α-actinin Abs-mediated nephritis, as greater expression of antigen may lead to enhanced glomerular antibody deposition (Zhao et al. 2005).

Anti-annexin II Antibodies

Annexin II is a calcium-dependent, phospholipid-binding protein that is expressed on the surface of a number of phagocytic cells, including mesangial cells. A recent study identified annexin II as a human mesangial cell membrane antigen that binds anti-dsDNA Abs. It was also shown that IgG and C3 deposits in LN co-localize with annexin II in the glomeruli, and that annexin II-binding activity of IgG in the sera of SLE patients correlated both with anti-dsDNA Abs levels and nephritis activity (Yung et al. 2010). Cross-reactivity of anti-dsDNA Abs with mesangial cell annexin II may lead to antibody internalization, mesangial cell activation via the ERK intracellular signaling pathway, proliferation, and eventually apoptosis. At the same time, this process induces IL-6 as well. Thus, the presence of anti-annexin II antibodies is associated with active LN (Yung et al. 2010).

Anti-C1q Antibodies

C1q is the first component of the classical pathway of complement, binding to the Fc portion of immune complexes and initializing complement activation. C1q is important in self-antigen clearance following apoptosis as well. Structurally, it contains six globular heads responsible for Fc receptor recognition, and a collagen-like region. AutoAbs to C1q are mainly of the IgG2 isotype, and recognize epitopes in the collagen-like region. Anti-C1q antibodies were identified in SLE patients, but also in a number of other conditions, including hypocomplementemic urticarial vasculitis (HUS), Sjögren's syndrome, IgA nephropathy,

and even in normal individuals. While anti-C1q Abs are highly sensitive for HUS (found in 100 % of patients), they are neither sensitive, nor specific to SLE. However, they have been found to be more prevalent in SLE patients with LN (including both glomeruloproliferative and membranous forms), compared to patients without nephritis. In a group of 43 SLE patients followed longitudinally by Coremans et al., anti-C1q Abs were positive in 82 % of LN patients, while only 38 % of non-renal SLE patients were positive for these Abs. Furthermore, in most LN patients positive for C1q Abs, Abs titers rose significantly prior to a renal flare. At the same time, of the relatively small percentage of non-LN SLE patients who had C1q Abs, only 50 % demonstrated an increase in Abs titers prior to a non-renal flare. Of note, anti-dsDNA Abs measured in these patients over the same period of time were positive in most patients regardless of their LN status, and often rose prior to the flare, whether renal or not. This finding may indicate that fluctuations in anti-C1q Abs are more specific than changes in anti-dsDNA Abs titers for renal involvement (Coremans et al. 1995; Kallenberg 2008).

Support for a pathogenic role for anti-C1q Abs can be found in the 50-fold enrichment of anti-C1q Abs present in glomeruli of LN kidneys. It was also demonstrated that anti-C1q Abs deposit along glomerular and tubular basement membrane, in a similar pattern to C1q deposits (Mannik and Wener 1997). Nevertheless, HUS patients and some SLE patients do not develop nephritis despite having high titers of anti-C1q Abs (Sinico et al. 2009).

In experimental murine models, injection of anti-C1q Abs into normal mice led to C1q depletion, and deposition of C1q and anti-C1q Abs along the GBM. Nevertheless, only a mild granulocyte influx was noted, and no proteinuria resulted. Rather, co-treatment with anti-GBM Abs and anti-C1q Abs was required in order to bring about full-blown nephritis (Trouw et al. 2004; Kallenberg 2008). Thus, it would appear that the association of anti-C1q Abs with nephritis is through the binding of C1q to immune complexes along the GBM, and recognition of these bound C1q molecules by anti-C1q Abs. Consequently, the normal functions of C1q in immune complex solubilization and clearance of apoptotic material are disturbed, both enhancing local inflammation (Sinico et al. 2009).

Anti-ribosomal P Abs

Anti-ribosomal P Abs are detected in 12–16 % of SLE patients (Hirohata 2011), more often in Asian patients than in Caucasians, African Americans, or Hispanics (Toubi and Shoenfeld 2007). They ligate three ribosomal serine phosphorylated proteins (P0, P1, and P2) involved in the elongation step of protein synthesis when associated with the 60S subunit of the ribosome. These ribosomal proteins appear on membranes of multiple cells, including mesangial cells and blood cells (Toubi and Shoenfeld 2007).

The clinical association of anti-ribosomal P Abs with LN was demonstrated in a series of studies by Reichlin's group. In 69 SLE patients, anti-ribosomal P Abs were more prevalent in LN patients (75 %) as compared to the overall prevalence of these autoAbs in the study cohort (30 %). A strong association between anti-ribosomal P Abs and anti-dsDNA Abs was demonstrated, as 81 % of patients with positive anti-ribosomal P Abs were also positive for anti-dsDNA Abs, while only 41 % of patients without anti-ribosomal P Abs had increased titers of anti-dsDNA Abs (Chindalore et al. 1998). Additionally, in the presence of anti-ribosomal P Abs, anti-dsDNA titers were much higher in LN patients than in non-LN patients (Reichlin and Wolfson-Reichlin 2003). This can indicate cross-reactivity between the two autoAbs, although such cross-reactivity was never unequivocally proven (Hirohata 2011). Interestingly, it has been suggested that isolated anti-ribosomal P Abs are more prevalent in patients with pure membranous LN (71 % of studied patients with isolated anti-ribosomal P Abs had pure membranous LN), while the presence of anti-dsDNA Abs together with anti-ribosomal P Abs was more typically found in patients with both proliferative and membranous lesions (67 %) (Toubi and Shoenfeld 2007; Hirohata 2011).

The mechanism of pathogenicity of anti-ribosomal P Abs has not been confirmed, but a number of possibilities have been proposed. The first scenario stipulates that anti-dsDNA Abs cross-react with ribosomal P proteins. Supporting this hypothesis is the finding that the carboxyl-terminal 20 amino acids of the ribosomal P proteins were the target antigen of anti-DNA Abs on rat glomerular mesangial cells, leading to inhibited proliferation and apoptosis of these cells. Further support comes from the observations of strong association between the titers of the two autoAbs. A second possible theory relies on the fact that diffuse proliferative LN patients are skewed toward a TH1 immunologic phenotype. Anti-ribosomal P Abs (through ligation of ribosomal P epitopes on the surface of monocytes) enhance expression of IL-12, which in turn induces differentiation of CD4+ T cells to TH1 cells. Nevertheless, anti-ribosomal P Abs have been associated specifically with membranous LN, as opposed to the TH1-induced proliferative LN (Hirohata 2011). Another mechanism by which anti-ribosomal P Abs may contribute to the pathogenesis of SLE is through their ability to penetrate into cells, disturbing cellular physiologic functions such as protein synthesis and leading to apoptosis. Cellular penetration is thought to be mediated by a membrane form of the P0 ribosomal protein. This process was demonstrated in vitro in HepG2 cells, and was postulated to underlie the pathogenesis of a number of autoimmune hepatic diseases. Furthermore, treatment with monoclonal anti-ribosomal P Abs promoted apoptosis of Jurkat T cells in vitro. Thus, anti-ribosomal P Abs may be involved in the pathogenesis of the lymphocytic dysfunction in SLE (Toubi and Shoenfeld 2007). Currently, however, there is no direct evidence of the ability of anti-ribosomal P Abs to penetrate into renal cells, and it is yet unknown if cellular penetration is relevant to LN pathogenesis.

Conclusion

SLE is characterized by the expression of numerous autoantibodies, only a subset of which is pathogenic and contributes directly to target organ damage. Lupus nephritis, one of the major causes of morbidity and mortality in SLE, is assumed to be initiated and perpetuated by an autoimmune response mediated via these pathogenic autoAbs. A number of mechanisms have been proposed for autoAb-mediated LN, including in situ immune complex deposition, cross-reactivity of anti-dsDNA Abs with glomerular antigen, direct cell activation and/or cytotoxicity, and antibody internalization. Nevertheless, while binding to DNA in the specificity most closely associated with LN, and anti-dsDNA autoAbs most probably play an important role in the nephritic process, injection of purified Abs only rarely induces overt histological damage, or reproduces the complete histological picture associated with proliferative LN. Therefore, it is important to recognize that anti-dsDNA or other nephritogenic antibodies are often a necessary, but not always sufficient component in the various pathways contributing to full expression of lupus nephritis.

Synonyms

Cutaneous small-vessel vasculitis; Cutaneous vasculitis; Hypersensitivity angiitis; Hypersensitivity vasculitis; Leukocytoclastic vasculitis; Small-vessel vasculitis; Vasculitis

Definition

Leukocytoclastic vasculitis is inflammation of the small blood vessels of the skin. It may occur alone or in association with a number of disease states and clinically results in characteristic skin lesions which are non-blanching and often on the lower extremities.

Background

Vasculitis refers to inflammation of blood vessel walls. This inflammation often leads to vessel destruction and subsequent ischemic damage of the organs supplied. This inflammation can affect multiple organs, but those with dense vascular supply such as the gastrointestinal tract, kidneys, lungs, and skin are the most severely clinically affected. Leukocytoclasia is a histopathological term referring to the presence of breakdown of neutrophils. The term leukocytoclastic vasculitis (LCV) is commonly interchangeably used to refer to cutaneous small-vessel vasculitis, which is the subject of this review, as it is the primary histologic finding in this condition although to be strictly precise leukocytoclasia can occur to some degree in any vasculitis. Similarly although the synonyms provided above are frequently used to refer to the same condition, they are not strictly identically defined, and readers should be careful when accessing the literature.

There are a variety of classification standards for further subdividing the different types of vasculitis (Luqmani et al. 2011). Although these differ somewhat, most incorporate the size of vessel involved, whether small-, medium-, or large-vessel vasculitis, as primary categorization criteria. As already noted "leukocytoclastic vasculitis" is a vasculitis of small vessels. In the skin this constitutes the arterioles and postcapillary venules of the papillary and mid-dermis.

Clinical Presentation

Skin lesions are most common on the lower legs but any area can be affected (Goldsmith and Fitzpatrick 2012). Lesions are usually small (1–3 mm) and round, although they may coalesce to form plaques. They are subtly palpable and are non-blanching, thus being described as purpura. In the early stages, lesions may be asymptomatic, itchy, or burning. Inflammation is particularly intense or persistent plaques can form areas of necrosis and ulceration and this can be intensely painful. This, as well as more retiform purpura, is more common in Henoch-Schönlein purpura (Goldsmith and Fitzpatrick 2012; Piette and Stone 1989).

Other organs may also be affected in LCV with the most common being the joints, kidney, and gastrointestinal tract. LCV may be acute, chronic, or recurrent. Chronic and recurrent forms are more commonly associated with an underlying systemic disease. Known triggers of LCV include infections, inflammatory disorders, malignancies, autoimmune diseases, and medications (see below). Despite these many associations, between 30 % and 50 % of cases remain idiopathic. Prognosis is best in those with acute LCV limited only to the skin and unassociated with any systemic disease.

Histology

Histology depends on the timing of the biopsy (McKee et al. 2005). In early or late lesions, characteristic changes may not be present with early lesions showing little change, whereas late lesions show a more mixed infiltrate and, if ulceration has occurred, extensive necrosis. Characteristic histology shows dense perivascular infiltration of neutrophils with invasion of the vessel walls by neutrophils. There is leukocytoclasia (neutrophil fragments), endothelial swelling, fibrinoid necrosis of the vessel walls, and often extravasation of erythrocytes (red blood cells). Eosinophils suggest urticarial vasculitis or drug-associated disease.

In Henoch-Schönlein purpura, immunofluorescent staining shows IgA deposits which can be helpful diagnostically. In other types of cutaneous vasculitis, immunofluorescent stains are not often clinically helpful but frequently show immunoglobulins (immunoglobulin G, immunoglobulin M) and complement components (e.g., C3, C4) deposited on the skin basement membrane. In one study, direct immunofluorescence was positive for at least one reactant in 62 % of cases with the most common deposit being C3 followed by IgG, IgA, and IgM (Khetan et al. 2012).

Immunology and Pathogenesis

There is good evidence, including the immunostaining findings above, to support the idea that most cutaneous vasculitis are pathogenically associated with deposition of circulating immune complexes. Individual triggers for this process vary and the initiation of this process is likely different for each. However, it seems clear that after the initial insult, a common pathway is followed in the majority of LCV where deposition of these circulating immune complexes into the vessel wall results in activation of the complement cascade, release of histamines and other vasoactive proteins leading to vessel leakage and erythrocyte extravasation, and cytokine release which recruits neutrophils to the site resulting in vessel damage.

In contrast, in conditions such as Wegener's granulomatosis, there is a strong association with ANCA recognizing epitopes on the neutrophil enzymes proteinase 3 and myeloperoxidase. These enzymes are confined neutrophil granules and reach the plasma membrane after specific stimuli, although for proteinase 3, a genetically encoded pattern may regulate expression in the absence of detectable stimuli (Kallenberg 2008). These ANCA promote deregulated inflammatory clearance of neutrophils, possibly directly resulting in leukocytoclasia. While LCV is not highly associated with ANCAs, LCV can occur in the context of systemic vasculitis as in Wegner's, and this may therefore be one mechanism for its formation.

Another factor which may be important in LCV is the host's ability to produce the prototypic long pentraxin 3 (PTX3). PTX3 is produced by inflammatory cells, including neutrophils, and tissues in response to inflammatory signals and TLR activation (Manfredi et al. 2008). Elevated PTX3 has been identified in both mouse models and human studies in patients with vascular damage from atherosclerotic disease or preeclampsia. PTX3 is believed to be protective and reduces the inflammation and effect of cytotoxic signals. This is reflected in experiments with PTX3-deficient mice which have an exacerbated damage after reperfusion. PTX3 has also been shown to be produced in small-vessel vasculitis lesions by endothelial and mononuclear cells (van Rossum et al. 2006). Patients with vasculitis had significantly higher concentrations of PTX3, and these levels could be lowered with immunosuppressive treatments (Fazzini et al. 2001). Finally, there is some evidence that the cross talk between activated platelets and circulating leucocytes may be disturbed in LCV (Maugeri et al. 2009; Tervaert 2009).

Epidemiology, Etiology, and Associated Conditions

LCV shows no apparent bias by gender, age, or ethnicity (Grzeszkiewicz and Fiorentino 2006).

The list of conditions and medications associated with LCV is broad, and these are therefore best broken down into categories. In bacterial infections, upper respiratory tract infections, particularly with beta-hemolytic streptococci, and gastrointestinal infections are implicated most often, but bacterial endocarditis can elicit an LCV. Of viral infections hepatitis B and C are commonly associated, with hepatitis C likely pathogenically linked through the presence of cryoglobulins. More common infections such as EBV have also been associated. Both HIV and its treatments are associated with LCV.

The most common drugs that can cause cutaneous vasculitis are antibiotics, particularly beta-lactam drugs, and whether an antibiotic or the original infection is the trigger is sometimes difficult to establish. Other common medications linked to LCV include nonsteroidal anti-inflammatory drugs and diuretics; however, the list of drugs that are potential causes is extensive (Doyle and Cuellar 2003). In addition to medications, other exogenous agents such as toxins, industrial chemicals, and even foods and food additives may cause vasculitis. Collagen-vascular diseases account for 10–15 % of vasculitis cases with rheumatoid arthritis and Sjögren syndrome having the highest association.

Inflammatory bowel disease may also be associated with cutaneous vasculitis. Malignancy accounts for less than 1 % of cases of cutaneous vasculitis.

The most common association of these is with lymphoproliferative diseases. In these cases treatment of the underlying malignancy is often curative, and LCV activity can track onset and recurrence. However, in some patients the immune activation is persistent independent of the underlying cause.

Cutaneous vasculitis may also be part of a larger-vessel vasculitis most commonly those that have mixed involvement of small and medium vessels such as Wegener's and microscopic polyarteritis but polyarteritis nodosa and Churg-Strauss syndrome can also demonstrate LCV at times in their course.

Work-Up

Given the broad differential work-up is often extensive but should begin with a full review of systems and detailed disease, medical, and medication history. Serologies should include complete blood cell count, erythrocyte sedimentation rate, and blood chemistry panel, and due to the risk of kidney involvement, a urinalysis should be performed. Chest x-ray and stool guaiac are often obtained as screenings. Antistreptolysin antibodies or cultures for URI or GI infections may be performed if clinically suggested. If no obvious cause (preceding upper respiratory infection) is present, further work-up should be guided by other clinical signs and personal and family medical history.

In patients suspected of a connective tissue disease, ANA, dsDNA, Ro/La, RNP, RF, and complement levels should be obtained, including total hemolytic complement (CH100 or CH50), C3 levels, and C4 levels. The latter should also be considered in cases of urticarial vasculitis. Serum protein electrophoresis and immunofixation should be checked in any patient where connective tissue or malignancy is of concern, as well as cryoglobulins, which should also be drawn if hepatitis B and C antibody is considered. Where further organ involvement is suspected, antinuclear antibody cANCA and pANCA should also be obtained. In sicker, febrile patients, cardiac ultrasonography and blood cultures should be considered. HIV testing should be performed in patients with risk factors.

A rigorous search for underlying malignancy is not usually pursued unless there is some clinical indication (e.g., weight loss, strong family history, toxic exposure risk), but what specific testing is obtained is often guided by that indication.

It is also recommended that pulmonary function tests should be obtained in patients with hypocomplementemic urticarial vasculitis.

Treatment and Prognosis

Initial treatment is guided by identification of the underlying cause, e.g., treatment of infections or withdrawal of medication. Symptomatic treatment involves elevation of dependent areas and simple wound care when skin breakdown occurs. Itch may be treated with sedating antihistamines.

Corticosteroids either topically, intralesionally, or systemically can provide rapid improvement in some varieties of LCV. In addition, colchicine and dapsone are considered first-line treatments for persistent cases of LCV and other neutrophilic dermatosis. Other agents that have been used with varying success include cyclosporine, potassium iodide, indomethacin, clofazimine, thalidomide, and CellCept, as well as biologic agents such as infliximab and etanercept, although LCV has also been reported as occurring secondary to TNF-alpha antagonist agents. Rituximab has also shown good promise for treatment in otherwise recalcitrant disease (Chung et al. 2006; Chung and Seo 2009).

While mostly benign and limited in duration, LCV can be chronic and can have severe complications both cutaneous and systemic. In these latter cases, it requires ongoing treatment for suppression.

Neutrophilic Dermatoses: Pyoderma Gangrenosum

Gideon P. Smith[1] and Andrew G. Franks Jr.[2]
[1]Department of Dermatology, Massachusetts General Hospital, Harvard Medical School, Boston, MA, USA
[2]Dermatology and Medicine (Rheumatology), Skin Lupus and Autoimmune Connective Tissue Disease Section, New York University School of Medicine, New York, NY, USA

Synonyms

Brocq's geometric phagedenism; Geometric phagedenism; Neutrophilic dermatosis; PG; "Pyoderma ecthyma gangrenosum"; Pyoderma gangrenosum; Vegetans gangrenosum

Definition

Pyoderma gangrenosum is a skin condition characterized by deep painful ulcers with undermined borders. It is associated with many diseases but can occur independently and represents a dense inflammation of neutrophils.

Historical Background

Retrospectively identified as the same entity, Louis Brocq reported in 1908 a series of cases of pyoderma gangrenosum, which he called "geometric phagedenism" to reflect the circular geometric appearance and rapid consumption of tissue (phageton [Greek], meaning food, consumption) (Farhi et al. 2008). Although such reports may be retrospectively identified as pyoderma gangrenosum (PG), the original report that used this name and identified this as an entity was from the Mayo Clinic Department of Dermatology in 1930. In that report Drs. Brunsting, Goeckerman, and O'Leary identified five patients with classic PG, four of

which had ulcerative colitis and one of which had chronic idiopathic purulent pleurisy. The word pyoderma was adopted as they believed this was due to a distant infectious process. It was not until later that the idea that this is an inflammatory reaction and not infectious was accepted, but by that time the term pyoderma gangrenosum had become established.

Classification and Clinical Presentation

PG is often classified into one of the four clinical variants depending on its appearance: classical (or ulcerative) PG, pustular PG, bullous PG, and vegetative PG. Classic or ulcerative PG skin lesions often start as a small papule or sterile pustule that then breaks down to form an ulcer. The ulcer is often deep, with a characteristic well-circumscribed, violaceous, undermined border that can expand rapidly. The lesions are often intensely painful and even after healing often leave cribriform scars. Lesions favor the lower extremities with the pretibial area most common, and peristomal (15 %) the second, but have been reported in almost all body locations. Lesions on the trunk can be induced by surgery with pathergy (new lesions at the site of minor trauma) occurring in 25–50 % of cases (Brooklyn et al. 2006).

In pustular PG the lesions do not form ulcers but instead persist at the pustular stage for months at a time. These lesions are also intensely painful but lead to less scarring and tend to occur with greater frequency on the trunk and extensor surfaces. It is more common in inflammatory bowel disease (IBD) patients.

Bullous PG in contrast more commonly occurs on the face and upper extremities. The bullae spread concentrically and, although may break down into ulcers with undermined edges, tend to be more superficial. This form of PG is more common in patients with a hematological malignancy.

Vegetative PG is usually a less aggressive form of the disease. It tends not to spread as rapidly and usually remains limited to one or a few locations. It also responds more readily to treatment.

In all forms patients may also exhibit systemic symptoms and appear sick with fever (>38 °C) as the most common non-cutaneous symptom, but malaise, headache, arthralgia, and myalgia may also occur. This may be concurrent or precede skin findings by days to weeks.

In addition to the skin, PG can affect many other systems producing diverse symptoms. Reports have been made of ocular lesions (Happle et al. 1977), sterile pulmonary nodules (Vignon-Pennamen et al. 1989), involvement of the liver and spleen (Vadillo et al. 1999), and myositis (Marie et al. 2001), as well as by direct extension to the bone.

Histology

The histology of PG depends in part on the timing of the biopsy. In very early PG inflammation may be of a mixed-cell infiltrate that is primarily in the upper dermis. However, this is soon replaced by intense neutrophilic infiltration, hemorrhage, and necrosis of the overlying epidermis. Although neutrophils are often around and occasionally within the vessel walls due to the density of the infiltrate, leukocytoclastic vasculitis, which would be indicated by fibrin deposition and neutrophils within vessel walls, is only present in 40 % of cases (Lever and Elder 2009). Histology may be supportive of a diagnosis of PG but is not diagnostic.

Diagnostic Criteria

With no set diagnostic criteria and nonspecific histology, diagnosis of PG is by exclusion. The differential diagnosis includes other neutrophilic dermatoses; vascular occlusive diseases; calciphylaxis; vasculitis; Wegener's granulomatosis; antiphospholipid syndrome; malignancy, most commonly squamous but also locally invasive or metastatic malignancies; infections, most notably deep fungal such as sporotrichosis or atypical mycobacterial infections, in the postsurgical patient gangrene or suppurative bacterial infections, cutaneous tuberculosis,

late syphilis, or deep herpetic infections; traumatic ulceration; factitial disease; arthropod assault, most notably arachnid; and non-PG forms of drug reactions. This differential is broad and can often be significantly narrowed based on a detailed history, with information on the patient's medical conditions, timing, and location of the lesion.

Epidemiology, Etiology, and Associated Conditions

Onset of classic PG is generally between the 2nd and 6th decade, with the incidence in the general population estimated at between 3 and 10 per million per year. It disproportionately affects women but shows no bias in ethnic background or geographic distribution (Wollina 2007).

As noted above PG can be associated with a variety of systemic illnesses. Classical PG is associated with inflammatory bowel disease; however, it may also be associated with underlying malignancy and can be drug induced. 10–15 % of PG is associated with ulcerative colitis and another 10–15 % with Crohn's (Wollina 2007). Despite this only 1–2 % of patients with IBD will suffer from PG (Bernstein et al. 2001). Despite the association with IBD, IBD-associated PG activity is unrelated to the activity of the underlying IBD disease. PG can also occur in association with hematological dyscrasias and malignancies, including leukemia, lymphoma, monoclonal gammopathy, and myelodysplastic syndrome. In contrast to IBD-associated PG, PG associated with malignancy often, but not always, marks the onset or recurrence of the underlying malignancy and is often put in remission by treatment of the underlying malignancy.

PG can also be associated with arthritis, both via association with standard rheumatological conditions such as psoriatic or rheumatoid arthritis and spondylitis, and as part of the PAPA syndrome (pyogenic arthritis, pyoderma gangrenosum, and acne) an autosomal dominant condition that can be caused by one of the two mutations in the PSTPIP1 gene on chromosome 15 that codes for CD2 binding protein 1 (Wise et al. 2002). In this latter condition, the arthritis usually presents first at a young age with the onset of skin findings at puberty. PG can rarely be associated with autoimmune diseases such as lupus erythematosus or Sjögren's syndrome.

Although PG has been reported in association with infections, it is usually in association with infections causing chronic inflammation. The classic example of this is in chronic hepatitis C infection (Smith et al. 1996) although it can also occur during hepatitis C treatment (Yurci et al. 2007), and reports of PG in association with colonic (Kim et al. 1994) and testicular forms (Anton Botella et al. 1989) of tuberculosis exist.

A variety of drugs have also been associated with inducing PG including isotretinoin (Gangaram et al. 1997), propylthiouracil (Darben et al. 1999), granulocyte colony-stimulating factor (Ross et al. 1991), and oncologic medications such as sunitinib (ten Freyhaus et al. 2008).

In addition to the above associations, there are many untested or single case report associations in the literature.

Work-Up

Given the above disease associations, a rigorous work-up is generally recommended but should be guided by the differential generated by the detailed history. Work-up therefore begins with a detailed history and physical. Lesional skin biopsy is sometimes warranted but is more useful for diagnosing items from the differential than PG itself. A complete blood cell count with leukocyte differential and platelet count should be performed, serum chemistries including liver function tests for evaluation of hepatic function and creatinine and a urinalysis for evaluation of renal function, and consideration of acute phase reactants such as the erythrocyte sedimentation rate or C-reactive protein for tracking of disease activity. Serologic hepatitis screening should be performed, and in the right clinical context, urine and fecal cultures, rheumatoid factor, and thyroid-stimulating hormone testing should also be performed.

Given the association with hematologic dyscrasias, serum and urine protein electrophoresis, peripheral smear, and bone marrow aspiration or biopsy should be considered where appropriate. In addition to the above, where cancer is suspected, it has also been suggested that fecal occult blood smear, carcinoembryonic antigen level, pap test in women, chest x-ray, as well as age- and symptom-appropriate cancer screenings such as endometrial biopsy in postmenopausal women with spotting, breast exam or mammogram, testicular and prostate exam, and colonoscopy in patients over 50 years of age be performed. Colonoscopy is also warranted when IBD symptoms are present, but a diagnosis has not as yet been made.

If infectious processes are in the differential, tissue cultures of the ulcer for bacteria, fungi, atypical mycobacteria, and viruses are needed.

Where traumatic or veno-occlusive disease is considered, x-ray or Doppler studies may be warranted.

Treatment and Prognosis

If an underlying cause can be identified, then treatment of the underlying cause, including chemotherapy of underlying malignancy, treatment of Hepatitis C, or withdrawal of the inciting medication, can be curative of the PG. Other than resection of tumor, surgical intervention plays little role in the treatment of PG given its propensity for pathergy and the inherent potential therefore of worsening the condition.

Corticosteroids either topically, intralesionally, or systemically can often provide rapid improvement in all varieties of PG (Wollina 2007). In addition, infliximab, cyclosporine, potassium iodide, colchicine, and dapsone may also be considered first-line therapies for this and other neutrophilic dermatosis. Other agents that have been used with varying success include indomethacin, clofazimine, thalidomide, and CellCept, as well as biologic agents such as etanercept (Yamauchi et al. 2006) although PG has also been reported as occurring secondary to TNF-alpha antagonist agents.

While mostly benign, PG can have severe complications and require ongoing treatment for suppression. Even after remission, PG may recur regardless of whether the remission was spontaneous or therapy induced.

[2]Dermatology and Medicine (Rheumatology), Skin Lupus and Autoimmune Connective Tissue Disease Section, New York University School of Medicine, New York, NY, USA

Synonyms

Acute febrile neutrophilic dermatosis; Gomm-Button disease; Sweet's syndrome

Definition

Sweet's is a condition in which dense neutrophil inflammation leads to abrupt onset of tender edematous papules and plaques on the skin, often accompanied by systemic symptoms such as fever and malaise and an elevation in white cell count.

Historical Background

Although prior reports (Costello et al. 1955) have been retrospectively identified as Sweet's syndrome (SS), the original report that identified this as an entity was in 1964, when Dr. Robert Douglas Sweet reported a series of eight women with the disease (Sweet 1964). Originally called Gomm-Button disease after the first two patients who were diagnosed with it, Dr. Sweet instead recommended that the disease be named descriptively and thus suggested the diagnostic moniker "acute febrile neutrophilic dermatosis." Despite this, the disease is popularly known as Sweet's syndrome after Dr. Sweet the author of the first report.

Classification and Clinical Presentation

Sweet's is often divided into classical, malignancy-associated and drug-induced forms of the disease, dependent on the underlying etiology. In all forms patients may appear very sick with fever (>38 °C), the most common non-cutaneous symptom. This may precede skin findings by days to weeks. Typical symptoms associated with high fevers such as malaise and headache are also common but arthralgia and myalgia may also occur. The skin lesions may be single or multiple and favor the upper extremities, face, and neck. They are red-brown to purple in color and often form raised edematous papules and plaques. Lesions may appear pseudo-vesiculate or ulcerate, although this is more common in the malignancy-associated variant, and in persistent lesions central clearing can lead to arcuate formations. Pathergy is characteristic with new lesions occurring at the sites of minor trauma. Oral mucosal lesions are rare but more common in Sweet's associated with hematologic malignancies. In contrast, ocular lesions are more common in classical Sweet's.

Clinical variants of Sweet's that have been reported include a pustular form, subcutaneous Sweet's characterized by erythema nodosum-like erythematous, tender dermal nodules on the extremities, and neutrophilic dermatosis of the dorsal hands, although some authors separate this

final entity from Sweet's by including in its definition the presence of a leukocytoclastic vasculitis.

In addition to the skin, Sweet's can affect many other systems producing diverse symptoms (Cohen and Kurzrock 2003), including psychiatric and neurologic (neuro-Sweet disease, encephalitis, aseptic meningitis, polyneuropathy), ophthalmologic and auricular (conjunctivitis, dacryoadenitis, episcleritis, glaucoma, iridocyclitis, iritis, retinitis, uveitis, idiopathic progressive bilateral sensorineural hearing loss), cardiovascular (aortic stenosis, aortitis, cardiomegaly, coronary artery occlusion, heart failure), pulmonary (pleural effusion and upper airway obstruction), renal (mesangiocapillary glomerulonephritis), gastrointestinal (ileal infiltrate, pancolitis), hepatosplenomegaly, and musculoskeletal systems (sterile arthritis and osteomyelitis, myositis, fasciitis, myalgias, tendinitis, and tenosynovitis).

Histology

Sweet's syndrome is characterized by a dense, diffuse infiltrate of mature neutrophils typically located in the papillary and upper reticular dermis with marked edema. In hematologic malignancy-related Sweet's skin lesions, leukemia cutis may be present, and in drug-induced Sweet's, occasional eosinophils may be noted. However, rare lymphocytes, histiocytes, and eosinophils may be noted in all varieties. Karyorrhexis or leukocytoclasia (fragmented neutrophil nuclei), swollen endothelial cells, and dilated small blood vessels may also be present. However, the overlying epidermis is normal, unless ulceration has occurred, and leukocytoclastic vasculitis, which would be indicated by fibrin deposition and neutrophils within vessel walls, is absent (Lever and Elder 2009).

Diagnostic Criteria

Diagnostic criteria, which depend on the subcategory of Sweet's, were first established in 1986 (Su and Liu 1986) with modification adopted in 1994 (von den Driesch 1994) and for drug-induced Sweet's in 1996 (Walker and Cohen 1996). The criteria include (1) abrupt onset of classical cutaneous lesions; (2) dense neutrophilic infiltrate on histology but without any evidence of leukocytoclastic vasculitis; (3) pyrexia $>38\,^{\circ}C$; (4) in malignancy-associated Sweet's association with an underlying hematologic or visceral malignancy, in classical Sweet's association with an inflammatory disease or pregnancy or preceded by an upper respiratory or gastrointestinal infection or vaccination, or in drug-induced Sweet's temporal relation to the administration of drug and its rechallenge; (5) excellent response to treatment with corticosteroids; (6) and three of the following: erythrocyte sedimentation rates >20 mm/h, positive C-reactive protein, $>8{,}000$ leukocytes, and >70 % neutrophils at presentation.

Epidemiology, Etiology, and Associated Conditions

Onset of classic Sweet's is generally between the fourth and seventhdecade, although patients as young as 10 days old have been reported (Parsapour et al. 2003). It disproportionately affects women but shows no bias in ethnic background or geographic distribution. Classic Sweet's is most commonly associated with upper respiratory tract (streptococcosis) and gastrointestinal tract infections (salmonellosis and yersiniosis), inflammatory bowel disease (both ulcerative colitis and Crohn's disease), and pregnancy.

A review of published studies suggested that 21 % of Sweet's cases have an underlying associated malignancy (Cohen and Kurzrock 1993). Malignancy-associated Sweet's occurs equally in men and women. The most common associated malignancy is acute myelogenous leukemia, and the most common solid-tumor malignancies are carcinomas of the genitourinary organs, breast, and gastrointestinal tract (Cohen 2007). Sweet's can predate, postdate, or be simultaneous with the discovery of the cancer or its relapse. Hematologic malignancies have been reported as long as 11 years after the first onset of Sweet's.

Many drugs from many different drug classes have been associated with drug-induced Sweet's. The most commonly associated is granulocyte colony-stimulating factor. The full range of causative drugs is reviewed elsewhere (Cohen 2007).

In addition to the above associations, there are many untested or single case report associations in the literature. Of these the most commonly reported associations include erythema nodosum, relapsing polychondritis, rheumatoid arthritis, sarcoidosis, and thyroid disease, including both Grave's disease and Hashimoto's thyroiditis (Cohen 2007).

Work-Up

Given the above diagnostic criteria and disease associations, a rigorous work-up is generally recommended. This should include a detailed history and physical exam, lesional skin biopsy, a complete blood cell count with leukocyte differential and platelet count, serum chemistries including liver function tests for evaluation of hepatic function and creatinine and a urinalysis for evaluation of renal function, and consideration of acute-phase reactants such as the erythrocyte sedimentation rate or C-reactive protein for tracking of disease activity. In the right clinical context, antistreptolysin-O antibody, urine and fecal cultures, rheumatoid factor, and thyroid stimulating hormone testing should also be performed.

In addition to the above, where cancer is suspected, it has also been suggested that fecal occult blood smear, carcinoembryonic antigen level, pap test in women, chest x-ray, and age- and symptom-appropriate cancer screenings such as endometrial biopsy in postmenopausal women with spotting, breast exam or mammogram, testicular and prostate exam, and colonoscopy in patients over 50 years of age be performed.

Treatment and Prognosis

If an underlying cause can be identified, then treatment of the underlying cause, including antibiotic treatment of gastrointestinal infections, delivery of pregnancy, surgical resection of a solid tumor, or withdrawal of the inciting medication, can be curative of the Sweet's. Other than resection of tumor, surgical intervention plays no role in the treatment of Sweet's given its propensity for pathergy and the inherent potential therefore of worsening the condition.

Corticosteroids either topically, intralesionally, or systemically by definition provide rapid improvement in all three varieties of Sweet's. In addition, potassium iodide (Horio et al. 1980) and colchicine (Suehisa and Tagami 1981) may also be considered first-line therapies for this dermatosis. Other agents that have been used with varying success include indomethacin, clofazimine, cyclosporin, and dapsone. Biologic agents, such as etanercept (Yamauchi et al. 2006), have also been used although Sweet's has also been reported as occurring secondary to TNF-alpha antagonist agents (Hawryluk et al. 2012).

While mostly benign, Sweet's can have severe complications both cutaneous and systemic and require ongoing treatment for suppression. Even after remission Sweet's syndrome may recur regardless of whether the remission was spontaneous or therapy induced, although recurrence is more common in malignancy-related Sweet's.

Neutrophils

Robert B. Zurier
Autoimmune and Musculoskeletal Diseases Center, Feinstein Institute for Medical Research, Manhasset, NY, USA

Synonyms

Granulocytes; Polymorphonuclear leukocytes (PMN)

Definition

Neutrophils, which are produced in the bone marrow and circulate in the blood, are the most abundant type of white blood cells (leukocytes) in mammals and form an essential part of the innate immune system. Neutrophils comprise more than 50 % of the white blood cell population and during bacterial infection may increase to more than 80 %. The name neutrophil derives from staining characteristics on hematoxylin- and eosin-stained histological or cytological preparations. Whereas the intracytoplasmic granules of neutrophils stain a neutral pink, the other polymorphonuclear (multilobed nucleus) cells stain dark blue (basophils) or bright red (eosinophils). Polymorphonuclear leukocytes (PMN) are circulating surveillance cells, scanning for infection or other inflammatory events, to which they respond within minutes (Borregaard 2010).

Activation and Function

To get to the place where they are needed, the neutrophils must sense the presence of "danger" from a distance. They first adhere to and pass through the endothelium of the postcapillary venules (diapedesis) and migrate along a chemical gradient of molecules (chemoattractants) to the source of the alarm (chemotaxis). Then, the neutrophils encounter the target, ingest it, and destroy it (activation). However, since too much neutrophil activation can result in tissue injury, activation must be regulated (Bokoch 1995). Cell surface receptors allow neutrophils to detect the chemoattractants, which include lipid mediators (leukotriene B4, platelet-activating factor), proteins, and peptides (interferon gamma, interleukin-8, the complement split product C5a, formylated peptides). Other lipids such as the eicosanoids prostaglandin J2, lipoxin A4, and resolvins act as stop signals and prevent neutrophil-induced tissue injury by suppressing neutrophil migration and increasing neutrophil death (apoptosis) and facilitate resolution of inflammation (Serhan et al. 2008). Inflammation is a primitive protective response, but it is impairment of its resolution that can lead to tissue damage.

Phagocytosis and Degranulation

Ingestion by the neutrophil of the target particle or bacterium (phagocytosis) requires direct contact

with the opsonized (from the Greek "to prepare for the table") target, that is, coated with immunoglobulin and/or complement components (Caron and Hall 1998). Phagocytosis involves extension of the neutrophil membrane and invagination of the neutrophil at the point of contact to surround the target to form a phagocytic vacuole. Two forms of degranulation can then take place. The enzyme-laden granules (lysosomes) can fuse with the neutrophil plasma membrane and spill their contents into the extracellular space (exocytosis) or fuse with the phagocytic vacuole to form a phagolysosome. Exocytosis favors mobilization of lighter granules (secretory and specific granules), whereas in phagolysosome formation, fusion of azurophilic granules with the phagocytic vacuole results in the delivery of proteolytic enzymes, myeloperoxidase, and antibacterial proteins to the site of the ingested bacterium (Scher et al. 2013).

In addition to the proteases and other antibacterial proteins in their granules, neutrophils can kill bacteria through generation of toxic oxygen metabolites, a process termed the respiratory burst. The respiratory burst involves activation of the enzyme nicotinamide adenine dinucleotide phosphate (NADPH) oxidase localized to the membrane of specific granules. When assembled and activated, the NADPH transfers electrons from NADPH to generate superoxide, a reactive oxygen species. A subsequent dismutase reaction produces hydrogen peroxide which is converted to hypochlorous acid, an oxidant with potent bactericidal activity (DeLeo and Quinn 1996).

Production of Mediators of Inflammation

Stimulated neutrophils release arachidonic acid (AA) from the plasma membrane. AA itself can attract and stimulate neutrophils, and AA metabolites (eicosanoids) are more important to regulation of inflammation (see entry "▶ Prostaglandins, Leukotrienes, and Related Compounds"). The most important lipid mediator of inflammation among these is leukotriene B4 (Samuelsson et al. 1987). In contrast, lipoxin A4, prostaglandin J2, and the resolvins facilitate resolution of inflammation.

Although the relative amount of cytokines produced by neutrophils is small, the large number of neutrophils in sites of inflammation can provide a concentration of cytokines sufficient to recruit additional neutrophils to the target area. Among the cytokines produced by neutrophils are interleukin-8 (IL-8), IL-12, transforming growth factor (TGF)-beta, and growth-related oncogene-alpha (GRO-a). However, activated neutrophils do not produce IL-1, IL-6, and TNF-alpha, the classical products of macrophages and synovial cells (Scapini et al. 2000).

Neutrophil Extracellular Traps

Spectacular images of microbe-activated neutrophils ejecting nuclear chromatin coated with granule-derived bactericidal peptides and enzymes such as elastase, cathepsin G, and myeloperoxidase were presented in 2004 (Brinkmann et al. 2004). These structures, called neutrophil extracellular traps (NETs) because they entangle bacteria, are efficient killing machines but also appear to participate in the pathogenesis of several autoimmune and inflammatory disorders. Therefore, in addition to serving as a part of the protective innate immune response, NETs may be generated by noninfectious stimuli (e.g., cytokines) and provide molecules that promote autoimmunity and tissue injury in susceptible individuals (Kaplan and Radic 2012). For example, NET-derived material is detected in blood and kidney biopsies from many patients with small vessel vasculitis, and autoantigens recognized by ANCAs (anti-neutrophil cytoplasmic antibodies characteristic of the disease) are found in these NET structures.

Diseases of Diminished Neutrophil Number

Severe congenital neutropenia (Kostmann's syndrome) results from arrest of bone marrow

myelopoiesis. Infants are prone to severe bacterial infections and at risk for malignancies, and mortality is high. Therapy includes antibiotics and granulocyte colony-stimulating factor (Germeshausen et al. 2010). A milder form (benign congenital neutropenia) has been observed, and cyclic neutropenia exhibits transient recurrent neutropenia on a 21-day cycle.

Leukocyte Adhesion Deficiencies (LAD)

Three leukocyte adhesion disorders have been described: LAD1 results from an autosomal defect in the gene encoding for beta2 integrins. Thus, bloodstream neutrophils are unable to adhere to vascular walls and migrate to target areas. Bone marrow transplantation is the only curative therapy. LAD2 results from a defect in a neutrophil ligand that allows neutrophils to roll along the endothelium. In addition to the symptoms associated with LAD1, patients may have mental retardation and short stature. In patients with LAD3, integrin activation is impaired in platelets as well as in PMN, so that patients are at increased risk for bleeding and for infections (McDowall et al. 2003).

Neutrophil Granule Defects

The best known of these disorders is the Chediak-Higashi syndrome, an autosomal recessive defect in the gene for lysosomal transport protein, in which granules fuse to create giant dysfunctional lysosomes. Patients present with partial oculocutaneous albinism, neutropenia, frequent infection, mild bleeding, and neurologic abnormalities (Zurier 1977; Barbosa et al. 1996). Ascorbic acid has been useful treatment, but patients who survive childhood often succumb to a lymphoma-like disease (Boxer et al. 1979).

Oxidase Deficiencies: Chronic Granulomatous Disease (CGD)

CGD is a group of diseases. In each, a genetic defect in a different component of NADPH oxidase results in failure of neutrophils to generate superoxide, impairing intracellular killing and the ability to generate NETS. The accumulation of neutrophils that cannot kill bacteria at a site of infection results in granuloma formation rather than clearance of bacteria and cells (van den Berg et al. 2009).

Neutrophils in Endothelial Damage

J. Vidya Sarma and Peter A. Ward
Department of Pathology, University of Michigan Medical School, Ann Arbor, MI, USA

Definition

Neutrophils are vital innate immune cells that are indispensable in defending the body against invading pathogens. Neutrophils migrate from the lumen of blood vessels, crossing the endothelial cell barrier in order to reach the infection sites. Neutrophils release a number of enzymes and reactive products such as oxidants while eliminating pathogens. If the products released by the neutrophils are not quickly neutralized, they cause unintended damage to endothelial cells and surrounding tissues, often resulting in pathological conditions such as acute lung injury and arthritis.

Neutrophils

Neutrophils (PMNs) are an integral part of the innate immunity arsenal that protects against invading pathogens such as bacteria but also in "sterile inflammation" (in the absence of pathogens) that occurs as a consequence of hypoxia/reperfusion injury, wound repair, and crystal-induced injury such as in gout when monosodium urate crystals are deposited in joints. PMNs are the first responders to invading pathogens and limit the spread of infection. In normal adult humans, PMNs are the most abundant innate immune cells in blood and are produced in the bone marrow from stem cells. As many as $1-2 \times 10^{11}$ PMNs can be generated per day (Borregaard 2010). PMNs are highly motile phagocytic cells that engulf and degrade bacteria with the help of factors stored in intracellular granules as well as the generation of reactive oxygen species (ROS) via the nicotinamide adenine dinucleotide phosphate (NADPH) oxidase (NOX) pathway. In addition, recent studies suggest that PMNs are capable of killing bacteria extracellularly by releasing neutrophil extracellular traps (NETs) consisting of extruded chromatin embedded with microbicidal peptides including histones, which can attack and eliminate the entrapped bacteria. Further, there is a growing appreciation that PMNs, when activated, release a number of cytokines and initiate "cross talk" with other cells involved in innate and adaptive immunity, such as dendritic cells and Th17 cells. In turn, this intercellular communication results in recruitment of more PMNs and release of mediators at the site of infection, underscoring the complexity of PMN function (Mantovani et al. 2011).

Under normal circumstances, PMNs are continuously produced by the bone marrow and removed from tissue or blood by macrophages in the spleen, bone marrow, and liver (Bratton and Henson 2011). PMNs have a short life-span (in the order of hours) in the circulation, although recent reports suggest more in the order of a few days (Bratton and Henson 2011). Maintenance of adequate PMN numbers is dependent on the intrinsic ability of aging neutrophils to undergo apoptosis. However, during infections or injury, PMN production can be ramped up by accelerated release of PMNs from the bone marrow. In this context, G-CSF is produced, causing both a rapid expansion of PMNs in the bone marrow and PMN release into the blood.

Endothelial Cells

Far from being an irrelevant bystander, the endothelium serves as barrier between the circulating blood and the extravascular environment and plays an active and dynamic role in facilitating the transport of leukocytes, plasma proteins, and fluids across this barrier while maintaining tissue homeostasis (Komarova and Malik 2010). Endothelial cells maintain blood flow in a non-thrombotic environment by actively inhibiting coagulation. This is achieved by the expression of thrombomodulin on endothelial cell surfaces that binds thrombin and helps in the activation of protein C, a potent anticoagulant. Expression of tissue factor pathway inhibitors that bind to activated clotting factors X and VIIa complexed with the strong procoagulant, tissue factor, prevents downstream effects leading to intravascular clot formation. The expression of heparan sulfate proteoglycans results in inactivation of thrombin, thus preventing clot formation (Pober and Sessa 2007). The endothelium also maintains vascular tone and helps to direct and traffic leukocytes to the appropriate extravascular inflammatory sites. Endothelial cells are relatively impermeable to leukocytes and to various proteins such as albumin and IgG molecules due to tight (containing proteins such as occludin) and adherens junctions (containing proteins such as VE-cadherin and β-catenin) found between adjoining endothelial cells. Nitric oxide (NO; vasodilator) and prostacyclin are also produced by endothelial cells. Together, they inhibit platelet aggregation and adherence of platelets to the endothelial cell membrane. Transport of solutes such as albumin, lipids, insulin, and hormones also occurs with the help of vesicles called caveolae that coalesce with the endothelial cell surface in an energy-dependent process (Komarova and Malik 2010).

Factors that can affect vascular permeability include histamine, bradykinin, thrombin, lipopolysaccharide, TNF-α, and vascular endothelial growth factor (VEGF), to name just a few. These permeability-inducing factors bind to receptors on endothelial cell surfaces and signal through guanine nucleotide-binding proteins (G proteins), leading to actin and myosin polymerization, which results in endothelial cell contraction and reversible disruption of junctions, thereby allowing solutes and fluid to pass into extravascular locales (DiStasi and Ley 2009).

Products of Neutrophils That Are Injurious to the Endothelium

Enzymes and Proteases

Various PMN-associated functions are mediated in part by the contents of the cytoplasmic granules and vesicles. The granules are classified into distinct subsets based on their characteristic contents (Table 1). *Primary* (azurophilic) granules contain antimicrobial proteins including myeloperoxidase (MPO) which forms hypochlorous acid (HOCl) in the presence of H_2O_2 produced by the NADPH oxidase system. In addition, primary granules contain defensins which are small peptides (approximately 3.5 kDa) that are cytotoxic to bacteria by generating pores in the bacterial cell membranes. Primary granules also contain serine proteases that aid in phagocytosis. *Secondary* (specific) granules contain lactoferrin (that has antimicrobial activity), lysozyme, and components of the NADPH oxidase system, facilitating antimicrobial defense. *Tertiary* (gelatinase) granules contain gelatinase and other matrix-degrading enzymes (matrix metalloproteinases, MMPs) and membrane receptors that are involved in extravasation or diapedesis of PMNs from the blood vessel into tissues. Additionally, PMNs also contain secretory vesicles that act as storage organelles for membrane proteins including complement receptors and integrins. Upon mobilization of the PMN, the secretory vesicles merge with the cell membrane, resulting in addition of vesicle receptors to the PMN cell membrane. These membrane proteins enhance attachment to the endothelium in addition to replacing plasma membrane proteins expended during phagocytosis. Secretory vesicles are thought to be mobilized first, followed by tertiary granules, secondary granules, and primary granules, although the exact order may vary depending on circumstances of the inflammatory response. Many of the PMN

Neutrophils in Endothelial Damage, Table 1 A representative list of proteins and enzymes found in various neutrophil granules and vesicles

Primary granules (azurophilic)	Secondary granules (specific)	Tertiary granules (gelatinase)	Secretory vesicles
Myeloperoxidase	Lactoferrin	Gelatinase	Complement receptor-1
Lysozyme	Collagenase	Cytochrome b_{558}	CD11a/CD18 (LFA-1)
Elastase	Gelatinase	β_2-microglobulin	CD11b/CD18 (MAC-1)
Hydrolases	Lysozyme	fMLP receptor	
Defensin	Cytochrome b_{558}		
Phospholipases			
Azurocidin			

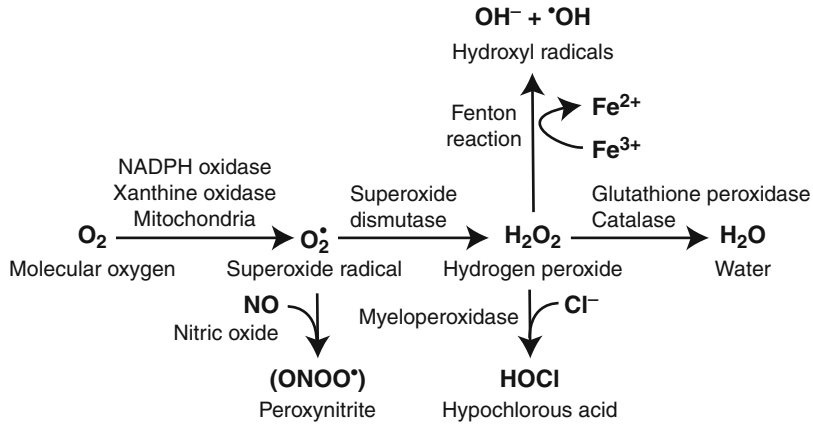
enzymes or proteases such as collagenase (MMP-8), gelatinase (MMP-9), and leukolysin (MMP-25) are stored in an inactive form and are activated by proteolytic cleavage during the process of degranulation. These enzymes participate in breakdown of the extracellular proteins such as laminin, fibronectin, collagen type IV, and heparan sulfate proteoglycans, all linked to the extravasation process of PMNs (Faurschou and Borregaard 2003). Although the release of these granule-derived mediators is a tightly regulated exocytosis process, there occurs unintended collateral damage to the tissues that are infiltrated by the PMNs (Nathan 2006; Borregaard 2010).

Oxidants

PMNs upon activation assemble the potent NADPH oxidase system at their cell surfaces, resulting in the formation of highly reactive oxygen metabolites that help combat pathogens. NADPH oxidase catalyzes the conversion of molecular oxygen (O_2) to superoxide anion (O_2•). NADPH oxidase is one of the main sources of oxidant generation in vivo. NADPH oxidase of PMNs contains a number of subunits, with gp91 phox and p22 phox together constituting the membrane-bound cytochrome b_{558} subunit, along with several cytosolic subunits: p67phox, p47phox, p40phox, and Rac 1 and Rac 2 small Rho guanosine triphosphatases (Babior 2004). When activated, the cytosolic subunits translocate and associate with membrane-bound subunits, leading to the formation of the active enzyme NADPH oxidase. There are seven homologues of gp91 phox that have been found to date. gp91 phox is also referred to as NOX2 gp91 and is found in phagocytic cells and in endothelial cells along with the NOX1, NOX4, and NOX5 isoforms. Although O_2• has a limited half-life, it is quickly converted to H_2O_2 in the presence of superoxide dismutase (SOD) (Fig. 1). MPO catalyzes conversion of H_2O_2 to hypochlorous acid (HOCl) or hypobromous acid (HOBr) in the presence of chloride or bromide. Catalases and peroxidases (such as glutathione peroxidase) convert H_2O_2 into H_2O and O_2, while glutathione peroxidase converts H_2O_2 to H_2O. Iron (Fe^{3+}) is present in endothelial cells and bound to ferritin. It interacts with O_2•, resulting in reduction of Fe^{3+} to Fe^{2+}. Fe^{2+} then interacts with H_2O_2 to form the hydroxyl radical, HO•. Hydroxyl radicals are highly reactive with proteins and lipids. Collectively, these ROS products importantly combat invading pathogens. Recent studies suggest that ROS can subserve several functions, especially in cell signaling. They appear to be not only involved in host defense but also in maintaining homeostasis. ROS can activate signaling molecules such as MAP kinases and transcription factors such as NFκB and regulate gene expression by affecting histone acetylation and deacetylation in the nucleus (Ma 2010). Excessive levels of ROS will lead to tissue damage.

The Inflammasome

PMNs can also detect bacteria and other microbes by germ line-encoded pattern recognition receptors (PRRs) such as toll-like receptors (TLRs) expressed on the cell surface, and nucleotide-binding oligomerization domain-like

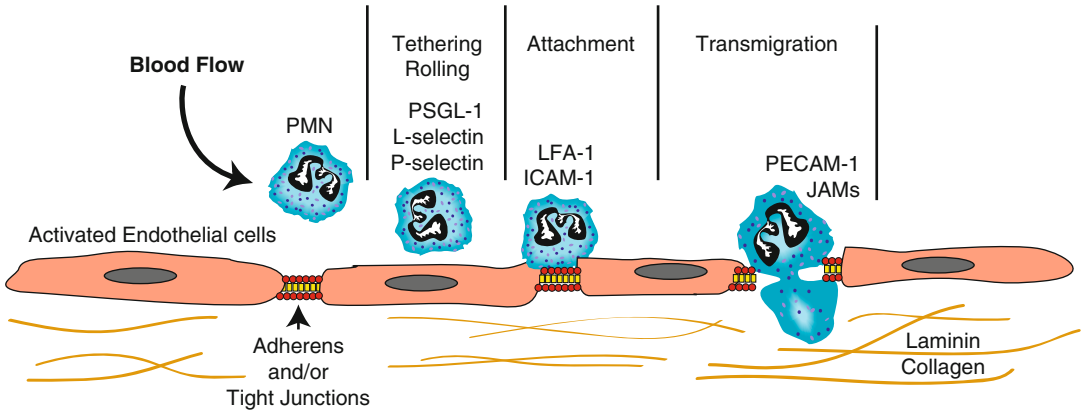


Neutrophils in Endothelial Damage, Fig. 1 Examples of pathways leading to generation of reactive oxygen species (ROS). Superoxide (O_2•) and hydrogen peroxide (H_2O_2) are formed when molecular oxygen (O_2) is reduced. Glutathione peroxidase and catalase catalyze the conversion of H_2O_2 to water (H_2O) and molecular oxygen (O_2). The Fenton reaction (in the presence of Fe^{2+}) leads to the formation of highly unstable hydroxyl radical ($OH^•$) from H_2O_2. Myeloperoxidase converts H_2O_2 to hypochlorous acid (HOCl) in the presence of chloride ions (Cl^-). Peroxynitrite is formed when nitrous oxide (NO) interacts with superoxide

receptors (NLRs) expressed intracellularly. On detecting pathogens in the cytosol, the intracellular PRRs form a multiprotein complex called the "inflammasome," resulting in activation of the cysteine protease, caspase-1. In turn, activated caspase 1 (and perhaps other caspases) promotes the proteolytic cleavage of the inactive precursor forms of IL-1β and IL-18 to active forms, which are then secreted from PMNs. Inflammasomes promote clearance of the infected cells and initiate caspase 1-mediated apoptosis or pyroptosis (Lamkanfi and Dixit 2011). The inflammasome has been linked to diabetes mellitus as well as crystal-induced joint damage (gout) and a variety of other inflammatory responses.

Evidence of Neutrophil-Mediated Endothelial/Tissue Damage

Endothelial cell injury by activated PMNs both in vivo and in vitro is now well known. Endothelial damage in vitro by complement activated PMNs was originally described by Sacks et al. (Sacks et al. 1978). There is now abundant evidence that PMNs in large part mediate endothelial cell/tissue damage in vivo by a wide variety of mechanisms, such as release of damaging oxidants and proteolytic enzymes (Guo and Ward 2002; Gao et al. 2006) when activated PMNs become more adherent to the endothelium and extravasate through the vascular wall into tissues. There is unequivocal evidence in vivo that PMNs contribute to tissue and organ damage due to release of proteases as well as oxidants (ROS, RNS). PMNs contribute to the pathophysiology of many conditions including stroke, rheumatoid arthritis, myocardial infarction, immune vasculitis, inflammatory bowel disease, acute lung injury (ALI), and acute respiratory distress syndrome (ARDS). In patients with ARDS, the number of PMNs present in the bronchoalveolar lavage fluids, as well as presence of complement activation product, component 5a (C5a), correlates with the severity of ARDS (Pittet et al. 1997). Lung edema, disruption of the endothelial and epithelial barrier due to gap and bleb formation, and increased PMN infiltration into the interstitium and bronchoalveolar spaces are associated with release of proinflammatory mediators such as TNF-α and IL-8, causing compromised lung function and air exchange. In systemic inflammation, the presence of inflammatory mediators including C5a, together with IL-8 and TNF-α, is associated with neutrophilia and organ damage.



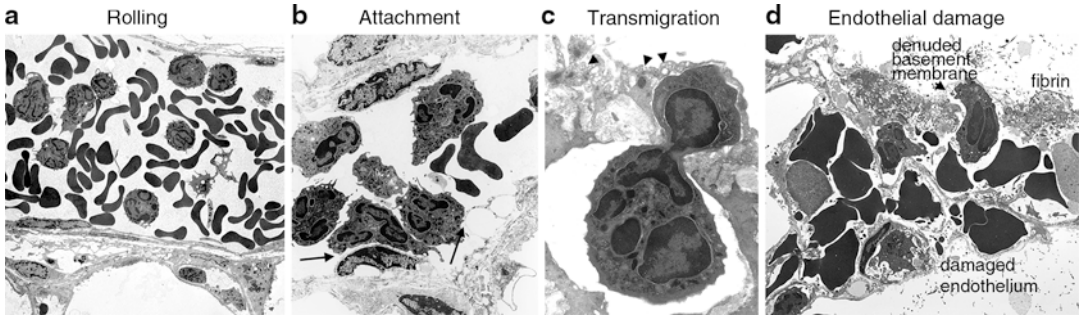
Neutrophils in Endothelial Damage, Fig. 2 Intermittent adherence of PMNs to the endothelium, followed by firm attachment and transmigration. Normally, the tight junctions as well as the adherens junctions maintain integrity of the endothelial cell wall and prevent leakage of water and soluble plasma contents into extra vascular spaces

In a rodent model of acute lung injury, deposition of IgG immune complexes (IgGIC) in the lung leads to complement activation and to lung PMN accumulation, with compromise of the lung endothelial and epithelial barrier functions (Guo and Ward 2002; Gao et al. 2006). When lungs were treated with anti-elastase, lung injury was significantly reduced, further implicating PMNs in inflicting tissue damage and thus participating in the pathogenesis of lung injury (Guo and Ward 2002; Gao et al. 2006).

In the collagen-induced arthritis model (where arthritis is induced by immunization with type II collagen) and the K/BxN arthritis model (arthritis model based on the expression of the T cell receptor transgene KRN and the MHC class II molecule A(g7) where mice develop autoantibodies against glucose-6-phosphate isomerase (GPI)) that closely resemble human arthritis, PMNs play an early role in the development of the disease process. PMNs are the first innate immune cells to infiltrate the joint, persisting in the synovial fluid and in synovial tissues during the course of the disease, further underscoring PMN-mediated tissue/organ damage. In PMN-depleted animals, arthritis fails to develop, while in animals with arthritic joints, systemic depletion of PMNs leads to reversal of the disease manifestations (Wright et al. 2010).

Neutrophil-Endothelial Cell Interaction

One of the first steps involved in the recruitment of PMNs to the site of inflammation is known as "rolling." It involves the dynamic interaction of the PMNs with the endothelium with the help of transmembrane adhesion proteins and their cognate ligands (Figs. 2 and 3). These include selectins, integrins, and immunoglobulin superfamily members such as vascular cell adhesion molecule-1 (VCAM-1) and intercellular adhesion molecule-1 (ICAM-1). P-selectin stored in Weibel-Palade granules in endothelial cells and E-selectin produced de novo in endothelial cells, appearing on apical surfaces, bind to P-selectin glycoprotein ligand-1 (PSGL-1), E-selectin ligand (ESGL), and CD44 that are expressed by PMNs (Phillipson and Kubes 2011). This results in transient binding of PMNs to the endothelial surfaces (rolling). ICAM-1 present on the endothelium interacts with the β_2-integrins CD11a/CD18 (LFA-1), while VCAM-1 interacts with α_4-integrins ($\alpha_4\beta_1$, $\alpha_4\beta_7$), resulting in slowing of rolling PMNs and their firm adhesion to the endothelium followed by migration into the tissue with the help of endothelial membrane proteins: platelet endothelial cell adhesion molecule-1 (PECAM-1), endothelial cell-selective adhesion molecule-1 (ESAM-1), and CD99 and the β-integrin CD11b/CD18 (Mac 1) on PMNs.



Neutrophils in Endothelial Damage, Fig. 3 Transmission electron micrographs of neutrophil-endothelial cell interactions in rat lungs following acute lung injury. Transient binding of PMNs to the endothelial cell (frame **a**, rolling) leads to firm attachment of PMNs to the endothelium (*arrows* in frame **b**), followed by transmigration (frame **c**, *small arrows* indicate the presence of caveolae) into extravascular sites. This process sometimes results in endothelial damage (frame **d**), resulting in denuded basement membrane and fibrin deposits (fixation by glutaraldehyde, staining with uranyl acetate and lead citrate; **a**, X1750; **b** and **d**, X2150; **c**, 3550)

Junction adhesion molecule c (JAM-c) present at the junctions of inter-endothelial contacts prevents reverse migration into the blood vessel lumen (Phillipson and Kubes 2011). Activated PMNs can extravasate into tissues or interstitium by modifying junctional proteins (via phosphorylation) mediated by PMN-generated products including ROS.

Animal models have been helpful in confirming the roles of various adhesion molecules in mediating PMN recruitment. In the IgG model of lung injury, PMN recruitment and consequent development of lung injury were greatly reduced when L-, P-, or E-selectins were blocked using neutralizing antibodies. Similarly, blocking of ICAM-1 with antibodies caused significant reductions in vascular permeability and MPO levels in tissues (a marker for PMN degranulation) (Guo and Ward 2002; Gao et al. 2006).

During the resolution phase of the inflammation, PMNs undergo apoptosis resulting in signals that alert local macrophages for quick removal of PMNs before these cells release their cytoplasmic contents into the milieu. If PMNs are not cleared and their products of degranulation are not neutralized by the endothelium, tissue injury can proceed. Products of PMNs such as MPO can cause endothelial cell blebbing and endothelial cell detachment, while proteinase 3 present in primary granules can induce apoptosis (Tesfamariam and DeFelice 2007). Elastase and cathepsin increase vascular permeability. The activity of these proteinases and MMPs is regulated by endogenous proteinase inhibitors such as α_1-proteinase inhibitor, α_2-macroglobulin, secretory leukocyte protease inhibitor (SLP1), and tissue inhibitor of metalloproteinase-1 (TIMP-1) (Gao et al. 2006) present in the endothelium.

Further, there are several sources of oxidants in the endothelium. NADPH oxidase, xanthine oxidase, and mitochondria can each contribute to oxidant formation. Endothelial cells produce nitric oxide (NO) by nitric oxide synthase (NOS), employing L-arginine. These cells contain eNOS or NOS3 isoforms that are calcium dependent. NO can interact with oxidants to form peroxynitrite ($ONOO^-$) that is cell toxic (Fig. 1). Additionally, there are several enzymatic and nonenzymatic antioxidants that can neutralize ROS (Forstermann 2010). For instance, beta-carotene and vitamins E and C act as nonenzymatic antioxidants, while superoxide dismutase, catalase, thioredoxin, hemeoxygenases, and glutathione peroxidase act as enzymatic antioxidants. Excessive oxidant products lead to tissue damage or destruction by oxidant-mediated modifications of cellular

proteins, carbohydrates, lipids, and DNA leading to their altered function (Lum and Roebuck 2001). For example, changes in permeability can be ascribed to oxidation of lipids in the cell membrane. Superoxide generation is thought to compromise the endothelial barrier to permeability.

Interestingly, repeated infections are found in patients with either inadequate numbers (neutropenia) or inadequate functional capacity of PMNs. Neutropenia can occur due to congenital defects, acquired autoimmunity, or bone marrow failure brought about by metastatic tumor, hematopoietic cancers, or chemotherapy. Leukocyte adhesion deficiencies (LADs), chronic granulomatous disease (CGD), and specific granule deficiency are the result of defective functional components of the NADPH oxidase (CGD), defective adhesion molecules (LAD), and lack of production of granule proteins (SGD).

Conclusion

PMNs play an important role in host defenses. However, in the deployment of the powerful arsenal that PMNs possess in combating invading pathogens and local "sterile" (uninfected) inflammation, unintended consequences can occur, leading to endothelial/tissue damage. Some therapeutic interventions such as corticosteroids can minimize tissue damage while still facilitating the ability of PMNs to eliminate harmful organisms and also produce mediators of injury repair, as occurs in noninfected tissues/organs damaged by ischemic conditions.

Synonyms

c-Rel; NF-κB2 (p52 and its precursor p100); Nuclear factor κB; NF-κB1 (p50 and its precursor p105); RelA (p65); RelB

Definition

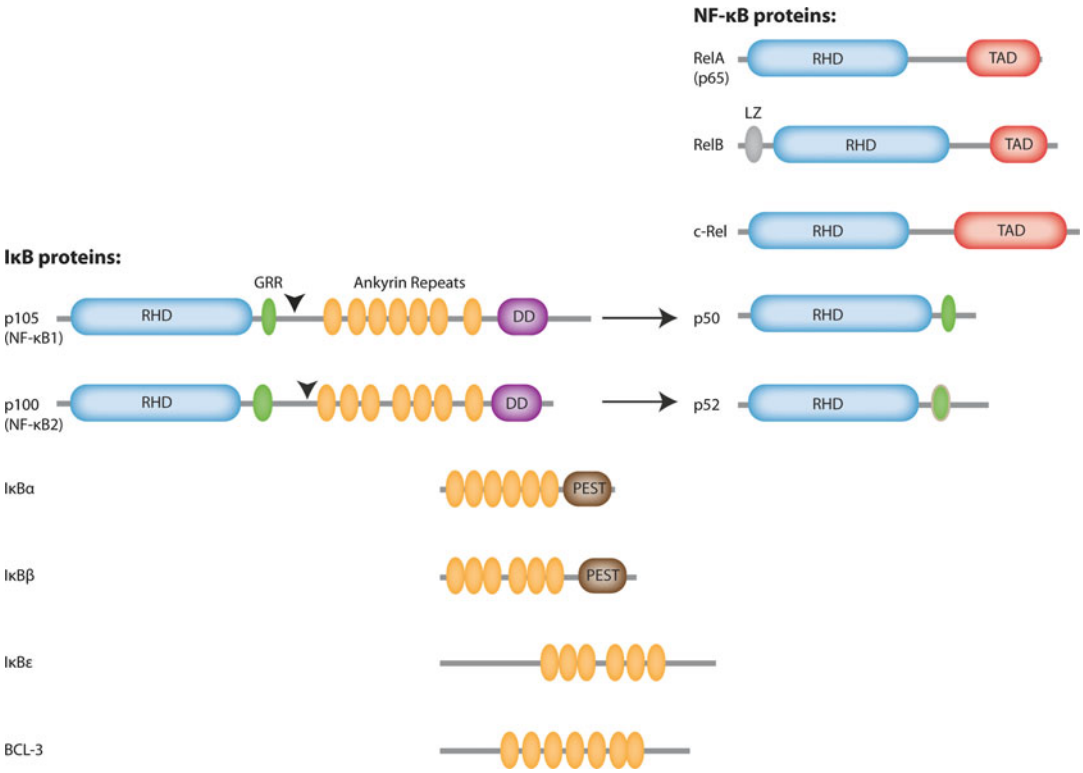
NF-κB is a dimeric transcription factor complex active throughout all cell types. It is present in the cytoplasm in an inactive state, can rapidly be activated in response to various stimuli, and subsequently translocates to the nucleus. NF-κB has a pivotal role in the control of proliferation and apoptosis. Increased NF-κB activity has been shown to contribute to tumorigenesis. Furthermore, it has important functions in both innate and adaptive immune responses.

The NF-κB Transcription Factors

The NF-κB activity was identified more than 25 years ago by defining a nuclear factor that binds DNA sequences in the immunoglobulin κ-light chain region in activated B cells (Sen and Baltimore 1986). This factor was shown to be preexisting in an inactive state in cells and was readily activated by a variety of stimuli. There are five NF-κB family members, namely, RelA (p65), RelB, c-Rel, p50, and p52 (Fig. 1). In their amino-terminus, they have a common Rel-homology domain (RHD), which confers DNA binding and contains a nuclear localization signal (NLS) (Fig. 1) (Ghosh et al. 2012). Only three members, RelA, RelB and c-Rel, have a transactivation domain (TAD) in their carboxy-terminal part and are directly able to induce transcription. p50 and p52 are produced from precursors p105 and p100, respectively (Fig. 1), and are processed by the proteasome. NF-κB transcription factors function as homo- or heterodimers. They interact via the RHD region in the amino-terminus and bind to DNA in a sequence-specific manner (Ghosh et al. 2012). Homodimers of either p50 or p52 can act as transcriptional repressors either by competing for DNA binding or by recruiting histone deacetylases (HDACs) leading to a closed chromatin formation. Most of the other NF-κB dimers activate gene transcription by interaction with the transcription machinery or via recruitment of histone acetylases (HAT), which open up the chromatin and favor the assembly of the preinitiation complex (PIC) on promoter regions (Hayden and Ghosh 2012).

Regulation of NF-κB Activity

The NF-κB transcription factors are kept inactive through the binding of cytoplasmic inhibitors of NF-κB (IκBs), which include the small IκBα, IκBβ, and IκBε proteins, as well as the larger cytoplasmic precursor proteins of p50 and p52, termed p105 and p100, respectively (Fig. 1) (Hinz et al. 2012). The IκBs contain ankyrin repeats through which they bind Rel-homology domains (Fig. 2). Small IκB proteins can bind NF-κB dimers and mask their NLS and additionally contain nuclear export signals (NES). Both mechanisms confer effective cytoplasmic sequestration of the complex, preventing NF-κB from binding to DNA. Upon activation, signal-induced proteolysis of IκBs releases the bound transcription factors that then translocate to the

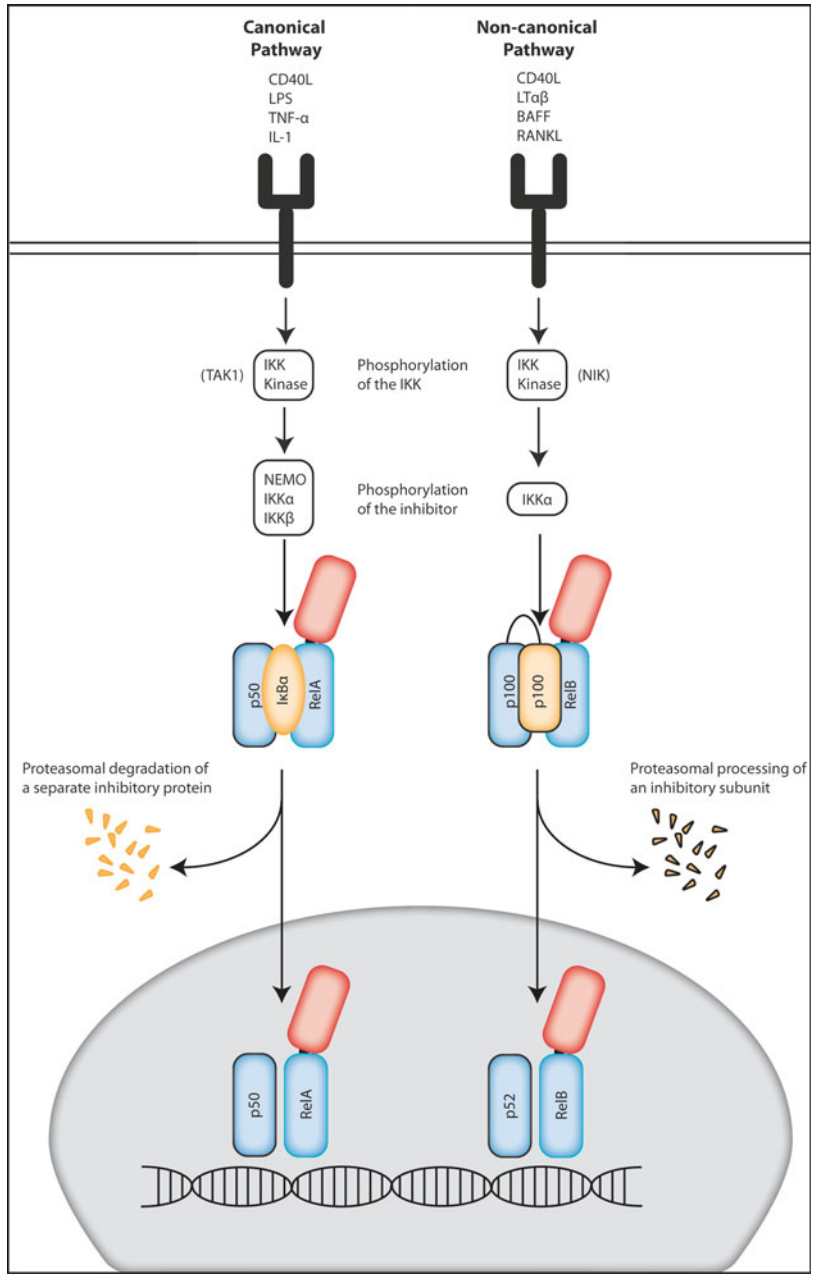


NF-κB, Fig. 1 NF-κB and IκB family members. The domain structure of the human NF-κB and IκB proteins is schematically displayed. *Arrowheads* at p105 and p100 indicate the sites of proteasomal processing. *RHD* Rel-homology domain, *TAD* transactivation domain, *LZ* leucine zipper, *DD* death domain, *GRR* glycine rich region, *PEST* domain rich in proline (P), glutamate (E), serine (S), and threonine (T), *Bcl-3* B cell lymphoma-3

nucleus and activate transcription (Fig. 2) (Ghosh et al. 2012). Not all IκBs are cytoplasmic; the Bcl-3 protein, for example, is an atypical nuclear IκB (Fig. 1), which can bind to p50 or p52 homodimers to form ternary complexes on DNA in vitro (Bours et al. 1993; Fujita et al. 1993). Bcl-3 controls the expression of certain target genes; however, at the moment, it is unclear through which molecular mechanism Bcl-3 actually exerts this function (Vallabhapurapu and Karin 2009). The ankyrin repeats that form an IκB are also found in the carboxy-terminal part of the NF-κB members p50 and p52, which are produced as the precursors p105 and p100 (Fig. 1) (Hinz et al. 2012). The IκB-containing carboxy-terminus is removed by proteasomal processing. The p105 protein is constitutively and co-translationally processed to p50, whereas p100 is processed to p52 in an inducible manner (see below). Transcriptional NF-κB activity is typically achieved by activation of p50/p65 and p50/c-Rel heterodimers or of p52/RelB through the pathways of canonical and noncanonical NF-κB activation, respectively.

Canonical and Noncanonical NF-κB Signaling

Nuclear translocation and transcriptional activity of NF-κB can be induced in all cell types and through a variety of stimuli. NF-κB activating agents typically induce the catalytic activity of the IκB kinases IKKα or IKKβ. In the canonical NF-κB signal transduction cascade (Fig. 2, left panel), transcriptional activation of p50/p65 or p50/c-Rel heterodimers is induced. This occurs, for example, in response to stimulation by



NF-κB, Fig. 2 The canonical and noncanonical NF-κB pathways. Two pathways are triggered by different stimuli and differ mainly in the mechanism of inhibition: the canonical pathway uses a separate inhibitor protein (IκB), and the noncanonical pathway uses a precursor protein (p100), which contains both an inhibitory domain and an RHD domain (for details, see text). The RHD responsible for DNA binding is shown in *blue*, and the TAD is shown in *red*. In the canonical pathway, IκB is marked for proteasomal degradation by the IKKα/IKKβ/NEMO complex, whereas in the noncanonical pathway, phosphorylation of p100 is conducted by IKKα alone. At present, the best candidates for the IKK upstream kinases are NIK (NF-κB-inducing kinase) in the noncanonical pathway and TAK1 (TGF-β activated kinase 1) in the canonical pathway

TNF-α causing the predominant activation of IKKβ within a heterotrimeric complex with IKKα and the regulatory subunit IKKγ, also called NEMO (NF-κB essential modulator) (Fig. 2), and results in the phosphorylation of the small IκB protein IκBα at serines 32 and 36 for the human protein (Vallabhapurapu and Karin 2009). These phosphorylation marks are then recognized by the phosphorylation-specific SCF^{IkB} E3 ubiquitin ligase complex. This complex confers phosphorylation-dependent polyubiquitination at lysine 19 by building Lys-48-linked ubiquitin chains. Lys-48-linked polyubiquitination triggers proteasomal degradation of the IκBα protein and frees the prototypic NF-κB heterodimer p50/p65 (Fig. 2) (Hinz et al. 2012). Importantly, several

genes that encode for IκBs, for example, *IκBα*, *p105*, and *p100*, are themselves induced by NF-κB transcription factors. Thereby, a negative feedback loop ensures the rapid inactivation of NF-κB gene activation after cellular stimulation. In fact, the small IκBα protein translocates to the nucleus and terminates NF-κB activation by binding to NF-κB transcription factors (Ghosh et al. 2012). Canonical NF-κB signaling includes the release of cytoplasmic NF-κB heterodimers or homodimers that have been sequestered by small IκBs like IκBα, IκBβ, or IκBε. These small IκBs contain similar motifs for IKK-dependent phosphorylation and are also recognized by the same E3 ligase for phosphorylation-dependent polyubiquitination. They are degraded with different kinetics and have different binding preferences for certain NF-κB hetero- or homodimers (Vallabhapurapu and Karin 2009). Canonical NF-κB signaling not only releases NF-κB dimers from small IκBs but also mobilizes p50 homodimers through complete degradation of p105 (Heissmeyer et al. 1999, 2001). This degradation of p105 is different from the co-translational partial degradation of p105 to p50 but similarly liberates p105-associated Rel proteins and thereby markedly increases the abundance of nuclear p50 homodimers (Beinke and Ley 2004). These homodimers lack transactivation potential and have therefore been involved in transcriptional repression of target genes. However, p50 homodimers may also transactivate when bound to DNA in ternary complexes with the nuclear IκB Bcl-3 (Fujita et al. 1993).

The p105 protein can either be processed to p50 or completely degraded after stimulation and is part of the canonical NF-κB signaling pathway. In contrast, p100 is partially degraded to p52 by the proteasome, and its signal-induced processing has been termed noncanonical or alternative NF-κB signaling (Fig. 2, right panel). The p100 protein has a binding preference for RelB, and its partial degradation thereby releases p52/RelB heterodimers. The induced processing of p100 to p52 is independent from IKKβ and IKKγ but depends on the kinase activity of IKKα (Fig. 2) (Hayden and Ghosh 2012). Similar to canonical NF-κB signaling, the phosphorylation marks trigger polyubiquitination due to recognition by the SCF^{IkB} E3 ubiquitin ligase complex (Vallabhapurapu and Karin 2009). However, noncanonical NF-κB signaling occurs in response to a different set of receptors and requires different upstream signal transduction than canonical NF-κB signaling (Fig. 2). In general, the canonical NF-κB pathway is triggered by pro-inflammatory signals like TNF-α, IL-1, and LPS. The noncanonical NF-κB pathway reacts to stimuli like lymphotoxin (LT), BAFF (B cell activating factor), and RANKL (receptor activator of NF-κB ligand) (Beinke and Ley 2004). CD40L is able to activate both pathways.

The signal transduction cascades from the receptors of noncanonical or canonical NF-κB signal transduction involve multiple steps towards the activation of the IKK complex but ultimately lead to the activation of a kinase that stimulates the activity of IκB kinases. Activation of TAK1 (TGF-β activated kinase 1) triggers predominantly IKKβ-dependent canonical signaling (Vallabhapurapu and Karin 2009), whereas activation of the NF-κB-inducing kinase (NIK) triggers predominantly IKKα-dependent noncanonical signaling (Fig. 2) (Sun 2012). Both cascades somehow use the ubiquitin system. They either activate the ubiquitin recognizing scaffold protein NEMO/IKKγ and recruit the complex to the receptor during canonical signaling or ubiquitinate and degrade NIK constitutively but stabilize it in an inducible fashion for noncanonical NF-κB activation. Despite differential activation of heterodimers by the noncanonical and canonical activation pathways and the potential to control a very specific set of target genes, there is extensive crosstalk and cross-regulation within both pathways. Therefore, only certain NF-κB-dependent phenotypes exhibit strict selectivity for one of the pathways. Besides, the potential regulation of differential target genes by both pathways differs in their activation kinetics. It is likely that the rather fast induction and rapid termination in the canonical pathway compared to the rather slow and more persistent activation in the noncanonical pathway accounts for the importance of both pathways.

NF-κB in the Immune System

NF-κB family members are involved in the regulation of numerous biological processes in all cell types. NF-κB controls cell proliferation and survival and thereby influences developmental processes, but it is at the same time essential for many forms of cellular activation and cell communication (Gerondakis and Siebenlist 2010).

In the innate immune response, the encounter of pathogen triggers Toll-like receptors (TLR) or Nod-like receptors (NLR) that activate NF-κB. In this first line of defense, NF-κB induces and amplifies the production of inflammatory cytokines by innate immune cells. In addition, NF-κB drives the expression of antimicrobial peptides and the production of nitrogen species and plays a major role in increasing the life span and activation of normally very short-lived innate immune cells, such as dendritic cells and neutrophils (Hayden and Ghosh 2011).

Activation of NF-κB in endothelial cells at the site of infection induces upregulation of adhesion molecules that lead to the recruitment and extravasation of leukocytes from the circulation into the inflamed tissue (Hayden and Ghosh 2011). Recruitment of leukocytes into the inflamed tissue enables activated effector lymphocytes to deploy their defense mechanisms in adaptive immunity, in which NF-κB, again, plays a pivotal role.

In the adaptive immune response, NF-κB is activated downstream of antigen and costimulatory receptors and subsequently regulates the maintenance, activation, proliferation, and effector functions of B and T lymphocytes. During activation, T lymphocytes are especially dependent on NF-κB signaling. Aside from their protection from apoptosis by NF-κB, they depend on the autocrine or paracrine stimulation by IL-2 (Hayden and Ghosh 2011). The *IL-2* gene locus is activated by T cell receptor (TCR)- and costimulation-induced NFAT and AP-1 transcription factors but is critically controlled by multiple NF-κB members. The locus is believed to be repressed by the highly abundant p50 homodimers in naive T cells but is then activated after TCR/CD28 stimulation by induced p50/c-Rel and p50/p65 dimers, and c-Rel has been shown to initiate chromatin remodeling of that locus. In differentiated T helper (Th) 1 cells, p65 transactivates *Il-2* gene transcription but is removed from this locus by the transcription factor T-bet (Hwang et al. 2005). This renders Th1 cells dependent on the cytokines IFN-γ and IL-12, the main cytokines that skew primed T cells towards the Th1 lineage. NF-κB signaling also participates in CD4 T helper cell differentiation, and several members contribute to distinct differentiation pathways. For example, p50 and Bcl-3 are essential for Th2 differentiation, whereas RelB and c-Rel are required for the Th1 phenotype (Hayden and Ghosh 2011). Moreover, the noncanonical pathway is critical for the formation of Th17 cells (Sun 2012). The NF-κB pathway influences not only the biology of mature lymphocytes but also their development (Vallabhapurapu and Karin 2009). During thymocyte differentiation, NF-κB supports several developmental stages of conventional and regulatory T cells. There is no influence on NKT development, but in the periphery, their terminal maturation is also under control of the NF-κB pathway. NK cells are exceptional, as uncontrolled NF-κB activity abrogates their development.

A similar importance is evident in the B cell lineage. NF-κB signaling controls B cell development in the bone marrow and regulates virtually all stages in the life of B lymphocytes, where the canonical pathway plays a prominent role. In B cells, NF-κB can be activated through several signal transduction pathways: through the B cell receptor (BCR) itself, through TNF receptor family members like CD40 and the BAFF receptor, or through the TLRs (Kaileh and Sen 2012). The BCR induces the canonical pathway in a transient manner, in contrast to CD40, which activates the canonical and the noncanonical pathways persistently (Kaileh and Sen 2012). Canonical NF-κB signaling delivers a survival signal for early B cell development in the bone marrow as well as for mature B cells in the periphery. In contrast, the noncanonical pathway activated by the BAFF receptor mainly contributes to mature B cell survival but exerts this effect in combination with

BCR signals. Furthermore, the canonical NF-κB pathway is required for B cell activation, class switch recombination, and both T-dependent and T-independent B cell responses (Hayden and Ghosh 2011). The noncanonical NF-κB pathway has two unique functions in B cells: it is essential for the development of marginal zone B cells in the spleen (Vallabhapurapu and Karin 2009) and is responsible for the induction of ICOSL expression on B cells (Hu et al. 2011). This supports the generation of T follicular helper (T_{FH}) cells, which provide B cell help in the germinal center reaction.

Apart from immune cell-intrinsic effects, essential control of lymphocyte development and function is exerted through NF-κB activity in non-hematopoietic cells. For example, thymocyte selection is controlled by NF-κB activity in non-hematopoietic stroma cells such as medullary thymic epithelial cells (mTEC). The NF-κB pathway also contributes to the development and spatial organization of secondary lymphoid organs (Sun 2012). The microarchitecture is essential for coordinated lymphocyte interactions and enables a productive adaptive immune response. The regulation of lymphoid organogenesis is a unique characteristic of the noncanonical NF-κB pathway. RANK signaling stimulates hematopoietic cells to express high levels of $LT\alpha_1\beta_2$ on the surface (Hayden and Ghosh 2011). This triggers the LTβR on stromal cells and leads to the production of chemokines and cell adhesion molecules, which guide lymphocytes during recruitment and distinct zonal segregation within secondary lymphoid organs. The analysis of mice deficient in signaling components of the noncanonical NF-κB pathway underlines their importance, as these mice exhibit severe defects in lymphoid organogenesis ranging from disorganized splenic architecture to a complete lack of lymph nodes and Peyer's patches.

NF-κB in Cancer

The importance of NF-κB for leukemias and lymphomas initially became evident through the apparent sequence homology between the transforming retroviral protein v-Rel and its cellular counterpart c-Rel (Gilmore 2003). Furthermore, chromosomal translocations that removed the IκB part of p100 and allowed expression of a truncated NF-κB2 (i.e., mostly the p52 part of p100) were found in B and T cell lymphomas (Neri et al. 1991). Since then, a number of studies have firmly established constitutive NF-κB activity in tumor lines or tumor samples isolated from patients with acute lymphocyte leukemia, multiple myeloma, chronic myelogenous leukemia, myelodysplastic syndromes, Hodgkin's lymphoma, activated B cell-like diffuse large B cell lymphoma (ABC-DLBCL), or mucosa-associated lymphoid tissue (MALT) lymphoma (Didonato et al. 2012). In addition, increased NF-κB activity was determined in the majority of human cancers, including colon, gastric, pancreatic, ovarian, hepatocellular, breast, head and neck carcinomas, or melanoma (Didonato et al. 2012).

A major advantage that arises from constitutive NF-κB activity for tumor cells or for cells that undergo malignant transformation is the effective protection from apoptosis. This antiapoptotic effect of NF-κB became obvious in p65-deficient mouse embryos. These embryos die in utero due to TNF-induced hepatocyte apoptosis, as they lack the normal and similarly TNF-stimulation-induced protection against apoptosis by NF-κB. The pronounced antiapoptotic effect of NF-κB is mediated, for example, through its transcriptional antiapoptotic targets *BCL2* and *BCLXL* (Vallabhapurapu and Karin 2009). Another critical function of constitutive NF-κB in malignancies is the induction of cell proliferation, which is achieved through upregulation, for example, of *cyclin D1*, *cyclin D2*, and *c-Myc* as well as *c-Myb* target genes (Vallabhapurapu and Karin 2009). A number of lymphoid malignancies have been shown to depend on NF-κB, making this pathway attractive for the development of pharmacological inhibitors (Vallabhapurapu and Karin 2009). In addition, several lymphoid cancers have been found to arise from specific mutations that either activate NF-κB signal

transduction components or inactivate inhibitory cellular regulators of NF-κB (Staudt 2010). In the absence of somatic mutations that could activate this pathway in solid malignancies, NF-κB is nevertheless induced by pro-inflammatory stimuli in the tumor microenvironment or in preceding chronic inflammatory diseases that later on give rise to tumor formation. A recent experimental focus has investigated the connection between inflammation and tumor formation and has involved NF-κB in several cell types. NF-κB is critical in these settings, but it has also been shown to have positive as well as negative effects in different mouse models of tumorigenesis (Didonato et al. 2012).

Conclusion

NF-κB is a family of transcription factors that contain a Rel-homology domain. These Rel proteins form hetero- or homodimers that are present in all cells. NF-κB is normally inactive since the transcription factors are sequestered in the cytoplasm by members of the IκB family. A variety of signals induce a transduction cascade that rapidly causes the proteolysis of IκBs and releases NF-κB dimers from inhibition. Two different NF-κB induction pathways serve overlapping but also unique functions: the canonical pathway is fast but transient, whereas the noncanonical pathway is slower but long-lasting. Stimuli and inducers of canonical and noncanonical activation rapidly induce NF-κB to translocate into the nucleus, where it activates the expression of target genes. Prominent among them are cytokine genes that have pro-inflammatory effects, mediate cell proliferation, or inhibit apoptosis. After NF-κB is induced, it also upregulates target genes from the NF-κB family or from the functionally linked IκB family, leading into positive or negative feedback loops. The biological roles of the NF-κB pathway are numerous and diverse. It plays important roles in the development and homeostasis of innate and adaptive immune cells. In addition, NF-κB is essential for T and B cell activation by their antigen receptors and constitutes the major pathway downstream of receptors that sense pathogen-associated molecular patterns. The breakdown of the tight control of the NF-κB pathway has a well-documented role in inflammation and tumorigenesis.

Definition

Nitric oxide (NO) is a radical compound formed when a single nitrogen is covalently bonded with a single oxygen (·N = O). Nitric oxide is produced endogenously from the catabolism of L-arginine by a nitric oxide synthase (NOS).

The Janus Nature of Nitric Oxide: Immunotoxicant and Immunomodulator

As for most, if not all, endogenous and exogenous compounds that have differential effects on the immune or any organ system, their dose and time of exposure affect whether the outcome is positive (stimulatory) or negative (inhibitory). Originally described by Venchikov (1960) for biological effect dependent on dose, a chemical, such as iron, can have a wide biological range of effects. Based on the exposure dose, the effects can range from being essential for existence to positive physiologically stimulatory effect, to negative physiological interferences due to affects on the wrong cell type or cellular compartment, to positive pharmacological influences, and, finally, to negative toxicological effects. Oxygen, itself, as well as NO, possess this dynamic range in potential biological effects. Some of the immunobiology/pathology of NO can be direct effects on particular types of immune cells, as later described, and some can be indirect effects on the immune system, e.g., through influences on cardiovascular functions (Moncada et al. 1991), which are depicted by the synonym for NO, endothelium-derived relaxing factor, that can alter cell trafficking and distribution of soluble immunoregulatory factors. The dynamic range of NO activity is related to its "ubiquitous, highly diffusible, and promiscuously reactive" nature (Hollenberg and Cinel 2009). The ubiquitous nature of NO is due to its production by different cell types throughout the body. The monocytic lineage of the immune system, including macrophages, microglia, monocyte-derived dendritic cells, and monocytic myeloid-derived suppressor cells, has an

inducible enzyme (inducible nitric oxide synthase, iNOS or NOS2) that converts L-arginine to NO and citrulline, whereas the other isoforms of NOS (endothelial (e)NOS or NOS3 and neuronal (n)NOS or NOS1) can constitutively produce NO. In addition to the dose effects of NO on immunity, NO and its more powerful oxidant peroxynitrite ($ONOO^-$), which forms rapidly and spontaneously when NO interacts with superoxide anion (O_2^-), may differentially affect immunity dependent on whether the exposure occurs before, with, or after other immunomodulatory exposures. Although most studies of infectious diseases and tumor immunology discuss NO with regard to its killing (toxic) potential on bacteria, viral-infected cells, or cancer cells, NO is involved in several physiological processes (Pacher et al. 2007) including tissue repair processes (Witte and Barbul 2002; Schwentker and Billiar 2003) and angiogenesis (Ziche and Morbidelli 2000).

NO involvement in the immune response to pathogens and cancers was first indicated when the levels of nitrite and nitrate (NO metabolites) were shown to increase (Tannenbaum 1987; Hibbs et al. 1987). Once macrophages are activated by bacterial products such as lipopolysaccharide (LPS), other pattern-recognition receptor (PRP) stimulators, or the interferon-gamma (IFN-γ), iNOS can generate variant doses of NO (Espey et al. 2000) dependent on additional cofactors such as tetrahydrobiopterin, calmodulin, and flavin nucleotides. The ability to produce NO is also dependent on the availability of its substrate L-arginine. NO itself influences its own activity and production, respectively, by reacting with superoxide to form the more active peroxynitrite and by generating N-hydroxyarginine, which both lowers the availability of arginine (the NOS substrate for NO production) and inhibits the activity of arginase (Boucher et al. 1994), the enzyme that eliminates arginine. For infection controls, NO often can regulate or collaborate with the production of reactive oxygen species (ROS), including O_2^- and hydrogen peroxide (H_2O_2) to regulate the level of oxidative stress. The metabolic products generated by the convoluted pathways of NO and ROS interactions include a wide range of molecules with diverse functions, such as polyamines, glutathione (GSH), leukotrienes, and prostaglandins; these molecules each have their own individual positive or negative effects on immunity. The combination of NO, $ONOO^-$, and ROS maintains cytotoxic activity and immune regulation. The interplay of NO and ROS at low levels initially aids immune cell activation. They then participate in the proinflammatory response, which is needed to kill pathogens, but then they eventually must assist termination of inflammation by inducing anti-inflammatory signals. Otherwise, excessive inflammation will cause tissue damage, as apparent in tuberculoid leprosy. Discussion of ROS and antioxidant activity is in a separate section entitled "► Antioxidants."

Inducible (i) NOS

Although there are differences in the transcriptional activation between species, there are some common transcription factors including nuclear factor-κB (NF-κB), signal transducer and activator of transcription (STAT)-1α, and interferon regulatory factor-1 (Pautz et al. 2010). The transcription factor NF-κB is intimately involved in the biphasic nature of the early low-level NO/ROS turn-on effects and the later higher-level turnoff of proinflammatory cytokine production. The low-level oxidative processes activate NF-κB by enhancing its dissociation from IκB, but excessive oxidative levels prevent NF-κB from binding to its promoter site and activating transcription. IL-1β and TNF-α influence NF-κB activation, whereas STAT-1 is activated by interferon-gamma (IFN-γ). NO, itself, is able to regulate iNOS expression; NO mediates superinduction and inhibition of iNOS expression (Connelly et al. 2001; Pérez-Sala et al. 2001). This dual activity, which also relates to its influence on NF-κB expression (Connelly et al. 2001), probably relates to its interactions with ROS constituents, which affect the signaling pathways being modified. Although both rodents and humans can express iNOS in cell types other than macrophages, such as epithelial cells, astrocytes, and endothelial cells, human

hepatocytes express iNOS in the absence of an infection and human neurons express iNOS with certain neurodegenerative conditions, such as Alzheimer's disease. The differences in iNOS expression relate to differences in the transcription factors and promoter region of iNOS (Weinberg 1998). Unlike eNOS and nNOS, the activity of iNOS is independent of the intracellular Ca^{2+} concentration, which is due to the fact that iNOS exists in tight association with the calcium-binding calmodulin protein. All three NOS isoforms are homodimeric hemo-flavoproteins; their N-terminal half contains the iron protoporphyrin IX (heme). This heme domain or the oxygenase domain of NOS is the site that binds the tetrahydrobiopterin cofactor and the substrate arginine. The C-terminal half of NOS is the flavin-binding domain (or reductase domain), and it contains Flavin Adenine Dinucleotide (FAD)-, Flavin Mononucleotide (FMN)-, and Nicotinamide Adenine Dinucleotide Phosphate or Glutamine Synthase (NADPH)-binding sites.

Molecular Modes of Action

Once NO is generated, it can modify many different cellular processes by S-nitrosylation, which alters the structure and function of proteins by adding NO to the free thiol of a cysteine forming a S-nitrosothiol. The thiols of other molecules, such as coenzyme A or GSH, also can be modified. Proteins critical to cell survival and proliferation can, thus, be altered, especially those of proteins that require iron for their activity, such as ribonucleotide reductase and aconitase. NO also affects the activity of soluble guanylate cyclase, Adenosine Diphosphate (ADP) ribosylation of proteins, and iron regulatory factor activation.

Different Types of Immune Cells Produce NO and Are Regulated by NO

Macrophages are the cells usually considered the main immune cell producing NO, and neutrophils are the main cell type producing ROS. However, NO from endothelial and epithelial cells and even neurons can affect immune responses; additionally, there are multiple subtypes of macrophages and cells of the monocytic lineage, and only some of them are induced to express iNOS. Classically activated (or M1 macrophages) as well as a macrophage subset that has been referred to as type II macrophages can express iNOS and produce NO (Edwards et al. 2006). Mouse M2 macrophages do not express iNOS; in fact, they express arginase, which, as stated earlier, interferes with the availability of arginine, and thus, M2 macrophages inhibit production of NO. Like iNOS, arginase is an inducible enzyme, and it has two isoforms: arginase-1 (cytosolic) and arginase-2 (mitochondria associated). M1 and M2 cells are well defined in mice, but in humans, $CD16^{-}$ and $CD16^{+}$ monocyte/macrophage subsets are functionally less well defined. Human $CD16^{+}$ macrophages are more inflammatory-mediating, but they express both iNOS and arginase. Mouse M1 macrophages release IL-12, which preferentially enhances development of Th1 cells, and Th1 cells produce IFN-γ, which in turn induces M1 macrophages to express iNOS and produce NO. On the other hand, Th2 cells release IL-4, which induces the M2 macrophage phenotype, and M2 macrophages produce IL-10 and TGF-β, which inhibit cell-mediated immune activities of Th1 and M1 macrophages. The biochemical complexities of NO and ROS interactions at times seem paradoxical in that both act together to kill pathogens via their oxidative capacity; however, O_2^{-} production declines when NOS activity and NO levels are high and NO levels inhibit oxidative mechanisms associated with ROS. ROS and peroxynitrite decrease the major antioxidant in cells, glutathione (GSH), and when GSH levels are low, M1 macrophages are inactive and M2 macrophages are active (Murata et al. 2002). With the decline in GSH, the antioxidant response element (ARE) pathway is activated, which leads to the induction of nuclear factor erythroid-2 (NRF2), which affects γ-glutamylcysteine ligase, the rate-limiting enzyme for GSH biosynthesis, and glutathione reductase.

The M1 macrophages drive the inflammatory response with their release of inflammatory cytokines (IL-1β, TNF-α, and IL-6) as well as production of NO and ROS and proteases and chemokines. However, the expression of the inflammatory cytokines is not equally affected by the level of the NO, in that TNF-α positivity correlates with NO but higher levels of NO inhibit IL-1β. The release of IL-12 from the M1 macrophages also promotes Th1 development (M1 macrophages are antigen-presenting cells (APC) for preferential development of Th1 cells), and Th1 release of IFN-γ will further enhance M1 activities. As noted, if inflammation continues much beyond the elimination of an infection, there will be further tissue damage and inhibition of tissue repair; thus, there is the need for regulation. The NO and ROS interactions affect the timing controls needed to allow an adequate amount of inflammation but not an excess; the necessary regulatory controls are mediated, in part, by influences of NO and ROS on the balance between the M1-Th1 and M2-Th2 pathways. Additionally, NO affects development of a separate subpopulation of regulatory T cells, IL-10 releasing Treg cells (Niedbala et al. 2007). However, NO also interferes with FoxP3 expression, and thus Treg development during the induction of experimental autoimmune encephalomyelitis (Brahmachari and Pahan 2010), which may relate to the differential regulatory influences of timing and dose of NO exposure. The anti-inflammatory cytokines from Th2 cells and Treg cells are IL-4, IL-13, IL-10, and TGF-β. As the activation of iNOS decreases, there is an increase in the level of the prostaglandin PGE2, which enhances the cAMP level, and cAMP aids preferential activation of Th2 cells. Interestingly, high NO levels lower the IL-1β level, and IL-1β has been suggested to favor Th2 development. The NO/ROS level also leads to activation of ARE signaling with expression of NRF2, which besides enhancing antioxidant levels enhances expression of inducible heme oxygenase (HO-1), a microsomal enzyme that cleaves heme-containing enzymes, including iNOS, and generates products that can inhibit TNF-α-mediated cell death.

The T cell subsets associated with NO induction are not restricted to the Th1 and Th2 cells. The $CD4^+$ Th subsets include Th9, Th17, and Th22 cells. Similar to Th1 cells, Th17 and Th22 have been suggested to induce iNOS expression via IL-17 and IL-22, respectively (Mühl et al. 2011). NO and ROS also may interfere with the production of IL-12 and IL-27, which promote Th1 cells, and IL-23, which promotes Th17 cells, since these cytokines are disulfide cross-linked heterodimers and loss of the free thiols of the monomers would block their formation. NO also can be immunosuppressive by enhancing the activity of other cells of the myeloid monocytic lineage. The myeloid-derived suppressor cell ($CD14^+CD15^-$ MHC class II^{low}) can produce NO, and like M2 macrophages, it releases IL-10 and TGF-β, but unlike M2 macrophages, it is not an APC.

NO and Disorders

As might be expected due to the ubiquitous nature of NO and its diversity of influences on multiple cell types, NO is involved in both exacerbation of pathologies as well as the suppression of immune-mediated pathologies and tissue repair as described earlier. Many reports have described the influence of NO in inflammatory bowel disorder, and both endogenous cells as well as the microbiome can affect the levels of NO. Mesenchymal stem cells (MSC) reduce inflammation after spinal cord injury and promote functional recovery by shifting the presence of M1 to M2 macrophages (Nakajima et al. 2012), and proinflammatory-activated MSC can produce chemokines and iNOS leading to immunosuppression of T cell proliferation (Ren et al. 2008). The compartmentalization of NO in the cells of various organs or lack thereof relates to the resolution or mediation of several clinical conditions (Villanueva and Giulivi 2010).

NK Cell Activation

Maren Claus, Doris Urlaub and Carsten Watzl
Leibniz Research Center for Working Environment and Human Factors, IfADo, Dortmund, Germany

Definition

Natural killer (NK) cells are a third subpopulation of lymphocytes. They are part of the innate immune system, but also contribute to the adaptive immune response. In 1975, NK cells were identified by their ability to lyse allogeneic tumor cells in mice without prior sensitization. The term “natural cytotoxicity” was introduced to describe this activity, and subsequently the

cells mediating this effect were termed natural killer cells. NK cells and T cells both derive from the common lymphocyte progenitor, but in contrast to T cells, NK cells develop in the bone marrow. They are not dependent on a functional thymus but need cytokines like interleukin (IL-) 2 and IL-15 for differentiation. Unlike T and B cells, NK cells express germ-line-encoded surface receptors and do not undergo somatic recombination (Sun and Lanier 2011).

NK Subsets

NK cells constitute about 5–15 % of peripheral blood lymphocytes. Further, they circulate through several lymphoid and non-lymphoid tissues like liver, spleen, tonsils, or lung. According to their function and phenotype, distinct subsets of human NK cells were defined: $CD16^{+}$ $CD56^{dim}$ NK cells are mainly found in peripheral blood and are assumed to be the mature, cytotoxic NK subtype. In contrast, $CD16^{-}$ $CD56^{bright}$ NK cells are preferentially located in secondary lymphoid organs and are thought to be the main producers of cytokines (Sun and Lanier 2011). However, both NK subsets can actually fulfill both functions. Uterine NK cells (Manaster and Mandelboim 2010) constitute another specialized subset. They secrete a variety of cytokines, growth factors, and angiogenic factors that might promote implantation and vascularization during early pregnancy. Innate lymphocytes sharing several features with NK cells are found in the intestinal mucosa. These cells do not exhibit cytotoxic activity but instead secrete IL-22 and are involved in mucosal homeostasis (Sanos et al. 2011).

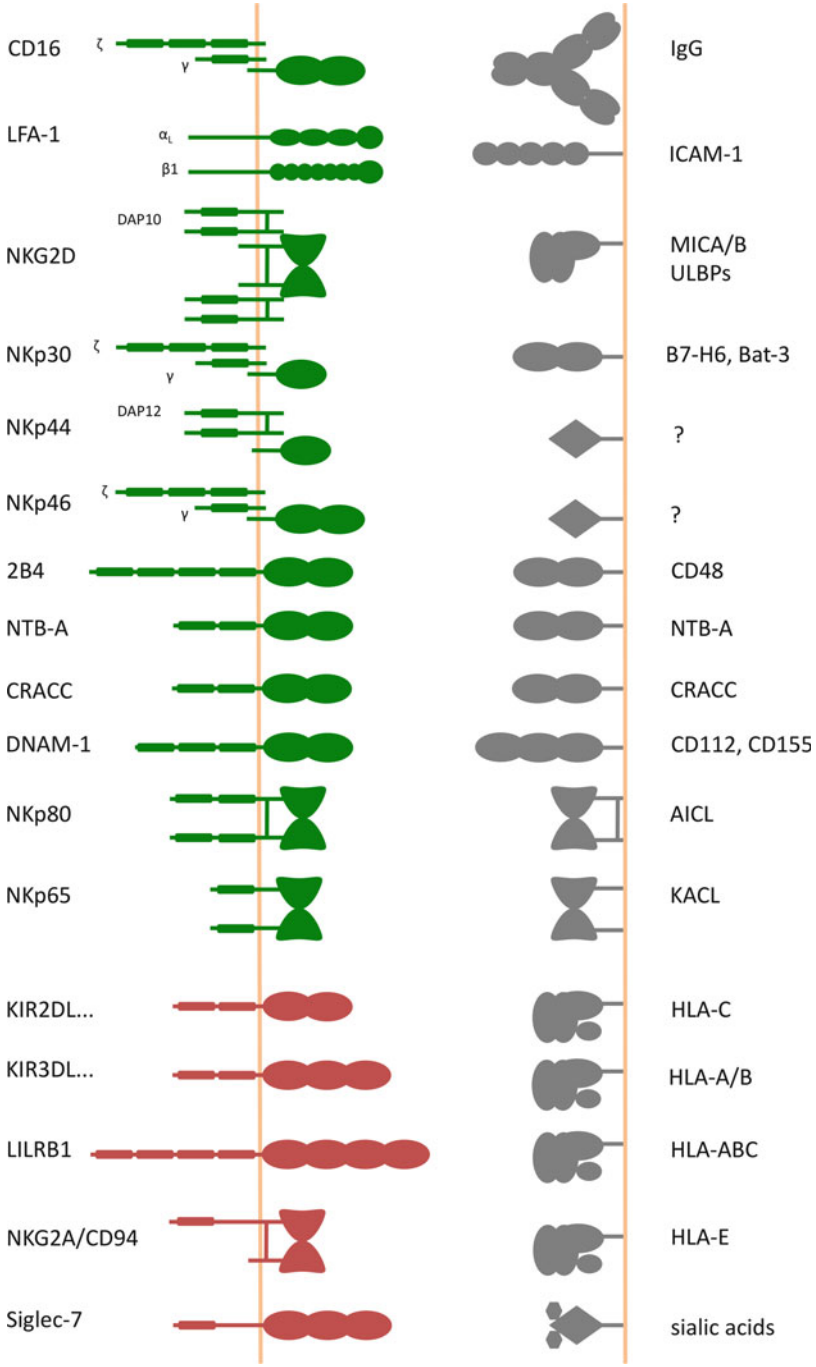
NK Cell Functions

NK cells provide a first line of defense against parasites, viruses, and cancer (Chavez-Galan et al. 2009; Lodoen and Lanier 2006; Vesely et al. 2011). One feature of NK cells is their cytotoxic activity against infected or transformed cells. NK cells carry large numbers of preformed cytotoxic granules. Upon binding to the target and activation of the NK cell, granule content is released towards the target and induces target cell apoptosis. The mechanisms of synapse formation and target cell killing share some properties with cytotoxic T lymphocytes.

After stimulation by direct target cell contact or through cytokines like IL-12 or IL-18, NK cells produce several mainly proinflammatory cytokines. NK cells play a crucial role in the direct control of viral replication and contribute to the communication between innate and adaptive immune system. Especially IFN-γ and TNF-α are essential for tuning the T cell-mediated response against intracellular pathogens and tumors. NK cell helper function is vital for the crosstalk with dendritic cells, either by direct contact or by cytokine release (Moretta et al. 2008).

Inhibitory Receptors: Self-Tolerance and Education

NK cell activity is regulated by various activating and inhibitory surface receptors (Fig. 1). Since several ligands for activating NK cell receptors are also expressed on normal, healthy cells, NK cell activity has to be inhibited by healthy tissue to avoid auto-reactivity. NK cells express inhibitory killer cell immunoglobulin-like receptors (KIR) and the Ig-like LILRB1 that recognize MHC class Ia and Ib molecules, and the NKG2A/CD94 heterodimer, which binds HLA-E. KIR contain two (KIR2D) or three (KIR3D) Ig-like extracellular domains and immunoreceptor tyrosine-based inhibition motifs (ITIMs) in their long intracellular part. Different KIR specifically recognize distinct human leukocyte antigen (HLA)-A, (HLA)-B, or (HLA)-C allotypes, but in contrast to the TCR, binding is, for the most part, not peptide specific. There are also activating KIR with a short intracellular tail, which transduces signals via immunoreceptor tyrosine-based activation motif (ITAM) containing adapters. However, the role of activating KIR variants for NK cell function is still not entirely clear.



NK Cell Activation, Fig. 1 Activating and inhibitory NK cell receptors and their ligands. The upper part shows a schematic representation of several important activating NK cell receptors. Some of these receptors couple to signaling partner chains such as DAP10, DAP12, CD3ζ, or FcεRIγ; others have signaling motifs in their cytoplasmatic domain. Cellular ligands for some of the receptors are still unknown. The lower part shows a summary of inhibitory receptors. KIR are specific for certain HLA alleles; LILRB1 binds a wide range of HLA alleles. Siglec-7 recognizes sialic acid modifications

During viral infection or tumorigenesis MHC class I expression is often downregulated or even lost from the cell surface to evade T cell-mediated responses. However, NK cells can be activated by these MHC I low target cells. This feature led to the development of the so-called missing self hypothesis. Yet, target cells that do not express any functional NK cell ligands for activating (or inhibitory) receptors are not recognized at all. The presence of stimulating ligands is

indispensable to fully activate NK cells. Some of these ligands are constitutively expressed on all cells; some are upregulated upon virus infection, tumor transformation, or cellular stress. Increased expression levels of such ligands can overcome dominant inhibitory signals and finally lead to induction of cytotoxicity even in the presence of self-MHC class I molecules. This concept has been termed "induced self" (Elliott and Yokoyama 2011).

However, NK cells are not overreactive in humans or mice deficient in expression of MHC class I. Instead, NK cells which developed in this MHC class I-deficient environment are hyporesponsive to MHC class I-deficient targets. Therefore, NK cells can sense which host MHC class I alleles are expressed in their environment and if there are compatible inhibitory KIR on the particular NK cell. NK cells that do not express at least one inhibitory receptor that fits to the MHC class I molecules expressed as self are functionally incompetent. The flexibility of this system is underscored by the finding that hyporesponsive mouse NK cells from an MHC-deficient donor can regain their reactivity after transfer into an MHC-sufficient recipient. The mechanisms behind this process are still not fully understood. Several models have been proposed which are summarized under the terms "MHC class I-dependent education" or "licensing" (Elliott and Yokoyama 2011). Recent data have suggested that this mechanism is not a static "yes-no" system but that the potency of an NK cell response is dependent on the strength of the "licensing" input. An NK cell that expresses multiple receptors for inhibitory self-ligands receives strong licensing signals. This NK cell would generate stronger activating responses than NK cells with less or weaker inhibitory contacts. Yet, NK cells that lack inhibitory receptors, and are therefore per definition "unlicensed," are apparently not completely unresponsive: Mouse NK cells without any inhibitory receptors were recently identified as the major producers of cytokines in response to infection with MCMV (Orr and Lanier 2011).

Activating Receptors

The panel of activating NK cell receptors is very heterogeneous. They cover several receptor families that recognize a large variety of different ligands and use different signaling pathways to transduce activating signals (Moretta et al. 2001). CD16 (FcγRIIIA) has a distinctive role among the receptors, as it does not bind to cellular ligands but triggers antibody-dependent cellular cytotoxicity (ADCC) upon binding to the Fc part of antibody complexes or antibodies bound to target cells. CD16 is the only NK receptor that can induce cytotoxicity without co-stimulation by other receptors in resting NK cells. Further, NK cells express members of the Ig-like SLAM-related-receptor family (SRR), including 2B4, NTB-A, and CRACC (Claus et al. 2008). While NTB-A and CRACC are homophilic receptors, 2B4 binds a distinct ligand, the GPI-anchored Ig-like protein CD48, that is expressed on all hematopoietic cells. SRR are not confined to NK cells but are also expressed on B and T cells, allowing for crosstalk between these cell types. The homodimer NKG2D belongs to the C-type lectin family and recognizes a variety of stress-induced ligands such as MICA and MICB and proteins of the ULBP family. NKp65 binds to KACL on keratinocytes. NKp80 is another member of this family that recognizes AICL, which is upregulated on myeloid cells upon TLR stimulation. DNAM-1 binds PVR and nectin-1, both expressed on tumor cells. Finally, the Ig-like natural cytotoxicity receptors (NCRs) NKp30, NKp44, and NKp46 are important receptors that induce strong activation signals. NKp30 and NKp46 are expressed on all NK cells, while NKp44 expression is induced upon NK cell activation. Although the importance of NCRs for tumor rejection has been demonstrated, only cellular ligands for NKp30 have been identified so far. The Ig-like protein B7-H6 is a tumor-specific surface marker, whereas the nuclear chaperone BAT-3 can be released from tumor cells and dendritic cells in exosomes and vesicles. It is known that NCR ligands are expressed on many different tumor cells and that these receptors can bind to heparan sulfate moieties and recognize different

viral hemagglutinins on infected cells, and they may also interact with bacterial proteins (Chaushu et al. 2012). NK cell activity is further modulated by proinflammatory cytokines, ▶ chemokines, and other soluble agents (Moretta et al. 2008).

First Contact: Adhesion and Initial Signaling

In the following section we will describe the signaling events during NK cell activation upon encounter of a target cell. We will describe these events in chronological order, starting from early adhesion events to the lysis of the target cell.

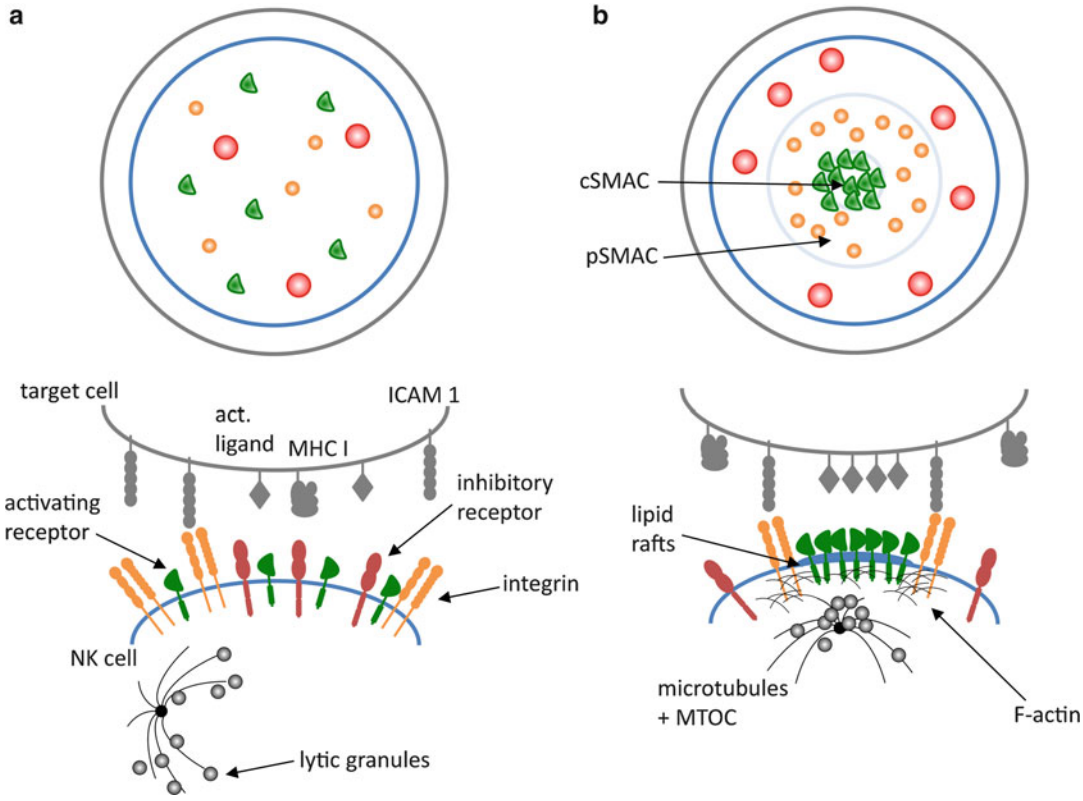
Upon first contact between an NK cell and a potential target cell, selectins (L-selectin) and integrins (LFA-1, MAC-1) (▶ Cell Adhesion Molecules) can loosely bind to the target and thus promote initial adhesion and signaling. The integrin LFA-1 (CD11a;CD18, αL;β1) (Hogg et al. 2011) recognizes the adhesion molecules ICAM-1, ICAM-2, and ICAM-3, which are expressed on endothelial cells and are upregulated during inflammation. In contrast to T cells, isolated triggering of LFA-1 on NK cells is sufficient to induce early activation signals. These drive polarization and directed recruitment of activating NK cell receptors towards the contact site and facilitate scanning for the presence of additional activating ligands. Simultaneous engagement of inhibitory receptors by MHC class I ligands interferes with NK cell activation already at this early signaling stage.

The adhesion strength of LFA-1 is determined by the affinity and avidity for ICAM (Hogg et al. 2011). The cytoplasmic domain of β1 integrin associates with adapter proteins like talin that link the integrin to the actin cytoskeleton and to downstream signals that arrive from other activating receptors. This "inside-out" signaling induces conformational changes in the intracellular part of the LFA-1 heterodimer. These are passed through the transmembrane segments and result in the formation of a high-affinity conformation of LFA-1, which strengthens the initial interaction between effector and target cell. Engaged LFA-1 in turn is able to transduce signals into the cell via outside-in signaling (Hogg et al. 2011). Concerted signaling of the different activating receptors promotes reorganization of the actin cytoskeleton, actin-dependent clustering of membrane microdomains, and recruitment of additional receptors and adapters into these signaling platforms, finally leading to the formation of a highly ordered and tight interface between effector and target, called immunological synapse (IS) (Fig. 2).

The IS is organized in discrete concentric regions that are defined by the accumulation of distinct proteins into supramolecular activation clusters (SMACs): the central cSMAC is constituted by activating receptors and their corresponding adapters and signaling molecules. This area is enclosed by the peripheral pSMAC, consisting of an F-actin ring and adhesion molecules such as LFA-1. The surrounding zone where inhibitory receptors or CD45, which are excluded from the IS, are found is sometimes referred to as distal dSMAC (Orange 2008). It has been shown that signaling microclusters do also form outside the IS. But for directed NK cell cytotoxicity, the functional IS is crucial as it ensures close contact to the target cell, and it provides the platform for signal amplification by concentrating receptors, co-stimulators, and cytoplasmic signaling molecules. In the mature IS, activating and adhesion signaling is further amplified until the activation threshold is reached and the cytolytic machinery is turned on.

Signaling of Inhibitory Receptors

A common signaling motif for inhibitory mouse Ly49, human KIR, and the conserved NKG2/CD94 receptors is the ITIM in the cytoplasmatic tail of these receptors (Watzl and Long 2010; Watzl and Urlaub 2011). Upon ligand binding, the ITIMs are tyrosine phosphorylated and can recruit the protein tyrosine phosphatases SHP-1 and SHP-2 and the SH2-domain-containing inositol phosphatase (SHIP). This binding to the receptors, and probably also phosphorylation,

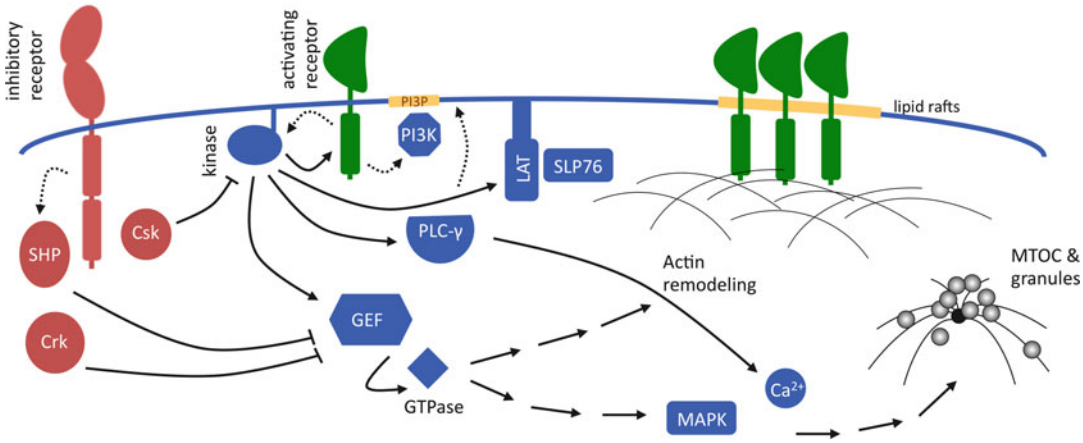


NK Cell Activation, Fig. 2 Immunological synapse. (**a**) First contact between NK cell and target cell involves adhesion molecules like LFA-1 and activating and inhibitory receptors, which are diffusely distributed on the cell surface. (**b**) Dominant activating signals lead to synapse formation, F-actin remodeling, recruitment of activating receptors into membrane microdomains, and signal amplification. Lytic granules and MTOC polarize towards the target cell

increases the activity of the phosphatases, which is considered a major mechanism necessary for NK cell inhibition. Other signaling events that contribute to ITIM-mediated inhibition include the phosphorylation of the small adapter Crk. This leads to an active disassembly of activating signaling complexes containing c-Cbl and the GTP-exchange-factor (GEF) C3G. Additionally, the C-terminal Src kinase (Csk) phosphorylates the inhibitory tyrosine of Src-family kinases, which stabilizes their inactive conformation.

Signaling of Activating Receptors

The multitude of activating NK cell receptors uses different signaling motifs and partner chains (Fig. 3). Resulting from this diversity, receptor proximal signaling events are also very variable and can trigger different signaling pathways (Watzl and Long 2010; Watzl and Urlaub 2011). Receptors that are associated to ITAM-based signaling partners induce signals similar to B or T cell activation. Engagement of the receptors CD16, NKp30, and NKp46 that are coupled to the CD3ζ chain or NKp44, which signals via DAP12, results in Src-family-kinase-dependent phosphorylation of the associated molecules' ITAMs. Once these motifs are phosphorylated, they can recruit the kinases ZAP70 and Syk, which in turn activate adapter proteins like ▶ LAT, LAT2, or SLP76 by phosphorylation. Emanating from the adapter proteins, signaling complexes are assembled, leading to the activation of further pathways. GEFs like Vav are important connections to cytoskeleton



NK Cell Activation, Fig. 3 Signaling pathways of NK cell receptors. Activating receptors initiate signals via various pathways. Important mediators are GTPases, the MAPK cascade, and Ca^{2+} signals, leading to cytoskeleton remodeling, polarization of the lytic machinery, and degranulation. Inhibitory receptors can intercept these signals at early steps

remodeling. ITAM signals mainly activate the Vav family members 2 and 3.

Other NK cell receptors or their associated signaling molecules contain tyrosine-based motifs different from ITAMs. The NKG2D receptor can also signal via DAP12 in mice, but in humans exclusively couples to DAP10, which contains a YINM motif. Similar to ITAMs, this motif can be phosphorylated by Src-family kinases and recruit phosphatidyl-inositol-3-OH kinase (▶ PI3K) or the adapter Grb2, which leads to the recruitment of Vav1.

SLAM-family receptors do not couple to signaling partner chains, but possess their own typical signaling motif, called immunoreceptor tyrosine-based switch motif (ITSM) (Claus et al. 2008). This motif can also be phosphorylated by Src-family kinases and recruits small SH2 domain-containing adapter molecules SAP, EAT-2, and in mice additionally ERT. SAP can bind to the Src-family kinase Fyn, which is probably responsible for activating signals transmitted by the SLAM-family receptors 2B4 and NTB-A that include phospholipase C (PLC)-γ1 and Vav1. The receptor CRACC is independent of SAP but interacts with EAT-2. It is still unclear how EAT-2 can contribute to NK cell activation. The ITSM motif has another special property: the ability to bind phosphatases (SHP-1 and SHP-2, ▶ SH2 Domain-containing Inositol Phosphatase-1 (SHIP)) instead of the small adapter molecules. This interaction explains how these receptors can transmit inhibitory signals, which can be observed under certain conditions. In X-linked lymphoproliferative syndrome (XLP) patients, the lack of functional SAP can cause an inhibitory function of 2B4. In NK cell precursors, which do not yet express MHC I-specific inhibitory receptors, the SAP level is very low. Inhibitory 2B4 signals could maintain the tolerance of these cells.

Other receptors such as DNAM-1, NKp80, or NKp65 have different tyrosine-based signaling motifs in their cytoplasmic tails, which have not yet been investigated in detail. In addition to their important role in adhesion to the prospective target cell, integrins have also the ability to transmit an outside-in signal. These signals also lead to the activation of Vav1 and play a major role in polarization of the lytic machinery towards the target (Watzl and Long 2010).

Downstream Activation

Despite the multitude of activating NK cell receptors and their various signaling motifs,

there are many common downstream signaling pathways. Src-family kinases are involved in the induction of most of these signaling events by phosphorylating the various tyrosine-based signaling motifs. These kinases therefore account for the recruitment of subsequent signaling mediators, but often they are also necessary to activate these mediators by phosphorylation. Only ITAM-based receptors additionally need the kinases Syk and ZAP70 to transmit the signal. Phosphatidyl-inositol-3-OH kinase (PI3K) can be activated either by direct binding to receptor complexes or by secondary events. By increasing the amount of phosphatidyl-inositol-3,4,5-triphosphate (PI3P), active PI3K enables the recruitment of Tec family kinases, PLC-γ1 or PLC-γ2, Akt, and Vav1, to the stimulated receptor. The induction of Ca^{2+} flux via PLC-γ is one of the essential events that are triggered by many receptors, as it is necessary for the exocytosis of lytic granules. Vav1 contributes to the activation of Rho-family ► GTPases like Rac1 and Cdc42 that are important regulators of actin reorganization. The MAP kinase ERK is activated in pathways following PI3K-Akt and Vav1-Rac1 and plays a key role in initializing granule polarization and release (Orange 2008; Watzl and Urlaub 2011).

The reorganization of the actin cytoskeleton is central for the activation of NK cells. The actin-dependent clustering of activating receptors at the IS creates an amplification of activating signals (Orange 2008). The process of activating receptor clustering is paralleled by an accumulation of cholesterol-enriched membrane microdomains at the IS. The environment of these microdomains seems to be crucial for the phosphorylation and function of activating receptors.

In a physiological setting, NK cells receive a multitude of signals via a combination of activating receptors. Some of these signals are able to synergize in the activation of human NK cells, while other combinations merely show an additive effect. Uncovering the complex signal integration of this crosstalk still is in a very early stage (Watzl and Urlaub 2011).

Integration of Activating and Inhibitory Signals

NK cell activation can be blocked at a very early step if inhibitory receptors are triggered simultaneously (Watzl and Long 2010; Watzl and Urlaub 2011). Already the initial adhesion to a prospective target is affected by inhibitory signals through the regulation of integrin affinity. The induction of the high-affinity conformation of LFA-1 by different activating NK cell receptors via inside-out signaling is susceptible to inhibitory signals. The recruitment of activating receptors such as 2B4 and NKG2D to membrane microdomains can also be blocked by inhibitory signals thereby depriving activating receptors of the environment required for phosphorylation. These results show that inhibitory receptors can interfere with the earliest stages of NK cell activation. As a result, later events including the phosphorylation of various signaling molecules, Ca^{2+} flux, the polarization of lytic granules, and ultimately degranulation cannot be initiated.

These effects of inhibitory signals are closely linked to their influence on actin dynamics. Triggering of inhibitory receptors prevents the accumulation of actin at the IS which is necessary for the clustering of activating receptors. In contrast to activating receptors, inhibitory interactions can occur independently from actin and membrane microdomain rearrangement. The inhibitory event is spatially restricted to individual contact sites and does not affect the entire cell. An NK cell that is simultaneously attached to a resistant and a susceptible target cell can still recognize and attack the susceptible target.

The question of how inhibitory receptors effectively block the signals mediated by many different activating receptors and combinations of these receptors is a major question when it comes to understanding NK cell function. SHIP is recruited to various inhibitory receptors and reduces the PI3P level, thereby affecting the recruitment of activation mediators. Src-family kinases are playing a central role in signal initiation of activating and inhibitory receptors, and

their activity is depending on phosphorylation states. The C-terminal phosphorylation can keep the kinase in a closed, inactive conformation. This site is phosphorylated by Csk and can be dephosphorylated by the phosphatase CD45. In contrast to T cells, this phosphatase is not essential for the activation process in NK cells. Phosphorylation of the catalytic site of Src-family kinases increases their activity, but neither for NK nor T cells, a stimulation-dependent induction of this phosphorylation could be shown. Probably the steady-state activity of these kinases is sufficient for signal initiation and therefore not subject to regulation (Watzl and Long 2010).

The GEF Vav1 is phosphorylated early after stimulation of activating receptors and has been identified as a direct target for SHP-1 when recruited by an inhibitory NK cell receptor. This may therefore represent an important integration step for activating and inhibitory signals. Phosphorylated Vav1 serves as GEF for Rho-family GTPases, which mediate many events essential for NK cell activation, like actin polymerization, recruitment of activating receptors, and IS formation. This process can create a positive feedback loop, as the early phosphorylation of Vav1 would result in actin polymerization, recruitment of activating receptors, and the proper formation of the IS. The increased number of activating receptors would further enhance Vav1 phosphorylation. By dephosphorylating Vav1 via the phosphatase SHP-1, inhibitory signals could prevent polarization of activating receptors and signaling components towards the target. A second regulatory mechanism, also targeting the polarization of the NK cell, is the phosphorylation of Crk after stimulation of inhibitory receptors. Complexes of Crk, c-Cbl, and C3G, which are also regulators of actin dynamics, are disassembled after Crk phosphorylation. These mechanisms would be consistent with the observation that blocking the polarization of the NK cell towards the target is the focus of inhibitory signals. Additionally this could explain how the cell manages to restrict the inhibitory signal to a confined region within the cell, thereby still allowing the killing of other sensitive targets (Watzl and Urlaub 2011).

These inhibitory pathways have the potential to control NK cell activation mediated by a multitude of activating receptors as they affect signaling events that are central to NK cell activation. However, it cannot be excluded that other events that act in parallel also contribute to NK cell inhibition.

Cytoskeleton: Essential for Activation and Degranulation

Reorganization of the actin cytoskeleton is essential for NK cell activation. An activating feedback loop between stimuli causing actin polarization and F-actin stabilizing the contact and recruiting signaling mediators initiates the activation process. GEFs like Vav1 and C3G are important mediators, as they transduce incoming signals to small GTPases (Watzl and Long 2010). These signals are necessary for the correct recruitment and activation of Wiskott-Aldrich syndrome protein (WASp), which is involved in the proper actin polymerization at the IS.

Once the activation threshold is reached, many downstream signaling pathways act in concert. The microtubule organizing center (MTOC) can polarize towards the IS and the lytic granules move along the microtubules in a dynein-dependent manner towards the MTOC (Orange 2008). The Cdc42-interacting protein 4 (CIP4) probably acts as an important link between WASp and the MTOC. The attachment of microtubule plus ends to the F-actin meshwork at the IS might also be involved in correct relocalization of the MTOC. PLC-γ triggers a calcium signal, including the influx of extracellular Ca^{2+} via the channel ORAI1, which is essential for degranulation, but not polarization of lytic granules. The mitogen-activated protein kinase (MAPK) pathway becomes activated, depending on the activity of small GTPases like Rac or Ras. Especially activation of the MAPKs JNK and ERK by phosphorylation is required for cytotoxicity (Orange 2008).

The actin cortex at the IS is very dense, but nevertheless it is possible for the granules to pass through this mesh. It has recently been shown that the granules can fuse with the membrane in areas with low actin density (Sanborn and Orange 2010). As the motor protein Myosin IIa is also necessary for NK cell degranulation, this passage is probably an active process.

Defects in the degranulation mechanisms result in a disease called familial hemophagocytic lymphohistiocytosis (FHL) (Filipovich 2011). Analysis of patients suffering from this syndrome identified several proteins which are essential for proper degranulation. Rab27a is required for the docking of granules to the membrane. SNARE proteins and their interacting partners are important regulators of the fusion step. MUNC13-4 and syntaxin11 are necessary for the docking and fusion process.

Important cytotoxic effectors in the lytic granules are perforin, granzymes (Chavez-Galan et al. 2009), and the saposin-like granulysin. The acidic pH and the proteoglycan matrix inside the granules keep the effectors inactive before degranulation. Perforin can insert in the target cells' membrane and form pores by polymerization. This is essential for granzyme-mediated killing of the target, although the exact mechanism is still debated. It has been speculated that granzymes simply diffuse through the perforin pores. But recent results suggest that they are taken up by endocytosis, which is probably linked to perforin-induced damage signals. Inside the target, granzymes activate apoptotic pathways through their serine protease activity. They make use of different pathways, some granzymes cleaving multiple targets, to prevent evasion by tumor cells. One of the most abundant family members, granzyme B, activates caspases but can also cause apoptosis via the mitochondrial pathway and via DNA damage (Chavez-Galan et al. 2009). A different way to kill target cells is the triggering of death receptors, which also induces apoptosis of these cells. Death receptors like ▶ Fas (CD95) and TRAIL-R are stimulated in a cell contact-dependent manner, whereas the TNFR bind the soluble cytokine TNF-α.

Outlook

NK cells are defined by their name as cytotoxic effector cells. This entry has therefore focused on this prominent and impressive activity of these cells. However, NK cells are much more than just innate killers. They combat infections and cancer and regulate adaptive immunity through a variety of mechanisms including direct cellular interactions and the secretion of cytokines and chemokines. They even have the capacity to memory-like responses. Additionally, their activity is not only regulated by target cell contact but also influenced by different cytokines. Therefore, the signaling events leading to target cell lysis as described above are just the beginning when it comes to understanding NK cell regulation.

Normal Immune Function and Barrier: Defensins

Gideon P. Smith
Department of Dermatology, Massachusetts General Hospital, Harvard Medical School, Boston, MA, USA

Synonyms

Antimicrobial peptides; Defensins; Natural antibiotic peptides

Definition

Defensins are cationic polypeptides of fewer than 100 amino acids that possess a characteristic β-sheet-rich fold and a framework of six disulfide-linked cysteines (Ganz 2003). They are ubiquitously present on the skin, as well as being found in bowel and lung, and have potent antimicrobial activity. As such they form an essential part of the cutaneous innate immune system.

Historical Background

Defensins were first reported in rabbit leukocytes in the 1960s (Zeya and Spitznagel 1963), but since that time have been found not only in humans, but in all mammalian species for which they have been sought, and even in plants (Carvalho Ade and Gomes 2011). In addition, in the animal kingdom, and in humans, their presence is not just limited to leukocytes but they are also secreted by epithelial cells. It is therefore believed that they occurred very early from an evolutionary standpoint (Oppenheim et al. 2003; Zhu and Gao 2013). On the basis of the number of amino acids and structural differences in disulfide bonding, defensins are classified into alpha, beta, and theta categories. Both alpha- and beta-defensins are found in humans but theta-defensins are not. In humans, alpha-defensins are found in neutrophils, some macrophages, and Paneth cells of the small intestine (Kaushansky and Williams 2010). Beta-defensins are the defensins found in skin (Bolognia et al. 2012).

Function

Beta-defensins, along with cathelicidins, a related but structurally distinct set of antimicrobial peptides, were originally thought to operate in the skin as a barrier against microbacteria passing through the stratum corneum. They have broad activity, disrupting cell membranes of both gram-positive and gram-negative bacteria (Wolff and Fitzpatrick 2008), fungi, and viral envelopes. The exact mechanism by which they do this is poorly understood and is believed to be multifaceted. One mechanism is believed to depend on their strong positive charge which allows them to bind to cell membranes of bacteria which are negative due to lipopolysaccharides creating pores in the bacterial membrane through

which cell contents can escape destroying cell homeostasis (White et al. 1995). However, it is unclear how they attack many fungi and why they are nontoxic to host cells.

However, there is strong and growing evidence that these peptides not only act as passive endogenous antibiotics but are inducible upon exposure blocking infection before it occurs as well as fulfilling additional roles unrelated to infection (Niyonsaba et al. 2006). In alpha-defensins there is binding to the CXCR4 receptor which is essential for HIV infection of the cell thereby blocking viral entry (Levinson 2006); however, beta-defensins are also induced by exposure to HIV (Niyonsaba et al. 2006). Beta-defensins are also implicated via CCR-6 signaling as chemoattractants resulting in recruitment of immature dendritic cells and memory T cells to sites of wounds or infection (Yang et al. 1999) and there is some suggestion they may be involved in wound healing, initiation of angiogenesis, and reepithelization.

Dysregulation in Disease States

In addition to the normal homeostasis and immunity within the skin, defensins have been shown to have an important role in a number of cutaneous and mucosal disease states including atopic dermatitis where defensins are significantly downregulated providing one possible explanation of why patients with atopic dermatitis are prone to bacterial infections, primarily *Staphylococcus aureus*, as well as warts, molluscum, and HSV (Rich 2013; Schauber and Gallo 2009). Defensin levels have also been shown to be altered in psoriasis and rosacea (Niyonsaba et al. 2006). In additional defensin profiles are altered in the saliva of patients with primary Sjögren's syndrome (Peluso et al. 2007) suggesting that decreases in salivary secretion are not the only mechanism for the periodontal disease experienced by these patients. Subsequently they also hold significant promise for therapeutics either through the manipulation of resident defensin levels or introduction of topicals that work via similar mechanisms. Indeed, defensins upregulation of inflammation may be one potential mechanism by which ultraviolet light works in many cutaneous conditions, as it has been shown that UV light downregulates defensin density on the skin, in part through its induction of vitamin D (Schwalfenberg 2011).

Normal Immune Function and Barrier: Epithelial Barrier

Gideon P. Smith
Department of Dermatology, Massachusetts General Hospital, Harvard Medical School, Boston, MA, USA

Synonyms

Enteric epithelium; Epidermis; Epithelial barrier; Epithelium; Gastric mucosa; Mucosa; Skin

Definition

The epithelial barrier is the physical barrier that prevents exogenous substances, whether bacterial, fungal, viral, or just toxic, from entering into the body. In addition, the epithelial barrier of the skin must also serve the specialized function of protecting against dehydration and heat loss. This is achieved in a number of ways both passive, such as impermeability, and by the secretion of antimicrobial peptides such as defensins and cathelicidins which are dealt with elsewhere, active recruitment of inflammatory cells by the resident epithelial cells, and active protection from the epithelial cells themselves (Abbas et al. 2012). Epithelium exists on all areas where an interface between the internal and external organisms exists. The most obvious of these is the skin, but epithelial barriers also line other organs which process or form a barrier to external substances such as the lung and gastrointestinal tract. As such they form an essential part of the innate and adaptive immune systems.

Types of Epithelial Barrier

Given the variety of locations and functions served, there exist several classes of epithelia designed for each purpose. In most internal organs epithelia do serve as a barrier but also must allow absorption of substances and so consist of simple epithelia. As protection, rather than absorption, becomes more and more prominent, so the layer of epithelium tends to thicken. In the esophagus and buccal mucosa, there is stratified squamous epithelia; in the gingival and hard palate, there are parakeratinizing stratified squamous epithelia; and on the epidermis, there is orthokeratinizing stratified squamous epithelia (Bolognia et al. 2012). In this entry we focus on the latter of these and include discussion of the external cornified layer of the skin, a layer that is unique to the skin, essential in its function, and for a long time, poorly understood.

The External Cornified Layer

The skin is composed of stratified squamous epithelium. Keratinocytes are continuously turned over from the basal layer and mature as they rise through the epidermis. As they reach the outermost layer, they undergo terminal differentiation forming mechanically resilient cornified cells (termed corneocytes) (McKee 1996). Initially these layers were thought of as "dead" cells as they did not differentiate further and had lost all organelles including the cell nucleus. However, while these cells lack the power to further evolve, they still form part of a rich and complex environment which we have only recently begun to appreciate. The outer layer of these cells is composed of an insoluble proteinaceous layer termed the cornified envelope. This insolubility is currently believed to be due to both disulfide bonding and extensive cross-linking by N^e-(gamma-glutamyl)lysineisopeptide bonds

between transglutaminases (Kalinin et al. 2002). While this layer account for much of the stratum corneum's physical resilience, equally important is its impermeability. This is largely contributed by a monomolecular layer of ceramides that is covalently bound to the cornified envelope, forming a moisture-resistant lipid envelope. This lipid envelope prevents maceration of the proteinaceous layer, but impermeability is aided by intercellular lipid lamellae made up of ceramides, free fatty acids, cholesterol, and its esters. These low water content, acidic pH, and a resident microflora (Moens and Veldhoen 2012) all contribute to the barrier against colonization and invasion by pathogens (Elias 2007).

In addition to the physical barriers, epithelia also possess a complex immunologic defense system against exogenous agents (Rich and ebrary Inc. 2013). Keratinocytes and gastric epithelia secrete, both passively and in response to stimuli, proteins such as defensins and cathelicidins, antimicrobial peptides, with broad activity, disrupting cell membranes of both gram-positive and gram-negative bacteria, fungi, and viral envelopes. In addition to being able to recruit inflammatory cells from the circulation, the epithelia also host resident lymphocytes, dendritic cells, and natural killer cells which form part of the permanent defense system of this barrier (Wolff and Fitzpatrick 2008). These are each treated in their own sections and will not be dealt with further here.

Keratinocytes and Tight Junctions

Keratinocytes, the precursors of the cornified layer in the skin, not only provide a source of stratum corneum but also help secrete much of the lipid envelope. In addition keratinocytes secrete defensins and chemoattractants in times of wounding, infection, or inflammation and maintain a complex balance between defense and homeostasis, allowing a partially protective bacterial flora to coexist (Schroder 2010). Keratinocytes also produce structural proteins, named keratins, which form filaments that bind the tissue together ensuring cell and tissue integrity (Presland and Jurevic 2002). In addition to these filaments, keratinocytes exhibit two types of cell adhesion structures: desmosomes function to connect keratinocytes to one another whereas hemidesmosomes attach the basal keratinocytes to the basement membrane. Desmosomes are transmembrane proteins with five extracellular domains and calcium-binding motifs that bind their extracellular domains, made of cell adhesion proteins, such as desmoglein and desmocollin, via homophilic binding to the extracellular domains of neighboring cells (Presland and Dale 2000). In addition the skin exhibits adherens and tight junctions which form even tighter intercellular contacts that seal the space between cells separating tissue compartments (Sapra et al. 2012).

Normal Immune Function and Barrier: Gamma Delta T-Cells

Gideon P. Smith
Department of Dermatology, Massachusetts General Hospital, Harvard Medical School, Boston, MA, USA

Synonyms

Dendritic epidermal T-cells; Gamma delta T-cells; γδ-T-cells

Definition

T-cells express T-cell receptors (TCR) on their surface. Although the majority express alpha and beta heterodimer TCRs, γδ-T-cells express gamma and delta chains instead (Bolognia et al. 2012). These γδ-T-cells are prominent in epithelial tissues including the skin, gut, and lung and under normal conditions make up 10 % (Kaushansky and Williams 2010) of all T-cells in these tissues, although in leprosy or leishmaniasis this figure can increase to 33 %. Our understanding of γδ-T-cells continues to expand as new subtypes are identified. γδ-T-cells form a highly heterogeneous population of cells with a variety of physiological roles (Pang et al. 2012). In addition they are thought to remain partially activated at all times, and as such they form an essential part of the rapid response of both the cutaneous adaptive and innate immune systems (Rich 2013).

Differences Between αβ-T-Cells and γδ-T-Cells

There exist a number of differences between the more ubiquitous αβ-T-cells and the γδ-T-cell subset. In contrast to αβ-T-cells which are generally categorized as CD4+ or CD8+, γδ-T-cells are usually both CD4- and CD8-. While αβ-T-cell activation is regulated by MHC class I and II molecules, the activation of γδ-T-cells is not, using instead the junctional adhesion molecule like protein, and the coxsackie- and adenovirus receptor as co-stimulatory molecules. Diversity in the TCR loci is determined by recombination of the variable (V), diversity (D; for β and δ chains), and junctional (J) region sequence elements (Murphy et al. 2012). While in αβ-T-cells in general and γδ-T-cells in the spleen, this leads to a great variation in TCRs, γδ-T-cells in epithelia have much more restricted TCR diversity (Thedrez et al. 2007). While γδ-T-cells can adapt, this response to a more limited, preprogrammed set of antigens makes them also like the innate immune response.

It is likely that γδ-T-cells also play a very different role to αβ-T-cells. γδ-T-cells appear to be responsible for self-regulation and destruction of epithelial cells that have become transformed virally or by malignant transformation (Girardi et al. 2001), metabolically dysregulated, or otherwise stressed. In addition, in the skin, dendritic epidermal T-cells (DETCs), in a manner more similar to Langerhans cells than other T-cells, form a dendritic network in the suprabasal epidermis (Girardi 2006), where they have a role in the promotion of wound healing (Jameson et al. 2004). Finally there is some suggestion that αβ-T-cells may in part be downregulated by γδ-T-cell with γδ-T-cells serving to prevent

excessive inflammatory responses, and that because of their role in dampening immune responses and their regulation of damaged self-cells, they may play a role in autoimmune diseases such as multiple sclerosis (Blink and Miller 2009).

γδ-T-Cells in Infection

γδ-T-cells have been shown to proliferate in a wide variety of infectious states including tularemia, salmonellosis, brucellosis, legionellosis, listeriosis blood, *H. influenzae*, *N. meningitidis*, *S. pneumoniae*, meningitis, ehrlichiosis, Coxiella burnetii, Q-fever, Chlamydia psittaci, malaria, toxoplasmosis, leishmaniasis, *M. tuberculosis*, *M. avium*, and leprosy (Chen and Letvin 2003). γδ-T-cells appear to fulfil multiple roles in infection. First they are recognized to have cytotoxic effects when stimulated by isopentenyl pyrophosphate and alkylamines, compounds found in plants and bacteria (Girardi 2006). Second through secretion of IFN-γ, they may stimulate NK, NKT, and αβ-T-cells. Finally they serve as antigen-presenting cells to αβ-T-cells.

γδ-T-Cells in Malignancy

Just as in infection, in malignancy surveillance γδ-T-cells are believed to have effects via direct cytotoxic mechanisms and induction of cytokines and downregulate a subset of tumor-promoting αβ-T-cells (Marquez-Medina et al. 2012). Like NK cells and αβ-T-cells, γδ-T-cells express NKG2D which in humans binds MHC class I chain-related A and B (MICA and MICB). These are expressed on a variety of tumor cells suggesting an antineoplastic role for γδ-T-cells. In addition, γδ-T-cell-deficient mice are shown to have lower levels of IFN-γ, a cytokine known to be important in tumor immunity, as well as higher rates of tumor development, suggesting a second, cytokine-driven, mechanism for neoplasm surveillance in γδ-T-cells (Gao et al. 2003). As a result a variety of γδ-T-cell-based antineoplastic therapies are currently under investigation.

γδ-T-Cells in Downregulation of the Inflammatory Response

γδ-T-cells are thought to also have a role parallel to that of T-regs. In infection and autoimmunity they have been shown to produce anti-inflammatory cytokines such as interleukin-2 (IL-2), IL-4, interferon-γ (IFN-γ), IL-10, and transforming growth factor-β (TGF-β) (Mukasa et al. 1998). In γδ-T-cells knockout mice skin inflammation is spontaneous, and models of inflammatory skin conditions notably are worse. Finally, a number of other anti-inflammatory properties have been associated with these cells including expression of Fas ligand and expression of lymphoid thymosin-β 4 which has been shown to be anti-inflammatory (Girardi 2006).

Normal Immune Function and Barrier: Langerhans Cells

Gideon P. Smith
Department of Dermatology, Massachusetts General Hospital, Harvard Medical School, Boston, MA, USA

Synonyms

Antigen-presenting cell; Dendritic cell; Langerhans cell

Definition

Langerhans cells (LCs) are the primary antigen-presenting cells of the skin. As such they form an essential part of the cutaneous adaptive immune system.

Historical Background

Langerhans cells were named after Paul Langerhans who first described these cells in 1868 (Langerhans 1886). Initially believed to be neural in origin due to their dendritic form, it was only much later that they were identified as originating in bone marrow and being in the general category of antigen-presenting cells (Goldsmith and Fitzpatrick 2012).

Histology

Langerhans cells are present in the skin and oral mucosa. While they can be found in any layer in normal skin, they are at greatest concentration in the stratum spinosum (Young 2006), although their location is more variable in mucosal surfaces (Upadhyay et al. 2013). LCs can also be subdivided by type. Type 1 LCs have more dendrites, a lucent cytoplasm on electron microscopy, and numerous granules and are more often located in the suprabasal layers. In contrast, type 2 LCs have less dendrites, an electron-dense cytoplasm, and fewer Birbeck granules. Type 2 LCs are found in the basal layer. LCs account for 25 % of the skin's surface area (Upadhyay et al. 2013), having from 5 to 9 dendrites in the plane of the skin, although these decrease in density with age (Weedon and Strutton 2002). They are not visible on normal hematoxylin and eosinophil-stained sections but can be seen on electron microscopy or histochemical sections. While a variety of markers, such as ATPase, CD45, peanut lectin, S100, vimentin, and HLA-DR, can be used to highlight LCs, CD1a is more commonly used as within the epidermis it is unique to LCs (Weedon and Strutton 2002). The characteristic structural feature of LCs is the Birbeck granules which on electron microscopy are visible as rod-shaped endosomal organelles that functionally are responsible for both antigen capture and presentation (Collin et al. 2013).

Function

LCs are important in both the sensitization and effector phases of the adaptive immune response (Henri et al. 2010; Rich 2013; Zaba et al. 2009). Initially LCs remain quiescent in the skin until stimulated by exposure to microbial or nonmicrobial antigens. In this immature state, LCs express a variety of surface receptors

including Toll-like receptors, C-type lectin receptors, Fc-g, and complement receptors (Cutler and Jotwani 2004). Upon first exposure to a new antigen, LCs change from high E-cadherin to low E-cadherin levels, reducing their adherence and allowing them to migrate out of the epidermis. Activated LCs also express CCR7, a cell surface receptor that is specific for chemotactating cytokine produced in the T-cell zone of lymph nodes, and they therefore home to these upon entering the afferent lymphatics (Rich 2013). These activated LCs then present the antigen to naïve T cells in the draining lymph nodes, causing T-cell differentiation (Igyarto and Kaplan 2013). A subset of these memory T cells migrate to the skin and remain dormant until stimulated in the effector phase, and some remain in regional lymph nodes. During the effector phase, prior exposure has already occurred, and in this case, LCs first activate tissue-resident memory T cells that have been pre-primed to the antigen to become T-effector cells. In addition, some activated LCs migrate to the draining lymph nodes where they can again present the antigen and activate resident memory T cells to become skin homing for increased response. While initially LCs' primary role was believed to be in the adaptive response to microbial antigens, increasing evidence suggests that they have a multiplicity of roles and may be equally important in responding to cutaneous malignancy (Yanofsky et al. 2013). The presentation of exogenous antigen-derived peptides occurs primarily via the MHC class II presentation to CD4 + helper T cells. However, LCs have also been shown to play a role in MHC class I restricted cytotoxic (CD8+) T-cell responses, as well as stimulating NK cells via production of IL-12. In addition, they have a significant stimulatory role via cytokine production including IL-α, IL-β, IL-6, IL-7, IL-12, IL-15, IL-18, TNF-α, TGF-β, M-CSF, and GM-CSF (Upadhyay et al. 2013).

Disease States

In addition to the normal homeostasis and immunity within the skin, LCs have been shown to have a dominant role in a number of cutaneous and mucosal disease states including atopic dermatitis (Bolognia et al. 2012; Novak 2012) and lichen planus (Sugerman et al. 2002), as well as being deranged in graft versus host disease and HIV, the latter of which is primarily thought of as a CD4 T-cell disease but which has prominent skin findings associated with its effect on LCs. LCs are also indicated in a number of diseases where the primary cell is the LC such as Langerhans cell histiocytosis. Subsequently they also hold significant promise for induction of immune response in therapy, where this is desired such as in administration of vaccines (Teunissen et al. 2012) and antineoplastic therapies (Yanofsky et al. 2013).

Normal Immune Function and Barrier: Vitamin D

Gideon P. Smith
Department of Dermatology, Massachusetts General Hospital, Harvard Medical School, Boston, MA, USA

Synonyms

1,25(OH)2D3; 1,25-Dihydroxyvitamin D (1,25(OH)2D3); 22-Dihydroergocalciferol; 25(OH)D3; 25-Hydroxycholecalciferol; 25-Hydroxyvitamin D; Calcidiol; Calcifediol; Calcitriol; Cholecalciferol; Ergocalciferol; Sitocalciferol; Vitamin D; Vitamin D2; Vitamin D3; Vitamin D4; Vitamin D5

Definition

Vitamin D is not one molecule, but a family of molecules, all of which are in the category of secosteroids, which are steroids in which one of the bonds in the steroid rings is broken. In human health, the two most important molecules in the family of vitamin D are currently believed to be vitamin D3, or cholecalciferol, and vitamin D2, or ergocalciferol, and most commonly when discussing vitamin D, it is in reference to one or both of these molecules. However, in total there are five vitamin D molecules including vitamin D1, ergocalciferol with lumisterol; vitamin D2, ergocalciferol; vitamin D3, cholecalciferol; vitamin D4, 22-dihydroergocalciferol; and vitamin D5, sitocalciferol (Harrison and Longo 2013).

Sources and Biosynthesis of Vitamin D

Both vitamin D2 and vitamin D3 can be ingested in the diet. In the skin, ultraviolet light at a wavelength of 280–320 nM converts 7-dehydrocholesterol to provitamin D3, which is then rapidly converted to vitamin D3 at the plasma membrane (Fitzpatrick and Wolff 2008; Holick et al. 2007). Vitamin D3 is then converted to calcidiol (25-hydroxycholecalciferol). Vitamin D2 (ergocalciferol) is converted in the liver to 25-hydroxyergocalciferol. These metabolites are the molecules measured in serum to determine if a patient is vitamin D deficient. The majority of metabolically active vitamin D is then produced by further breakdown in the kidneys to form 1,25 dihydroxyvitamin D ($1,25(OH)_2D$). However, a small amount of 1,25 dihydroxyvitamin D ($1,25(OH)_2D$) is also produced locally in the skin as keratinocytes also possess small quantities of the relevant enzymes (CYP27A1, the 25-hydroxylase, and CYP27 B1, the 1-hydroxylase) (Bikle 2012).

Vitamin D and Structure and Integrity of the Epithelial Barrier

Vitamin D plays a role in the structure and function of a number of essential components of the epithelial barrier. Adherens junctions are complexes of E-cadherin and nectin and cytosolic scaffolds, α-catenin, β-catenin, and p120-catenin in the plasma membrane of epithelial cells which allow intercellular signaling and help bind cells of the epithelial barrier together

(Hartsock and Nelson 2008). In particular the β-catenin pathway has been identified as contributing to both homeostasis and neoplastic surveillance and is in part regulated by activation of the vitamin D receptor (VDR) (Campbell et al. 1997; Leyssens et al. 2013).

Similar to adherens tight junctions are important in epithelial barrier, but serve to prevent passage across the barrier between cells and maintain homoeostasis (Niessen 2007). One of the most well-established roles of vitamin D is in calcium homeostasis and signaling. It has been shown that claudin-2 and 12 molecules within the tight junction are important co-regulators in this vitamin D-controlled regulation across epithelial barriers (Sun 2010) and that conversely tight junction function can be hampered by downregulation of occludin, ZO-1 and claudin 2, 10b, 12 and 15 in vitamin D deficiency (Hwang et al. 2013; Yin et al. 2011). In addition, dysregulation of vitamin D-mediated calcium signaling leads to poor differentiation in keratinocytes.

While calcium-starved keratinocytes do proliferate, they do so at a reduced rate; in addition, they do not stratify or form strong intercellular contacts, and fail to produce cornified envelopes an essential part of the integrity of the epithelial barrier (Bikle 2012).

Vitamin D and the Immune Defense of the Normal Epithelial Barrier

Vitamin D is believed to play an important role in homoeostasis as $1,25(OH)_2D3$ both supports maintenance of innate surveillance and suppresses the adaptive response (Hart et al. 2011). Immature macrophages and dendritic cells within the epithelial barrier, as well as circulating cells which can home to the barrier express higher levels of VDR. Stimulation of the VDR suppresses the adaptive response of these cells, and in mature, activated cells, VDR production is suppressed, allowing them to function normally.

In addition to this $1,25(OH)_2D3$ induces monocytes, macrophages, neutrophils, and epithelial cells to secrete antimicrobial peptides, such as defensins and cathelicidins, which also make up an essential component of the innate immune response of epithelia (Hewison 2011). In addition to its effect on dendritic cells, the primary antigen-presenting cell in the epithelia, vitamin D3 promotes T_{Reg} cell development while simultaneously suppressing T_H1 and T_H17 cells (Baeke et al. 2010; Hart et al. 2011). Vitamin D3 also suppresses differentiation of B cells into memory and plasma B cell subtypes and antibody production. Finally vitamin D3 appears to modulate both B and T cells homing to the skin and other epithelial barriers. Despite the above studies however, and the clear role for vitamin D in normal epithelial barrier and immune response, studies of the relation of vitamin D to disease states have been variable. In addition, while this has been widely studied, the evidence to support therapeutic value in interventional vitamin D is much weaker although topical vitamin D analogs are common in, e.g., psoriasis and eczema. This suggests that some variation in vitamin D levels in disease states may be a result of the disease process and should not be confused with the hypothesis, which to date remains unsupported by the available scientific data, that vitamin D is instead the prime mechanism of disease production (Autier and Gandini 2007).

Definition

Treatment of autoimmune diseases such as systemic lupus erythematosus invariably requires the use of immunosuppressive medications. Better understanding of the pathophysiology of these diseases has allowed the identification of new selective targets for therapeutic intervention.

Historical Background

Systemic lupus erythematosus (SLE) is a systemic autoimmune disease associated with significant morbidity and mortality. The pathogenesis of SLE involves multiple levels of immune dysfunction, as well as multiple organ systems, and therefore, therapy has traditionally required broad-based immunosuppression. Corticosteroids in particular are the mainstay of SLE treatment. Though effective, use of steroids is limited by their long-term toxicities. Other therapies such as cyclophosphamide, mycophenolate mofetil, and azathioprine have markedly improved patient outcomes over the past 20 years. However, these agents still carry risks of toxic side effects, secondary malignancies, and opportunistic infection.

Recently, much effort has been spent in developing newer, targeted therapies that theoretically carry fewer risks and are less immunosuppressive. It is often said that SLE is a heterogeneous disease, since it can present in myriad different ways in different patients. It is therefore likely that the underlying immune dysfunction and other factors are also quite variable from patient to patient, and the selection of targeted therapy may in future be guided by the individual phenotype.

The pathogenesis of SLE is quite complex and remains incompletely understood (Tsokos 2011). Both innate and adaptive arms of the immune system are dysregulated with regard to clearance of antigen and apoptotic debris, antigen presentation, response to stimulation, and cytokine production. At present, the development of targeted therapies has been focused on immune abnormalities; however, genetic, epigenetic,

environmental, and hormonal influences all play a role in SLE pathogenesis and these areas may represent new areas for therapeutic intervention in future.

Therapy Directed Against B Cells

SLE is characterized by the presence of autoantibodies, which can precede the onset of clinical symptoms by many years. However, only some of these autoantibodies have been shown to play a direct role in pathogenesis. For example, antibodies directed against double-stranded DNA (dsDNA) have been shown to induce inflammation by depositing in the kidney, either as part of immune complexes formed elsewhere or due to cross-reactivity with kidney antigens (Deshmukh et al. 2006). Serum titers of anti-dsDNA antibodies correlate with lupus nephritis disease activity. Similar disease correlations have been proposed for other autoantibodies found in SLE, and the cytopenias in SLE have also been attributed to autoantibody-mediated destruction. Therefore, several different B cell–directed therapies attempting to decrease autoantibody production have been proposed (Table 1).

B Cell Depletion

Rituximab, a chimeric monoclonal antibody directed against CD20, was first developed for the treatment of B cell lymphomas. Its use has subsequently been expanded to include the treatment of a wide variety of autoimmune conditions, including SLE, rheumatoid arthritis, and vasculitis. As CD20 is a surface marker expressed on B cells (through development from pre-B cell precursors to mature and memory B cells), rituximab induces rapid and sometimes long-lasting depletion of circulating B cells. The effect on B cells in the periphery is less quantifiable and probably variable. Notably, antibody-producing plasma cells do not express CD20 and therefore are not affected by rituximab administration. Total serum immunoglobulin levels are also not usually affected. However, levels of autoantibodies such as anti-dsDNA in SLE have been shown to decline after rituximab treatment. Interestingly, rituximab's clinical benefits are often apparent much sooner than detectable changes in autoantibody levels. This discrepancy suggests a mechanism of action beyond inhibition of autoantibodies. In addition to production of autoantibodies, B cells may potentiate SLE pathogenesis through abnormal antigen presentation and costimulation of T cells, setting up a cycle of hyperreactivity. Another hypothesis suggests that clearance of B cells opsonized by rituximab may divert complement and inflammatory cells from sites of immune complex deposition that might otherwise lead to damage. While multiple small case series of SLE patients have described improved outcomes with rituximab, several large, randomized controlled trials have failed to show significant benefit (Lateef and Petri 2010). Use of rituximab for the treatment of SLE, though commonly accepted, remains off-label.

Other B cell–depleting antibodies are also in development. Ocrelizumab and ofatumumab are also antibodies directed against CD20; both bind to different epitopes as compared to rituximab and this binding may allow for more efficient cell killing. Further development of ocrelizumab has been halted due to concern for increased risk of infection. Epratuzumab is a humanized anti-CD22 monoclonal antibody; CD22 is a surface marker expressed on mature B cells. Epratuzumab is currently under phase III investigation for treatment of SLE. Combination therapy with epratuzumab and rituximab, theorized to enhance efficiency of treatment, is also being studied in patients with lymphoma. Antibodies directed against CD19 (expressed through development from pro-B precursors to mature B cells) are also in development (Lateef and Petri 2010). Finally, targeted inhibition of antibody-secreting plasma cells has also been considered. While such agents exist for the treatment of myeloma, detailed studies in patients with SLE have not been published.

B Cell Cytokine Inhibition

Another approach has been to target cytokine signaling in order to inhibit B cell activity and function. Belimumab, a humanized monoclonal

Novel Targets in Systemic Lupus Erythematosus, Table 1 Development of targeted therapies for treatment of SLE

Target	Drug	Mechanism	Development phase
B cell			
CD20	Rituximab	mAb against CD20; depletes mature B cells and B cell precursors	Large phase II/III studies did not meet primary endpoint; commonly used off-label
	Ocrelizumab	mAb against CD20	Phase III halted due to infections; other trials ongoing in RA and multiple sclerosis
	Ofatumumab	mAb against CD20	Trials in lymphoma and leukemia; no studies in SLE
	Veltuzumab	mAb against CD20	Trials in RA, ITP, and lymphoma; no studies in SLE
CD22	Epratuzumab	mAb against CD22; depletes mature B cells	Phase III study in progress
BLyS/BAFF	Belimumab	mAb against BAFF	FDA approved for SLE
	Atacicept	Fusion protein of TACI receptor with Fc	Phase II/III completed, results pending
	Briobacept	Fusion protein of BAFFR with Fc	Preclinical development
B cell tolerogen	Edratide	Peptide derived from human anti-DNA antibody	Phase II did not meet primary endpoint
	Abetimus	Oligonucleotide that binds anti-dsDNA antibodies	Phase III halted for lack of efficacy
T cell			
IL-17	AIN457	mAb against IL-17A	Trials in psoriasis, uveitis, RA; no studies in SLE
IL-23	Ustekinumab	mAb against p40 subunit of IL-12 and IL-23	FDA approved for psoriasis; no studies in SLE
Syk	Fostamatinib	Syk inhibitor	Phase II/III studies for RA; no studies in SLE
Jak	Tofacitinib	Jak1/Jak3 inhibitor	FDA approved for RA; no studies in SLE
	LY3009104	Jak1/Jak2 inhibitor	Phase II studies for RA; no studies in SLE
ROCK	Fasudil	ROCK inhibitor	Phase I for secondary Raynaud's showed no benefit; no studies in SLE
Metabolism	Sirolimus	mTOR inhibitor	Phase II studies in progress
Costimulation			
CD40:CD40L	BG9588	mAb against CD40L	Phase II halted due to thromboembolic complications
	IDEC-131	mAb against CD40L	Phase II did not meet primary endpoint
CD28:B7	Abatacept	Fusion of CTLA-4 with Fc	Phase III in progress
	Belatacept	Fusion of CTLA-4 with Fc	Trials in RA, renal transplant; no studies in SLE
ICOS:B7RP1	AMG 557	mAb against B7RP-1	Phase I studies in progress
Other cytokines			
IL-6	Tocilizumab	mAb against IL-6R	Phase I; neutropenia was common side effect
TNF-α	Infliximab	mAb against TNF-α	Phase II/III terminated for logistical reasons
IFN-α	Rontalizumab	mAb against IFN-α	Phase II in progress
	Sifalimumab	mAb against IFN-α	Phase II in progress
	MEDI-546	mAb against IFNAR	Phase II in progress
IFN-γ	AMG 811	mAb against IFN-γ	Phase I in progress
Other			
ROS	*N*-acetylcysteine	Antioxidant	Phase I/II in progress
Complement	Eculizumab	mAb against C5	Phase I/II terminated for logistical reasons
TLR	DV1179	TLR7 and TLR9 inhibitor	Preclinical development

mAb monoclonal antibody, *Fc* Fc portion of IgG, *RA* rheumatoid arthritis, *ITP* idiopathic thrombocytopenia, *IFNAR* IFN alpha receptor

antibody directed against the cytokine B cell activating factor of the TNF family (BAFF, also known as B lymphocyte stimulator, or BLyS), was approved in 2011 for treatment of SLE. BAFF is widely secreted by monocytes and other myeloid cells and is a key regulator of B cell function and homeostasis. The BAFF receptor (BAFF-R) is expressed on effector T cells and B cells throughout development. BAFF additionally binds to two other B cell receptors, TACI (transmembrane activator and CAML interactor) and, with lesser affinity, BCMA (B cell maturation antigen). TACI signaling has negative regulatory properties; mutations in TACI have been associated with common variable immunodeficiency (CVID) and CVID-related autoimmunity. A BAFF-related cytokine named APRIL (a proliferation inducing ligand) also binds to both TACI and BCMA to mediate distinct but overlapping effects. BCMA has higher affinity for APRIL than for BAFF, and is the predominant receptor on plasma cells. APRIL additionally binds heparan sulfate proteoglycans, which likely function as a co-receptor in part by increasing APRIL's interaction with BCMA and TACI. BAFF and APRIL signaling plays critical roles in promoting B cell survival and influencing responses to antigen, including the germinal center responses, immunoglobulin production, and class switching (Rickert et al. 2011).

Increased levels of BAFF have been described in several autoimmune conditions, and SLE in particular. Depletion of BAFF with belimumab in mouse models of SLE leads to a decrease in circulating mature B cell numbers, with a concomitant decline in activated T cells and inflammatory cytokines. In humans, a large phase III study (BLISS 52) showed higher clinical responses and fewer flares in patients treated with belimumab as compared to placebo. A second phase III study, BLISS 76, showed a similar benefit although the difference was not as apparent. Based on these results, belimumab was the first new drug to receive FDA approval for the treatment of SLE in more than 50 years (Davidson 2010). The BAFF signaling pathway has also been targeted using a receptor fusion protein. Atacicept combines the Fc portion of human IgG with the extracellular domain of TACI, thus inhibiting both BAFF and APRIL signaling. Of note, APRIL/BCMA signaling is important for survival of antibody-producing plasma cells. It is therefore possible that atacicept would have a more significant effect on immunoglobulin levels than belimumab. Indeed, a phase II/III study of atacicept in combination with mycophenolate mofetil in SLE patients was stopped prematurely due to unexpectedly profound drops in immunoglobulin levels (Ginzler et al. 2012; Davidson 2010).

Interleukin-6 (IL-6) is another important cytokine made by cells of both the adaptive and innate immune systems. Among many other pro-inflammatory effects, IL-6 encourages the growth and survival of antibody-producing B cells. IL-6 also influences T cell differentiation by promoting IL-17 production and inhibiting regulatory T cell development. Patients with SLE demonstrate higher levels of IL-6 in serum and, in patients with lupus nephritis, also in urine. IL-6 polymorphisms have also been described in patients with lupus. Tocilizumab, a monoclonal antibody directed against the IL-6 receptor, is approved for the treatment of rheumatoid arthritis. The utility of tocilizumab therapy in lupus remains unknown; a small phase I clinical study showed improvement in disease parameters for most patients, but neutropenia was a limiting side effect (reviewed in Lo and Tsokos 2012).

B Cell Tolerogens

Autoantibodies themselves have also been targeted for therapeutic intervention. Edratide is a synthetic peptide based on the complementarity-determining region of anti-DNA antibodies. In mouse models of lupus, immunization with edratide was capable of inducing tolerance and ameliorating disease. However, human studies were disappointing. Another molecule, abetimus (previously LJP-394), was also designed to target anti-dsDNA antibodies. This molecule is comprised of four double-stranded oligonucleotides that bind anti-dsDNA antibodies, cross-linking Ig molecules that are either free-floating or membrane-bound on B cells. Fixation of

antibody by abetimus on B cell surfaces is not immunostimulatory but rather induces apoptosis of the B cell, producing anti-dsDNA antibodies. Abetimus' mechanism of action as a B cell "tolerogen," therefore, is via depletion of circulating anti-dsDNA antibodies as well as downregulation of anti-dsDNA production itself. While initial trials in human patients with SLE were promising, larger follow-up studies did not show significant benefit with treatment (Lo and Tsokos 2012).

Therapy Directed Against T Cells

Although SLE is often thought of as an autoantibody-mediated disease, T cell function is also markedly altered. T cells from SLE patients show skewed phenotypes and cytokine profiles, and demonstrate intrinsic signaling abnormalities that can be potentially targeted for therapy (Kyttaris and Tsokos 2011).

T Cell Cytokine Inhibition

Th17 cells are a helper T cell subset that secretes IL-17, a cytokine that promotes local inflammation in peripheral tissue through recruitment of inflammatory cells and other mechanisms. More recently, other T cell subtypes (particularly innate immune cells such as TCRγ/δ T cells) have also been shown to secrete IL-17. Th17 cells and IL-17 signaling have been increasingly implicated in the pathogenesis of several autoimmune conditions, including inflammatory bowel disease, multiple sclerosis, and psoriasis (Zhu and Qian 2012). In SLE patients, increased numbers of IL-17-secreting T cells have been found both in affected kidneys as well as in peripheral circulation; serum titers of IL-17 are also increased and correlate with disease activity.

Attempts to inhibit IL-17/IL-17R signaling for therapy of autoimmune disorders have used various approaches targeting upstream and downstream factors. IL-6 is another pro-inflammatory cytokine necessary for the differentiation of Th17 cells; a trial of tocilizumab in SLE patients was associated with neutropenia as described earlier. Th17 development and expansion is also dependent on IL-23, which has been successfully targeted by the monoclonal antibody ustekinumab, approved for treatment of psoriasis (Zhu and Qian 2012). Clinical trials studying ustekinumab in multiple sclerosis and inflammatory bowel disease are currently in progress. AIN457, a monoclonal antibody directed against IL-17A itself, is also in clinical development for treatment of psoriasis and other autoimmune conditions.

T Cell Signaling Inhibition

TCR Signaling

Activation of the T cell receptor (TCR) in SLE T cells induces a hyperactive calcium flux response compared to normal T cells. Despite this, SLE T cells produce less IL-2 and do not proliferate as well in vitro. This discrepancy is not fully understood. The aberrant calcium flux response can be traced back to the TCR complex itself. SLE T cells express lower levels of CD3ζ, which typically signals as part of the surface TCR complex through the intracellular tyrosine kinase zeta-associated protein 70 (ZAP70). CD3ζ is substituted in SLE T cells by FcRγ, a homologous receptor normally expressed as part of the FcεRI, FcαR, FcγRI, and FcγRIII receptor complexes on myeloid and NK cells. FcRγ, in turn, partners with spleen tyrosine kinase (Syk) rather than ZAP70. This signaling pathway through Syk activation leads to much faster and stronger calcium flux responses (Kyttaris and Tsokos 2011). Notably, Syk is expressed in a wide variety of cell types and is particularly critical for B cell receptor signaling. Platelet activation is also mediated in part through Syk. Syk inhibition may thus have far-reaching effects beyond correction of T cell signaling abnormalities; mice with autoimmune diabetes treated with Syk inhibitors showed lower B cell numbers and immunoglobulin levels (Colonna et al. 2010). In lupus-prone mice, inhibition of Syk with fostamatinib (previously known as R788) attenuated disease manifestations (Lo and Tsokos 2012). In humans, Syk inhibitors are also being studied for the treatment of rheumatoid arthritis and other autoimmune

conditions. Fostamatinib, a small molecule inhibitor of Syk, showed significant benefit over placebo in a large phase III study of patients with rheumatoid arthritis, with few side effects (Weinblatt et al. 2010); follow-up studies are ongoing.

Jak/STAT Signaling

The Janus kinases (Jak) and signal transducers and activators of transcription (STAT) proteins partner together in different combinations to mediate cytokine signaling (Zerbini and Lomonte 2012). For example, the IL-2 receptor complex signals through binding of the common gamma chain (γc) receptor to Jak3, which in turn phosphorylates STAT5. Phosphorylated STAT5 forms homodimers and translocates to the nucleus where it directly binds promoter regions to activate gene transcription. Similarly, IL-6 signal transduction pathway is via Jak1 and Jak2, which partner with STAT1 and STAT3 to mediate gene activation. Several different Jak inhibitors are currently under development in the treatment of autoimmune diseases. Tofacitinib is a small molecule kinase inhibitor of Jak1 and Jak3, with weaker effects on Jak2. In vitro studies show that tofacitinib inhibits IL-4-dependent differentiation of Th2 and Th17 cells, among other effects. In humans, tofacitinib induced significant response rates compared placebo in a phase III study of rheumatoid arthritis. Studies of tofacitinib in other autoimmune diseases are ongoing (Zerbini and Lomonte 2012). Other selective Jak inhibitors are also being developed in an effort to avoid over-immunosuppression, since Jak3 is a critical component of all cytokine signaling pathways that utilize the common γc receptor (IL-2, IL-4, IL-7, IL-9, IL-15, and IL-21); congenital Jak3 deficiency results in severe combined immunodeficiency. Selective Jak2 inhibition decreases IL-6- and IFNγ-mediated inflammation without affecting IL-2 signaling. This may be especially advantageous in patients with SLE, in whom lower regulatory T cell numbers have been linked to lower levels of IL-2. A Jak2 inhibitor was recently shown to reduce disease manifestations in mouse models of lupus. Other selective Jak inhibitors are also being studied in patients with rheumatoid arthritis (Lu et al. 2011).

Calcium Signaling

As described above, TCR activation leads to rapid influx of calcium that activates calcineurin. This calcium flux response is increased in SLE T cells. Calcineurin is a phosphatase that dephosphorylates the transcription factor NFAT, allowing it to translocate to the nucleus and mediate cytokine gene expression. Thus, the calcineurin inhibitors cyclosporine and tacrolimus act primarily by inhibiting T cell cytokine production. Cyclosporine and tacrolimus are sometimes given as second-line agents in the treatment of lupus, particularly lupus nephritis, but their use is limited by renal toxicity. Recently, dipyridamole, an inhibitor of platelet aggregation, was also found to inhibit calcineurin activity in vitro, and it attenuated disease activity in mouse models of lupus (Kyttaris and Tsokos 2011).

Rho Kinase

Tissue damage in SLE is due in part to increased migration of inflammatory cells to end organs. T cells in SLE patients express higher levels of surface markers such as chemokine receptors and CD44, a glycoprotein that binds hyaluronic acid. CD44+ cells have been found infiltrating the kidneys of patients with lupus nephritis. CD44 binds to a family of proteins (ezrin, radixin, and moesin, collectively known as ERM) that link the cell surface to the intracellular cytoskeleton to promote cell adhesion and migration. The activity of the ERM proteins is dependent on phosphorylation by the rho kinase ROCK, and this activity is increased in SLE T cells. Another rho kinase, ROCK2, activates interferon regulatory factor-4 (IRF-4), a transcription factor important for Th17 differentiation. In mouse models of lupus, fasudil, a ROCK inhibitor, decreased IL-17 and IL-21 production and improve manifestations of disease (Stirzaker et al. 2012). While ROCK inhibitors have not yet been studied in humans with lupus, fasudil also has vasodilatory properties and is currently being investigated for the treatment of Raynaud's phenomenon.

Mitochondrial Dysfunction

The mammalian target of rapamycin (mTOR) is a mitochondrial membrane protein that controls transmembrane potential. Lymphocytes from SLE patients demonstrate abnormal mitochondrial function with hyperpolarization, higher production of reactive oxygen intermediates, increased oxidative stress, and lower ATP content. SLE T cells have normal levels of mTOR expression but show increased mTOR activity. Treatment of SLE T cells in vitro with an mTOR inhibitor (rapamycin, also known as sirolimus, used to prevent organ rejection in transplantation) increased CD3ζ expression and normalized calcium flux responses. In SLE patients treated with rapamycin, similar normalization of T cell signaling was also observed. This effect appears to be unrelated to rapamycin's other immunomodulatory properties (Perl 2010).

Costimulation

The costimulatory interactions between T cells, B cells, and antigen-presenting cells (APC) are critical for the perpetuation of inflammation in autoimmune disease. Naïve T cell activation is strongly enhanced by CD28 interaction with costimulatory molecules B7-1 (CD80) and B7-2 (CD86) on activated APCs; CD28 signaling responses influence T cell cytokine production and differentiation. CD28 is a member of a family of homologous receptors that have different downstream effects, both inflammatory and inhibitory. CTLA-4 is one such homolog expressed on regulatory T cells and activated T cells. CTLA-4 binds to the B7 ligands with even stronger affinity than CD28; this binding induces an inhibitory signal important for T cell tolerance (Abbas et al. 2010). Taking advantage of CTLA-4's strong binding affinity, proteins fusing the CTLA-4 extracellular portion to the Fc portion of immunoglobulin have been developed to disrupt CD28:B7 interaction. Abatacept, the first such protein, is already approved for the treatment of rheumatoid arthritis. A phase IIb study of abatacept in SLE patients showed modest therapeutic effects but did not reach its primary endpoint; a larger study in lupus nephritis is in progress (Lateef and Petri 2010).

CD40L (also known as CD154), expressed on activated T cells, binds to B cells and other APCs expressing CD40. This interaction has pro-inflammatory effects via induction of cytokine expression and upregulation of costimulatory receptors; in B cells, immunoglobulin isotype switching, antibody production, and germinal center formation are all dependent on CD40: CD40L interaction. T cell activation and differentiation is influenced indirectly by these effects on the APC (Abbas et al. 2010). SLE patients show higher levels of CD40L expression on T cells as well as higher soluble CD40L levels in peripheral blood. Monoclonal antibodies designed to block CD40L showed promising effects in mouse models of lupus. However, a clinical trial of anti-CD40L in SLE patients was halted due to unexpected thromboembolic events. More recently, CD40L has also been shown to interact with several different integrins, including GPIIb/IIIa on platelets. The effects of anti-CD40L antibodies on platelet activation and thrombus formation are still unclear (Alaaeddine et al. 2012).

Innate Immune System Targets

There appear to be many different points in the adaptive immune system of patients with SLE where tolerance is breached. However, the central role of innate immune system dysregulation in lupus pathogenesis has also become increasingly apparent. Abnormalities in apoptosis, clearance of apoptotic debris, antigen presentation, and immune complex formation have all been described. The type I interferon pathway in particular is perturbed in SLE.

Classically, the type I interferons (IFNα, made by monocytes and dendritic cells, and IFNβ, made primarily by fibroblasts) mediate the innate immune response to viral infection. Activation of pattern recognition receptors such as the Toll-like receptors (TLRs), which recognize foreign DNA, RNA, and other motifs, leads to local IFN production. The response to IFN occurs via activation of Jak/STAT signaling to induce upregulation of antiviral genes (Abbas et al. 2010). In patients with

lupus, increased IFNα levels in serum correlate with a pattern of upregulated IFN-inducible genes in peripheral blood mononuclear cells, termed the "type 1 interferon signature." TLR9 activation in plasmacytoid dendritic cells by unmethylated CpG-DNA is thought to be primarily responsible for this IFN overactivity. Further, genetic studies in SLE patients have identified risk alleles in multiple genes associated with the IFN pathway, strengthening the importance of IFN dysregulation in lupus pathogenesis. Increased IFNα activity may potentiate stimulation of T cells during antigen presentation and inhibit regulatory T cells. This activity has been targeted using anti-IFNα monoclonal antibodies. In phase I studies, sifalimumab and rontalizumab, both anti-IFNα antibodies currently in development, were able to normalize the interferon signature of SLE patients. Clinical studies of MEDI-546, an anti-IFN receptor antibody, are also underway. Finally, an IFNα vaccine has shown encouraging results in early clinical trials. This novel approach uses inactivated cytokine to induce endogenous anti-IFNα autoantibodies (Lichtman et al. 2012).

Hydroxychloroquine is one of the few medications approved by the FDA for treatment of lupus. The antimalarial medications chloroquine and hydroxychloroquine have long been known to have anti-inflammatory effects, although the mechanisms have only recently been elucidated. Both drugs inhibit acidification of lysosomes, interfering with peptide binding to MHC (thus affecting antigen processing and presentation) as well as nucleic acid activation of TLRs. Antimalarial medications may also directly inhibit TLR activation through mechanisms that are not yet understood (Lafyatis et al. 2006). Newer, more potent TLR inhibitors are in development using oligonucleotides with non-stimulatory DNA sequences to block TLR7 and TLR9 activation.

Dysregulated complement activation is a characteristic feature of SLE. Inherited complement deficiencies (especially C1q and C4) are strongly associated with the development of lupus-like disease, suggesting a protective role for complement proteins. Conversely, SLE patients also show acquired complement deficiencies due to immune complex formation. Deposition of complement-containing immune complexes contributes to inflammation and damage in peripheral tissues such as the kidney. Eculizumab, a humanized monoclonal antibody that binds C5 and inhibits its cleavage to C5a and C5b, significantly reduced renal disease in mouse models of lupus. Informative studies in humans with SLE are still pending, although eculizumab has shown clinical efficacy in trials of paroxysmal nocturnal hemoglobinuria, a disorder characterized by spontaneous complement activation causing hemolysis (Bao and Quigg 2007).

Hormonal Therapy

As with many other autoimmune diseases, SLE disproportionately affects women of childbearing age. This observation has led to intense examination of the role of estrogen and other sex hormones in lupus pathogenesis. Estrogen receptors are present in both T and B cells, and estrogen has a number of described effects in vitro, including altered cytokine expression and increased antibody production. Dehydroepiandrosterone (DHEA), a precursor of sex hormones, declines with age and this decline has been proposed to play a role in immune senescence. In vitro, DHEA appears to enhance immune responses and increases IL-2 production in T cells. DHEA levels were observed to be low in patients with SLE and other autoimmune diseases. A randomized controlled trial of DHEA supplementation in women with SLE showed beneficial effects over placebo (Hazeldine et al. 2010).

Environmental and Epigenetic Influences

Environmental exposures such as UV light, infections, medications, and free radical exposure have all been described to contribute to lupus pathogenesis. Reactive oxygen intermediates (ROI)

produced as a by-product of normal metabolism can, when increased by environmental influences, contribute to DNA damage and lead to abnormal cell death. ROI also affects T cell activation and cytokine production, in part by inhibiting expression of CD3ζ. In mouse models of lupus, the antioxidant *N*-acetylcysteine (NAC) improved survival; studies of NAC in humans with SLE have not yet been published (Perl 2010).

Gene expression is also affected by environmental influences through epigenetic modification. In general, SLE lymphocytes show a global pattern of hypomethylation correlating with increased gene expression, including expression of genes implicated in SLE pathogenesis. For example, hydralazine and procainamide are both medications associated with drug-induced lupus. It is now recognized that this phenomenon is related to demethylation of CpG-DNA. Hydralazine directly inhibits the DNA methyltransferase DNMT1, while procainamide inhibits a kinase pathway necessary for DNMT1 and DNMT3 expression; both medications induce a gene expression pattern in T cells similar to that of SLE T cells. Histone modification patterns are also altered in SLE. Histone acetylation of some genes may have protective effects while others may contribute to the SLE phenotype. Histone deacetylase (HDAC) inhibitors are in development for cancer therapy and, based on animal models of lupus, may also hold potential for the treatment of SLE (Hedrich and Tsokos 2011).

Conclusion

Recent advances in the understanding of lupus pathogenesis have allowed for the opportunity to develop new, targeted therapies that will hopefully carry fewer infectious risks than the broader immunosuppressive medications currently in use. One such example has been belimumab, the first new drug approved by the FDA for the treatment of SLE in over 50 years. The biologic medications carry great promise for the treatment of autoimmune diseases but remain expensive to manufacture and administer. The new small molecule inhibitors have the advantage of easier oral dosing, but potential toxicities are less well understood. The eventual success of the targeted therapies discussed here will depend in part on the development of better biomarkers to delineate individual immune phenotypes, optimizing the specificity of care.

Nuclear Factor of Activated T Cells (NFAT)

Jose Aramburu and Cristina López-Rodriguez
Immunology unit, Department of Experimental and Health Sciences, Universitat Pompeu Fabra, Barcelona, Spain

Synonyms

NFAT; NF-AT; Nuclear factor of activated T cells

Definition

The name nuclear factor of activated T cells (NFAT) identifies a group of transcription factors characterized by a conserved DNA-binding domain, which is homologous to the Rel-like DNA-binding domain of NF-κB (nuclear factor kappa-light-chain-enhancer of activated B cells) proteins. The NFAT family comprises five proteins, four of which are characteristically activated upon dephosphorylation of their amino-terminal region by calcineurin, plus a fifth one, NFAT5/TonEBP, which lacks calcineurin-binding motifs and is regulated by different mechanisms. The calcineurin-dependent NFATs are known as NFAT1 (or NFATc2 or NFATp), NFAT2 (or NFATc1 or NFATc), NFAT3 (or NFATc4), and NFAT4 (or NFATc3 or NFATx). The calcineurin-independent NFAT5 is also known as TonEBP (tonicity enhancer binding protein), referring to its function as a hypertonicity-activated factor.

Historical Background

NFAT was first described in 1988 as a DNA-binding protein present in the nucleus of mitogen-activated T lymphocytes and capable of recognizing particular sequences in the human interleukin (IL)-2 gene enhancer and the long terminal repeat of the human immunodeficiency

virus (HIV LTR) (Shaw et al. 1988). As it was also found that unstimulated lymphocytes already contained NFAT in their cytosol in an inactive state, the protein received the names NFATp, the "p" meaning preexisting, and NFATc, the "c" standing for cytosolic. NFAT translocated to the nucleus in response to T cell receptor stimulation or pharmacological agonists of its signaling and associated with a nuclear partner with which it bound to DNA. The first partner identified for NFAT was the heterodimeric transcription factor Fos/Jun (generally known as activator protein-1, AP-1) (Jain et al. 1992), and other transcription factors have been shown to interact with NFAT proteins onto specific DNA sequences. Importantly, the activity of NFAT was found to be inhibited by the immunosuppressants cyclosporin A and FK506 (also known as tacrolimus) by virtue of its dependence on the calcium-activated phosphatase calcineurin.

The first molecular cloning of an NFAT protein, NFAT1, was described by Rao and colleagues in 1993 (McCaffrey et al. 1993) and was followed by the subsequent identification of other NFATs and their respective isoforms. The latest NFAT identified, in 1999, was the calcineurin-independent factor NFAT5 (Miyakawa et al. 1999; Lopez-Rodriguez et al. 1999).

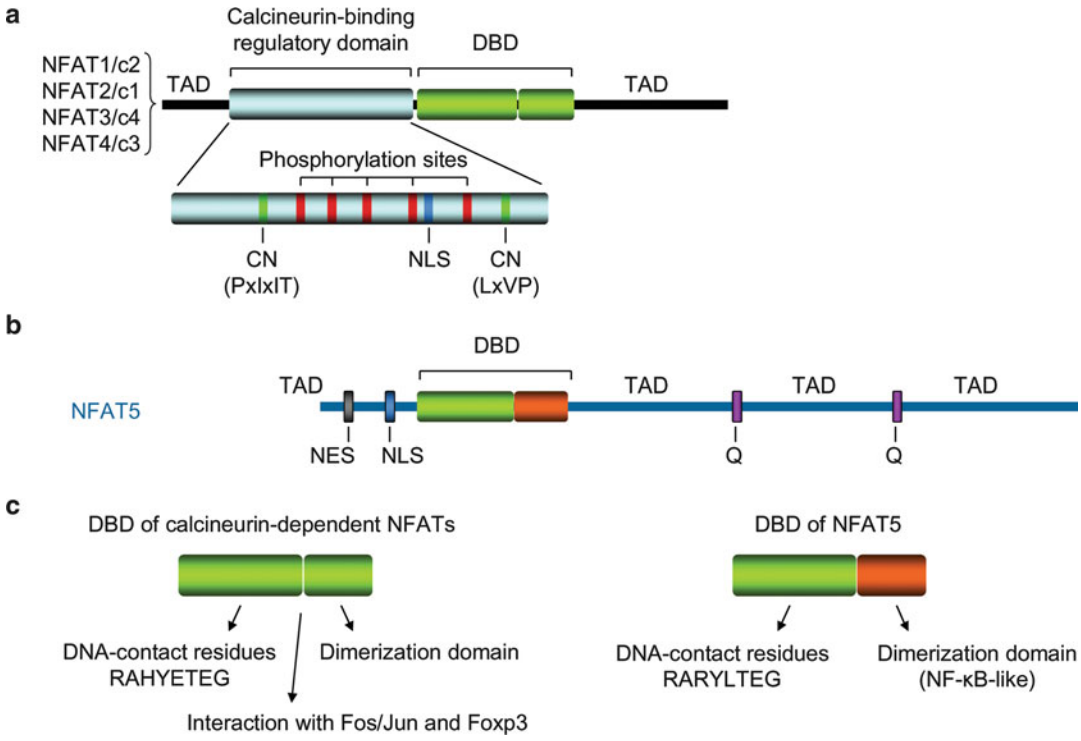
Despite their original name, NFAT proteins are not restricted to T lymphocytes, and they are expressed and functional in different types of immune cells, including B cells, natural killer (NK) cells, neutrophils, macrophages, and megakaryocytes, as well as in nonimmune cells such as neurons, skeletal muscle, cardiomyocytes, endothelial cells, fibroblasts, and adipocytes. Considering the variety of cell types known to use NFAT proteins, it is probably correct to assume that they are present and functional in all nucleated mammalian cell types.

Evolution and Diversity of NFAT Proteins

NFATs are found in vertebrates, and they evolved in two separate branches, one that gave rise to the calcineurin-dependent NFATs and another to NFAT5. Their common Rel-like DNA-binding domain arose from an ancestor that also gave rise to NF-κB proteins (Graef et al. 2001). Factors with a recognizably conserved NFAT-like DNA-binding domain have been described in chordates, such as *Ciona intestinalis*, and in insects, but they lack the calcineurin-binding and phosphorylation-regulated motifs characteristic of the calcineurin-dependent NFATs and are considered to be NFAT5-like proteins. The NFAT found in the fly *Drosophila melanogaster*, known as dNFAT, is capable of conferring resistance to osmotic stress, similarly to NFAT5 in vertebrates. NFATs are not expressed in plants and other commonly studied eukaryotic model organisms, such as yeast and the worm *Caenorhabditis elegans*.

Shared and Distinct Features in the Regulation and Function of NFAT Proteins

Calcineurin-Dependent NFAT Proteins. The calcineurin-dependent NFATs (NFAT1/NFATc2, NFAT2/NFATc1, NFAT3/NFATc4, NFAT4/NFATc3) are encoded in separate genes and contain a well-conserved amino-terminal regulatory region of about 400 amino acids that comprises the nuclear import and export signals and the calcineurin-docking and phosphorylation-regulated sites involved in controlling their nucleocytoplasmic localization (Fig. 1). The two calcineurin-docking motifs of these NFATs contain the conserved amino acid sequences "proline-x-isoleucine-x-isoleucine-threonine" (PxIxIT motif) and "leucine-x-valine-proline" (LxVP motif). In them, the x position can be occupied by different amino acids. The amino-terminal region also includes several key serine residues that can be phosphorylated by diverse kinases and dephosphorylated by calcineurin (Li et al. 2011). Besides these functional features, this region contains a small domain with transactivation function. Their DNA-binding domain (DBD),



Nuclear Factor of Activated T Cells (NFAT), Fig. 1 *Schematic representation of NFAT proteins and their functional domains*. The diagrams in (**a**) and (**b**) represent schematically the main domains of the calcineurin-dependent NFAT proteins (**a**) (NFAT1/NFATc2, NFAT2/NFATc1, NFAT3/NFATc4, and NFAT4/NFATc3) and the calcineurin-independent NFAT5 (**b**). In (**a**), the enlarged section illustrates the characteristic amino-terminal region with the calcineurin (CN)-docking sites corresponding to the amino acid motifs Pro-x-Ile-x-Ile-Thr (PxIxIT) and Leu-x-Val-Pro (LxVP) (the x position can be occupied by different amino acids), the clusters of phosphorylation sites, and the nuclear localization signal (NLS). The DNA-binding domain is indicated as DBD. The transactivation domains in the amino- and carboxy-terminal regions are indicated as TAD. (**b**) Representation of NFAT5, with the nuclear export (NES) and import (NLS) signals in its amino-terminal region, the DBD, and the long carboxy-terminal region with two glutamine-rich regions (Q). The main transactivation domain of NFAT5 is located in its carboxy-terminal region, although a smaller TAD has been described in the amino-terminal region of one of its isoforms. (**c**) Represents the main features of the DNA-binding domains (DBD) of the calcineurin-dependent NFATs and NFAT5. In the former, the residues involved in contacting with Fos/Jun and Foxp3 are not clustered in a discrete motif but located at separated positions in the primary amino acid sequence. The homodimerization domain of NFAT5 is recognizably similar to that of NF-κB proteins but different to that of the calcineurin-dependent NFATs

also referred to as Rel-homology region (RHR), is about 250 amino acids long, and besides conferring specific DNA recognition, it contains specific residues that enable these NFATs to interact with Fos and Jun proteins (Fig. 1). Most of the residues involved in contacts with Fos and Jun in the calcineurin-dependent NFATs are not conserved in NFAT5. The calcineurin-regulated NFATs contain distinct carboxy-terminal regions of varying length, which have transactivation function and are different for each NFAT (Fig. 1). In addition, several isoforms have been described for the various calcineurin-dependent NFATs. These variants differ mainly in their amino- and carboxy-terminal regions and have been shown to have specific functional properties.

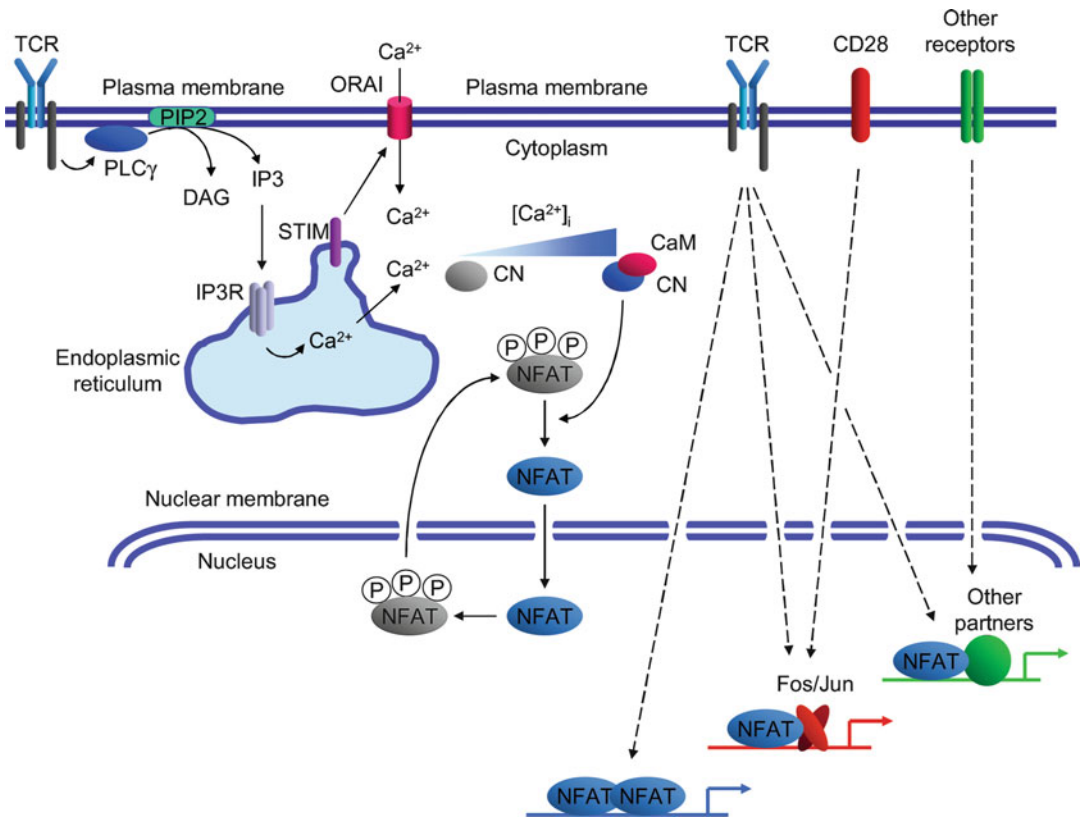
The DNA sequence recognized by the DNA-binding domain (DBD) of NFATs contains a core element "guanine-guanine-adenine-adenine-(adenine/guanine)" (GGAA(A/G)), which can be flanked by different combinations of nucleotides. One important characteristic of the

calcineurin-dependent NFATs is their ability to bind what are known as composite sites in DNA in association with other transcription factors such as homodimers of Jun/Jun, heterodimers of Fos/Jun, or Foxp3 (Macian 2005; Muller and Rao 2010). A prototypical composite site is the ARRE2 found in the enhancer of interleukin-2 (IL-2), an essential T lymphocyte growth factor. As shown for NFAT1, its binding affinity for this site is substantially enhanced by associating with the Fos/Jun heterodimer, which in turn also requires NFAT1 for efficient binding to this site. Importantly, despite that NFAT1 can make specific protein-protein contacts with Fos and Jun, it does not associate with them unless both are simultaneously bound to the appropriate DNA composite sequence and form a ternary complex NFAT-Fos/Jun-DNA. Regarding NFAT5, its DBD can bind the same type of DNA sequence as other NFATs but requires a longer core element "deoxythymidine-deoxyguanosine-deoxyguanosine-deoxyadenosine-deoxyadenosine-deoxyadenosine" (TGGAAA) (Lopez-Rodriguez et al. 1999). Therefore, sites that could be potentially bound by calcineurin-dependent NFATs may not be recognized by NFAT5.

A key functional feature shared by all the calcineurin-dependent NFATs is that their activation is strictly dependent on being dephosphorylated by the calcium- and calmodulin-activated serine/threonine phosphatase calcineurin, also known as PP2B (Fig. 2). Calcineurin is activated in response to elevations of the cytosolic concentration of calcium ion Ca^{2+}, which occurs in response to the engagement of surface receptors capable of activating phospholipase C gamma (PLCγ). Activated PLCγ hydrolyzes the plasma membrane phospholipid component phosphatidylinositol-4,5-bisphosphate (PIP2) to yield diacylglycerol (DAG) and inositol-1,4,5-trisphosphate (IP3). IP3 binds to a specific receptor in the endoplasmic reticulum and induces the release of stored Ca^{2+} into the cytosol, giving rise to a first wave of calcineurin activation, mediated by its association with calcium-bound calmodulin. This initial increase in the concentration of cytosolic calcium ($[Ca^{2+}]_i$) causes the activation of calcium-activated Ca^{2+} channels in the plasma membrane, such as ORAI, causing the influx of extracellular calcium and a further increase of the $[Ca^{2+}]_i$, which in turn causes the activation of a greater number of calcineurin molecules (Muller and Rao 2010). In the absence of calcium-mobilizing stimuli, NFATs are phosphorylated at multiple serines in their amino-terminal region, and in this state, they are maintained in the cytosol and prevented from translocating to the nucleus. The inhibitory phosphorylation of NFAT is maintained by diverse kinases, some of them constitutively active, such as glycogen synthase kinase 3 (GSK3), casein kinase 1 (CK1), and the dual-specificity tyrosine-phosphorylation-regulated kinase (Dyrk), and others inducible in response to diverse stimuli, such as the stress-activated kinase p38, protein kinase A (PKA), and c-Jun N-terminal kinase (JNK) (Macian et al. 2001; Muller and Rao 2010). Interestingly, JNK has been shown to have both inhibitory and stimulatory effects on different NFATs, suggesting that the positive or negative effect of specific kinases on some NFATs might be regulated by the context of other signaling pathways occurring simultaneously.

Although specific aspects of this regulation have been worked out for different NFATs, it is generally accepted that the four calcineurin-dependent NFATs are regulated by a common mechanism based on a conformational change of the amino-terminal region controlled by its phosphorylation status. Phosphorylated NFATs have their nuclear localization signal (NLS) inaccessible to the import machinery, whereas when dephosphorylated, they adopt a different conformation that exposes the NLS (Fig. 2).

When calcineurin is activated, NFATs are dephosphorylated and translocate to the nucleus, where they will bind to specific sites in regulatory regions of their target genes. Calcineurin-mediated dephosphorylation not only enables the nuclear translocation of NFATs but also enhances their DNA-binding capacity and transcriptional activity. Upon cessation of the stimulus and decrease in the $[Ca^{2+}]_i$, calcineurin is inactivated and NFAT rephosphorylated, which causes its dissociation from DNA and export out of the nucleus (Fig. 2).



Nuclear Factor of Activated T Cells (NFAT), Fig. 2 *Schematic representation of the activation cycle of the calcineurin-dependent NFAT proteins*. Phospholipase C gamma (PLCγ) activated by the T cell receptor (TCR) hydrolyzes phosphatidylinositol-4,5-bisphosphate (PIP2) in the plasma membrane to yield diacylglycerol (DAG) and inositol-1,4,5-trisphosphate (IP3). IP3 binds to a specific receptor (IP3R) in the endoplasmic reticulum and induces the release of Ca^{2+} into the cytoplasm. Calcium mobilization can be induced by different types of surface receptors that signal through PLCγ. The ER protein STIM senses the decrease in intra-ER calcium concentration and activates the calcium channel protein ORAI in the plasma membrane, giving rise to the entry of calcium from the extracellular space and a further increase the concentration of cytosolic calcium ($[Ca^{2+}]_i$). Calcium binds to calmodulin (CaM), which in turns activates calcineurin (CN). Calcineurin dephosphorylates the amino-terminal region of NFAT, which undergoes a conformational change that exposes its nuclear localization signal. The nuclear import/export cycle of the calcineurin-dependent NFATs is controlled by the balance between active calcineurin and opposing kinases that phosphorylate the amino-terminal region of NFAT. NFAT can bind DNA alone or in association with other transcriptional partners, such as Fos/Jun, activated by the TCR or other signaling pathways. These functional associations enable NFATs to regulate different transcriptional programs in diverse contexts

NFAT5/TonEBP. This protein is similar to other NFATs only at the level of its DBD, which shows about 45 % homology with those of the calcineurin-dependent NFATs (Aramburu et al. 2006) (Fig. 1). Three NFAT5 isoforms differing in the beginning portion of their amino-terminal regions have been described. NFAT5 binds DNA elements very similar to those recognized by the calcineurin-dependent NFATs, and indeed, its DNA recognition motif "arginine-alanine-arginine-tyrosine-leucine-threonine-glutamic acid-glycine" (RARYLTEG) is highly similar to that of the other NFATs, "arginine-alanine-histidine-tyrosine-glutamic acid-threonine-glutamic acid-glycine" (RAHYETEG). On the other hand, while calcineurin-dependent NFATs can bind DNA efficiently as monomers or dimers depending on the DNA site, NFAT5 is a constitutive homodimer

and needs to be dimeric to bind DNA (Lopez-Rodriguez et al. 2001). It also lacks most of the Fos/Jun-interaction residues and is unable to associate with Fos/Jun at composite sites such as the ARRE2 (Lopez-Rodriguez et al. 1999). Notably, the dimeric structure of NFAT5 resembles that of NF-κB proteins, which constitute a group of transcription factors related to NFATs by virtue of the similarity of their DBD, generically known as Rel-like DBD. In this regard, the dimerization interface of NFAT5 is recognizably similar to that of NF-κB proteins (Lopez-Rodriguez et al. 2001; Aramburu et al. 2006).

The two main distinguishing features of NFAT5 that set it apart from the calcineurin-dependent NFATs are its ability to be activated by hyperosmotic stress and its lack of a calcineurin-regulated module with calcineurin-docking sites and regulatory phosphoserines to control its nucleocytoplasmic localization (Aramburu et al. 2006). Because of these characteristics, some researchers consider NFAT5 not to be a genuine NFAT and prefer to refer to it as TonEBP to indicate its osmotic stress response function. Nonetheless, although NFAT5 has been more extensively characterized as a regulator of osmostress responses, it also has osmostress-independent functions.

In response to osmotic stress, such as when cells are exposed to fluids with elevated sodium concentration, NFAT5 activates the expression of genes whose products encode for enzymes and transporters that allow cells to accumulate by synthesis or uptake from the extracellular medium, substances known as compatible osmolytes. These osmolytes, generally derived from sugars or amino acids, prevent the excessive buildup of sodium ions, and hence ionic strength, that occurs when cells are exposed to hypertonic solutions. Since elevation of the intracellular ionic strength above physiologic levels can be harmful for numerous cellular processes, NFAT5 plays an essential role in allowing cells to survive and maintain proliferative capacity for extended periods under hyperosmotic stress. This function is clearly illustrated by the severe renal phenotype of NFAT5-deficient mice. As cells in the renal medulla are naturally exposed to elevated hypertonicity levels, their survival is dependent on NFAT5, and lack of this factor causes atrophy of the renal medulla and pathological alterations of the morphology and function of the kidney (Aramburu et al. 2006). Besides the kidney, NFAT5 is expressed in essentially all types of mammalian cells, and its osmoprotective function has been shown in cell types as diverse as neurons, nucleus pulposus cells, cardiomyocytes, skeletal muscle, fibroblasts, macrophages, and lymphocytes.

The fact that NFAT5 is expressed in many cell types led researchers to investigate whether NFAT5 could also have osmostress-independent functions. Although this area is still less explored than its function under osmostress, already a number of osmotic stress-independent roles have been identified for NFAT5: it regulates migration in response to integrin signaling in certain carcinoma cell lines, myoblast differentiation, resistance of cardiomyocytes to some chemotherapeutic drugs, development of the embryonic heart, and macrophage activation and inflammatory responses to pathogen-derived products. It is expected that future research will uncover novel functions for this factor.

NFAT Proteins in Immunity

Calcineurin-Dependent NFAT Proteins. Through almost 25 years of recorded NFAT history, the calcineurin-dependent NFATs have been shown to be major regulators of gene expression in immune cells in response to a wide variety of calcium mobilization-coupled receptors. The molecular cloning of individual NFATs combined with gene-targeting strategies in mice has yielded a wealth of information about their functions in different cell types and immune processes. The calcineurin-dependent NFATs regulate the proliferative capacity of T cells, sensitivity to apoptosis inducers, their ability to differentiate towards specialized effector and regulatory phenotypes, and induction of anergy, this latter characterized by the inability of T cell receptor-stimulated lymphocytes to respond to a new restimulation of their T cell receptor (TCR).

This they do by regulating the expression of genes whose products work intracellularly, as well as others encoding for surface receptors and secreted cytokines (Hogan et al. 2003; Macian 2005; Muller and Rao 2010; Hermann-Kleiter and Baier 2010).

The calcineurin-dependent NFATs have been shown to regulate functions of CD4 and CD8 T cells, as well as other types of immune cells, including B lymphocytes, NK cells, macrophages, dendritic cells, and mast cells (Rao et al. 1997). Besides the TCR, different receptors in diverse immune cells can activate NFATs: for instance, the B cell receptor and CD40 in B lymphocytes, Fc receptors in macrophages and NK cells, activating receptors for the major histocompatibility complex (MHC)-class I in NK cells, immunoglobulin E (IgE) receptor in mastocytes, or the C-type lectin carbohydrate receptor Dectin-1 in macrophages and dendritic cells (Muller and Rao 2010).

NFAT functions have been more extensively characterized in $CD4^+$ T lymphocytes, and this section highlights some of the key features of these factors. T cells express three calcineurin-dependent NFATs: NFAT1/NFATc2, NFAT4/NFATc3, and NFAT2/NFATc1. These NFATs can have partially overlapping or redundant functions but also specific ones. For instance, production of IL-2 or tumor necrosis factor-alpha (TNF-α) can be induced by any of the three NFATs, whereas other functions are more selectively dependent on one or another NFAT. This is the case of T cell specialization towards IL-4-producing T helper type 2 (Th2), which is facilitated in the absence of NFAT1 but less effective in lymphocytes lacking NFAT2. The ability of NFAT to cooperate with specific transcription factor partners allows that different combination of signals transduced by surface receptors will give rise to distinct profiles of expressed NFAT-regulated genes. Relevant variables in how NFATs shape particular gene expression profiles are the duration and magnitude of their activation resulting from varying intensities of receptor stimulation, the relative abundance of each NFAT and its respective isoforms, and their temporal overlapping with windows in which other transcription factors such as Fos/Jun or Foxp3 are activated in response to other signals. As an illustrative example of different outcomes regulated by a single NFAT, NFAT1 can promote T cell anergy if cells do not receive appropriate costimulatory signals when activated by their TCR. In this case, NFAT1 induces a particular anergy-associated gene expression program. On the other hand, NFAT1 will enhance T cell activation towards effector phenotypes when T cells receive simultaneous signaling from the TCR in concert with costimulatory receptors such as CD28. Finally, NFAT1 can promote differentiation of inducible T regulatory cells (iTreg) by cooperating with Foxp3 (Muller and Rao 2010).

In summary, the expression of several calcineurin-dependent NFATs in T cells, together with the different functional properties of each NFAT and their ability to interact functionally with other transcriptional regulators, endows T cells with a versatile module to translate signals received from calcineurin-activating receptors in combination with other signals to induce a complex variety of gene expression patterns.

NFAT5/TonEBP. The function of NFAT5 in T cells is much less explored than that of the calcineurin-dependent NFATs. As known for other cell types, NFAT5 plays an important osmoregulatory role in T cells, and this function is required for survival and cell-cycle progression of T cells under osmotic stress in vitro and in vivo. In this regard, NFAT5-deficient mice suffer T cell immunodeficiency, which is in part due to inefficient adaptation to the chronic hypernatremia observed in these mice (Berga-Bolaños et al. 2010). Notably, NFAT5 activated by osmotic stress does not only induce gene products with a direct osmoprotective function but can promote the expression of cytokines, such as TNF-α or lymphotoxin-β, and is a potent transcriptional inducer of CD24, a surface glycoprotein involved in homeostatic cell survival and proliferation, in mature T lymphocytes (Berga-Bolaños et al. 2010).

These observations have suggested that NFAT5 may not just regulate T cell survival under osmostress but perhaps other T cell functions in specific stress contexts.

Independently of its osmoresponsive function, NFAT5 has been recently found to respond to microbial products via Toll-like receptors in macrophages and regulate the expression of inducible nitric oxide synthase (iNOS) and different inflammatory cytokines (Buxadé et al. 2012). This novel function of NFAT5 in anti-pathogen responses reveals a relevant function for this factor in the immune system beyond its previously known osmoregulatory role.

Functions of NFAT Proteins Beyond the Immune System

Essentially, all nucleated cell types express calcineurin-dependent NFATs and NFAT5. The former have been shown to regulate the development of the embryonic cardiovascular system, cardiac function in the adult as well as pathologic cardiac hypertrophy, angiogenesis and activity of endothelial cells, skeletal and smooth muscle cell function, neuronal function, and even glucose and insulin metabolism. Another important aspect of calcineurin-dependent NFATs is their involvement in cancer, both of hematopoietic origin and other types, by virtue of their ability to influence, positively or negatively, the expression of cell-cycle regulatory proteins such as cyclin A and cyclin-dependent kinase 4 (CDK4), apoptotic inducers such as Fas ligand, processes important for metastasis (cellular chemotaxis, invasion and migration capacity of tumor cells), and support of tumor growth via angiogenesis (Muller and Rao 2010; Gachet and Ghysdael 2009; Mancini and Toker 2009). The wide range of processes in multiple cell types that are sensitive to the signaling-transcription axis formed by calcineurin and NFATs make this pathway attractive for pharmacological intervention in different scenarios but also pose the problem of achieving selectivity.

Pharmacological Relevance of NFAT Proteins

Even before NFATs were identified and their functional features elucidated, two microbial products, cyclosporin A produced by the fungus *Tolypocladium inflatum* and FK506 (tacrolimus) produced by the bacterium *Streptomyces tsukubaensis*, were revolutionizing the field of transplantation due to their potent immunosuppressive effect. Both compounds were found to inhibit the same intracellular target, calcineurin. They do this upon binding to intracellular proteins generically known as immunophilins. While neither compound can bind to calcineurin, the respective complexes formed by cyclosporin A associated with cyclophilin, and FK506 associated with FK506-binding protein 12 (FKBP12), are able to bind with very high affinity to the A subunit of calcineurin near its active site (Li et al. 2011). Of note, another bacterial compound with immunosuppressive properties, rapamycin (also known as sirolimus), produced by the bacterium *Streptomyces hygroscopicus*, also works by forming a complex with FKBP12, although the target of this complex is not calcineurin but the kinase mTOR, a central regulator of cell growth and biosynthesis. Since the finding that calcineurin was essential for the function of NFATs, it became clear that one key immunosuppressive mechanism of cyclosporin A and FK506 was the inhibition of these factors.

Different approaches in cells or mouse models have shown that suppression or overactivation of NFAT function, either directly or by interfering with calcineurin and NFAT-regulatory kinases, can affect numerous processes from immune responses to cardiovascular function to tumor progression. Thus, the notion of pharmacologic manipulation of NFATs for therapeutic intervention would be attractive in different scenarios. Potential approaches might fall into four main categories: (a) targeting signaling pathways that control the activity of calcineurin and NFAT-regulatory kinases or pathways impinging on the activation of NFAT transcriptional

partners; (b) interfering with protein-protein interactions between NFATs and regulators such as calcineurin or particular transcriptional partners, such as AP-1 or Foxp3; (c) altering the expression level of endogenous NFATs and their regulators by, for instance, using RNA interference or other approaches that could increase or decrease their stability and degradation; and (d) targeting the expression or activity of NFAT-induced gene products. At present, the calcineurin inhibitors cyclosporin A and FK506 are the only drugs targeting the direct activation of NFAT that are used in the clinic, but it can be expected that future studies might spur the development of therapeutic approaches based on these factors. In this regard, one avenue towards developing NFAT-selective inhibitors was opened by the finding that calcineurin needs to dock at specific sites (the PxIxIT and LxVP motifs) on NFATs in order to dephosphorylate them (Li et al. 2011). Experiments showed that intracellular expression of short peptides with PxIxIT or LxVP-like sequences could inhibit the activity of NFATs in live cells. A further development came with the identification of small molecule chemicals that bound to calcineurin and impaired its interaction with the PxIxIT site of NFATs (Roehrl et al. 2004). These cell-permeant compounds were capable of inhibiting the activation of NFATs by calcineurin and induction of NFAT-dependent cytokine genes without impairing the phosphatase activity of calcineurin. Although further research will be needed to elucidate whether these compound, or others using a similar mechanism of action, can be made into effective NFAT inhibitors in animal models and finally translated to humans, these findings provide a stimulating example of the potential for the development of novel types of NFAT modulators.

Definition

Paraneoplastic neurological syndromes (PNS) are a group of disorders resulting from damage to the nervous system in the setting of cancer, but remote from the site of cancer, and not related to metastasis, infection, or metabolic derangements otherwise associated with cancer. They result from direct damage to neural tissue through an immune-mediated mechanism itself triggered either by an immunologic disturbance caused by the tumor or by tumors that express neuronal proteins. PNS may affect either the central or peripheral nervous system or both, and they may be isolated to a single neuronal cell type or site or affect more diffuse involvement of the nervous system. Antineuronal antibodies, useful as diagnostic markers of PNS and the underlying cancer, are often associated with these immune responses, some being strongly associated with specific tumor types, some less so (Graus et al. 2004). Several recognizable clinical syndromes have been identified (Table 1) and will be the focus of discussion in this entry.

Clinical Features

Symptom onset is usually acute to subacute, over weeks to months, producing severe progressive disability followed by stabilization. While PNS may present in a known cancer patient, most commonly it is the presenting symptom in a previously healthy person. Consequently, as the neurologist will likely be the first physician to encounter the patient given the neurologic nature of these syndromes, it is important for her/him to be familiar with these syndromes, recognize them as possibly paraneoplastic, and initiate a search for an underlying neoplasm. Most PNS are neurologically debilitating and, given an underlying pathology of immune-mediated neuronal loss, predominately irreversible.

Paraneoplastic syndromes are often associated with evidence of inflammation in the nervous system including pleocytosis (30–40 cells/ml), elevated protein levels (50–100 mg/dL), and positive oligoclonal bands in the cerebrospinal fluid (Darnell and Posner 2003). Inflammatory infiltration of tumor tissue in PNS suggests a similar immune attack against the tumor itself. Imaging studies of the nervous system are usually normal, although there may be abnormalities on magnetic resonance imaging (MRI), such as hyperintense

Paraneoplastic Neurological Syndromes, Overview, Table 1 Paraneoplastic syndromes of the nervous system

Central nervous system
Multifocal encephalomyelitis
Limbic encephalitis
Anti-NMDA receptor encephalitis
Cerebellar degeneration
Opsoclonus-myoclonus
Optic neuritis
Retinal degeneration
Brainstem encephalitis
Stiff person syndrome
Motor neuron disease and motor neuronopathy
Necrotizing myelopathy
Chorea
Parkinsonism
Tremor
Peripheral nervous system
Sensory neuronopathy
Motor neuropathy
Acute sensorimotor neuropathy (Guillain-Barre, Plexitis)
Chronic sensorimotor neuropathy
Neuropathy associated with malignant monoclonal gammopathies
Vasculitis of nerve and muscle
neuromyotonia
Chronic gastrointestinal pseudo-obstruction/autonomic neuropathy
Lambert-Eaton myasthenic syndrome
Myasthenia gravis
Inflammatory myopathy
Acute necrotizing myopathy

T2/fluid-attenuated inversion recovery (FLAIR) signal and contrast enhancement of the mesial temporal lobes in limbic encephalitis (Lawn et al. 2003) (see Pathology below).

Another unifying characteristic of PNS is the discovery of antibodies against neural tissue in serum and cerebrospinal fluid. Many of these antibodies have been well characterized through the use of antiserum samples from patients with PNS to screen complementary DNA libraries to determine the target antigens (Darnell 2004, Musunuru and Darnell 2001). These target antigens are termed onconeural antigens and are expressed by both the tumor cells and neuronal tissue. Discovery of these antibodies aids in diagnosis, especially when an occult malignancy is undetectable. Many of these antibodies, some named after the surname of the index patient, are specific to one or a group of clinical syndromes as well as tumor type, suggesting the potential site of an underlying cancer (anti-Hu antibody suggests small-cell lung cancer, anti-Yo suggests breast or ovarian cancer) (Table 2). Although the presence of paraneoplastic antibodies in the appropriate clinical setting is virtually diagnostic, the yield can be low, less than 1 % in a large study from the Mayo Clinic (Pottock et al. 2004). Furthermore, the presence of antibodies does not confer disease, as some paraneoplastic antibodies are present in cancer patients without a PNS, usually in low levels, and in <1 % of healthy individuals (Raspotnig et al. 2011).

Epidemiology

PNS are rare, estimated to occur in 0.01 % of cancer patients (Darnell and Posner 2003), but certain malignancies are more commonly associated with PNS. Fewer than 1 % of breast or ovarian cancer patients develop PNS, approximately 1–3 % of patients with small-cell lung cancer develop Lambert-Eaton myasthenic syndrome (Suete et al. 2004), 40 % of thymoma patients develop myasthenia gravis (Vernino and Lennon 2004), and 10 % of monoclonal gammopathy patients develop peripheral neuropathy (Latov 1995).

Other malignancies commonly associated with PNS include Hodgkin's and non-Hodgkin's lymphoma, testicular cancer, and neuroblastoma. However, virtually any neoplasm may be associated with a paraneoplastic syndrome (Bataller and Dalmau 2003).

Diagnosis

Over the years, certain clinical presentations have been found to represent classic paraneoplastic syndromes and to be associated with certain malignancies and well-characterized onconeural antibodies. There is, however, significant variability. Not all patients with PNS have paraneoplastic antibodies and not all patients with paraneoplastic antibodies have a PNS.

Paraneoplastic Neurological Syndromes, Overview, Table 2 Antibodies associated with paraneoplastic neurologic disorders

Antibody	Associated cancer	Syndrome
Antibodies that are markers of paraneoplasia		
Anti-Hu	SCLC, other	Encephalomyelitis, sensory neuronopathy
Anti-Yo	Gynecological, breast	Cerebellar degeneration
Anti-Ri	Breast, gynecological,	SCLC cerebellar ataxia, opsoclonus, brainstem encephalitis
Anti-Tr	Hodgkin's lymphoma	Cerebellar degeneration
Anti-CV2/CRMP5	SCLC, thymoma, other	Encephalomyelitis, striatal encephalitis (chorea), cerebellar degeneration, uveitis, peripheral neuropathy
[a]Anti-Ma proteins	Testicular germ cell tumors and other neoplasms	Limbic, diencephalic (hypothalamic), and upper brainstem encephalitis; rarely cerebellar degeneration
Anti-amphiphysin	Breast, SCLC	Stiff man syndrome, encephalomyelitis
Anti-NMDAR	Teratoma of the ovary or mediastinum	Encephalitis with predominant psychiatric symptoms, autonomic dysfunction, dyskinesias, hypoventilation.
		Infrequently presents as classical limbic encephalitis
Antibodies that are not markers of paraneoplasia		
(Associated with the indicated neurologic syndromes whether they are paraneoplastic or not)		
Anti-VGKC	Thymoma, SCLC	Neuromyotonia, limbic encephalitis, Morvan's syndrome
Anti-VGCC	SCLC	LEMS, cerebellar degeneration
Anti-AChR	Thymoma	Myasthenia gravis
(*muscle*)		
Anti-AChR	SCLC and other	Autonomic neuropathy
(*neuronal*)		

[a]Antibodies limited to Ma2 (also called anti-Ta antibodies) usually associate with limbic and brainstem encephalitis and germ cell tumors. Antibodies directed at Ma1 and Ma2 usually associate with brainstem encephalitis, cerebellar degeneration, and several types of cancer (lung, breast, ovary, among others). *Antibodies in italics* denote that are directed against cell membrane antigens. The other antibodies are directed against intracellular antigens. *NMDAR* *N*-methyl-d-aspartate receptor, *VGKC* voltage-gated potassium channels, *VGCC* voltage-gated calcium channels, *LEMS* Lambert-Eaton myasthenic syndrome, *AChR* acetylcholine receptor (From Paraneoplastic Syndromes of the Nervous System. Myrna R. Rosenfeld MD, PhD, and Josep Dalmau, MD, PhD. Originally published in *Current Clinical Oncology*: *Cancer Neurology in Clinical Practice*, Edited by: D. Schiff, S. Kesari, and P. Y. Wen © Humana Press, USA part of Springer Science+Business Media. 2010. With permission)

Furthermore, there are patients in whom no tumor is ever detected despite presenting with classic PNS and high titers of a well-characterized onconeural antibody (Greenlee 2004).

To address the diagnostic difficulty, a panel of neurologists developed guidelines to provide more rigorous diagnostic criteria for PNS (Graus et al. 2004). The panel began by defining a list of "classical" syndromes, which included encephalomyelitis, limbic encephalitis, subacute cerebellar degeneration, opsoclonus-myoclonus, subacute sensory neuropathy, chronic gastrointestinal pseudo-obstruction, Lambert-Eaton myasthenic syndrome, and dermatomyositis. Myasthenia gravis and paraproteinemic neuropathies were excluded from this list, as historically they are discussed in other clinical forums. The panel then defined a list of "well-characterized" paraneoplastic antibodies, based on their association with neurological syndromes, the number of case reports, their frequency in patients without cancer, and their identification among different studies. These include anti-Hu, anti-Yo, anti-CV2, anti-Ri, anti-Ma2, and anti-amphiphysin. Diagnostic criteria were then created to define a given neurological syndrome as "definite" or "possible" PNS (Table 3).

As noted, PNS usually presents in patients with no known cancer history. In 80 %, cancer will be diagnosed within months to years (Honnorat and Antoine 2007). If the symptoms represent a classic PNS or if PNS is suspected,

Paraneoplastic Neurological Syndromes, Overview, Table 3 Diagnostic criteria for paraneoplastic neurological syndromes

Definite PNS
1. A classical syndrome and cancer that develops within 5 years of the diagnosis of the neurological disorder
2. A nonclassical syndrome that resolves or significantly improves after cancer treatment without concomitant immunotherapy provided that the syndrome is not susceptible to spontaneous remission
3. A nonclassical syndrome with onconeural antibodies (well characterized or not) and cancer that develops within 5 years of the diagnosis of the neurological disorder
4. A neurological syndrome (classic or not) with well-characterized onconeural antibodies (anti-Hu, Yo, CV2, Ri, Ma2, amphiphysin) and no cancer
Possible PNS
1. A classical syndrome, no onconeural antibodies, no cancer but a high risk to have an underlying tumor
2. A neurological syndrome (classic or not) with partially characterized onconeural antibodies and no cancer
3. A nonclassical syndrome, no onconeural antibodies, and cancer present within 2 years of diagnosis

(Graus et al. 2004, with permission)

MRI, neurophysiologic studies, cerebrospinal fluid analysis, and evaluation for serum paraneoplastic antibodies are warranted. If onconeural antibodies are present or if clinical suspicion is high, a search for underlying cancer is undertaken with both full body CT and ^{18}F fluoro-2-deoxy-glucose (FDG)-positron emission tomography (PET) scanning to increase sensitivity of tumor diagnosis (Younes-Mhenni et al. 2004).

If cancer is not detected initially, continued surveillance at regular intervals is necessary (Graus et al. 2001; Raspotnig et al. 2011; Titulaer et al. 2011). If the cancer detected is not one commonly associated with a classical syndrome, further evaluation is recommended to identify a second, more typical malignancy, unless it can be demonstrated that the primary tumor expresses the onconeural antigen in question (Graus et al. 2001, 2004).

Pathophysiology

Currently, autoimmunity is postulated to underlie the pathophysiology of PNS. In PNS patients, tumor cells express antigens normally found only in the nervous system, an immunologically privileged site (Darnell and Posner 2006). The onconeural antigen is identified by the immune system as foreign; the body mounts an immune attack, produces an antitumor immune response, and suppresses tumor growth, indeed accounting for the difficulty at presentation in identifying the underlying cancer (Graus et al. 2001). An antitumor immune response is commonly seen without an autoimmune component, given the presence of paraneoplastic antibodies in non-PNS patients with cancer, and may portend compete response to therapy and improved survival (Darnell and DeAngelis 1993).

In a subset of PNS patients, the immune system recognizes onconeural antigens in normal nervous tissue and mounts an immune attack against that normal tissue. While paraneoplastic antibodies may be present in non-PNS patients with cancer, titers are usually considerably higher in PNS patients (Roberts and Darnell 2004). High cerebrospinal fluid (CSF) paraneoplastic antibody titers in PNS affecting the brain indicate local synthesis within the central nervous system, from B cells that crossed the blood–brain barrier.

The function of paraneoplastic antigens in PNS remains unclear but may relate to the relative roles of humoral versus cellular immunity. Certain antibodies have a clear role in the clinical syndrome, such as voltage-gated calcium channel antibodies (VGCC-Ab) in Lambert-Eaton myasthenic syndrome (LEMS) and acetylcholine receptor antibodies (AchR-Ab) in MG, evidenced by the development of the characteristic electrophysiologic abnormalities in mice following passive transfer of purified immunoglobulin G (IgG) (Kim 1986). Similar mechanisms seem to occur in PNS that affect the nervous system outside the blood–brain barrier when the target antigens are cell surface receptors. However, many onconeural antigens are expressed intracellularly, within the blood–brain barrier, and passive transfer of these antigens into experimental animals does not produce disease or cause injury to cultured neurons in vitro (Tanaka et al. 2004). In these instances, a cellular component to the immune attack is believed to be responsible. Clear evidence of such is demonstrated in patients with paraneoplastic

cerebellar degeneration where circulating, antigen-specific, cytotoxic T lymphocytes (CTL) are present in the cerebrospinal fluid (Roberts and Darnell 2004), suggesting, in certain PNS, that while paraneoplastic antibodies may play a crucial role in diagnosis, they have little role in disease pathogenesis.

The number of known paraneoplastic antibodies has been steadily growing since the mid-1980s, suggesting that further antibodies are yet to be discovered (Table 3). Consequently, suspected PNS patients in whom no known antibody is detected may, on further testing, have a previously unrecognized antibody. Therefore, a negative antibody assay does not rule out PNS or the presence of an underlying neoplasm.

Pathology

Histologically, PNS, as a group, demonstrate neuronal loss, gliosis, microglial proliferation, and perivascular lymphocytic inflammatory infiltrates, usually T cells, but occasionally, plasma cells. In limbic encephalitis, neuronal loss and inflammation predominantly affects the medial temporal and inferior frontal lobes, the insular cortex, and the cingulate gyrus. The medulla is the primary focus of involvement in brainstem encephalitis, whereas the Purkinje cells undergo severe loss in paraneoplastic cerebellar degeneration. In the opsoclonus-myoclonus-ataxia syndrome, no specific pathology is described but Purkinje cells will be lost in 50 %. Dorsal root ganglia demonstrate inflammation and cell loss in paraneoplastic sensory neuronopathy. Electron microscopy plays no role in PNS diagnosis but may be useful in demonstrating microorganisms which can cause infectious encephalitis that mimics the histology of PNS (Fuller et al. 2010).

PBC Genetics

Pietro Invernizzi
Liver Unit and Center for Autoimmune Liver Diseases, Humanitas Clinical and Research Center, Rozzano, MI, Italy

Synonyms

Chronic nonsuppurative destructive cholangitis; Primary biliary cirrhosis

Primary Biliary Cirrhosis

Primary biliary cirrhosis (PBC) is a chronic cholestatic liver disease characterized by progressive destruction of small/medium intrahepatic bile ducts which leads to cirrhosis and finally to liver transplantation or death (Invernizzi et al. 2010). PBC is a rare condition being present in about 1 of 1,000 women over the age of 40, and ursodeoxycholic acid is the only approved therapy. Liver transplantation is also a possible therapeutic option in patients with end-stage liver disease. The presence of specific serum and cell-mediated responses against defined self-antigens, the increased risk of developing PBC or another autoimmune disorder among family members, and a striking female predominance (female to male ratio up to 10:1) indicated the autoimmune pathogenesis of PBC (Invernizzi et al. 2008). The current hypothesis on its etiopathogenesis implies that the disease results from a genetic predisposition that is permissive for an unknown environmental factor (Invernizzi et al. 2010).

The Background Evidence for Genetic Predisposition in PBC

In the past, a scenario named "familial PBC" has been proposed based on a number of studies reporting an increased risk of developing PBC within family members of affected individuals (Hirschfield and Invernizzi 2011). The main part of these studies as well as population-based epidemiological reports were performed in Great Britain, where the prevalence rates of familial PBC was reported to be 6.4 % (Jones et al. 1999). A number of studies from North America, Europe, and Japan reported a similar figure ranging between 3.8 % and 9.0 %. Also the sibling relative risk, another estimate of the familial prevalence of PBC, was found to be increased (Jones et al. 1999). Finally, a recent large-scale US study showed an increased risk of disease (odds ratio at 10.7) in first-degree relative with PBC (Gershwin et al. 2005). Of course, these findings might be explained by some shared environmental factors by family members. Also the coexistence with other autoimmune diseases in more than one third of patients with PBC strongly suggest a role for genetic factor in this disease (Gershwin et al. 2005). Again, by evaluating eight monozygotic and eight dizygotic twin pairs in which at least one subject was affected by PBC, a concordance rate of 63 % was found, the highest among autoimmune diseases (Selmi et al. 2004). Finally, a role for genetics in PBC is also suggested by animal models of this disease (Hirschfield and Invernizzi 2011), being most of them spontaneous models due to a number of different genetic changes.

Non-HLA Associations and PBC

A large number of classical case-control studies tried to identify genes with a role in disease susceptibility and progression by evaluating one or few single-nucleotide polymorphisms (Hirschfield and Invernizzi 2011). Because of the autoimmune nature of PBC, most of these genes were already implicated in other autoimmune disorders and/or code for immune-related molecules, such as cytotoxic T lymphocyte antigen-4 (CTLA-4); tumor necrosis factor (TNF); vitamin D receptor; caspase 8; toll-like receptors; interleukins (ILs) 1, 2, and 10; and numerous cytokine and chemokine receptors (Hirschfield and Invernizzi 2011). However, such approaches have led to very few insights into the genetic

basis of PBC, mainly for small sample size and lack of solid replication. The data related to CTLA-4 gene association studies provide a paradigmatic example of a long list of studies performed with a long story of contrasting evidences and a not yet clear answer. Classical candidate gene studies with appropriate size and replication should only focus on investigating variant frequencies in different geographical areas, on dissecting interaction between risk loci, and on risk loci influencing outcomes, symptoms, and treatment response.

Role of Sex Chromosome Defects

It has been proposed that the presence of sex chromosome defects might explain both the genetic predisposition to the disease and the female preponderance in PBC (Bianchi et al. 2012). Indeed, it has been reported an age-dependent enhanced monosomy X in the peripheral white blood cells of women with PBC (Invernizzi et al. 2004), we later demonstrated that one X chromosome is preferentially lost (Miozzo et al. 2007), and finally that epigenetic factors influencing PBC onset are more complex than methylation differences at X-linked promoters (Mitchell et al. 2011).

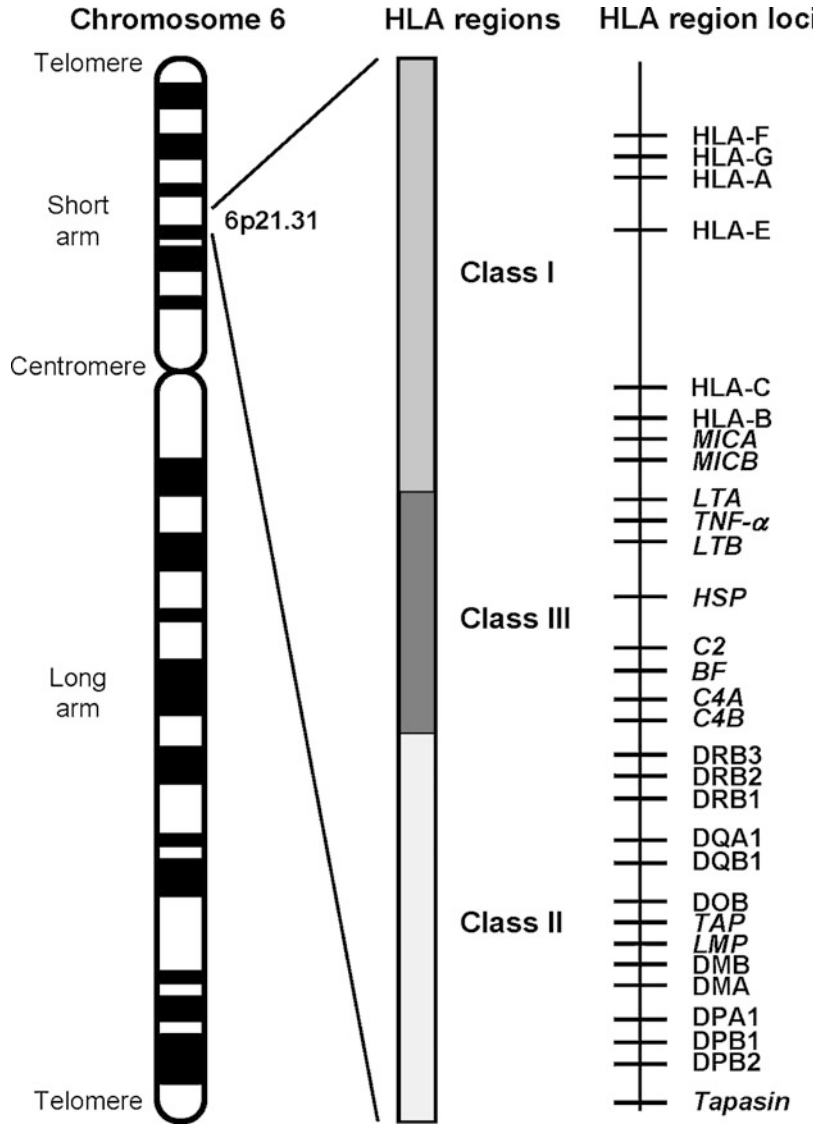
Human Leukocytes Antigen (HLA) Associations and PBC

The human leukocyte antigen (HLA), located in the major histocompatibility complex, is one of the most widely studied regions in human genome because it contains important genetic information of many complex genetic diseases (Invernizzi 2011) (Fig. 1). The role of HLA genes have yet to be fully dissected, but it is known that HLA genes encode cell-surface molecules that, by means of peptides presentation, mediate immunological events, such as cellular immune responses to tumors and pathogens, or definition of self-tolerance. Similar to other genetically complex diseases (Invernizzi 2011), HLA has been extensively studied in PBC, but for a long time data have suggested only a low risk conferred by the HLA DRB1*08 allele (Invernizzi 2011). The reason was likely because early studies manifested limitations such as insufficient statistical power and lack of careful matching between cases and controls and because multiple replications have rarely been carried out.

Only recently the story began to change when, in order to overcome these flows, it has been evaluated the HLA variants in the largest PBC series ever reported (Invernizzi et al. 2008, 2005), thus showing that PBC susceptibility is associated not only with the HLA DRB1*08 allele but also with the protective DRB1*11 and DRB1*13 alleles. A finding later confirmed in other geographical areas (Donaldson et al. 2006). Interestingly, because these protective alleles influence the penetrance of a number of infectious agents, these findings support the infectious theory in PBC origin. However, the interest for HLA genes in PBC arising from these studies was overcome by the three recent genome-wide association studies (GWAS) in PBC which identified the HLA region as the strongest associations (Hirschfield et al. 2009; Liu et al. 2010; Mells et al. 2011). Even more interesting a recent study was able to better define the association of PBC with HLA, by genotyping 676 Italian cases and 1440 controls with dense single-nucleotide polymorphisms (SNPs) for which classical HLA alleles and amino acids were imputed (Invernizzi et al. 2012) (Fig. 2). Interestingly, not only has it been demonstrated that the HLA signals can be attributed to classical DRB1 and DPB1 genes, but it has been provided evidences by conditional analyses supporting a predominant role of DRB1 (mostly *08, *11 and *14) and the independent association of DPB1 (Invernizzi et al. 2012) (Fig. 3).

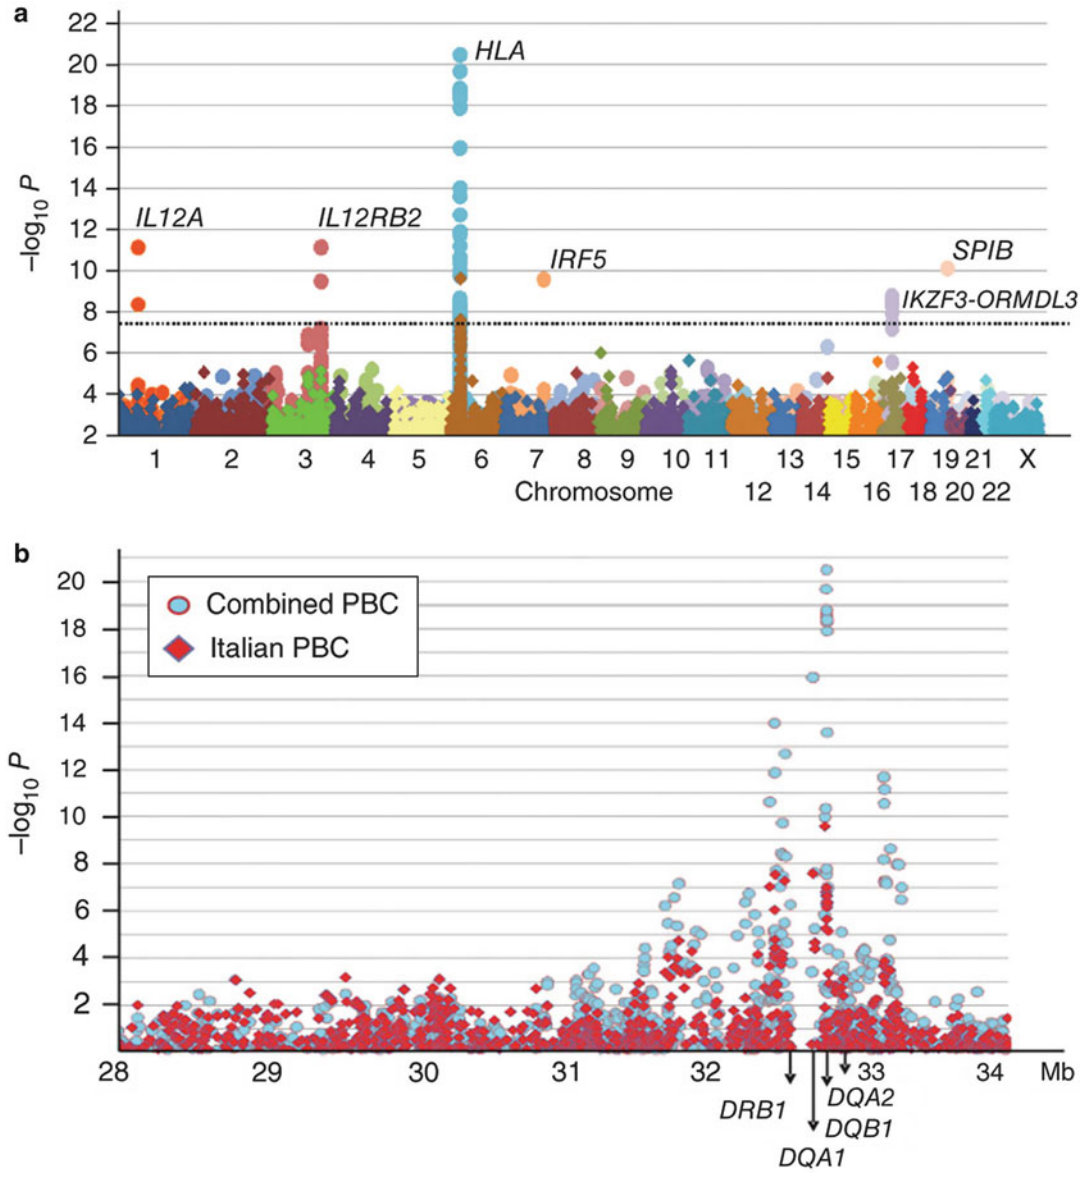
Hints from GWAS in PBC

Since the recent completion of the human genome sequence and thanks to impressive advances in molecular technology, the field of human genetics has recently changed, and we are now witnessing an explosion of new information about the allelic architecture of PBC as well as of many other human complex diseases (Hirschfield and Invernizzi 2011). The three GWAS in PBC identified a number of non-HLA loci, with plausible candidate genes that indicate

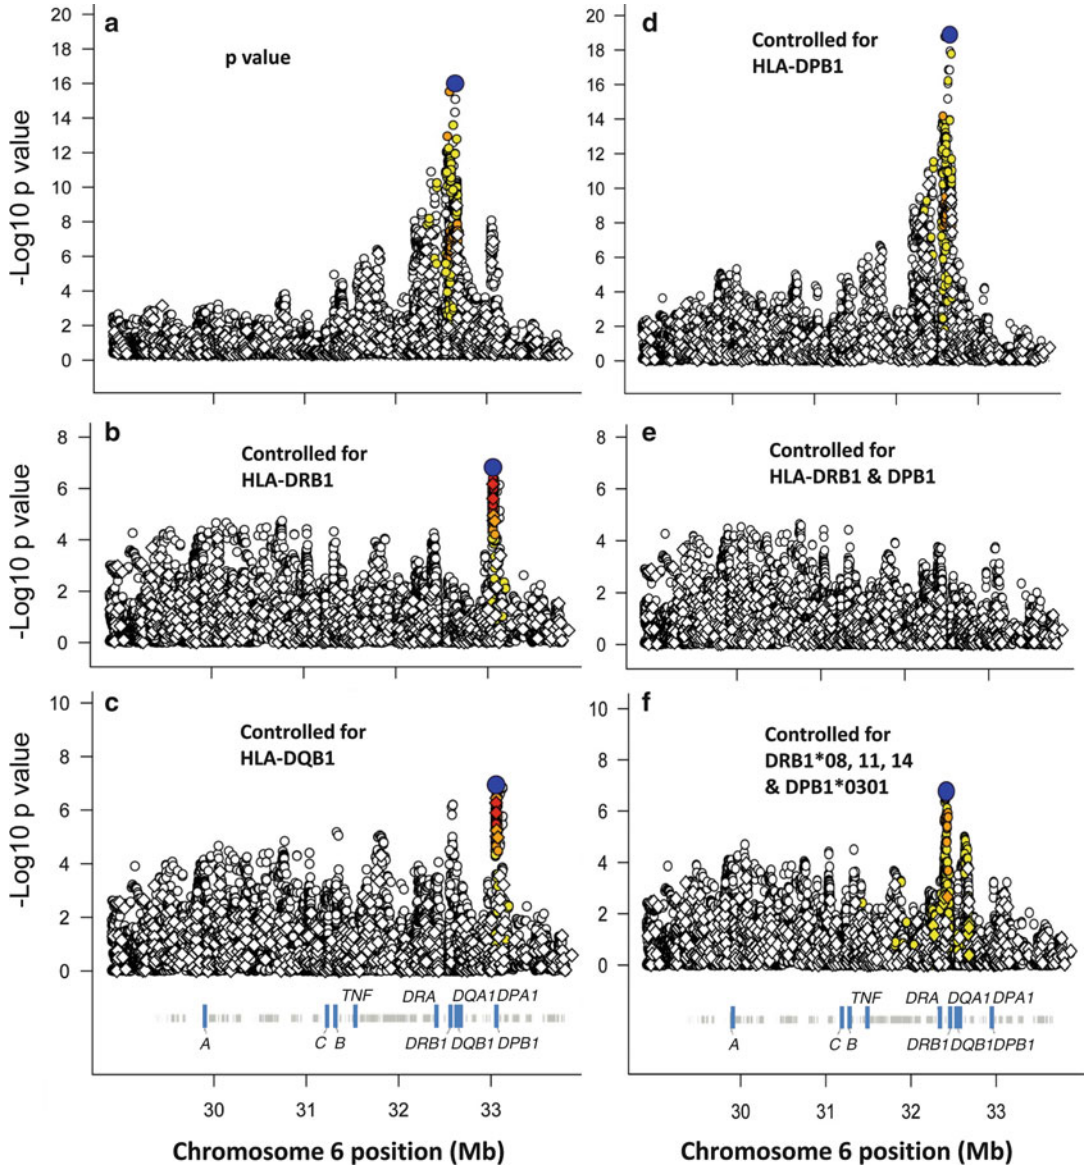


PBC Genetics, Fig. 1 *Human leukocyte antigen (HLA) complex on human chromosome 6.* The small region (6p21.31) in the short arm of chromosome 6 is conventionally divided into three regions (class I, II, and III) and contains many loci that are involved in inflammatory responses. Some of them are shown. Abbreviations: *MICA* major histocompatibility complex class I chain genes A; *MICB* major histocompatibility complex class I chain genes B; *LTA* lymphotoxins A; *TNF-a* tumor necrosis factor-*a*; *LTB* lymphotoxins B; HSP heat-shock protein; *C2* complement component 2; *BF* complement factor B; *C4A* and *C4B* complement components 4A and 4B, respectively; *TAP* transporter associated with antigen processing; *LMP* large multifunctional protease; Tapasin TAP-binding protein (Reproduced with permission of the Hepatology; © 2012. All rights reserved)

the involvement of the innate and adaptive immune systems in the etiopathogenesis of PBC (Hirschfield et al. 2009; Liu et al. 2010; Mells et al. 2011). The first GWAS was performed in cases from North America (Hirschfield et al. 2009), then more solid data were provided by combining datasets from the North American GWAS with a separate Italian GWAS (Liu et al. 2010), and finally a UK GWAS was reported (Mells et al. 2011). Taken together, these findings support the role for the TNF, TLR, and NF-kB pathways, and among the associations consistently reported are those with the IL12A and IL12RB2 loci, the gene encoding interferon regulatory factor 5 (IRF5), the gene encoding the SPi-B transcription factor (SPIB) as well as two other loci, the gene encoding the IKAROS family zinc finger 3 (IKZF3), and that encoding ORM1-like 2 (ORMDL3) also implicated in risk for other autoimmune diseases. Suggestive associations were also observed between PBC and DENND1B and the signal transducer and



PBC Genetics, Fig. 2 *Results of genome-wide association tests for PBC*. The ordinate shows the level of significance for each SNP along each chromosome (**a**) or for the HLA region on chromosome 6 (**b**). The Italian PBC subset (*diamond symbols*) and combined European dataset (*circle symbols*) are shown. The *dashed line* corresponds to $P = 5 \times 10^{-8}$. For HLA, the strongest association was for rs7774434 for both the Italian alone ($P = 2.05 \times 10^{-11}$, odds ratio = 1.74) and for the combined dataset ($P = 1.31 \times 10^{-27}$, odds ratio = 1.71). Abbreviations: HLA-DQB1 denotes the gene encoding HLA class II DQ β-chain 1; IL12A, the gene encoding interleukin-12α; IL12RB2, the gene encoding interleukin-12 receptor β2; IRF5, the gene encoding interferon regulatory factor 5; SPIB, the gene encoding the SPi-B transcription factor; IKZF3, the gene encoding the IKAROS family zinc finger 3; and ORMLD3 encoding ORM1-like 2 (Reproduced with permission of the Nature Genetics; © 2010. All rights reserved)



PBC Genetics, Fig. 3 *Analysis of the HLA region association signals in PBC*. In each panel, the symbols show the strength of the association signal (ordinate) for the corresponding position (Mb, HG19) on chromosome 6 (abscissa). For panel **A**, the *p* value before conditioning is shown. For panels **B–F**, the *p* values are shown after conditioning on the HLA determinant(s) indicated in the panel. The *blue color-coded symbols* denote the strongest associated marker with *p* value $<10^{-6}$, and the other markers are color coded to indicate marker LD with the strongest associated marker: markers with strong LD ($r^2 > 0.8$) (*red*), moderate LD ($r^2 > 0.5$) (*orange*), weak LD ($r^2 > 0.2$) (*yellow*), and little or no LD (*open symbols*) are shown. The SNPs with the strongest associations were rs115721871 at bp 32653792 (panels **A** and **D**), rs9277558 at bp 33056711 (panels **B** and **C**), and rs9268668 at bp 32413889 (panel **F**) (Reproduced with permission of the Genes and Immunity; © 2012. All rights reserved)

activator of transcription 4 (STAT4), two other loci associated with other autoimmune conditions. It is to note that the list of associate genes is still growing and the most recent UK GWAS identified novel associations between PBC and loci, such as NFKB1, IL7R, CD80, CXCR5, and TNFAIP2 (16). This suggests caution and the reasonable need to focus our future research

studies, for example, to rare variants or to copy number variants or to gene expression. A second observation is the impressive consistency among the findings of these three GWAS, thus indicating the presence of a common genetic pattern for PBC. In the future it will be important to replicate the reported associations also in non-European populations. Indeed, a recent study from Japan failed to confirm some GWAS-associated variants (Tanaka et al. 2011).

Conclusions

It is currently believed that the development of PBC, as well as of most of complex diseases, requires that an environmental factor, particularly an infection, initiates an autoimmune reaction in a genetically predisposed individual. However, although strongly implicated by family and twin studies, no specific genetic factors involved in susceptibility to PBC were identified. Up to date, we tried to discover autoimmune risk variants for PBC pathogenesis, but further studies will allow to identify more of the common and uncommon gene variants associated with disease and additional genetic variants that explain sub-phenotypes of PBC and its outcome. Taken together this has the potential to allow the identification of novel therapeutic options.

Pemphigus

Bryan D. Sofen and Nicholas A. Soter
The Ronald O. Perelman Department of Dermatology, New York University School of Medicine, New York, NY, USA

Subcorneal Blistering Diseases

Pemphigus Foliaceus

Synonyms

Fogo selvagem (endemic form in South America); Superficial pemphigus

Introduction/Definition

The term "pemphigus" once represented most of the bullous diseases of the skin, but they have been reclassified with advances in diagnostic testing. Pemphigus now refers to a disease with several subgroups that are characterized by autoantibodies of the IgG type which are directed against epidermal cadherins, a family of calcium-dependant cell-cell adhesion glycoproteins. Cell-cell adhesion is mediated by the classic cadherins (E-, P-, and N-cadherins) and the desmosomal cadherins (desmogleins and desmocollins) that interact with plaque proteins α- and β-catenin, as well as with plakoglobin.

Pemphigus vulgaris and pemphigus foliaceus are the two primary subtypes, with unique target antigens (desmoglein-3 in vulgaris and desmoglein-1 in foliaceus) that cause a difference in the level of cleavage in the epidermis. The clinical phenotype correlates with the target antigen. However, cases may not show this traditional relationship, which indicates that antidesmoglein antibodies are not the sole effectors in pemphigus (Herrero-Gonzalez et al. 2006).

Accounting for 10-20 % of pemphigus cases and (unlike pemphigus vulgaris) which affects children and young adults, pemphigus foliaceus is usually sporadic, but endemic cases have been reported in Tunisia and Brazil (Diaz et al. 1989). HLA types D1, DRB1, DR4, and DQ1 have been linked to the development of this disorder (Moraes et al. 1997).

Clinical

The blistering in pemphigus foliaceus, which is less severe than that observed in pemphigus vulgaris, is high in the epidermis, either just beneath the stratum corneum or in the granular layer. Intact, flaccid blisters are rarely seen, with widespread scaling and well-demarcated, crusted erosions being more common. Nikolsky's sign, which is blistering induced by rubbing the skin, is positive in pemphigus foliaceus. There is little mucosal involvement in pemphigus foliaceus as the principal target antigen, desmoglein-1, is only weakly expressed in mucosa (Shirakata et al. 1998). Pemphigus foliaceus is a chronic condition with appreciable morbidity but is rarely fatal, possibly owing to the superficiality of the lesions and lack of mucosal involvement.

Cleavage at desmoglein-1 is also observed with exfoliative toxins from *Staphylococcus aureus* which lead to (clinically and histopathologically similar) bullous impetigo and staphylococcal scalded skin syndrome.

By histopathologic examination, acantholytic cells (separated keratinocytes with lost cell-cell adhesion) may be difficult to detect in pemphigus foliaceus owing to the fragility of blisters but may be found on the blister roof. A loss of desmosomes is observed with dyskeratosis (abnormal keratinization) and detachment of keratin tonofilaments.

Pathophysiology

In pemphigus foliaceus, pathogenic autoantibodies target desmoglein-1 (Dsg-1), which is a 160 kDa desmosomal cadherin. Antibodies

recognize epitopes of the extracellular aminoterminal domain, with the specific site differing between cases. A long cytoplasmic domain distinguishes Dsg-1 from other epithelial cadherins, with this domain mediating the interaction with the 85 kDa plakoglobin and other intracellular adhesion proteins. The pathogenic autoantibodies are largely of the IgG4 type, with titers correlating to the activity and extent of disease. Rarely, antibodies to desmosomal plakins (intracellular desmosomal plaque proteins) have also been identified in patients with pemphigus foliaceus but their relevance is unknown (Jiao & Bystryn 1998).

Direct IF shows positivity around keratinocytes throughout the epidermis, but sera bind more avidly to desmosomes in the upper rather than in the lower epidermis – the opposite is seen with pemphigus vulgaris (Shimizu et al. 1995). C3 may be present, but complement is not required for blistering. A moderate number of acute inflammatory cells and mediators are observed, including eosinophils and plasminogen activator. High concentrations of plasminogen further contribute to cellular acantholysis.

By enzyme-linked immunosorbent assay (ELISA), some reports have shown that sera from patients with pemphigus foliaceus have autoantibodies directed against desmoglein-3, desmocollin 1, and desmocollin 2, but positivity is rare and the relevance is unknown. Some cases of foliaceus that are positive for antidesmoglein-3 antibodies do evolve into clinical pemphigus vulgaris.

Autoantibody production is T-cell dependant.

Pemphigus Erythematosus

Synonym

Senear-Usher syndrome

Introduction/Definition

Pemphigus erythematosus is a variant of pemphigus foliaceus, which shows immunopathological features of both pemphigus and systemic lupus erythematosus (American & Ahmed 1985).

Clinical

Photosensitive lesions on the trunk are similar to those seen in pemphigus foliaceus, and scaly, erythematous plaques over the nose and cheeks may resemble the malar distribution of cutaneous lupus erythematosus. Progression to systemic lupus erythematosus is rare, but pemphigus erythematosus may be associated with myasthenia gravis or thymomas, an observation that is similar to the paraneoplastic form of pemphigus.

Histopathologic features of pemphigus erythematosus are the same as pemphigus foliaceus.

Pathophysiology

The blistering process in pemphigus erythematosus is similar to that in pemphigus foliaceus. Pathogenic IgG autoantibodies target the pemphigus foliaceus antigen desmoglein-1, and circulating antinuclear antibodies (ANA) also are present. Direct IF shows intercellular IgG and C3 in the epidermis, as well as a granular deposition of IgG and C3 at the BMZ (Gomi et al. 1999).

Drug-Induced Pemphigus

Pemphigus foliaceus and vulgaris have also been reported to be exacerbated or induced by radiotherapy, thermal or electrical injury, and numerous drugs. Links to penicillamine, captopril, and other ACE (angiotensin converting enzyme) and ARB (angiotensin II receptor) inhibitors are well documented. Other cases have been linked with chemotherapy, especially with fludarabine. It is unclear whether these cases are truly a result of the chemotherapeutic agent rather than the affiliated malignant condition and paraneoplastic pemphigus.

Intraepidermal Blistering Diseases

Pemphigus Vulgaris

Introduction/Definition

Pemphigus vulgaris, which accounts for roughly 70 % of all cases of pemphigus and affects predominantly the middle aged and elderly, may be the most common autoimmune bullous disease in Eastern countries but is less common in the West. Certain MHC class II genotypes are more frequent in pemphigus vulgaris patients, with

alleles of HLA-DR4, DRB1 (*0402 and 1401), and DQB1*0503 appearing to predispose patients to disease. This effect may be due to structural differences in peptide binding sites that influence antigen presentation and T-cell recognition.

There are two principal subtypes of pemphigus vulgaris – the mucosal-dominant form and the mucocutaneous form. Mucosal-dominant cases may evolve to more mucocutaneous forms or from pemphigus vulgaris to pemphigus foliaceus (rarely vice versa) with correlating shifts in antibody reactivity and specificity to different desmoglein isoforms (Harman et al. 2002). Despite some homology between antigens, antibodies against desmoglein-1 and desmoglein-3 are not thought to be cross-reactive. Passive transfer of maternal IgG antibodies across the placenta may induce transient blisters in newborns. This effect is rarely seen in mothers with pemphigus foliaceus.

It is possible for pemphigus and bullous pemphigoid to coexist.

Clinical

In pemphigus vulgaris, the level of cleavage is lower in the epidermis when compared to that of pemphigus foliaceus, owing to the suprabasal predilection for the pemphigus vulgaris antigen desmoglein-3 (Dsg-3). In contrast to the target antigen of pemphigus foliaceus (Dsg-1), Dsg-3 is also more strongly expressed on the scalp and in the buccal mucosa. This observation accounts for the much more significant degree (50-70 % of cases) of mucosal involvement in pemphigus vulgaris (Shirakata et al. 1998). In patients with autoantibodies due solely to Dsg-3, lesions and acantholysis tend to be limited to mucous membranes where the relative lack of Dsg-1 is unable to compensate and maintain intercellular adhesion (Amagai et al. 1999; Ding et al. 1997). These patients represent the mucosal-dominant form of pemphigus vulgaris. Patients with the mucocutaneous form have autoantibodies to both Dsg-3 and Dsg-1 and clinically present with more severe and widespread blistering of the skin and mucous membranes. The disease is typically widespread and has a penchant for the groin, axillae, face, scalp, and pressure points.

Nail dystrophy, subungual hematoma, and acute paronychias have been reported, but nail involvement is not common.

Basal cells lose lateral adhesion and separate from each other but remain attached to the basement membrane and resemble a "row of tombstones" on histopathologic examination. Keratinocyte necrosis is not seen.

Pathophysiology

The target antigen of Th1 and Th2 pathogenic autoantibodies is desmoglein-3 (Dsg-3), which is a 130 kDa desmosomal cadherin on the keratinocyte surface. Dsg-3 is found primarily in the lower epidermis where it functions in mediating intercellular adhesion (Hertl 2000). Antibodies may be of either (or both) subclasses IgG1 or IgG4, with those of IgG4 thought to be more pathogenic. As with other blistering disorders, disease activity typically correlates with antibody titer. Antibody binding triggers intracellular signaling processes through phosphorylation of EGF receptors and downstream substrates p38 mitogen-activated protein kinase and the Fas apoptotic cascade. After an initial widening of the intercellular space, the tonofilaments of the intracellular cytoskeleton retract around the nucleus causing keratinocyte shrinkage, and acantholysis occurs. However, the specific mechanisms of acantholysis in pemphigus vulgaris are not yet fully understood.

Pemphigus autoantibodies also fix complement to the keratinocyte surface which enhances pathogenicity, although complement is not required for disease (Kawana et al. 1989). In addition to complement fixation, pemphigus antibodies also lead to T-cell activation and recruitment through release of inflammatory mediators interleukin-1 (IL-1), tumor necrosis factor-α (TNF-α), thromboxane B2, leukotriene B4, and plasminogen activator (Grando et al. 1989; Zillikens et al. 1993).

The pathogenicity of anti-Dsg-3 antibodies has been well described, but autoantibodies to desmocollins, desmoplakin, e-cadherin, and non-cadherin targets in pemphigus vulgaris patients have also been reported. The relevance of these findings is unclear.

Direct IF shows IgG deposition on keratinocyte surfaces throughout the epidermis, with indirect IF detecting circulating autoantibodies in 80 % of cases. Rarely, IgA and/or IgM are present. A more robust staining in the lower epidermis in vulgaris patients may differentiate the direct IF pattern from pemphigus foliaceus. This reflects the higher density of Dsg-3 on desmosomes in this region.

Pemphigus Vegetans

Synonym

Vegetating bullous pemphigoid

Introduction/Definition

A rare variant of pemphigus vulgaris, pemphigus vegetans is defined by the formation of vegetating granulations mostly in flexural lesions and within skin folds. Pemphigus vegetans has two subtypes, the mild Hallopeau form and the more severe Neumann form, although these divisions are now of mainly historic interest.

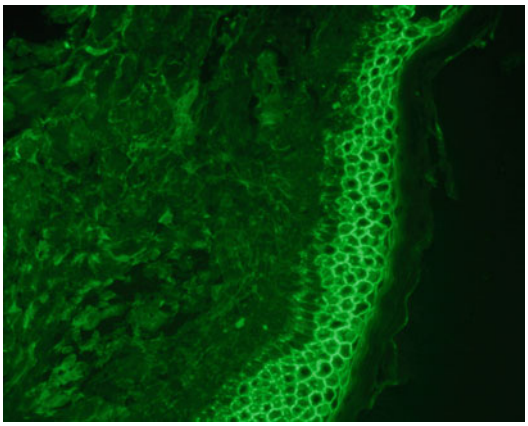
Clinical

Affecting primarily middle-aged adults, lesions show the classic acantholysis of other forms of pemphigus but are more papillomatous and hyperkeratotic. In the Neumann type, vesicles and bullae rupture and form easily bleeding hypertrophic and granular erosions. The erosions evolve into purulent, vegetating lesions that eventually become hyperkeratotic, dry, and fissured. The Hallopeau type differs in that pustules rather than vesicles characterize early lesions. However, pustules are observed in more advanced lesions of both Hallopeau and Neumann types.

Pathophysiology

Both forms of pemphigus vegetans show antibodies that target Dsg-3, the same antigen as pemphigus vulgaris. The Hallopeau type may also show reactivity with desmocollins 1 and 2. A dense infiltrate of neutrophils and eosinophils is observed along with complement fixation, all of which contribute to the purulent and vegetative nature of these lesions.

As with other forms of pemphigus, direct IF shows intercellular IgG (Fig. 1) and sometimes C3 (Fig. 2), with indirect IF detecting circulating intercellular antibodies in most patients.



Pemphigus, Fig. 1 Direct immunofluorescence figures. Intercellular IgG surrounding keratinocytes throughout the epidermis in pemphigus vulgaris

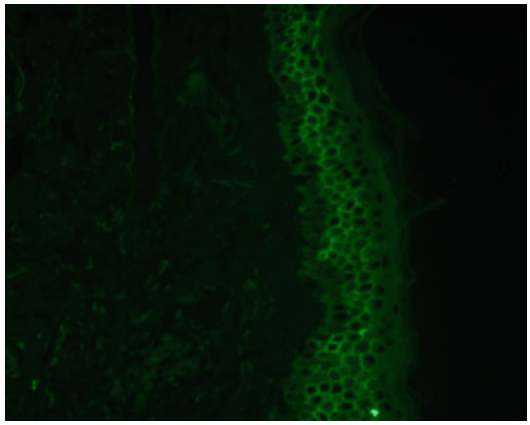
Paraneoplastic Pemphigus

Introduction/Definition

Paraneoplastic pemphigus (PNP) is a distinct form that is associated with an underlying neoplasm, most frequently B-cell lymphomas and other hematologic and lymphoproliferative malignant conditions such as chronic lymphocytic leukemia and giant follicular hyperplasia (Castleman's tumor). Association with thymomas and several other types of carcinoma and sarcoma has also been reported (Anhalt et al. 1990). Blistering may be the initial finding, but typically the neoplasm is already detected at the time of PNP diagnosis (Robinson et al. 1999). PNP is a devastating illness with much more profound morbidity than is observed in other forms of pemphigus; mortality often is attributed to the underlying malignant conditions as well. Many patients succumb to sepsis, gastrointestinal bleeding, and respiratory or multi-organ failure (Robinson et al. 1999; Anhalt 1997). Low-grade disease may improve after treatment of the associated neoplasm.

Clinical

Clinically overlapping with erythema multiforme (EM) and lichen planus pemphigoides (LPP), patients present with more severe and refractory



Pemphigus, Fig. 2 C3 is often present surrounding keratinocytes throughout the epidermis in pemphigus vulgaris

mucosal erosions (especially oral stomatitis) and polymorphous cutaneous findings, which range from blisters and erosions to palmoplantar target lesions (Anhalt et al. 1990; Robinson et al. 1999; Zillikens & Brocker 1994). PNP shows a distinct combination of keratinocyte necrosis (resembling EM), suprabasilar acantholysis (resembling pemphigus vulgaris), and a possible lichenoid eruption (resembling LPP). PNP is a multisystem disease, and beyond the skin, autoantibody deposits may also be found in the kidney, bladder, respiratory and digestive tract epithelia, and in both smooth and striated muscle.

Considerable variety exists histopathologically in cutaneous lesions of paraneoplastic pemphigus. Suprabasilar acantholysis, individual keratinocyte necrosis, basal cell liquifactive degeneration, and a band-like dense lymphocytic infiltrate in the upper dermis may all be seen.

Pathophysiology

The antigenic target(s) and humoral response of PNP are more heterogeneous and less defined than those in other forms of pemphigus, with pathogenic antibodies of principally the IgG1 subclass targeting linker subdomains of envoplakin (210 kDa) and periplakin (190 kDa) and also other desmosomal plakins (intracellular desmosomal plaque proteins) which include desmoplakin-1 (250 kDa), desmoplakin-2 (215 kDa), plectin (500 kDa), and the hemidesmosomal bullous pemphigoid antigen (230 kDa). The broad specificity of autoantibodies, combined with the addition of cell-mediated cytotoxicity to the humoral effect, causes the widespread systemic effects associated with PNP.

Antiplakin antibodies are not specific to PNP and have also been identified in patients with pemphigus foliaceus, bullous pemphigoid, toxic epidermal necrolysis, and erythema multiforme.

Direct IF shows IgG with or without C3 deposited along epidermal cell surfaces and variably along the basement membrane zone. Indirect IF shows autoantibodies that also react with simple or transitional epithelia, unlike those of classic pemphigus vulgaris.

Laboratory of Lymphocyte Signalling and Development, Babraham Institute, Cambridge, UK

Synonyms

Phosphatidylinositol 3-kinase; Phosphoinositide 3-kinase; PI 3-kinase

Definition

PI3Ks are a family of enzymes that can phosphorylate the inositol head group of phosphoinositides (PtdIns) on the D3 position.

History

PI3Ks were initially discovered by Lewis Cantley and colleagues as an enzyme that could phosphorylate membrane inositol lipids on the D3 position (Whitman et al. 1988). In contrast to PtdIns phosphorylated on the 4 and 5 positions, PtdIns phosphorylated on the D3 position was found to be resistant to hydrolysis by phospholipases. PI3K was found to be associated with tyrosine-phosphorylated Src and SV40 middle T antigens, which suggested that it may play a role in cancer, but was also found in complex with insulin and growth factor receptors, suggesting a broader role in growth and development. PI3K activity was also found in complex with Gβγ proteins in neutrophils which indicated a role for PI3K in inflammation. The class III PI3K vacuolar protein sorting 34 (Vps34) was first discovered in a yeast mutant with abnormal vacuoles, whereas the class II PI3K isoforms were identified by homology cloning and completed the collection of 8 PI3K catalytic subunits encoded by mammalian genomes. The discovery that wortmannin specifically inhibits PI3K and the development of PI3K inhibitor LY294002 by Eli Lilly allowed investigators to probe the function of PI3K in cells. PI3Ks are now known to be central signal transducers in fundamental cellular biological processes such as metabolism, migration, differentiation, proliferation, and autophagy. PI3Ks influence many physiological processes and are also important factors that promote cancer, immune-mediated diseases, and metabolic disorders (Engelman et al. 2006).

The PI3K Family

Humans have eight different PI3Ks divided in three classes (Vanhaesebroeck et al. 2010a).

The **class I PI3Ks** p110α, p110β, p110δ, and p110γ preferentially phosphorylate PtdIns(4,5)P_2 to produce PtdIns(3,4,5)P_3. p110α, p110β, and p110δ are bound by a p85 regulatory subunit (or the smaller p55 or p50 variants) which has SH2 domains that bind phosphorylated tyrosines, typically associated with plasma membrane

receptors. P110γ binds a p101 or p84 regulatory subunit that associates with Gβγ subunit of G protein-coupled receptors. As a consequence, many receptors expressed by immune cells can activate one or more of the PI3K isoforms. The p110δ and p110γ isoforms have received much attention by immunologists as these are expressed at much higher levels in white blood cells than in other cell types.

The **class II PI3Ks** C2α, C2β, and C2γ phosphorylate PI or PI4P to produce PI3P or $PI(3,4)P_2$. Little is known about the role of this class of PI3Ks in immunity.

The only **class III PI3K**, Vps34, phosphorylates PI to produce PI3P. Vps34 binds to the Vps15 regulatory subunit. Vps34 is the only PI3K found in yeast. It is therefore likely that the other PI3Ks evolved from this founding member. Vps34 has received much attention in recent years as a central regulator of autophagy – the process in which cells self-digest when faced with inadequate nutrient supply.

Signaling by PI3Ks

Receptors that can engage and activate class I PI3K on immune cells include growth factor receptors, such as colony-stimulating factor 1 (CSF1); antigen receptors, such as the B cell receptor (BCR) and T cell receptor (TCR); costimulatory receptors such as CD28 and inducible costimulator (ICOS); cytokine receptors such as interleukin-2 (IL-2) and IL-4; and various chemokine receptors. Some receptors such as the B cell-activating factor (BAFF) receptor on B cells may engage the PI3K pathway indirectly by stimulating the transcription of proteins that activate PI3K (Okkenhaug and Fruman 2010).

$PtdIns(3,4,5)P_3$ acts as a lipid anchor in the inner leaflet of the plasma membrane. There are more than 300 proteins with PH domains, and it is estimated that 20–100 of these bind preferentially to $PtdIns(3,4,5)P_3$ over other membrane lipids and proteins. Most prominent of the $PtdIns(3,4,5)P_3$-binding proteins is Akt which is the only $PtdIns(3,4,5)P_3$ effector protein also found in some simpler organisms such as worms. Akt becomes recruited to the plasma membrane by $PtdIns(3,4,5)P_3$ where it gets phosphorylated by Pdk1 and by the mammalian target of rapamycin complex 2 (mTORc2). Akt then phosphorylates a number of substrates. Two main downstream pathways have been explored extensively in immune cells: the activation of mTORc1 and the inhibition of Foxo. mTOR is a kinase that regulates protein translation and lipid synthesis and therefore is a central controller of cell growth. The two complexes, mTORc1 and mTORc2, contain the same central mTOR catalytic subunit in association with the regulatory subunits such as Raptor and Rictor, respectively. Foxo is a family of transcription factors that control the expression of genes that promote apoptosis, cell cycle arrest, and, perhaps most pertinently in immune cells, cytokine receptors and receptors involved in cell trafficking (Hawkins et al. 2006; Finlay and Cantrell 2011).

PI3K signaling is antagonized by phosphatases. Pten removes the phosphate at the D3 position of $PtdIns(3,4,5)P_3$, whereas Ship removes the D5 phosphate, and Inpp4 removes the D4 phosphate. Mice lacking Pten in hematopoietic cells present with leukemia and autoimmunity. Mice lacking Ship also present with autoimmunity. Ship has received much attention from immunologists as it is bound by the cytoplasmic immunoreceptor tyrosine-based inhibition motifs (ITIMs) of a number of inhibitory receptors such as FcγRIIB on B cells (Okkenhaug and Fruman 2010; Leslie et al. 2011).

Role of PI3K in Innate Immunity

Neutrophils are among the first cells to arrive at the site of infection. p110γ, which is activated by chemokine receptors, plays an important role in promoting the recruitment of neutrophils to the site of infections. Once there, neutrophils phagocytose bacteria and kill them, in part by generating reactive oxygen species (ROS). In primed human neutrophils, p110γ and p110δ are

sequentially activated to promote a full ROS response when exposed to a bacterial peptide agonist. Antibodies bound by antigen can also elicit a ROS response in neutrophils. Curiously, in this case, p110β is the most important isoform, followed by p110δ. P110γ appears not to control antibody-stimulated ROS production in neutrophils. As neutrophils are major causes of inflammation, inhibiting p110β, p110γ, or p110δ may have beneficial effects in some clinical settings (Hawkins et al. 2006; Kulkarni et al. 2011).

Macrophages and dendritic cells are also important scavengers of bacteria and in addition form an important link between innate and adaptive immunity. In these cell types, PI3Ks appear to antagonize the response to certain bacterial cell membrane constituents, such as lipopolysaccharide (LPS). Thus inhibiting PI3K can enhance the production of cytokines such as IL-12 which is a central mediator of cell-mediated immunity. Consequently, inhibition of PI3K in innate cells can enhance immunity against intracellular pathogens (Okkenhaug and Fruman 2010).

Both p110γ and p110δ have been shown to control various function in natural killer (NK) cells. NK cells are important for the elimination of neoplasms, and p110δ and p110γ can control both the recruitment of NK cells to tumors and, to some extent, the ability of NK cells to kill tumor cells (Kerr and Colucci 2011).

Role of PI3K in Adaptive Immunity

Lymphocytes become fully activated several days after the initial infection. PI3Ks play important roles in the development and function of lymphocytes. P110α and p110δ are essential for B cell development, whereas p110γ and p110δ are essential for T cell development. P110δ plays a very important role in humoral B cell responses, both by regulating the development of certain B cell subsets and by promoting the expansion or survival of specialized T cells that provide essential help for B cells to undergo immunoglobulin class switching and affinity maturation. Indeed, p110δ controls the expression of a number of cytokines produced by CD4 and CD8 T cells. P110δ-deficient mice have fewer regulatory T cells (Treg), and these are less capable of suppressing immune responses than wild-type Treg. Therefore, while inhibition of PI3K is generally thought to suppress immune responses (e.g., antibody response), there are circumstances where the ability of p110δ to suppress Treg function means that, on balance, the immune response of p110δ-deficient mice is enhanced. In most cases, however, the net result of inhibiting p110δ is the suppression of immune function (Okkenhaug and Fruman 2010).

PI3Ks in Autoimmunity and Inflammation

Studies have shown that inhibition of p110γ and/or p110δ (and in one case p110β) can reduce the severity of diseases in mouse models of rheumatoid asthma, arthritis, multiple sclerosis, and systemic lupus erythematosus. Broadly speaking, p110γ has a stronger impact on innate immunity, whereas p110δ inhibition mostly affects adaptive immune responses – however, this is only a rule of thumb – many exceptions are known. To what extent these preclinical findings will be translated to the clinic remains to be determined (Rommel 2010; Vanhaesebroeck et al. 2010b).

PI3Ks as Pharmaceutical Drug Targets

Because PI3Ks are involved in many facets of immune cell function, there is a considerable effort to target these enzymes to treat or cure immune-mediated diseases. PI3Ks are sufficiently devolved from protein and other lipid kinases that it is relatively easy to target this family specifically. Moreover, in recent years, highly selective inhibitors against specific PI3K isoforms have been generated. The p110δ-selective inhibitor CAL-101 was developed by Calistoga which was subsequently taken over by Gilead who now call it GS-1101. GS-1101 has entered phase II/III clinical trials in

chronic lymphocytic leukemia and indolent non-Hodgkin's lymphoma after patients in phase I trials showed promising clinical responses with few obvious side effects (Burger 2011).

Conclusion

The PI3K family controls diverse biological processes of relevance to the immunologist. PI3Ks regulate multiple processes during immune cell development, activation, and migration. In addition, drugs that target selected PI3K isoforms are beginning to show promise in the clinic.

PKC-θ

Zuoming Sun
Division of Immunology, Beckman Research Institute of the City of Hope, Duarte, CA, USA

Synonyms

PKC-θ; Protein kinase C theta

Protein Kinase C Family

Protein kinase C (PKC) is family of serine/threonine kinases that can be divided into three subfamilies (Newton 1997): conventional PKC, including PKCα, β, and γ, which are activated by Ca^{2+} and diacylglycerol (DAG); novel PKC, including PKCδ, θ, η, and ε, in which activation is dependent on DAG but independent of Ca^{2+}; and atypical PKC, including PKCζ and λ, in which activation is independent of both Ca^{2+} and DAG. PKC-θ is predominantly expressed in T cells. Upon T cell activation, PKC-θ specifically translocates to the immunological synapse and mediates T cell receptor (TCR) signaling critical for the regulation of T cell function (Barouch-Bentov et al. 2005; Dustin 2009).

PKC-θ Mediates TCR Signals Required for T Cell Activation

T cells play a critical role in adaptive immune response. Defects or dysregulation of T cell activation or function leads to immunodeficiencies or autoimmunity. Coordinated activation of T cells in response to antigen leads to clonal expansion and differentiation of antigen-specific T cells. T cell activation is controlled by numerous signaling pathways initiated by the TCR and co-stimulatory molecules (Weiss and Littman 1994). Biochemical signals initiated by the TCR determine the specificity of T cell activation and the signaling pathways mediated by co-stimulatory molecules modulate the activation threshold. As a result of antigen binding to the TCR, PKC-θ translocates to the immunological synapse where it mediates TCR signaling pathways (Monks et al. 1998). TCR signaling is initiated by activation of the Src family lymphocyte-specific protein tyrosine kinase (LCK), which leads to recruitment and activation of zeta-chain-associated protein kinase 70 (ZAP70) and consequently of the adaptor proteins linker of activated T cells (LAT), SH2 domain-containing leukocyte protein of 76 kDa (SLP76), and VAV. LAT recruits phospholipase Cγ1 (PLCγ1), which catalyzes the breakdown of phosphatidylinositol 4,5-bisphosphate into inositol triphosphate (IP3), a Ca^{2+} mobilizer, and DAG, the PKC-θ activator (Weiss and Littman 1994). Upon activation by DAG, PKC-θ mediates the activation of nuclear factor kappa-light-chain-enhancer of activated B cells (NF-κB). Several adaptor proteins play a critical role in mediating PKC-θ-induced NF-κB activation including membrane-associated guanylate kinase (MAGUK), caspase recruitment domain (CARD)11 (CARMA1), B cell lymphoma 10 (Bcl10), and mucosa-associated lymphoid tissue 1 (MALT1). Together with PKC-θ, these adaptors facilitate the activation of IκB kinase (IKK), which leads to the phosphorylation, ubiquitination, and degradation of the IκBα protein, resulting in the release and translocation of NF-κB into the nucleus, where it stimulates the expression of target genes essential for T cell activation, including IL-2. Studies using PKC-θ-deficient T cells, or cells overexpressing a constitutively active form of PKC-θ or a catalytically inactive form of PKC-θ, have demonstrated that PKC-θ also activates the activator protein 1 (AP-1) signaling pathway (Sun et al. 2000). AP-1 is composed of c-Jun and c-Fos. Although the mechanism by which PKC-θ mediates activation of AP-1 is not completely understood, several studies have provided some insight into this process. Ras and the mitogen-activated protein kinases (MAP kinases), c-Jun N-terminal kinase (JNK), extracellular signal-regulated kinase (ERK), and P38 mitogen-activated protein kinase (P38) are all involved in PKC-θ-mediated AP-1 activation (Altman et al. 2000). A PKC-θ-interacting MAP kinase, originally termed Ste20/SPS1-related proline and alanine-rich kinase (SPAK or PASK) (Li et al. 2004), was isolated and shown to be involved in the PKC-θ-mediated activation of AP-1, but not NF-κB. Furthermore, activation of this kinase by TCR/CD28 stimulation was impaired in T cells from *PKC-θ*$^{-/-}$ mice, and SPAK-specific small interfering RNA (siRNA) inhibited PKC-θ-mediated AP-1, but not NF-κB, activation, suggesting that SPAK is responsible for activation of AP1 downstream of PKC-θ. Activation of T cells through the TCR also leads to IP3-mediated elevation of cytosolic $[Ca^{2+}]_i$ by inducing Ca^{2+} influx. Elevated intracellular Ca^{2+} ultimately leads to activation of the phosphatase calcineurin, which dephosphorylates nuclear factor of activated T cells (NFAT), resulting in its translocation into the nucleus. Translocated NFAT cooperates with AP-1 to activate interleukin-2 (IL-2) expression. It was shown that, in the absence of AP-1, NFAT activation could lead to T cell anergy. Several studies have shown that PKC-θ enhances the activation of NFAT by stimulating Ca^{2+} influx as TCR-induced Ca^{2+} influx and NFAT activation are defective in T cells from *PKC-θ*$^{-/-}$ mice (Manicassamy et al. 2006a; Pfeifhofer et al. 2003). It is clear that PKC-θ regulates Ca^{2+} signals via PLCγ1; however, it is not known how PKC-θ stimulates PLCγ1. The tyrosine kinase epithelial (TEK kinase) family member IL2-inducible T cell kinase (Itk) may be the missing link. Itk-deficient T cells display defective

Ca^{2+} influx and PLCγ1 activation. Furthermore, PLCγ1 activity is greatly stimulated by Itk overexpression. Therefore, it is possible that PKC-θ regulates PLCγ1 activation via Itk. Altogether, PKC-θ-mediated TCR signals regulate multiple signaling pathways including NF-κB, AP-1, and NFAT, all of which are critical for T cell activation. Inhibition of PKC-θ is therefore expected to prevent T cell activation by blocking these TCR signaling pathways (Altman et al. 2000; Manicassamy et al. 2006b).

PKC-θ Regulates the Differentiation of Naïve T Cells to Effective T Helpers

Peripheral naïve T cells cannot mediate actual immune responses unless they undergo a differentiation process to become effector T cells. Upon T cell activation, these same T cells can differentiate into inflammatory T helper 1 (Th1), T helper 2 (Th2), and T helper 17 (Th17) or inhibitory T regulatory cells (Treg). A fine balance between inflammatory and inhibitory T cells is required for a functional immune system. Overproduction of inflammatory T cells leads to aggravating autoimmunity, whereas overproduction of Tregs can induce tolerance, and PKC-θ is able to shift the balance between these T cell subtypes. *PKC-*$\theta^{-/-}$ mice display impaired Th2 responses following infection with *Nippostrongylus brasiliensis*, whereas they develop a normal Th1-mediated response against *Leishmania major* (Marsland et al. 2004). In addition, *PKC-*$\theta^{-/-}$ mice are resistant to the induction of experimental autoimmune encephalomyelitis (EAE), due to reduced Th17 responses (Tan et al. 2006). PKC-θ is therefore required to fully develop Th2, Th17, and even certain Th1 responses in vivo. Recently, it was shown that PKC-θ-mediated signals inhibit Treg differentiation via an AKT kinase-forkhead box O1/O3a (FOXO1/3a) pathway (Ma et al. 2012). Transforming growth factor β (TGF-β)-induced Treg differentiation was potentiated by a deletion of the PKC-θ gene or by treatment with a specific PKC-θ inhibitor but inhibited by treatment with phorbol myristate acetate (PMA), a PKC-θ activator, or by CD28 cross-linking. Furthermore, CD28 cross-linking inhibited Treg differentiation in wild-type (WT) T cells, but not in *PKC-*$\theta^{-/-}$ T cells or in WT T cells treated with a PKC-θ inhibitor, suggesting that PKC-θ-mediated CD28 signals are responsible for inhibiting Treg differentiation. Consistently, adoptively transferred naïve *PKC-*$\theta^{-/-}$ T cells formed significantly more Tregs in vivo than WT T cells. Furthermore, enhanced Treg differentiation of *PKC-*$\theta^{-/-}$ T cells was associated with lower AKT kinase activity, and forced expression of an active form of AKT kinase inhibited *PKC-*$\theta^{-/-}$ T cells from differentiating into Tregs, indicating a role for AKT downstream of PKC-θ in the inhibition of Treg differentiation. The downstream targets of AKT kinase-FOXO1/3a were also affected in *PKC-*$\theta^{-/-}$ T cells. Accordingly, overexpression or knockdown of FOXO1/3a promoted or inhibited Treg differentiation, respectively. Therefore, PKC-θ promotes inflammatory effector T cell differentiation via NFAT, AP-1, and NF-κB but inhibits Treg differentiation via an AKT-FOXO1/3a pathway. Taken together, PKC-θ is able to control T cell-mediated immune responses by shifting the balance between stimulatory effector T cells and inhibitory Treg cells. A recent study also showed that PKC-θ-mediated signals inhibit the suppressive function of Treg (Zanin-Zhorov et al. 2010). Therefore, PKC-θ regulates T cell-mediated immunity by affecting both the inflammatory and inhibitory arms of the immune system.

PKC-θ in Allograft Rejection

Solid organ transplantations that benefit end-stage organ failure patients are severely limited by the occurrence of rejection. Alloreactive T cells are critical targets for tolerance induction since they mediate immune responses required for rejection. The alloreactive T cell pool is very large, which explains why immune responses against allografts are at least two orders of magnitude stronger than the immune responses

against a specific antigen. Therefore, long-term tolerance to allografts is extremely difficult to establish. Alloreactive T cells can be tolerized through anergy, suppression, and deletion. Anergy is an unresponsive state of T cells, which can be overcome by exogenous IL-2. Suppression is usually mediated by suppressor cells, such as Foxp3-expressing Tregs. However, these two mechanisms are unlikely to change the size of the alloreactive T cell pool. A similar problem exists with the use of cyclosporin A (CsA), the most successful immunosuppressive drug used clinically so far. However, CsA also prevents apoptosis of alloreactive T cells by inhibition of T cell activation, resulting in the accumulation of large amounts of alloreactive T cells that can destroy allografts once immunosuppressive drugs are discontinued. Therefore, the prevention of allograft rejection usually requires transplant recipients to take lifelong immunosuppressive drugs, which can result in other complications including infections and malignancy. In contrast, deletion induces tolerance by decreasing the number of alloreactive T cells via apoptosis. Deletion can occur both in the thymus and peripheral lymphoid tissues. In the periphery, activated T cells are deleted by two different forms of apoptosis: activated induced cell death (AICD) and passive cell death. AICD eliminates clonally expanded T cells via tumor necrosis factor (TNF) family death receptors, such as Fas/FasL, which are largely independent of B cell lymphoma-extra large (Bcl-$x_{L)}$, whereas passive cell death can be inhibited by Bcl-x_L. Activated T cells upregulate Bcl-x_L which intrinsically enhances T cell survival. CD28-mediated co-stimulatory signals are responsible for Bcl-x_L upregulation via activation of the NF-κB pathway. Blockade of either co-stimulatory signals or the NF-κB pathway results in tolerance by induction of T cell apoptosis in WT mice, but not in mice expressing a *Bcl-x_L* transgene. These results demonstrate the critical role of passive T cell death in tolerance induction. It has been proposed that apoptotic reduction of the large pool of alloreactive T cells is required for tolerance induction (Wells et al. 1999). Because PKC-θ is a critical signaling molecule required for T cell activation and survival, the function of PKC-θ in allograft rejection was tested using a cardiac rejection model (Manicassamy et al. 2008). Recombination activating gene 1 $(Rag1)^{-/-}$ mice reconstituted with WT T cells readily rejected fully mismatched cardiac allografts, whereas $Rag1^{-/-}$ mice reconstituted with $PKC\text{-}\theta^{-/-}$ T cells failed to promote rejection, suggesting that PKC-θ is required for T cell-mediated allograft rejection. Since PKC-θ is required for survival of activated T cells (Manicassamy et al. 2006a), the role of PKC-θ-regulated survival in cardiac allograft rejection was tested and demonstrated that transgenic expression of Bcl-x_L in $PKC\text{-}\theta^{-/-}$ T cells was sufficient to restore cardiac allograft rejection (Manicassamy et al. 2008). In contrast to adoptive transfer experiments, intact $PKC\text{-}\theta^{-/-}$ mice displayed a delayed but successful cardiac allograft rejection, suggesting a potential compensatory pathway for PKC-θ function. Finally, subtherapeutic doses of anti-CD154 antibody or Cytotoxic T-Lymphocyte Antigen 4 Immunoglobulin (CTLA4-Ig), which were not sufficient to prevent cardiac allograft rejection in the WT mice, prevented heart rejection in the $PKC\text{-}\theta^{-/-}$ mice. This data strongly indicates that, in combination with other treatments, inhibition of PKC-θ can achieving long-term survival of allografts (Manicassamy et al. 2008; Wang et al. 2009).

Conclusion

PKC-θ controls fundamental processes in T cells that integrate TCR and CD28 signals leading to the activation of transcription factors, NF-κB, AP-1, and NFAT, which are essential for productive T cell activation and differentiation. Because PKC-θ regulates T cell-mediated immune responses in vivo, selective PKC-θ inhibitors are believed to have potential clinical applications in the treatment of autoimmunity and prevention of allograft rejection. However, PKC-θ regulates multiple T cell differentiation processes, and the detailed mechanisms involved

are not yet fully understood. Therefore, additional questions need to be addressed prior to clinical testing of PKC-θ inhibitors, including how PKC-θ mediates multiple signaling pathways, and how inhibition of PKC-θ affects normal T cell function in vivo. It is encouraging to report that many pharmaceutical companies have developed selective PKC-θ inhibitors, and therefore, many PKC-θ-regulated functions can be evaluated using these inhibitors instead of the $PKC\theta^{-/-}$ mice, which have potential developmental caveats. With the availability of PKC-θ inhibitors, it is now possible to test their efficacy in autoimmune diseases and allograft rejection, which in all likelihood will lead to clinical trials of PKC-θ-based treatments for human diseases (Kwon et al. 2010).

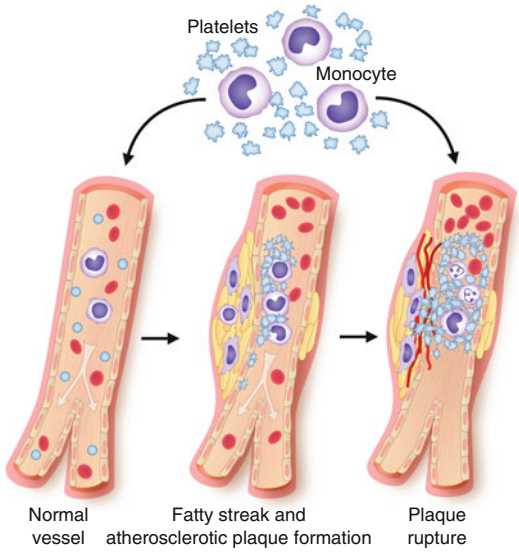
Definition

Platelets are anucleate, disc-shaped, colorless blood cells that are derived from a parent cell type, the megakaryocyte. Platelets have major functions in hemostasis and are the chief hemostatic cells in the blood. In addition to direct hemostatic activities, platelets contribute to activation of plasma coagulation proteins leading to fibrin formation (blood clotting). Platelets also have major inflammatory activities that include innate immune and adaptive immune functions.

There are no commonly used synonyms for platelet in modern medicine and biology. Terms that have been used in the past include Bizzozero's corpuscle, blood disc, blood plate, Deetjen's body, elementary body, elementary particle, Hayem's hemoblast, hemolamella, third corpuscle, Zimmermann's corpuscle, Zimmermann's elementary particle, and Zimmermann's granule. Thrombocyte is a term used for nucleated blood cells that perform the same functions as platelets in nonmammalian vertebrates, whereas mammalian platelets do not have nuclei.

Introduction

Atherosclerosis is a chronic syndrome that usually affects arteries in a discontinuous and segmental fashion. Immune cells and pathways are clearly involved in experimental and clinical atherosclerosis, and it is now accepted that atherosclerosis is a chronic inflammatory disease (Ross 1999; Galkina and Ley 2009; Kaplan 2009). While progressive insidious narrowing of vessels with local limitation of blood flow is a pathologic consequence, a second – and more clinically significant – outcome is ulceration or rupture of atherosclerotic plaques, which results in acute coronary syndromes, stroke, and ischemic peripheral vascular complications (Fig. 1). These acute sequelae are common, characteristically sudden, and often lethal. There is evidence that platelets contribute to both the smoldering progression of atherosclerosis and to the acute, explosive ischemic events (Figs. 1 and 2). In coronary artery plaque rupture triggering myocardial infarction and other acute coronary syndromes, and in carotid plaque ulceration or rupture, which precipitates ischemic stroke, platelets mediate vascular thrombosis (Davi and Patrono 2007; Michelson 2010; Nieswandt et al. 2011) (Figs. 1 and 3). This is consistent with the well-known activities of platelets as chief effector cells of pathologic, as well as physiologic, hemostasis (Michelson 2010; Nieswandt et al. 2011). In addition, however, there is emerging evidence that platelets are key inflammatory and immune effector cells in the initiation and progression of atherosclerosis, which set the stage for atherosclerotic complications. Thus, the activities of platelets in atherosclerosis are not limited to thrombosis and acute vascular occlusion. Their contributions to the chronic inflammation of atherosclerosis are consistent with abundant evidence from studies of their physiologic functions and their contributions to other inflammatory diseases and syndromes that demonstrate that they are major immune effector cells (reviewed in (Vieira-de-Abreu et al. 2012a, b)).

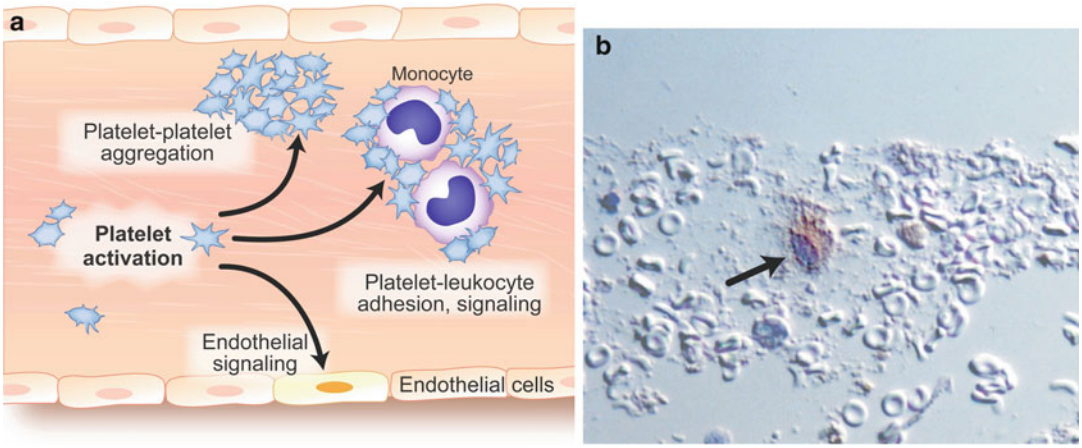


Platelets, Atherosclerosis, and Immunity, Fig. 1 Inflammatory activities of platelets contribute to the evolution of atherosclerotic plaques, which rupture and cause arterial occlusion. Early changes of atherosclerosis involve dysfunction and activation of endothelial cells, altering normal arteries (*left figure*) and initiating formation of "fatty streaks" consisting of monocytes, lipid-laden macrophages (foam cells), T lymphocytes, and extracellular lipids (*middle figure*). Fatty streaks progress to established plaques, which consist of additional leukocytes (monocytes, macrophages, and lymphocytes), smooth muscle cells, complex lipids and lipid crystals, and debris covered by a fibrin cap (Ross 1999). Recent studies utilizing mouse models of atherogenesis indicate that there is substantial leukocyte diversity in established plaques, including the presence of lymphocyte subsets and vascular dendritic cells, and that angiogenesis occurs in the plaques (Galkina and Ley 2009). Platelets are present on the intimal (endothelial) surface at each stage (Ross 1999) and can mediate endothelial activation, leukocyte accumulation and activation, lipid deposition, smooth muscle cell recruitment, angiogenesis, and fibrous responses (Davi and Patrono 2007; Michelson 2010; Nieswandt et al. 2011; Langer et al. 2012; Vieira-de-Abreu et al. 2012a, b). In atherosclerotic plaque rupture (*right figure*), platelets are exposed to collagen, other matrix proteins, lipids and lipid crystals, and leukocytes in the exposed core of the plaque (also see Panel B in Fig. 2). This environment causes intense local platelet activation, precipitating thrombosis (Davi and Patrono 2007; Michelson 2010; Nieswandt et al. 2011). Platelets can release metalloproteinases and locally interact with and signal monocytes, polymorphonuclear leukocytes (PMNs), and macrophages (Langer et al. 2012; Vieira-de-Abreu et al. 2012a, b), events that can amplify plaque instability and rupture. Platelet-monocyte and platelet-PMN aggregates form as a consequence of plaque rupture (Michelson et al. 2001) and can potentially mediate local, regional (i.e., in the coronary circulation), and/or systemic inflammation

Platelets as Immune Effector Cells

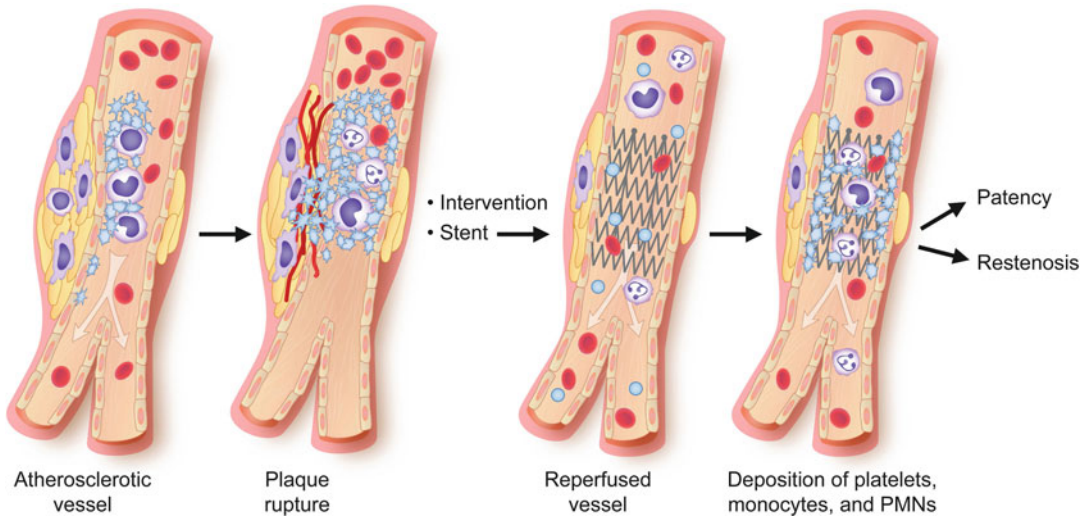
Platelets likely evolved from ancient multifunctional defensive cells with procoagulant, wound sealing, and pathogen capture, containment, and elimination functions. "Modern" platelets are unique, small, anucleate cells that are progeny of polyploid megakaryocytes (Davi and Patrono 2007; Vieira-de-Abreu et al. 2012a). Polyploid megakaryocytes and anucleate platelets are found only in mammals (Michelson 2010), suggesting key cellular specializations driven by evolutionary pressures. Platelets circulate in large numbers under normal conditions and in intact vessels they are preferentially distributed to regions of the blood stream adjacent to endothelial surfaces by rheologic features of the flowing blood and mechanical influences of larger blood cells (Michelson 2010). Platelets are first responders to endothelial injury and have intricate and extensive mechanisms for initiation and propagation of hemostasis at sites of injury and for clot remodeling (Davi and Patrono 2007; Michelson 2010; Nieswandt et al. 2011; Vieira-de-Abreu et al. 2012a). Thus, primary hemostasis is a central function and a chief specialization of platelets. Nevertheless, platelets also have activities that span the continuum from innate to adaptive immune responses and that contribute to complex cellular interactions in acute and chronic inflammation (Vieira-de-Abreu et al. 2012a, b).

Cellular activation is a critical event in the physiologic and pathologic behavior of platelets, dramatically altering their hemostatic and inflammatory phenotypes (Michelson 2010; Vieira-de-Abreu et al. 2012a). Platelets circulate in a resting, quiescent state under basal conditions. In response to activating signals, they rapidly undergo functional alterations that mediate primary hemostasis and also inflammation and immune responses (Davi and Patrono 2007; Michelson 2010; Nieswandt et al. 2011; Vieira-de-Abreu et al. 2012a). A classic and intensely studied general mechanism of platelet activation involves binding of specific ligands to G protein-coupled receptors on the platelet plasma membrane. These include receptors



Platelets, Atherosclerosis, and Immunity, Fig. 2 Platelets have an extensive repertoire of mechanisms that can drive atherogenesis and mediate inflammation in response to plaque rupture or ulceration. *Left panel*. Platelets are activated by agonists generated in atherosclerotic risk conditions and in evolving atherosclerosis (Davi and Patrono 2007; Michelson 2010; Langer et al. 2012). Platelet activation can induce their adhesion to endothelial surfaces, aggregation, release of preformed proatherogenic chemokines and cytokines (PF4, RANTES, CD40L, others), posttranscriptional synthesis of IL-1β, tissue factor, and other inflammatory gene products, and adhesive interactions with monocytes, lymphocytes, and other leukocyte subsets by mechanisms that include binding of P-selectin on activated platelets to PSGL-1 on leukocytes. Adhesive interactions of activated platelets with leukocytes facilitate their deposition on local endothelial surfaces and transmigration into plaques and also cause the formation of locally deposited and circulating platelet-leukocyte aggregates. Signaling of monocytes by platelets in aggregates induces the transcriptional and posttranscriptional expression of a variety of proinflammatory proteins and generation of other mediators (eicosanoids, oxygen radicals). Platelets can also deliver signals to endothelial cells that activate them and alter their gene expression profiles and synthetic functions, potentially amplifying very early endothelial activation events. These and other features of the innate and adaptive immune repertoire of activated platelets may be key pathogenetic features in atherogenesis (Davi and Patrono 2007; Langer et al. 2012). *Right panel*. Tissue from an ulcerated carotid artery plaque with a central macrophage (*arrow*) surrounded by adherent platelets and accumulated erythrocytes is shown. Platelet-platelet and platelet-leukocyte interactions mediate inflammatory responses (reviewed in (Vieira-de-Abreu et al. 2012a, b)) that may be important determinants in the acute, subacute, and long-term outcomes of plaque rupture (Davi and Patrono 2007; Langer et al. 2012) (Panel is reprinted from Weyrich AS, Lindemann S, Zimmerman GA. The evolving role of platelets in inflammation. J Thromb Haemost. 2003;1:1897–905. with permission)

that recognize the hemostatic and inflammatory protease thrombin (protease-activated receptors), purinoceptors that are activated by ADP released from platelet dense granules, the receptor for the endogenously synthesized eicosanoid thromboxane A_2, and other G protein-coupled receptors that recognize diverse ligands and agonists including 5-hydroxytryptamine, platelet-activating factor, and certain prostaglandins (Davi and Patrono 2007; Michelson 2010; Vieira-de-Abreu et al. 2012a). Platelet G protein-coupled receptor pathways are targets for molecular therapy in cardiovascular diseases (Michelson 2010). It has recently been recognized that platelets have toll-like receptors (TLRs), a major class of receptors that recognize microbial products and other exogenous and endogenous ligands. TLRs are critical in immune signaling, and expression of functional TLRs by human and murine platelets is further evidence for inflammatory and immune specializations of these cells (reviewed in (Vieira-de-Abreu et al. 2012a)). TLR signaling is a component or the pathophysiology of atherosclerosis based on studies in mice (Galkina and Ley 2009). Platelets also have a number of other classes of receptors, providing a diverse signaling repertoire. These include "immunoreceptors" such as classic Fc receptors and a unique platelet adhesive and signaling factor, glycoprotein VI (GPVI)



Platelets, Atherosclerosis, and Immunity, Fig. 3 Platelets are rapidly deposited in plaque rupture and vascular stenting and mediate leukocyte accumulation and other inflammatory responses. Evolution of atherosclerotic plaques frequently leads to plaque ulceration or rupture (*left figures*). Platelets are rapidly deposited at sites of atherosclerotic plaque ulceration or rupture and mediate local vascular thrombosis. Platelet activation and local cellular interactions also induce inflammation, in addition to pathologic hemostasis (see Fig. 1, the *right panel* of Fig. 2, and text). Vascular intervention, including stent placement, is a commonly utilized approach together with antithrombotic and other pharmacologic management. Activated platelets are rapidly deposited at sites of angioplasty and intravascular stent deployment and mediate monocyte and PMN deposition in these regions (Palmerini et al. 2002; Welt and Rogers 2002) (*right figure*). Activated platelets and myeloid leukocytes may be key cellular determinants of restenosis rather than long-term patency after stent placement, based on experimental studies (Welt and Rogers 2002). (Reprinted from Rondina et al. 2013 with permission)

(Nieswandt et al. 2011; Vieira-de-Abreu et al. 2012a). Outside-in activating signals delivered by platelet receptors are transmitted to transduction pathways that are linked to functional responses (Davi and Patrono 2007; Michelson 2010; Nieswandt et al. 2011; Vieira-de-Abreu et al. 2012a). Both hemostatic and inflammatory/immune responses of activated platelets are frequently induced by the same receptors and use common signal transduction cascades. Although many functional responses of activated platelets are rapidly induced, depending on the specific receptor system, some of the functional alterations are also sustained over hours based on in vitro studies. This contrasts with the traditional idea that all important functional responses of activated platelets are over in a few minutes.

Responses of activated platelets include (reviewed in (Davi and Patrono 2007; Michelson 2010; Nieswandt et al. 2011; Vieira-de-Abreu et al. 2012a)) amplified adhesion to exposed collagen and subendothelial matrix; inside-out signaling of integrin $\alpha_{II}\beta_3$ (GPIIb/IIIa) and other surface integrins; binding of fibrinogen and fibrin; aggregation; presentation of a procoagulant surface; degranulation with surface translocation of P-selectin and secretion of preformed chemokines, cytokines, and antimicrobial peptides; cleavage and release of surface CD40 ligand (CD40L; CD154); and intercellular interactions and signaling of endothelial cells, leukocytes, and – in some cases – extravascular cells. Many of these responses have been recognized and studied for decades. In addition, however, recent discoveries have revealed "new biology" of platelets, including the ability to undergo cellular fission and the capacity to alter the resting platelet proteome by activation-dependent processing and translation of RNA species that make up a complex and extensive transcriptome in these cells (reviewed in (Vieira-de-Abreu et al. 2012a, b)). In parallel,

it is now recognized that platelets participate in adaptive immune responses in addition to being important innate immune effector cells and that they have diverse activities in acute and chronic infection and inflammatory diseases (reviewed in (Vieira-de-Abreu et al. 2012a, b)). Some or all of these activities may operate in human subjects with atherosclerosis and may contribute to the development of intimal plaques and/or to the complications of plaque rupture (Fig. 1).

The capacity to signal other cells is key in the inflammatory and immune activities of platelets, including their contributions to atherogenesis and its pathologic sequelae (Langer et al. 2012; Vieira-de-Abreu et al. 2012a). The signaling repertoire of activated platelets is extensive both in terms of the diversity of molecular signaling factors (see next section) and modes of intercellular signaling. The latter include juxtacrine signaling by factors anchored in the platelet plasma membrane, release of soluble paracrine signaling molecules, and release of microvesicles (microparticles) that transport and present signaling factors to "target" cells (reviewed in (Vieira-de-Abreu et al. 2012a)).

Platelets in the Initiation of Atherosclerosis and Development of Atherosclerotic Plaques: Pathogenesis and Experimental Observations

The precise events that initiate atherosclerosis are not yet known, but platelets may be key effector cells early in the process. Mechanisms traditionally proposed for atherogenesis include endothelial injury and/or dysfunction, and inappropriate plasma levels and dysregulated uptake of cholesterol and oxidatively modified phospholipids (Ross 1999; Galkina and Ley 2009; Kaplan 2009). There is experimental and clinical evidence that these are critical and, likely, interacting pathogenetic events that then drive progressive inflammation in regions of the arterial endothelium that are destined for plaque involvement, dictated in part by hemodynamic forces (Ross 1999; Galkina and Ley 2009). Additional mechanisms have been proposed, including local vascular infection and/or pathologic endothelial responses to a systemic pathogen burden, reactivity to self-antigens, and autoimmunity (Ross 1999; Galkina and Ley 2009; Kaplan 2009). Because platelets are immediate responders to vascular injury, and because inflammation is a fundamental biologic response to metabolic and mechanical as well as traumatic tissue damage, it is likely that platelets are involved early in atherogenesis and that the inflammatory and immune repertoire of platelets contributes to the initiation and progression of atherogenesis. Platelets respond directly to oxidatively modified lipids and oxidized low-density lipoprotein (LDL) (Marathe et al. 2002; Podrez et al. 2007) and to a variety of agonists generated as a consequence of vascular injury (Davi and Patrono 2007; Michelson 2010). Reactive oxygen species may link arachidonate conversion and isoprostane formation, platelet activation, and leukocyte accumulation in conditions that predispose to atherosclerosis, including diabetes, obesity, hyperhomocystemia, and smoking (Davi and Patrono 2007). These observations suggest that there may be a plethora of early signals that induce platelet activation in atherosclerosis.

Platelet adhesion to endothelium in areas of atherosclerotic involvement and to the surfaces of early fatty streaks and established plaques (Fig. 1) is said to be ubiquitous in experimental animals and humans (Ross 1999). Studies in mice, although yet of uncertain relevance to human atherogenesis (Rader 2012), support this conclusion and suggest that platelet accumulation on atherosclerotic endothelium has pathogenetic relevance. Some of the key observations include the following (reviewed in (Davi and Patrono 2007; Langer et al. 2012)): Platelets were found to adhere to the endothelium in arteries of mice genetically deficient in apolipoprotein E (*Apoe*$^{-/-}$), a commonly used model, before atherosclerotic lesions were detectable. Genetic deletion of the α_{IIb} subunit of integrin $\alpha_{IIb}\beta_3$, which is unique to platelets and megakaryocytes and is critical in platelet aggregation, adhesion, and outside-in signaling, reduced atherosclerotic involvement of the aorta and carotid arteries in

Apoe$^{-/-}$ animals. Bone marrow transplant experiments in mice deficient in P-selectin indicated that platelet P-selectin is involved in atherosclerotic lesion development. In addition, circulating activated platelets contributed to atherogenesis in *Apoe*$^{-/-}$ mice by secreting proinflammatory chemokines (see below) and by forming platelet-monocyte aggregates and promoting leukocyte accumulation on endothelial surfaces in a P-selectin-dependent manner. These experimental findings are consistent with observations that platelets and platelet products are found with monocytes, lipid-laden macrophages, and lymphocytes on, and/or in, fatty streaks and atherosclerotic plaques (Fig. 1). In addition, inhibition of synthesis of thromboxane A_2 (TXA_2), a major metabolite of arachidonic acid in activated platelets, TXA_2 receptor blockade, or genetic deletion of the TXA_2 receptor retarded atherosclerotic development in mouse models. In recent studies, inhibition of GPVI, which is expressed only by platelets, reduced atherosclerotic progression in rodent models.

The functional repertoire of activated platelets provides a variety of inflammatory and immune mechanisms that may be involved in their contributions to atherosclerotic initiation and progression (Fig. 2). Intercellular signaling is one of these (reviewed in (Vieira-de-Abreu et al. 2012a)) and is critical in activities of platelets in other inflammatory and immune syndromes and diseases (reviewed in (Vieira-de-Abreu et al. 2012b)). P-selectin on the plasma membranes of activated platelets engages a ligand, P-selectin glycoprotein (PSGL-1), on monocytes, neutrophils, and lymphocyte subsets, binding the cells together to form aggregates (Fig. 2). In human studies, formation of platelet-monocyte aggregates and their detection in circulating blood have been reported in conditions that predispose to atherosclerosis, including diabetes and smoking (Vieira-de-Abreu et al. 2012b), and in established atherosclerosis and acute coronary syndromes (Michelson et al. 2001; Michelson 2010). Platelet-monocyte aggregates also form in baboons (Michelson et al. 2001) and in atherosclerosis-prone mice (Huo et al. 2003). Interactions of platelets with leukocytes in this manner can facilitate adhesion of specific leukocyte classes – including monocytes, which are ubiquitously present at all stages of atherogenesis (Ross 1999) – to areas of activated endothelium and promote transmigration of the white blood cells to subendothelial domains (reviewed in (Vieira-de-Abreu et al. 2012a)). These are key features in fatty streak formation and plaque evolution (Ross 1999; Galkina and Ley 2009). Engagement of PSGL-1 on monocytes by P-selectin on activated platelets also delivers outside-in signals to the leukocyte, alone or in combination with additional paracrine and adhesive signals from the platelet or, in some cases, autocrine signals from the monocyte (Dixon et al. 2006; Vieira-de-Abreu et al. 2012a). These molecular signaling cues induce functional alterations in monocytes, including new or altered expression of inflammatory gene products that have demonstrated, or potential, activities in atherosclerosis (reviewed in (Vieira-de-Abreu et al. 2012a)). Binding of platelets to monocytes by interaction of P-selectin with PSGL-1 also influences cell fate determination, delivering signals that induce differentiation of monocytes to macrophages or, in contrast, to dendritic cells (reviewed in (Vieira-de-Abreu et al. 2012a)). This may be important because monocyte-derived lipid-laden macrophages and other macrophage subsets are present throughout the evolution of atherosclerotic lesions and are key cellular components of established plaques (Ross 1999; Galkina and Ley 2009), and because there is recent evidence for vascular dendritic cell networks in the arterial intima of humans and rodents (Galkina and Ley 2009; Langer et al. 2012). The precise activities of dendritic cells in atherogenesis are not yet clear (Galkina and Ley 2009; Langer et al. 2012). Activated platelets also directly interact with macrophages, dendritic cells, and lymphocyte subclasses (Vieira-de-Abreu et al. 2012a). These and other observations indicate that activated platelets are intermediaries of information transfer between key cells that can initiate and drive complex inflammatory and immune pathways in atherosclerosis, including cellular dialogues that link innate and adaptive immune responses. Activated platelets also

deliver molecular signals that trigger major inflammatory responses of endothelial cells (Langer et al. 2012; Vieira-de-Abreu et al. 2012a, b) (see Fig. 2 and below).

In addition to adhesion-dependent signaling of leukocytes mediated by P-selectin and PSGL-1, activated platelets deliver paracrine or juxtacrine chemokine and cytokine signals that can trigger proinflammatory events in atherogenesis and fan the fire of vascular inflammation (Davi and Patrono 2007; Galkina and Ley 2009; Langer et al. 2012). Chemokines and cytokines are components of a complex platelet secretome that includes more than 300 identified factors (Vieira-de-Abreu et al. 2012a). Activated human and murine platelets release chemokines of both the CXC (characterized by a single amino acid residue between the first two cysteine residues) and CC (characterized by the first two cysteine residues adjacent to one another) classes. Platelet factor 4 (PF4, CXCL4) and regulated upon activation, normal T expressed, and presumably secreted (RANTES; CCL5), which are constitutively present in platelet granules and are released on activation (Vieira-de-Abreu et al. 2012a), may be key mediators of atherogenesis based on experimental observations. PF4 activates monocytes and induces their differentiation to macrophages, inhibits LDL catabolism and promotes uptake of oxidized LDL by macrophages, and induces binding of oxidized LDL to other cells of the vascular wall (reviewed in (Langer et al. 2012)). Activated platelets are reported to deposit heterodimers of PF4 and RANTES on endothelium, triggering monocyte arrest (Huo et al. 2003; Koenen et al. 2009). RANTES is a pleiotropic mediator of inflammation (reviewed in (Vieira-de-Abreu et al. 2012a)) and has the potential to drive multiple cellular events in atherosclerotic inflammation (reviewed in (Galkina and Ley 2009; Koenen et al. 2009; Langer et al. 2012)). In $Apoe^{-/-}$ mice, inhibitors that disrupted PF4-RANTES interactions reduced monocyte recruitment and atherosclerotic involvement of the aorta (Koenen et al. 2009). Targeted deletion of CCR5, a chemokine receptor that recognizes RANTES, yielded mixed results in $Apoe^{-/-}$ mice (reviewed in (Galkina and Ley 2009)).

Together with chemokines, platelet cytokines also deliver signals that can drive atherogenesis. Interleukin-1β (IL-1β), a pleiotropic inflammatory cytokine and immune modulator, is released by activated platelets associated with microparticles and in soluble form; in addition, IL-1β mediates juxtacrine signaling while retained on the platelet plasma membrane and is also deposited in model thrombi, suggesting that clots serve as an intravascular cytokine reservoir (reviewed in (Vieira-de-Abreu et al. 2012a)). Activated human and mouse platelets synthesize IL-1β by a mechanism that involves regulated splicing of the *IL-1β* pre-mRNA and translation of the mature, processed transcript (reviewed in (Vieira-de-Abreu et al. 2012b)). In addition to IL-1β, other protein products including tissue factor (Schwertz et al. 2006) – which has prothrombotic activities in atherosclerosis and its complications – are synthesized by activated platelets in this fashion (Davi and Patrono 2007; Vieira-de-Abreu et al. 2012a). IL-1β synthesized by activated platelets induces inflammatory responses by monocytes, endothelial cells, and other cell types both in vitro and in vivo (reviewed in (Vieira-de-Abreu et al. 2012a, b)). IL-1β has been linked to atherogenesis by a variety of observations, including experiments indicating that lack of IL-1β decreases atherosclerotic burden in the $Apoe^{-/-}$ murine model and more recent studies in which transfer of bone marrow genetically deficient in IL-1β or in the NLRP3 inflammasome – which converts pro-IL-1β to the soluble, active cytokine – reduced atherosclerotic involvement in LDL receptor-deficient mice (reviewed in (Galkina and Ley 2009; Rader 2012)). A clinical trial is currently under way to test the possibility that inhibition of IL-1β with a humanized monoclonal antibody will reduce major cardiovascular events in subjects with preexisting atherosclerotic disease (Rader 2012). Recent murine studies suggest that IL-1 signaling may have complicated effects on atherosclerotic vessels, however, and can mediate both pathologic and compensatory alterations (Alexander et al. 2012; Rader 2012). This provides a cautionary note to be considered in interventional clinical trials and illustrates the

key point that inflammation is fundamental to protection of the host and to tissue repair and that beneficial inflammatory activities may occur in parallel with pathologic inflammatory events. Thus, anti-inflammatory interventions in atherosclerosis and other inflammatory conditions may have unintended negative consequences (Rader 2012). The cellular sources of IL-1β in clinical and experimental atherosclerosis, and the extent to which platelet-derived IL-1β contributes, are unknown. Activated platelets also induce IL-1β synthesis by monocytes (Dixon et al. 2006), suggesting a mechanism by which effects of platelet-derived IL-1β could be amplified in atherosclerosis and other disorders.

CD40 ligand (CD40L; CD154) is rapidly translocated from intracellular stores to the surfaces of activated platelets. Cleavage of CD40L yields a soluble, biologically active, cytokine fragment; platelets are the principal source of plasma CD40L (Davi and Patrono 2007; Vieira-de-Abreu et al. 2012a). CD40L and its receptor, CD40 – which is also found on platelets – are immune modulators of the tumor necrosis factor (TNF) and TNF receptor families that mediate intricate interactions between lymphocytes, myeloid leukocytes, and endothelial cells. Early studies indicated that genetic deletion or antibody inhibition of CD40L reduces atherosclerotic involvement in *Apoe*$^{-/-}$ mice (Galkina and Ley 2009; Langer et al. 2012). In addition, in vitro experiments provided mechanistic correlates, including evidence that activation of human endothelial cells occurs in response to juxtacrine signaling mediated by platelet-associated CD40L (reviewed in (Langer et al. 2012)). More recently, injection of *CD40L*$^{+/+}$ platelets into *Apoe*$^{-/-}$ mice was reported to induce platelet-leukocyte aggregate formation and platelet and leukocyte accumulation at endothelial surfaces and to accelerate atherosclerotic plaque development. In contrast, these events were inhibited when *CD40L*$^{-/-}$ platelets were injected, and *CD40L*$^{-/-}$ platelets did not induce atherosclerotic lesions. Platelet CD40L also influenced levels of regulatory T lymphocytes in the blood and spleen in this study (Lievens et al. 2010). These observations indicate that the CD40L-CD40 axis, like the IL-1 signaling system and the chemokines PF4 and RANTES, may be a key component of initiating and/or amplifying cascades in atherosclerotic inflammation (Davi and Patrono 2007; Langer et al. 2012). Targeted deletion of CD40, the ligand for CD40L, in LDL receptor-null mice did not reduce atherosclerotic lesion formation, suggesting alternative signaling pathways (Galkina and Ley 2009).

Platelets as Immune Effector Cells in Atherosclerosis: Clinical Correlates

Immunohistochemical analysis of human atherosclerotic vascular tissues indicates that the deposition of PF4 is associated with lesion severity and with symptomatic atherosclerosis, suggesting that persistent platelet activation contributes to the evolution of atherosclerotic vasculopathy (Langer et al. 2012). This further supports the idea that platelets are present early and continuously at sites of developing fatty streaks and maturing atherosclerotic plaques (see above and Figs. 1 and 2) (Ross 1999). In addition, several other platelet chemokines and inflammatory mediators are reported to be present in atherosclerotic plaques (Davi and Patrono 2007). Further clinical evidence also suggests that platelets are effectors in clinical atherosclerosis. This includes the following (reviewed in (Davi and Patrono 2007)): High plasma levels of CD40L were reported to be a marker of risk for vascular events in a prospective study of healthy women. Persistent platelet activation, detected by increased levels of thromboxane metabolites, has been associated with risk factors that contribute to accelerated atherogenesis in clinical studies. Additionally, risk factors including cigarette smoking, type 2 diabetes, and the combination of hyperinsulinemia and hyperglycemia are associated with platelet activation and increased plasma levels of CD40L. In noninvasive studies, platelet activation was associated with increased carotid artery wall thickness, and platelet degranulation was correlated with progressive thickening of the intima-media region of the common

carotid artery in patients with type 2 diabetes mellitus. These and other observations (reviewed in (Davi and Patrono 2007)) support the concepts that platelet activation is a central pathogenetic mechanism in clinical atherosclerosis and that the inflammatory and immune effector activities of platelets are induced in conditions that increase risk for atherosclerosis and its complications. These clinical correlates are also consistent with evidence from experimental inquiries that link activated platelets to atherogenesis, as outlined above (reviewed in (Langer et al. 2012)). New clinical and experimental studies examining the activities of platelets in obesity, diabetes, and the metabolic syndrome are in progress and may yield additional mechanistic insights regarding contributions of platelets to atherosclerotic risk imposed by these conditions.

Platelets and Inflammation in Acute Coronary Syndromes and Vascular Intervention

As noted previously, platelets are critical in vascular thrombosis that accompanies acute coronary syndromes and ischemic cerebrovascular events (Davi and Patrono 2007; Michelson 2010; Nieswandt et al. 2011). Their prothrombotic activities may involve newly recognized responses, including synthesis of tissue factor (Schwertz et al. 2006; Davi and Patrono 2007; Vieira-de-Abreu et al. 2012a), and more traditionally studied (Ross 1999; Michelson 2010; Nieswandt et al. 2011) procoagulant mechanisms. Platelet activation and adhesion pathways are targets for molecular therapies aimed at reducing or preventing thrombotic complications in these cardiovascular sequelae of atherosclerosis (reviewed in (Michelson 2010)). Inflammation – in addition to thrombosis – is also a concomitant of acute coronary syndromes (Figs. 1 and 3) (Davi and Patrono 2007), and ischemic stroke is suggested to be a "thrombo-inflammatory" disorder (Nieswandt et al. 2011). Platelets are intensely activated in the regions of ruptured or ulcerated atherosclerotic plaques (Figs. 1–3), and many of their inflammatory and immune effector mechanisms appear to be triggered in this context (reviewed in (Langer et al. 2012)). For example, platelet-monocyte and platelet-PMN aggregates form and circulate in patients with acute myocardial infarction (Michelson et al. 2001). Circulating platelet-monocyte aggregates are a particularly sensitive index of in vivo platelet activation in acute coronary events (Michelson et al. 2001) and – potentially – in other inflammatory syndromes (Vieira-de-Abreu et al. 2012b). "Antiplatelet" therapies for acute atherosclerotic cardiovascular syndromes (Michelson 2010) may interrupt inflammatory activities of platelets, in addition to abrogating their thrombotic responses, and may blunt chronic inflammation when they are administered for the long term after being initiated during treatment for acute atherosclerotic complications (Fig. 1).

Vascular intervention, including angioplasty and placement of intravascular stents, is a common approach to improve flow through critical areas of involvement in atherosclerotic coronary arteries (Fig. 3). Intravascular stents are also being evaluated in atherosclerotic cerebrovascular disease. Vascular interventions can yield prolonged patency, but can be complicated by acute periprocedural or delayed thrombosis. Furthermore, the therapeutic outcome is often impaired by restenosis of the vessel in the stent region (Fig. 3). Rapid platelet deposition and accumulation of polymorphonuclear leukocytes (PMNs) and monocytes are acute local responses to the iatrogenic vascular trauma of stent placement in humans and experimental animals (Palmerini et al. 2002; Welt and Rogers 2002). Platelet-PMN and platelet-monocyte aggregates also form and circulate after percutaneous coronary intervention (Michelson et al. 2001). Later (days to weeks), macrophages accumulate in the stented region and are observed around the stent scaffold (Welt and Rogers 2002). There is experimental evidence that platelets recruit leukocytes to the stent milieu (Palmerini et al. 2002) and that leukocyte accumulation is causally related to neointimal hyperplasia and restenosis (Welt and Rogers 2002). In addition to promoting leukocyte

accumulation, a variety of proinflammatory activities of platelets (Langer et al. 2012; Vieira-de-Abreu et al. 2012a) may contribute to dysregulated repair of the vascular surface and to excessive neointima formation that lead to stent restenosis. Platelet inhibitory therapies can alter acute cellular events in the stented vessel (Palmerini et al. 2002), and it is possible that new or combination approaches (Michelson 2010) may improve long-term outcomes by interrupting proinflammatory activities of platelets in this context. Platelets also have signaling pathways that are altered or interrupted by pharmacologic agents delivered by "drug-eluting" stents including the mammalian target of rapamycin (mTOR) cascade (Vieira-de-Abreu et al. 2012a), which is inhibited by sirolimus (rapamycin) – one of the drugs used to impregnate stents for local delivery in hopes of reducing restenosis.

Chronic Immune and Inflammatory Disorders, Atherosclerosis, and Platelets

The risk of atherosclerotic complications is increased in several chronic immune diseases and syndromes, based on observational, epidemiologic, and prospective controlled investigations. Two examples are rheumatoid arthritis and systemic lupus erythematosus (SLE). Premature atherosclerotic cardiovascular disease develops in a significant number of patients with these diseases (reviewed in (Galkina and Ley 2009; Kaplan 2009)). Activation of circulating platelets occurs in both syndromes, and there is evolving clinical and experimental evidence indicating that platelets are inflammatory effector cells in the extravascular manifestations (articular, renal, other) of rheumatoid arthritis and SLE (reviewed in (Vieira-de-Abreu et al. 2012b)). Thus, platelets may also be central to the amplified and accelerated progression of chronic atherosclerotic vascular inflammation in these and other systemic immune syndromes. Molecular mechanisms that are unique to each inflammatory/immune disorder may converge to trigger and sustain platelet activation (Vieira-de-Abreu et al. 2012b). Therapeutic strategies that include disease-modifying drugs specific to the chronic syndrome (Kaplan 2009) together with mechanistically targeted platelet interventions (Michelson 2010) may ultimately be indentified and used to favorably alter the natural history of atherosclerotic vasculopathy in these disorders.

Polyarteritis Nodosa

Atul Khasnis and Leonard H. Calabrese
Department of Rheumatic and Immunologic Diseases, Section of Clinical Immunology, Cleveland Clinic Foundation, Cleveland, OH, USA

Definition

A systemic inflammatory disease characterized by necrotizing medium-vessel vasculitis.

History

Polyarteritis nodosa (PAN) was the first vasculitis to be described in the medical literature (Kussmaul and Maier 1866). While the initial descriptions of this illness included clinical manifestations and consequences of necrotizing small- and medium-vessel inflammation, microscopic polyangiitis was described as an independent disease in 1949, and the Chapel Hill Consensus Conference defined PAN strictly as a medium-vessel vasculitis (Jennette et al. 1994).

Epidemiology

The annual incidence of PAN has been reported to be 9.0 per million in Olmsted County, Minnesota (Kurland et al. 1984). Overall, PAN is a rare illness when carefully defined, and successful immunization against hepatitis B has led to a decline in cases associated with this infection. It tends to affect both genders equally and can involve patients of all ages.

Etiology

The etiology of PAN is unknown. It may occur as a primary (idiopathic) process or secondary to

other diseases such as viral infections (hepatitis B, hepatitis C, Human Immunodeficiency Virus infection), other systemic autoimmune or autoinflammatory diseases (such as Familial Mediterranean Fever), or malignancy (such as hairy cell leukemia) Guillevin et al. 2008.

Pathogenesis

PAN is characterized by segmental necrotizing inflammation of arteries with infiltration of neutrophils and monocytes, often with leukocytoclasis, with or without thrombosis (Jennette et al. 2002). The pathogenesis of PAN is incompletely understood, but the formation of immune complexes (composed of antigen, immunoglobulin, and complement) has been implicated with resultant immune activation and vascular inflammation and damage. Although this has been well documented in some models of the disease, it has been inconsistently demonstrated in clinical studies. The deposition of immune complexes at arterial branch points (probably for mechanical reasons related to blood flow) is likely responsible for the location of arterial lesions in PAN. Fibrinoid necrosis is a nonspecific pattern of acute necrotizing injury resulting from many forms of necrotizing vasculitis characterized by accumulation of plasma proteins, including coagulation factors that are converted to fibrin, at sites of tissue destruction. Over time, fibrinoid necrosis is replaced by collagenous scar. Necrotizing inflammation resulting in extensive destruction of the vessel wall and perivascular tissue can have two consequences: aneurysms or pseudoaneurysms from weakening of the vessel wall and/or vascular occlusion with downstream ischemia. Focal activation of neutrophils and monocytes at the interface of blood and artery appears to be an early pathogenic event resulting in leukocyte activation and transmural infiltration of the artery wall and necrotizing injury. Variations in host immune responses undoubtedly play a role in the initiation and maintenance of vascular injury.

Clinical Features

PAN may remain confined to the skin (cutaneous PAN) or involve medium-sized blood vessels in multiple visceral organs. PAN tends to be a systemic illness. In a recent study of patients with PAN (Pagnoux et al. 2010), general symptoms (fever, weight loss, arthralgia, myalgia) were reported in 93.1 %, neurologic manifestations (central and peripheral nervous system) in 79 %, skin involvement (nodules, ulcers, gangrene, livedo reticularis) in 49.7 %, and abdominal pain and hypertension in approximately 35 % each. Approximately 70 % of patients in this study had histologically proven PAN. Hypertension in patients with PAN can be a consequence of renal artery involvement or glucocorticoid therapy. Other organ involvements can include cardiac and gastrointestinal (mesenteric ischemia, hemorrhage, cholecystitis, and intestinal perforation). Patients with HBV-related PAN were reported to have a higher frequency of peripheral neuropathy, abdominal pain, cardiomyopathy, orchitis, and hypertension compared to patients with idiopathic PAN. Orchitis occurs in approximately 25 % patients with PAN; this finding should lead to a suspicion of PAN in the appropriate clinical context. In contrast to vasculitides involving smaller vessels, PAN does not typically cause glomerulonephritis, palpable purpura, and/or alveolar hemorrhage from pulmonary capillaritis. For unclear reasons, pulmonary involvement does not occur in patients with this illness.

Diagnosis

The diagnosis of PAN is based on a compatible clinical presentation accompanied by laboratory test results and/or imaging studies. The clinical presentation of systemic inflammation is often accompanied by concordant laboratory tests (normochromic normocytic anemia, leukocytosis, thrombocytosis, low serum albumin, and elevated erythrocyte sedimentation rate and C-reactive protein). Liver enzymes may be abnormal in the

setting of active viral hepatitis. Clinical features should guide advanced workup for PAN, and invasive testing of asymptomatic areas is not recommended. In patients with abdominal pain, or new-onset hypertension, a conventional dye arteriogram of the mesenteric and renal arterial circulation may reveal microaneurysms. Other vascular imaging modalities such as CT angiography or magnetic resonance angiography are not sensitive enough to detect the presence of microaneurysms. The presence of microaneurysms is not pathognomonic of PAN and should be interpreted as evidence supportive of PAN in patients with a compatible clinical picture. Similarly, nerve and muscle biopsy (typically sural nerve and gastrocnemius muscle) can be associated with significant morbidity and should not be performed in patients without clinical peripheral nerve involvement. Since renal involvement in PAN is not from glomerulonephritis, there is no role for a renal biopsy, and this procedure may actually be associated with the risk of hemorrhage from rupture of a renal artery microaneurysm. Patients with PAN typically do not elaborate anti-neutrophil cytoplasmic antibodies (ANCA); therefore, testing for ANCA has no role in the diagnosis of PAN and should not be ordered unless otherwise clinically indicated.

Treatment

The treatment of PAN is guided by the severity of disease. Untreated disease has a uniformly dismal prognosis. Although occasional patients may have "limited" or mild enough disease to warrant treatment only with glucocorticoids, most patients with PAN are treated with a combination of glucocorticoids and a second immunosuppressant Sergent et al. (2009).

In 1996, the French Vasculitis Study Group devised a five-factor score (FFS) (Guillevin et al. 1996) based on patients with PAN, MPA, and Churg-Strauss syndrome (CSS) which included proteinuria >1 g/d, renal insufficiency (stabilized peak creatinine >1.4 mg/dL), cardiomyopathy, severe gastrointestinal manifestations, and CNS involvement. The revised FFS (Guillevin et al. 2011) based on patients with PAN, MPA, CSS, and granulomatosis with polyangiitis (Wegener's) (GPA) found that age >65 years, cardiac symptoms, gastrointestinal involvement, and renal insufficiency (stabilized peak creatinine >1.69 mg/dl) were associated with a high 5-year mortality. The presence of each was assigned 1 point. Ear, nose, and throat (ENT) symptoms, most commonly affecting patients with GPA and CSS, were associated with a lower risk of death, and therefore their absence was assigned 1 point. An FFS = 0 reflects patients without poor prognostic factors and an FFS ≥ 1 suggests the presence of poor prognostic factors that potentially necessitate stronger immunosuppression. Even in patients with an FFS = 0, with a good overall 5-year survival, glucocorticoids have been reported to achieve and maintain remission in only about half of the patients with 40 % patients requiring additional immunosuppressive therapy (Ribi et al. 2010).

Induction therapy for PAN typically involves high-dose glucocorticoids (for the first month followed by a gradual taper) and oral cyclophosphamide (2 mg/kg/day) for a period of 6–12 months. Thereafter, cyclophosphamide is replaced by methotrexate (oral or subcutaneous), azathioprine, or mycophenolate mofetil with continued taper of glucocorticoids for maintenance of immunosuppression. The choice of the maintenance immunosuppressant should be individualized. Informed decision making by the patient in terms of risk and benefit is imperative in the selection of immunosuppression, and close clinical and laboratory monitoring is Stone et al. (2002). In patients with PAN secondary to infection (such as hepatitis B or C or HIV) or malignancy, concomitant appropriate treatment of the primary illness is indicated.

Prognosis

The FFS was also used to derive prognostic information in patients with PAN based on the

severity of illness. Based on the original FFS, scores of 0, 1, and >=2 were associated with 5-year mortality rates of 12 %, 26 %, and 46 %, respectively. According to the revised FFS, 5-year mortality rates for scores of 0, 1, and >=2 were 9 %, 21 %, and 40 %, respectively. In a study comparing outcomes of HBV-associated PAN to idiopathic PAN (Pagnoux et al. 2010), HBV-associated PAN was associated with lower relapse rates but higher all-cause mortality. Age >65 years, hypertension, and gastrointestinal manifestations requiring surgery or surgical consultation were identified as independent predictors of death, whereas patients with cutaneous manifestations or non-HBV-related PAN had a higher risk of relapse.

Conclusion

PAN is a systemic medium-vessel vasculitis that merits prompt recognition and treatment. The choice of immunosuppression is guided by the severity of illness and mandates close monitoring. If the PAN is secondary to another illness, treating the primary illness is of utmost importance. Future research into disease pathogenesis will likely provide us with newer therapies that are safer and more effective.

Polymyalgia Rheumatica

Dimitrios Vassilopoulos
2nd Department of Medicine, Athens University School of Medicine, Hippokration General Hospital, Athens, Greece

Definitions

Polymyalgia rheumatica (PMR): Chronic inflammatory condition that affects mainly joints and extra-articular structures of shoulders, neck, and pelvic girdle in individuals after the age of 50.

Definition: Criteria

Polymyalgia rheumatic (PMR) is a chronic inflammatory condition that affects particularly joints and extra-articular structures of shoulders, neck, and pelvic girdle in individuals after the age of 50 (Salvarani et al. 2012). The disease can occur either alone or together with giant cell arteritis (GCA). It has been estimated that approximately 20 % of patients with PMR have GCA, while on the other hand 40–50 % of patients with typical GCA have clinical features of PMR (Salvarani et al. 2012). There have been a number of proposed diagnostic criteria over time for PMR, but none is universally accepted (Salvarani et al. 2012). Recently, the American College of Rheumatology (ACR) and the European League Against Rheumatism (EULAR) have set new classification criteria for the disease (Dasgupta et al. 2012).

Epidemiology

Compared to GCA, PMR is a more common disease with an annual incidence that ranges from 10 to 60 new cases/100,000/year in different countries; the disease is more common in Northern than Southern countries. In the USA, PMR is the most common type of autoimmune inflammatory disease after the age of 50, with an estimated lifetime risk of 2.4 % for women and 1.7 % for men (Crowson et al. 2011). This risk is higher than rheumatoid arthritis (RA) in the same population.

Pathogenesis

Pathological studies have identified varying degrees of inflammation in joints (synovitis) and extra-articular structures (bursitis) in the shoulders, neck, and hips of patients with PMR (Salvarani et al. 2012). The infiltrating cells are mainly CD4+ T cells and macrophages. A similar cellular infiltration is present in temporal arteries of patients with PMR (without GCA), but in the absence of cytokines such as IFN-γ which is usually found in GCA patients. Imaging techniques such as the ^{18}F-FDG-PET scan have identified subclinical inflammation of large arteries in approximately 1/3 of patients with PMR, but in contrast to GCA, vascular complications are rare in PMR patients (Salvarani et al. 2012). The factors that are involved in the initiation of this inflammatory process have not been identified so far.

Clinical Manifestations

The clinical presentation of PMR is characteristic with the abrupt onset of pain and stiffness in both shoulders and often in the neck and hip areas (Salvarani et al. 2012). The symptoms are worse in the morning and night. About one in four patients has pain and swelling of peripheral joints (arthritis) such as the wrists and knees, whereas almost 40 % have systemic manifestations such as low grade fever, weight loss, and fatigue (Salvarani et al. 2012). As mentioned earlier, 20 % of patients can have cranial symptoms of GCA.

Diagnostic Assessments

There are no specific laboratory or imaging tests for the diagnosis of PMR; the diagnosis is clinical and one of exclusion. As in GCA, the majority of patients have elevated erythrocyte sedimentation rate (ESR) and/or C-reactive protein (CRP) at presentation (Salvarani et al. 2012). Imaging of neck, shoulders, and hips by US, MRI, or ^{18}F-FDG-PET scan reveals synovitis accompanied by prominent bursitis of the affected areas (Salvarani et al. 2012). Unfortunately, these findings are not specific for PMR and can be seen in other inflammatory conditions.

Differential Diagnosis

Late-onset rheumatoid arthritis (RA) is the disease that most commonly mimics PMR (Salvarani et al. 2012). The absence of

rheumatoid factor (RF)/anti-CCP antibodies, joint erosions, and the dramatic response to corticosteroids seen in PMR patients can help in the differential diagnosis. Less frequently, spondyloarthropathies, neoplastic diseases, infections, hypothyroidism, Parkinson's disease, and inflammatory myositis can present with a similar clinical picture.

Treatment

Similarly to GCA, corticosteroids are the first-line treatment for PMR (Salvarani et al. 2012; Dasgupta et al. 2010). A lower initial dose is used (prednisolone 15–20 mg/day) with gradual tapering of the dose. Though the optimal tapering schedule and duration of treatment is uncertain, the treatment duration is commonly 1–2 years; relapses occur in more than half of the cases (Salvarani et al. 2012). Despite the lower cumulative prednisone dose compared to GCA, steroid-induced side effects are frequent occurring in three quarters of patients (Salvarani et al. 2012). Methotrexate and anti-TNF agents have been used as steroid-sparing agents with unclear or limited efficacy (Salvarani et al. 2012).

Given the advanced age of most patients with PMR and their significant corticosteroid exposure, attention to bone health is important. Adequate calcium and vitamin D intake should be routinely encouraged; consideration should also be given to antiresorptive treatment (e.g., a bisphosphonate medication) and monitoring bone mineral density.

Pregnancy in Systemic Lupus Erythematosus

George Stojan and Alan N. Baer
Division of Rheumatology, Johns Hopkins University School of Medicine, Baltimore, MD, USA

Synonyms

Fertility; Lupus; Puerperium

Definition

Systemic lupus erythematosus (SLE) is a multisystem autoimmune disease which primarily affects women in their reproductive age years. Pregnancy in SLE is associated with increased risks of morbidity and mortality for both the fetus and the mother. These adverse outcomes have well-defined risk factors which are often amenable to modification with preconception planning and careful pregnancy management. The presence of these risk factors also

varies substantially among affected patients. Fortunately, pregnancy can now be managed successfully for most women with SLE. The frequency of pregnancy loss in lupus has dropped over the last 40 years from levels as high as 43 % in 1960–1965 to 17 % in 2000–2003, a level now commensurate with that of the general US population (Clark et al. 2005). In a recent prospective multicenter study of 333 pregnant women with SLE, 80 % had a favorable pregnancy outcome (Buyon et al. 2011). Successful pregnancies in lupus require family planning, preconception counseling, and often management of the patient in a high-risk clinic with the close collaboration of a maternal–fetal medicine specialist and a rheumatologist (Baer et al. 2011; Stojan and Baer 2012).

Pregnancy in Systemic Lupus Erythematosus, Table 1 Risk factors for development of preeclampsia in SLE [Data abstracted from Magee et al. (2008), Stojan and Baer (2012)]

Active lupus nephritis and renal insufficiency at the time of conception
Sustained use of prednisone in doses of 20 mg per day or greater during the pregnancy
Thrombocytopenia
Maternal age $\geq$ 40 years
Previous preeclampsia
Family history of preeclampsia
Antiphospholipid syndrome
Preexisting hypertension or diastolic blood pressure $\geq$ 90 mmHg at first antenatal visit
Preexisting renal disease or proteinuria at first antenatal visit
Preexisting diabetes mellitus
Obesity (body mass index $\geq$ 35 kg/m2)

Pregnancy Outcomes in SLE

The risk of maternal mortality is increased 20-fold, while the risks for maternal morbidity, including cesarean sections, preterm labor, and preeclampsia, are also substantially increased (Clowse et al. 2008). Preeclampsia complicates 13–35 % of lupus pregnancies, compared with 5–8 % of pregnancies in the general US population (Clowse 2007). The risk factors for the development of preeclampsia in SLE are diverse (Table 1).

The rate of pregnancy loss (spontaneous abortion, miscarriage, or stillbirth), preterm birth, and intrauterine growth retardation (IUGR) is higher in women with SLE than in the general obstetric population. A summary of the fetal outcomes of lupus pregnancies in eight-case series is given in Table 2. Adverse fetal outcomes in a lupus pregnancy relate to a variety of maternal disease factors (Table 3).

Flares of Lupus Associated with Pregnancy

A worsening of lupus disease activity (i.e., a flare) occurs during pregnancy or in the immediate postpartum period with reported rates ranging from 13.5 % to 65 % (Molad et al. 2005). Seven prospective comparative studies have examined whether lupus flares are more frequent in pregnant lupus as compared to nonpregnant lupus patients (Table 4) (Stojan and Baer 2012). Four of these studies did not identify an increased rate of flares, while three did. This disparity reflects variability in the severity of lupus among the patients in the study cohorts and in the criteria for defining a lupus flare. More recent prospective studies utilized validated measures of disease activity and found a two- to threefold increase in lupus disease activity during pregnancy (Clowse 2007). The skin, kidney, blood, and joints are the most commonly affected organs in pregnancy-related lupus flares (Clowse 2007). Approximately 15–30 % of patients who flare will have severe disease manifestations, with involvement of the kidneys and other internal organs (Clowse 2007).

Pathophysiology of Lupus Flares During Pregnancy

Estrogens augment immunologic reactivity and mediate in part the increased risk of women for autoimmune disease. A direct role for a sex

chromosome effect on SLE disease risk has also been demonstrated (Smith-Bouvier et al. 2008). A progressive increase in serum estrogen levels is normal during pregnancy and is thought to promote lupus flares. Interestingly, this increase in estrogen levels was not documented in a study of 17 pregnant lupus patients, possibly as a result of placental compromise (Doria et al. 2002).

Pathologic lesions in the placenta, including vasculopathy, thrombi, and infarction, are common in lupus patients and may underlie the poor gestational outcomes of their pregnancies. Placental weight is generally reduced. These lesions are evident in lupus pregnancies irrespective of the presence of antiphospholipid antibodies. The placental injury may stem from hypercoagulability, hypertension, and immune-mediated vessel damage.

Complement activation may be important to the pathogenesis of preeclampsia, fetal loss, and intrauterine growth restriction. The induction of fetal loss and growth restriction in a murine model of antiphospholipid antibody syndrome required complement activation (Salmon and de Groot 2008). During trophoblast differentiation, phosphatidylserine is externalized on the trophoblast outer leaflet, where it is a target for antiphospholipid antibodies. The binding of these antibodies to the trophoblast, followed by activation of complement, is thought to trigger an inflammatory response with placental injury and adverse effects on the fetus. In pregnant women with or without lupus, the presence of the complement activation product Bb in first-trimester serum samples was a strong predictor of the subsequent development of preeclampsia (Lynch et al. 2008).

Regulatory T cells (T_{REG} cells) are a subset of T lymphocytes that have a key role in the regulation of the immune response and the induction of self-tolerance. They express the surface markers CD4 and CD25 at high levels, as well as a specific T_{REG} marker, the transcription factor forkhead box protein P3 (FOXP3). T_{REG} cells inhibit B, $CD4^+$ and $CD8^+$ T, and natural killer cells and suppress cytokine and antibody production. In SLE, T_{REG} cell numbers are reduced and their function is impaired. T_{REG} cells isolated from patients with SLE have reduced migratory ability and a reduced ability to suppress $CD4^+CD25^-$

Pregnancy in Systemic Lupus Erythematosus, Table 4 Flare rates in SLE

effector T cell proliferation (Tower et al. 2011). The maternal T_{REG} cell population is expanded in murine pregnancy (Aluvihare et al. 2004). Lower levels of T_{REG} cells have been found in human pregnancy decidua obtained from first-trimester spontaneous abortions compared to those from induced abortions (Sasaki et al. 2004), implying that a reduced T_{REG} cell response is involved in abnormal pregnancy. Pregnancy complications in lupus may thus be the result of an intrinsically dysfunctional T_{REG} cell.

Neonatal lupus results from the transplacental passage of maternal SS-A (Ro) and SS-B (La) antibodies that bind to fetal tissue. In the heart, these antibodies trigger inflammation of the atrioventricular nodal and myocardial tissues. Fibrosis ensues, resulting in varying degrees of heart block and occasionally a cardiomyopathy.

Fertility in SLE patients

Women with SLE have normal fertility, unless they are amenorrheic as a result of high disease activity, have advanced renal disease, or have received cyclophosphamide therapy for more severe organ manifestations. Both intravenous pulse and daily oral cyclophosphamide regimens are associated with a high rate of ovarian failure. The prevention of ovarian toxicity during intravenous cyclophosphamide therapy is often attempted with the parallel administration of gonadotropin-releasing hormone agonists (e.g., leuprolide, 3.75 mg, 2 weeks prior to each cyclophosphamide infusion).

Preconception Counseling and Management

The identification of modifiable risk factors for poor pregnancy outcomes in lupus mandates the need for pregnancy planning. Prior to considering pregnancy, a woman with SLE should be advised by her rheumatologist and/or a maternal–fetal medicine specialist as to the risks of both maternal and fetal problems based on her lupus disease activity, comorbidities, and obstetric history. She should receive a specific management plan, including alterations in her medication regimen (if necessary) and monitoring. The outcomes of SLE pregnancies are far better if conception is delayed until more serious lupus disease activity has been absent for at least 6 months and the patient's medication regimen has been adjusted in advance (see below). Women with certain forms of advanced organ damage or disease complications should be advised against considering conception. These include severe pulmonary hypertension, symptomatic restrictive lung

disease, heart failure, chronic kidney disease (serum creatinine 2.8 mg/dl or higher), cerebrovascular accident within the previous 6 months, a history of severe preeclampsia or HELLP despite therapy with aspirin and heparin, and a severe lupus fare within the previous 6 months (Ruiz-Irastorza and Khamashta 2008).

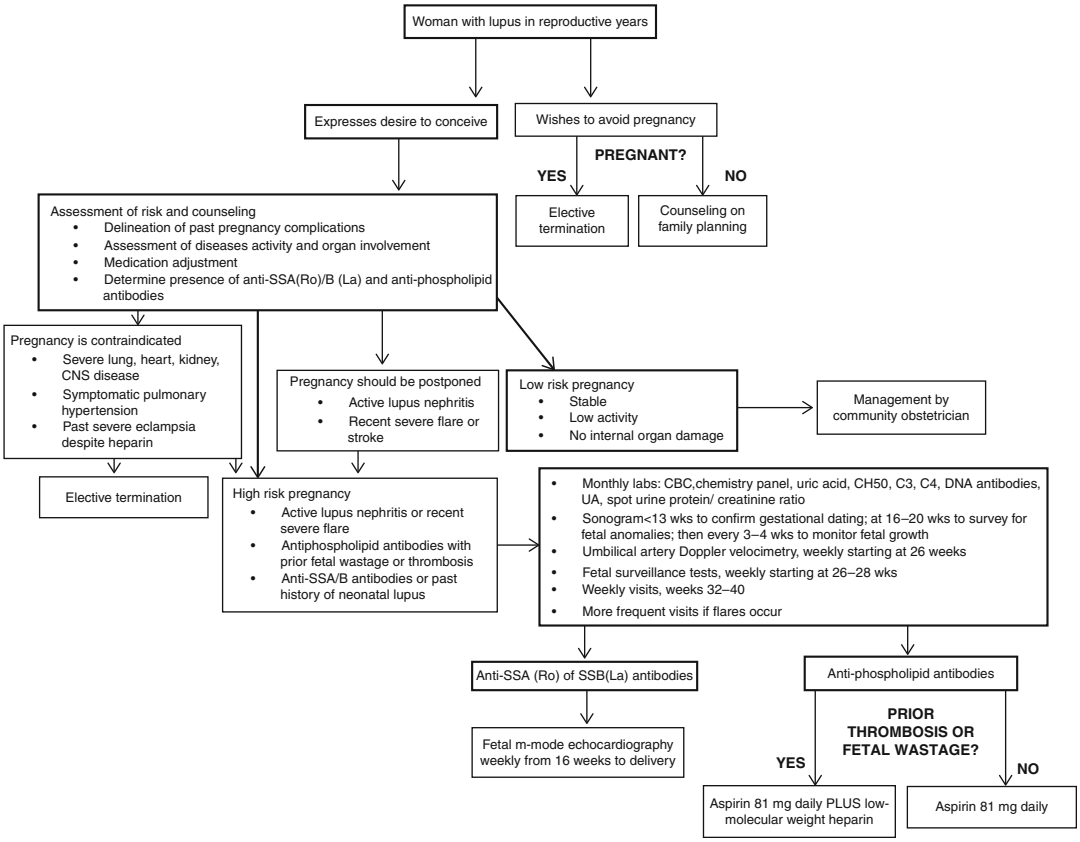
In the absence of any signs or symptoms of active SLE, affected patients require no specific treatment during pregnancy. Immunosuppressive medications with potential teratogenicity, including methotrexate, leflunomide, mycophenolate, and cyclophosphamide, should be stopped at least 3 months prior to conception. Leflunomide needs to be eliminated from the body with an 11-day course of oral cholestyramine, followed by a measurement of the blood level. Hydroxychloroquine is safe and should be continued during pregnancy. In fact, its discontinuation may place the patient at greater risk of increased lupus disease activity during her pregnancy. If there is a need for continued therapy with a nonsteroidal immunosuppressive agent, azathioprine is the safest because the fetal liver cannot metabolize azathioprine into its active form. Low-dose corticosteroid therapy can be maintained if needed for disease control, but the dose should be kept at levels equivalent to prednisone 10 mg daily or less. Higher corticosteroid doses have been reported to increase the risk of hypertension, preeclampsia, preterm birth, premature rupture of membranes, IUGR, and gestational diabetes in lupus patients. However, this has not been evident in the therapy of other conditions.

If antiphospholipid antibodies are present, prophylactic treatment is required to prevent fetal loss. In a first pregnancy, a woman with antiphospholipid antibodies but no history of thrombosis should be treated with low-dose (81 mg) aspirin alone. A woman with antiphospholipid antibodies and a past history of obstetric complications, such as late (>10 weeks) fetal death, IUGR, or preeclampsia, should be treated with low-dose aspirin plus low-molecular-weight heparin as soon as the pregnancy is confirmed. Enoxaparin 30 mg every 12 h or dalteparin 2,500 units every 12 h are used most commonly. Unfractionated heparin (5,000 units every 12 h) is an acceptable alternative. Low-molecular-weight heparin should be switched to unfractionated heparin 4 weeks before the anticipated delivery date. Unfractionated heparin is discontinued at the onset of labor or 8 h before planned cesarean delivery. Heparin is continued for 6 weeks postpartum. Low-dose aspirin alone may be an option for a woman with antiphospholipid antibodies and recurrent early (<10 weeks gestation) miscarriages, but many clinicians would prescribe concomitant heparin.

Diagnostic Testing During Pregnancy

The prenatal care of the pregnant woman with SLE generally requires management in a high-risk clinic and the close collaboration of the obstetrician with a rheumatologist. A detailed algorithm for the obstetric management of the pregnant lupus patient is provided in Fig. 1 and summarized in two recent reviews (Baer et al. 2011; Witter 2007).

At the onset of pregnancy, baseline laboratory tests should include, in addition to the standard registration labs, complete blood count (CBC) and chemistry panel as well as measures of renal function (urinalysis and spot urine protein-to-creatinine ratio) and lupus activity [complement 3 (C3), complement 4 (C4), total hemolytic complement activity (CH50), anti-double-stranded deoxyribonucleic acid (dsDNA)antibodies], estimates of the risk for neonatal lupus [anti-SS-A (Ro), anti-SS-B (La)] and for fetal loss (anticardiolipin antibodies, lupus anticoagulant). A baseline urate level should be obtained since an elevated serum urate level can be a marker of preeclampsia. On a monthly basis throughout the pregnancy, laboratory studies should include a CBC, chemistry panel with serum urate level, urinalysis, spot urine protein/creatinine ratio, C3, C4, CH50, and dsDNA antibodies. If there is protein by urine dipstick and/or an elevated spot urine protein-to-creatinine ratio, then a 24-h urine protein-to-creatinine ratio should be measured.



Pregnancy in Systemic Lupus Erythematosus, Fig. 1 Algorithm for the management of pregnancy in lupus [Figure from (Baer et al. 2011) and reproduced with permission]

A sonogram with measurement of crown-rump distance should be performed early in pregnancy to confirm gestational dating and again at 16–20 weeks of gestation, to survey for fetal anomalies, and to monitor fetal growth. Subsequent sonograms should be done at 4-week intervals or every 3 weeks in the setting of preeclampsia or suspected IUGR to monitor fetal growth and measure amniotic fluid volume. Uterine artery Doppler studies serve to define the adequacy of uteroplacental blood flow and may have utility as a predictor of preeclampsia. The first such study may be done around the 20th week of gestation and if abnormal, repeated 4 weeks later.

Fetal surveillance tests should be started at 26–28 weeks and continued weekly until birth. These include the nonstress test (NST) which can begin at 28 weeks, the biophysical profile which can begin at 26 weeks without the NST, and fetal umbilical artery Doppler velocimetry which can be begin at 26 weeks. Abnormal umbilical and uterine arterial blood flow assessed with Doppler velocimetry during the second trimester may be predictive of preeclampsia and IUGR. Detection of IUGR with these fetal surveillance tests should prompt closer monitoring and consideration of early delivery.

In utero heart block develops as a manifestation of neonatal lupus after 16 weeks of gestation. Most cases occur between 16 and 24 weeks, but some occur as late as 38–40 weeks. Since the early recognition of heart block in the fetus may allow for therapeutic intervention, close monitoring of at-risk fetuses is mandatory. The fetal heart rhythm should be monitored by m-mode echocardiography weekly from 16 weeks onward.

Recognition of a Lupus Flare During Pregnancy

Medical complications of a lupus pregnancy include lupus flares with or without glomerulonephritis, hypertension, preeclampsia, and the hemolysis, elevated liver enzymes, and low platelet counts (HELLP) syndrome (Stojan and Baer 2012). Recognition of a lupus flare during pregnancy may be difficult since the signs and symptoms may mimic those of normal pregnancy. Examples of this apply to most organ systems (Table 5). Severe fatigue, facial and palmar erythema, melasma, postpartum hair loss, dyspnea, arthralgias, and headaches frequently accompany normal pregnancy. Bland joint effusions occur in late pregnancy. The serum creatinine level is decreased as a result of increased renal blood flow and glomerular filtration rate. A serum creatinine of >0.8 mg/dl and blood urea nitrogen (BUN) >13 mg/dl are considered indicative of renal impairment in pregnancy. A creatinine level that remains stable throughout pregnancy and does not decrease can also be a sign of renal insufficiency. The increased renal blood flow of pregnancy results in increased tubular flow and urine protein spillage. Levels of proteinuria up to 300 mg/day are considered normal in pregnancy. In women with prior renal damage from lupus nephritis, the degree of urine protein loss may increase. However, a doubling in the amount of the baseline urine protein should be a cause for concern. Hepatic protein synthesis also increases in pregnancy, and this can result in higher levels of the serum complement components as well as fibrinogen. The latter may lead to a substantial increase in the erythrocyte sedimentation rate in a normal pregnancy.

Assessing Lupus Activity During Pregnancy

The established lupus activity scales, for example, the Lupus Activity Index (LAI), SLE Disease Activity Index (SLEDAI), and Systemic Lupus Activity Measure (SLAM), were validated with populations that excluded pregnant women and included men. Their shortcomings

Pregnancy in Systemic Lupus Erythematosus, Table 5 Assessment of lupus flares in pregnancy

Feature	Findings indicative of a lupus flare	Findings of normal pregnancy that can mimic a flare
Clinical	• Active rash of lupus • Inflammatory arthritis • Lymphadenopathy • Fever >38 °C (not related to infection or drug) • Pleuritis • Pericarditis	• Fatigue • Arthralgias • Bland effusions of knees • Myalgias • Malar and palmar erythema • Postpartum hair loss • Carpal tunnel syndrome • Edema of hands, legs, and face • Mild resting dyspnea
ESR	Increased	18–46 mm/h < 20 weeks gestation
		30–70 mm/h ≥ 20 weeks gestation
Anemia	Hemoglobin <10.5 g/dl	Hemoglobin >11 g/dl during first 20 weeks gestation
		Hemoglobin >10.5 g/dl hr after 20 weeks gestation
Thrombocytopenia	Platelet count <95,000	Mild in approximately 8 %
Urinalysis	Hematuria or cellular casts	Rare hematuria from vaginal contamination
Proteinuria	≥300 mg/d	<300 mg/dl
dsDNA antibodies	Rising titers	Negative or stable titers
Complement	≥25 % drop	Usually increased

Adapted from Baer, Witter, and Petri (2011) and Stojan and Baer (2012) and reproduced with permission

in distinguishing between physiologic changes seen in pregnancy and true lupus manifestations led to the development of the LAI-P and SLEPDAI, lupus activity scales specific for pregnant women (Stojan and Baer 2012).

Differentiation of Preeclampsia from a Lupus Nephritis Flare

Preeclampsia is defined as a blood pressure >140/90 mmHg and proteinuria >300 mg in a 24-h urine specimen detected for the first time after 20 weeks of gestation. It is often difficult to differentiate preeclampsia from lupus nephritis, since both entities may present with increasing proteinuria, hypertension, lower extremity edema, deterioration in renal function, and thrombocytopenia. The two conditions may coexist.

Features that distinguish preeclampsia from active lupus nephritis are summarized in Table 6. These include a serum uric acid >5.5 mg/dl, a urine calcium level of <195 mg/day, and rising liver enzyme levels. Features of active lupus nephritis include a rise in dsDNA antibody titer, low or dropping complement levels, increased lupus activity in other organs, and active urinary sediment. A renal biopsy may be needed to define the presence of active lupus glomerulonephritis; however, consideration should be given to the increased risk of bleeding following such biopsies in pregnancy. On occasion, this diagnostic dilemma can only be resolved with delivery of the fetus or a trial of empiric therapy.

Pregnancy in Systemic Lupus Erythematosus, Table 6 Differentiation of active lupus nephritis from preeclampsia

	Active lupus nephritis	Preeclampsia
Hypertension	Onset before 20 weeks	Onset after 20 weeks
Proteinuria	≥300 mg/d	≥300 mg/dl
Urinary sediment	Active	Inactive
Uric acid	≤5.5 mg/dl	>5.5 mg/dl
DNA antibody levels	Rising	Stable or negative
24-h urine calcium	≥195 mg/day	<195 mg/day
Complement levels	≥25 % drop	Normal

Adapted from Baer, Witter, and Petri (2011) and Stojan and Baer (2012) and reproduced with permission

Therapy of Lupus Flares During Pregnancy

The management of lupus flares during pregnancy depends on the severity and type of organ involvement. Nonsteroidal anti-inflammatory drug (NSAID) use after 20 weeks of pregnancy is avoided since it has been associated with premature closure of the patent ductus arteriosus, reversible oligohydramnios, gastrointestinal bleeding or perforation, increased risk of necrotizing enterocolitis, pulmonary hypertension, intracranial bleeding, and prolongation of labor. Hydroxychloroquine decreases the incidence of flares and should be maintained throughout pregnancy, particularly if it was being used prior to conception. It is generally effective for arthritis and skin manifestations of lupus. Lupus flares that are not adequately controlled with acetaminophen and hydroxychloroquine require corticosteroids. Anemia (hemoglobin <8 g/dl), sustained fever (>38.5 °C), and low serum albumin levels (<3 g/dl) threaten the developing fetus and demand more aggressive therapy (Lockshin and Sammaritano 2003). Prednisone and prednisolone are the preferred corticosteroids in pregnancy because they are readily inactivated by the placenta. The fluorinated glucocorticoids, dexamethasone and betamethasone, cross the placenta easily without being inactivated and should only be used if there is intent to treat the fetus, such as treating in utero heart block or inducing fetal lung maturation before preterm delivery. Low doses (<20 mg/day) of prednisone are used to treat mild lupus activity, while pulse doses of intravenous methylprednisolone are used to treat more severe lupus activity. There may be a twofold increased risk for cleft lip or palate with systemic corticosteroid use in the first trimester, although the absolute risk remains low (Pradat et al. 2003). Important adverse effects in pregnancy include hypertension, osteopenia, osteonecrosis,

susceptibility to infection, and an increased risk of gestational diabetes.

In order to minimize steroid exposure of patients with moderate to severe lupus activity, long-term management with a second-line, "steroid-sparing" agent may be needed. The preferred drug in this category is azathioprine at a daily dose not exceeding 2 mg/kg, although its use during pregnancy has been associated with IUGR and an increased rate of pregnancy loss. Cyclosporine is safe for the fetus and can be used to treat renal disease during pregnancy but poses risks of maternal nephrotoxicity. Many successful pregnancies have been reported in women with solid organ transplants who continue treatment with cyclosporine and tacrolimus during pregnancy, without any increased risk of congenital abnormalities when compared to the general population. Intravenous immunoglobulin has no known adverse effects on the fetus and is used for the treatment of thrombocytopenia during pregnancy. Mycophenolate is teratogenic and should be avoided during pregnancy.

Severe manifestations of lupus that do not respond to other therapies may require cyclophosphamide, with the understanding that the fetus may not survive without treatment of the mother. First-trimester use is associated with fetal malformations, whereas use in the second and third trimesters has been associated with growth retardation and suppression of fetal hematopoiesis.

Animal data on the safety of belimumab are encouraging since teratogenic effects were not identified. Due to insufficient data regarding fetal exposure to belimumab, the current Food and Drug Administration recommendations are to discontinue belimumab 4 months prior to anticipated conception. Rituximab is detectable in serum 3–6 months after completion of the treatment infusions and has been detected in the serum of infants exposed in utero. Studies of children who were exposed to rituximab early in pregnancy have not demonstrated any adverse outcomes to date; however, second- and third-trimester exposure causes B cell depletion in the fetus with unknown long-term effects. Although congenital malformations and neonatal infections were rarely seen among exposed neonates, women should continue to be counseled to avoid pregnancy for 6–12 months after rituximab exposure.

The optimal treatment for in utero heart block in a mother with anti-SS-A (Ro) or SS-B (La) antibodies has not been established. The use of hydroxychloroquine during pregnancy is associated with a reduced risk of fetal heart block, while intravenous immunoglobulin therapy does not reduce the incidence of fetal heart block in high-risk pregnant women with a previous pregnancy complicated by this disease (Pisoni et al. 2010). The initiation of maternal oral dexamethasone (4–8 mg/day for 2 weeks, followed by 4 mg/day) therapy is recommended at the first indication of heart block due to a significant reduction in morbidity and improved outcomes of routinely treated fetuses.

Conclusion

Successful pregnancies can be realized for the majority of women with systemic lupus erythematosus. However, the management of such pregnancies requires careful preconception planning and advanced adjustment of medications. The best outcomes for a lupus pregnancy occur when the disease has been in remission for at least the 6 months prior to conception.

Definition

Primary biliary cirrhosis (PBC) is a chronic inflammatory autoimmune disease that targets mainly the cholangiocytes of the interlobular bile ducts in the liver. The condition affects primarily middle-aged women. Without treatment, PBC generally progresses to cirrhosis and eventually liver failure over a period of 10–20 years.

The term "primary biliary cirrhosis" was coined to distinguish the disease from obstructive biliary cirrhosis by Dauphinée and Sinclair in 1949 (Dauphinee and Sinclair 1949) and used by Arhens and colleagues in 1950 in their description of the disease affecting middle-aged to older women with progressive jaundice, pruritus, and hepatosplenomegaly (Ahrens et al. 1950). In 1965, Rubin and colleagues coined the fundamental histological lesion as non-suppurative destructive cholangitis (NSDC) (Rubin et al. 1965). The disease-specific hallmark – the antimitochondrial antibody (AMA) – was identified the same year by Walker and colleagues, a discovery that allowed a confident diagnosis earlier in the course of the disease (Walker et al. 1965). Among the various mitochondrial antigens, the so-called M2 was shown latter to be specifically associated with PBC (Berg et al. 1982). Five years later, the cDNA for the major mitochondrial antigen of PBC was cloned from gene expression library and identified as the pyruvate dehydrogenase complex (Gershwin et al. 1987).

Epidemiology

The incidence and prevalence of PBC have increased over time. Most recent data in Europe, North America, and Japan show an incidence of 2–4 per 100,000 population per year and point prevalence at 20–40 cases per 100,000 (Poupon 2010). Geographic clustering is striking, suggesting genetic as well as environmental influences in its pathogenesis. Whether the higher incidence and prevalence rates reflect a genuine increase or whether they are due to a higher detection rate remains unknown.

Causes and Pathogenesis

PBC is thought to be a complex disease resulting from the combination of multiple genetic factors and superimposed environmental triggers (Poupon 2010). These factors may affect one or more components of the immune system and of the tissue targeted by the disease. Genetic predisposition is suggested by the familial clustering of the disease and the high degree concordance between monozygotic twins. The prevalence of PBC is 100 times higher in first-degree relatives

than in the general population. Allelic variations in MHC class II (DR,DQ), components of the innate (C4*Q0,C4B*2,NRAMP1/SLC11A1, MBL,VDR) and adaptive (CTLA4, Il beta, TNF alpha, IL12A, IL12RB2) immune systems, have been associated with PBC susceptibility. The genetic basis of variability in disease progression is poorly known. The French prospective study of genetic factors of PBC severity has suggested a role for TNF alpha and SLCA2/AE2 variants. Regarding environmental factors, mucosal infections, particularly urinary tract infections, and cigarette smoking have been consistently associated with PBC. Smoking not only predisposes to disease but may also accelerate its progression. The role of xenobiotics through covalent binding of 2-octynoic acid, a component of many chemicals, to proteins is suggested by experimental studies. The ratio of women to men affected by the disease is 10 to 1.

Clinical Presentation

There are three major forms of PBC. The typical or classical form is represented by the slowly progressive decline of small bile ducts and parallel increase in liver fibrosis, leading to biliary cirrhosis over a period of 10–20 years. A second form that affects 10–20 % of patients is characterized by the fluctuating or persistent presence of autoimmune hepatitis (AIH) features. These patients have a more severe course, with early development of hepatic fibrosis and liver failure. A third form that affects 5–10 % of patients is represented by the so-called premature ductopenic variant. Its hallmark is a very rapid onset of ductopenia, severe icteric cholestasis, and hyperlipidemia, progressing toward cirrhosis and liver failure in less than 5 years.

PBC is now diagnosed earlier in its clinical course than it was in the past. Half of the patients are asymptomatic at diagnosis. Fatigue and pruritus are the two symptoms of the early phase of the disease. Fatigue, a frequent complaint, is unrelated to the severity. Whether it is a specific symptom or not remains unknown. It is associated with cognitive and emotional dysfunction, depression, and sensory and autonomic abnormalities. It may be associated with excessive day-time somnolence. A mild pruritus affects about half the patients at diagnosis. This pruritus might be severe and affect the quality of life in the premature ductopenic variant.

In some patients, the diagnosis is made in the work-up of another autoimmune disease.

In 5 to 10 of the patients, the diagnosis is made at the stage of compensated or decompensated cirrhosis. The variant associated with AIH features might be misdiagnosed for acute cytolytic hepatitis.

Biochemistry of the typical form of the disease is predominantly characterized by elevation of serum alkaline and gamma-glutamyltranspeptidase activities while serum transaminases are mildly or only moderately increased. In the premature ductopenic variant of the disease, cholestasis is prominent and associated with considerable hypercholesterolemia affecting both HDL, LDL, and LPX fractions. In patients with both AIH and PBC features, serum transaminase activities may be markedly elevated and usually associated with marked elevation of IgG and presence of smooth muscle antibodies. Increased serum IgM level is detected in 80 % of the patients. Thrombocytopenia, polyclonal hyperglobulinemia, and hyperbilirubinemia are indices of cirrhosis. Low prothrombin index and hypoalbuminemia are usually observed in the late phase of the disease. However, mild hypoalbuminemia, occurring possibly as a result of the inflammatory process, may be present in the absence of cirrhosis in some patients with early stage disease.

Diagnostic Investigation

Good ultrasound investigation of the liver and biliary tree is mandatory in all patients with liver abnormalities. If ultrasound suggests a normal biliary system and if the patient is AMA type M2 positive, no further radiologic delineation of the bile ducts is necessary. Cholangiography might be necessary in the following settings: atypical presentation even in

case of AMA positivity, AMA negativity, and suspicion of comorbidity affecting the biliary tract.

A major PBC hallmark is the presence of serum AMA type M2. The AMA that reacts with the E2 component of pyruvate dehydrogenase serves as a diagnosis for PBC. A variety of antinuclear antibodies are associated with PBC. Antibodies recognizing proteins of the pore complex (gp 210, nucleoporin 62) and nuclear body protein (sp100) are almost totally specific.

Liver histologic examination is only mandatory for the diagnosis if the AMA test is negative or if the patient displays the atypical biochemical sign of PBC or is suspected of superimposed comorbidity. Nevertheless, it should be emphasized that histology is valuable for prognostic evaluation and treatment strategy.

The three following criteria allow PBC diagnosis: (a) abnormal biochemical tests with preferential elevation of serum alkaline phosphatase and gamma-glutamyltranspeptidase activities; (b) presence of antimitochondrial antibodies with M2 specificity by ELISA or immunoblotting; (c) histological evidence of LDC. These three criteria are sufficient for diagnosis considering the high specificity of anti-M2 antibody and LDC.

Patients with AMA and normal biochemical tests may be at risk of developing true PBC and their liver function tests should be reassessed annually.

AMA negative patients with biochemical evidence of cholestasis may have PBC if LCD or portal inflammation and ductopenia are observed in liver biopsies. The diagnosis is further supported in this setting if antinuclear antibodies against gp210, Nucleoporin 62, sp100 giving nuclear-rim or nuclear-dot pattern are present. LDC is highly suggestive of PBC but is not pathognomonic since it may be present in patients with AIH, primary sclerosing cholangitis, lymphoma, and viral hepatitis C and E.

AIH variant forms might display several concurrent PBC features and be difficult to diagnose. Antibodies specific for the M2 autoantigen could be found in a minority of AIH patients. Up to 24 % of AIH patients might display histological bile duct injury without biochemical cholestasis but they respond to AIH conventional therapy. Finally, up to 20 % of PBC patients might have features of AIH at presentation or during the follow-up (Poupon 2003). In this context, the so-called PBC-AIH overlap syndrome is defined by the simultaneous or consecutive concurrent main characteristics of the two conditions. The following score has been proposed to establish the diagnosis, e.g., presence of two of the three following features: (1) ALT activity $\geq$ 5 times upper limits of normal; (2) IgG $\geq$ 2 times upper limits of normal and/or positive anti-smooth muscle antibody; and (3) liver biopsy with moderate or severe periportal or periseptal inflammation. Patients with PBC-AIH overlap syndrome have a more severe disease compared to patients with PBC alone.

Treatment

Specific Therapy

UDCA Therapy

All PBC patients with abnormal liver function tests should be considered for therapy (Poupon 2010, 2003; European Association for the Study of the Liver 2009; Lindor et al. 2009). Daily treatment with 13–15 mg/kg of UDCA is currently considered the mainstay of PBC therapy. Randomized, double-blinded, placebo-control trials have consistently shown that UDCA improves liver function test parameters including serum bilirubin, the major prognostic marker in PBC. UDCA delays the progression of fibrosis and liver damage. A combined analysis of three randomized-controlled trials including 548 PBC sufferers showed that UDCA treatment for up to 4 years led to improved survival of patients with moderate to severe disease. These patients did not require liver transplantation. Long-term studies have shown that UDCA therapy provides a better survival than that predicted by the Mayo model. The survival rate of UDCA-treated patients at an early stage of the disease is similar to that of a control healthy population. In both Europe and

North America, the number of liver transplants for PBC is falling in parallel with increasing use of UDCA therapy. A meta-analysis that included short-term trials with low doses of UDCA (less than 12 mg/kg/day) has questioned UDCA efficacy. However, on the basis of all available data, it is currently recommended to treat PBC with UDCA using doses of at least 13 mg/kg/day and to start early. The aim of UDCA therapy is normalize serum bilirubin, alkaline phosphatase, and ALT or AST levels during the first year of therapy. Patients with normalized liver function test parameters have a null risk to progress to cirrhosis. This could not, however, be achieved in all patients. To be effective, UDCA should ideally be used to treat patients with serum bilirubin levels less than 1 mg/dl and AST levels less than twice the upper normal limit of normal, and alkaline phosphatase less than three times the upper normal limit of normal at the end of the first year of therapy. Indeed, the patients with these criteria have a 10-year life expectancy without liver transplantation similar to that of the control population. Other studies have reported that patients showing a > 50 % decline in serum alkaline phosphatase levels have an excellent long-term prognosis. About 40 % of patients have a suboptimal response to UDCA. These patients need an adjuvant therapy.

Adjuvant Therapies

Patients with features of AIH, severe interface hepatitis, abnormal serum bilirubin levels, or suboptimal response to UDCA (as defined above) deserve trials with adjuvant therapies. However, there is no consensus on how to treat these patients.

As stated by the EASL Clinical Practice Guidelines, combined therapy with UDCA and steroids is the recommended therapeutic option for patients with PBC-AIH overlap syndrome.

Glucocorticoids (prednisone or budesonide) and methotrexate could be also considered for patients with incomplete response and ongoing liver inflammation and destructive cholangitis. The rationale for the use of glucocorticoids is based on the following arguments. Glucocorticoids and specifically budesonide have been shown to be beneficial for UDCA-treated patients. Combination of both treatments improves liver function tests and decreases inflammation and fibrosis. The drug is, however, contraindicated for patients with cirrhosis. Patients with a suboptimal response to UDCA and marked periportal inflammation benefit from a treatment combining UDCA and glucocorticoids (in particular budesonide). In this setting, steroid-sparing agents, such as azathioprine or mycophenolate mofetil, could be used.

Methotrexate improved biochemical test results and liver histological findings when it was added to UDCA in patients who had marked portal and periportal inflammation and incomplete response to UDCA. However, other studies found no efficacy of methotrexate when used alone or in combination with UDCA. Several drugs, including cyclosporine, colchicine, chlorambucil, penicillamine, azathioprine, mycophenolate mophetil, malotilate, and thalidomide, have been evaluated for the treatment of PBC. Many of them are either ineffective or toxic. None of them have been shown to be effective in UDCA-treated patients with a risk of developing cirrhosis or liver failure as defined above.

New Medical Therapeutic Options

FXR is a major bile acid receptor that regulates the expression of genes involved in bile acid and lipid metabolism. It may also modulate innate immunity in the biliary tree and intestine. The FXR agonist, obeticholic acid, improved liver function tests and reduced IgM levels in PBC. The efficacy of this drug is currently assessed in a phase 3 clinical trial.

PPAR alpha agonists (bezafibrate, fenofibrate) are now recognized for their anti-inflammatory and immunomodulatory properties in several experimental models of autoimmunity. Short-term administration of fibrates leads to marked improvement of liver biochemistries and immunoglobulin levels in PBC. Whether it could improve liver inflammation and fibrosis remains unknown.

Liver Transplantation

Liver transplantation has greatly improved survival in patients with PBC (MacQuillan and Neuberger 2003). It is the only effective treatment for those with decompensated cirrhosis or liver failure. The patients featuring the premature ductopenic variant of PBC do not respond to any medical therapy and despite the absence of any decompensation draw a major benefit from liver transplantation. PBC recurs in about 20 % of patients at 5 years. Recurrence is more frequent in patients without a glucocorticoid and ciclosporin regimen. The beneficial long-term effect of UDCA in this setting remains unknown.

Treatment of Symptoms and Complications

Pruritus

Cholestyramine is widely used as first-line treatment although the evidence to support this use is limited. When both UDCA and cholestyramine are used, each drug should be administered at a minimum of 4 h apart to prevent binding and loss of efficacy. Although there is strong evidence that Rifampicin at a daily dosage of up 600 mg/day is effective to treat patients receiving UDCA, this drug induces occasionally hepatitis. Other therapies include glucocorticoids, sertraline, and opiate antagonists. Plasmapheresis or biliary drainage may be successful when other treatments fail. In very few patients, resistant pruritus may be an indication for liver transplantation.

Fatigue

The fatigue could be multifactorial and causes other than PBC should be considered. Modafinil, a drug approved for the treatment of narcolepsy, has been reported in open studies to provide significant benefit for PBC patients with fatigue. The drug used at a dose up to 400 mg/day seems to be well tolerated and seems effective in those with excessive fatigue and day-time somnolence.

Hypercholesterolemia

UDCA induces an average 15–20 % fall in total and LDL cholesterol at 1 year of therapy. Statins and fibrates are safe and effective in PBC.

Portal Hypertension

A minority of patients with PBC develop presinusoidal portal hypertension before developing cirrhosis. The management of portal hypertension in patients with PBC should be as for all cirrhotic patients. Severe portal hypertension even without any other sign of decompensation is a good indication of liver transplantation.

Osteopenia and Osteoporosis

Current treatments for osteopenia and osteoporosis that affect up to 30 % of PBC patients included physical activity, calcium, and vitamin D supplementation in order to achieve at least 30 ng/ml of serum 25OH D3, bisphosphonates or estrogens supplementation.

Conclusion

- Primary biliary cirrhosis is a chronic inflammatory autoimmune disease that targets mainly the cholangiocytes of the interlobular bile ducts.
- PBC is a rare disease that affects primarily middle-aged women.
- Risks factors include history of familial autoimmune disease, history of active or passive smoking, and recurrent urinary tract infections.
- PBC is associated with features of autoimmune hepatitis in 10 % of the patients.
- Diagnosis of PBC can be established when two of the following three criteria are met: unexplained chronic elevation of alkaline phosphatase, presence of AMA type 2, or histologic evidence of lymphocytic destructive cholangitis.
- Without treatment, PBC may progress to cirrhosis and eventually liver failure over of a 10–20-year period.
- Ursodeoxycholic acid is currently the only FDA-approved medical treatment for PBC. When administered at adequate doses of 13–15 mg/kg/day, a majority of the patients with PBC may have a normal life expectancy without additional therapeutic measures.

- One out of three patients does not adequately respond to UDCA therapy and may need adjuvant therapies.

Primary CNS vasculitis: Primary angiitis of the CNS

Definitions

Primary CNS vasculitis: Vasculitis of the blood vessels of the brain and/or spinal cord of unknown cause.

Introduction

Vasculitis of the central nervous system (CNS) may arise from primary involvement of blood vessels in the brain or spinal cord (primary CNS vasculitis), or from secondary involvement of the CNS by a systemic disorder such as systemic vasculitis, connective tissue disease, infection, or malignancy (Hajj-Ali and Calabrese 2012). CNS vasculitis is a rare condition of unknown cause that can ultimately lead to serious neurologic complications including stroke, cognitive impairment, and even death.

The diagnosis of primary CNS vasculitis is a great challenge for physicians (Hajj-Ali et al. 2011; Salvarani et al. 2012). First, it is quite rare. Second, the condition presents with nonspecific symptoms that may mimic conditions that are much more common such as stroke or multiple sclerosis. Clinicians caring for patients with suspected primary CNS vasculitis should be

familiar with its mimics to avoid misdiagnosis. In addition, there are no highly efficient, specific, non-invasive diagnostic modalities for this condition.

Definition

Primary CNS vasculitis is an inflammatory disease that affects vessels in the brain parenchyma, spinal cord, and leptomeninges without evidence of angiitis in other organs.

Epidemiology

Primary CNS vasculitis was first described by Cravioto and Feigin in 1959 in a small series of patients with a chronic, progressive, and fatal form of CNS vasculitis with pathologic findings of granulomatous vasculitis of the brain and spinal cord (Cravioto and Feigin 1959). The estimated annual incidence of primary CNS vasculitis is 2,4 cases/1,000,000, most commonly affecting middle-aged people (40–60 years), especially males (Salvarani et al. 2007).

Clinical and Pathologic Subsets

Recently, there has been an effort to better categorize patients with primary CNS vasculitis into distinct subtypes. This classification helps the clinician to better diagnose, monitor, and treat patients with primary CNS vasculitis (Hajj-Ali et al. 2011).

Granulomatous Angiitis of CNS (GACNS)

GACNS is considered the prototype of primary CNS vasculitis; it is characterized by granulomatous angiitis of predominantly small arteries confined to the brain (Hajj-Ali et al. 2011; Salvarani et al. 2012). It presents with chronic, insidious headache along with diffuse and focal neurologic deficits. Magnetic resonance imaging (MRI) of the brain is almost always abnormal showing nonspecific findings such as high-intensity lesions in the white (T2-FLAIR sequences), deep grey, and subcortical white matter, which tend to be bilateral. Cerebral angiography is not a sensitive test for detecting the small vessel vasculitis of GACNS because of its poor spatial resolution. Analysis of cerebrospinal fluid (CSF) usually reveals an aseptic meningitis profile (i.e., sterile fluid with a lymphocytic pleocytosis and elevated protein).

Cerebral Amyloid Beta-Related Angiitis

The deposition of amyloid beta (Aβ) protein in small and medium-sized vessels in the brain and leptomeninges can cause a number of inflammatory and noninflammmatory vasculopathies referred as cerebral amyloid angiopathy (CAA) and Aβ-related angiitis leading to intracerebral hemorrhages or mass-like lesions. Clinically, patients present with mental status changes, psychotic symptoms (such as hallucinations), and less commonly with focal neurologic deficits. MRI findings are nonspecific showing hyperintense white matter or mass-like lesions. The diagnosis can only be confirmed by brain biopsy showing the characteristic amyloid deposits.

Mass-Like Primary CNS Vasculitis

A subset of patients with CNS vasculitis can present with a solitary brain mass that creates diagnostic confusion with other diseases, especially neoplastic, lymphoproliferative, or infectious (Molloy et al. 2008). Brain biopsy with appropriate additional studies to exclude these diseases (including cultures; specific stains for bacteria, fungi, and mycobacteria; and immunohistochemistry) is imperative in order to make the diagnosis of this rare subtype of CNS vasculitis.

Atypical CNS Vasculitis

The most common category of primary CNS vasculitis is atypical CNS vasculitis (Hajj-Ali et al. 2011; Salvarani et al. 2012). This category

includes cases of biopsy-proven lymphocytic vasculitis (without granulomas) and patients with abnormal imaging (cerebral angiography, MRI) and CSF studies suggestive of CNS vasculitis. In such patients, a meticulous work-up is needed in order to exclude infectious and most importantly lymphoproliferative diseases.

Clinical Manifestations

Vessel inflammation with its resulting ischemia can affect any part of the CNS, causing a number of highly variable and nonspecific clinical manifestations. The most characteristic symptom is an insidious onset chronic headache accompanied in most cases by cognitive changes (Hajj-Ali et al. 2011; Salvarani et al. 2012). Recurrent strokes or transient ischemic attacks can also occur during the course of the disease (30–50 %) and should raise the suspicion for primary CNS vasculitis, especially in young patients when other common causes of strokes have been ruled out (such as cardiovascular disease or a hypercoagulable state). Less common presentations include seizures, myelopathy, and ataxia (Hajj-Ali et al. 2011; Salvarani et al. 2012). Typically, patients with primary CNS vasculitis lack systemic signs or symptoms of vasculitis such as fever, purpura, peripheral neuropathy, or weight loss.

For the diagnosis of the disease, specific simple criteria have been proposed by Calabrese et al. (Table 1) (Calabrese and Mallek 1988).

Diagnostic Assessments

Various laboratory tests of the peripheral blood or CSF, neuroimaging studies (MRI), cerebral angiography, and brain biopsy are included in the evaluation of patients with possible primary CNS vasculitis. However, other than biopsy, there is no specific test for the diagnosis of primary CNS vasculitis. Results of the various diagnostic tests should be interpreted in conjunction with each other by physicians with experience in the diagnosis and treatment of this rare disease.

Primary Central Nervous System Vasculitis, Table 1 Diagnostic criteria for primary vasculitis of the central nervous system

The presence of an acquired and otherwise unexplained neurological or psychiatric deficit
The presence of either classic angiographic or histopathological features of angiitis within the CNS
No evidence of systemic vasculitis or any disorder that could cause or mimic the angiographic or pathological features of the disease

Patients should meet all 3 criteria for the diagnosis of primary CNS vasculitis (Calabrese and Mallek 1988)

Laboratory Tests

Nonspecific markers of systemic inflammation such as the erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP) are usually normal in disease confined to the CNS such as primary CNS vasculitis (Hajj-Ali et al. 2011; Salvarani et al. 2012). Various serological tests for autoimmune diseases or diseases associated with CNS thrombosis (such as the antiphospholipid syndrome) are required to exclude them. This may include antinuclear antibodies (ANA), antineutrophilic cytoplasmic antibodies (ANCA), and antiphospholipid antibodies. Similarly, an extensive work-up is needed for the exclusion of infectious causes of CNS involvement including cultures (peripheral blood, CSF) and serological or nucleic acid (RNA, DNA) testing. The most important infectious organisms to consider include *Treponema pallidum* (syphilis), *Borrelia Burgdorferi* (neuroborreliosis), *Mycobacterium tuberculosis* (tuberculosis), herpes viruses (e.g., herpes zoster), human immunodeficiency virus (HIV), and various fungi (especially in immunosuppressed individuals) (see Table 2).

CSF analysis is an integral part of the diagnostic work-up of patients with possible primary CNS vasculitis. Although there are no specific abnormalities of the CSF, it is of great importance to obtain cultures, microbiologic stains and cultures, cytology and flow cytometry in order to rule out infectious or malignant processes. In approximately 80–90 % of patients with pathologically documented disease, CSF analysis is abnormal with elevated protein levels and modest lymphocytic pleocytosis.

Primary Central Nervous System Vasculitis, Table 2 Common diseases that may mimic primary CNS vasculitis

A. Secondary CNS vasculitides
1. *Infectious*
Viral (HIV, herpes zoster)
Bacterial (syphilis, tuberculosis, neuroborelliosis)
F*ungal (aspergillosis)*
2. *Rheumatologic disorders*
Behçet's disease
ANCA-associated vasculitides (Granulomatosis with polyangiitis, Churg-Strauss syndrome)
Systemic lupus erythematosus
Sjögren's syndrome
3. *Neoplastic disorders*
Lymphomas (Hodgkin and Non-Hodgkin)
Leukemia
Lung cancer
Angiocentric lymphoproliferative disorders
B. Non-vasculitic disorders
Reversible cerebral vasoconstriction syndromes (RCVS)
Antiphospholipid syndrome and other hypercoagulable disorders
Atherosclerosis
Embolic diseases
Miscellaneous (e.g., sarcoidosis or genetic diseases, such as Cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy (CADASIL))

Imaging Studies

Brain MRI

The vast majority of patients with primary CNS vasculitis have abnormal MRI (90–100 %) which makes it an important study to perform early in the evaluation. A normal MRI is a strong argument against the diagnosis of CNS vasculitis (Hajj-Ali et al. 2011; Salvarani et al. 2012). Typical MRI findings include multiple infarcts in different vascular territories, nonspecific high-intensity white matter lesions, and, less frequently, leptomeningeal enhancement or mass-like lesions. MRI has a greater sensitivity than CT and is the preferred initial imaging modality.

Angiography

Imaging of the CNS vasculature either by invasive angiography or CT/MR-angiography can reveal a number of lumenal abnormalities in visualized vessels including the characteristic stenosis followed by dilated lesions ("beading") in one or (more characteristically) multiple vessels. Despite the significant advances in imaging techniques, angiography still has a rather poor sensitivity (~60 %), primarily due to the small size of affected vessels (<300 μm) which is lower than the minimal size that the angiography can detect (>500 μm). Furthermore, "vasculitis-like" lesions can be seen in a number of non-vasculitic disorders such as vasospasm, atherosclerosis, and infection. This limits the specificity of the test for the diagnosis of primary CNS vasculitis to approximately 30 %.

Brain Biopsy

Brain and leptomeningeal biopsy remains the gold standard for the diagnosis of primary CNS vasculitis and most importantly for the exclusion of "vasculitis-mimics" (such as infectious or malignant diseases). Despite concerns about potential neurological complications, brain biopsy has a low risk (1 %) when performed in experienced centers (Salvarani et al. 2012).

Typical findings include granulomatous, necrotizing, or lymphocytic transmural inflammation of small- or medium-sized arteries. Given the focal and segmental distribution of the involved lesions, the sensitivity of the biopsy ranges from 53 % to 63 %. Nevertheless, directed biopsy of a radiographically abnormal or suspicious lesion can increase its sensitivity to 78 % (Salvarani et al. 2012). Collectively, these data emphasize the importance of a directed biopsy in the diagnostic work-up of patients with suspected primary CNS vasculitis. But, it is equally essential to recognize that a number of patients can still have primary CNS vasculitis with a negative brain biopsy.

Differential Diagnosis

Numerous diseases that affect the CNS and have similar clinical, angiographic, imaging,

or histological appearance to primary CNS vasculitis can create diagnostic confusion (see Table 2).

Among them, the group of reversible cerebral vasoconstriction syndromes (RCVS) is frequently mistaken as primary CNS vasculitis (Calabrese et al. 2007). This group is characterized by prolonged but reversible vasoconstriction of the cerebral arteries and includes Call-Fleming syndrome, drug-induced angiopathy (especially due to cocaine), migraine, benign angiopathy of the central nervous system, pheochromocytoma, poorly controlled or malignant hypertension, postpartum angiopathy, and drug-induced vasospasm. RCVS usually presents with sudden onset thunderclap type of headache accompanied in almost half of the cases by focal neurologic deficits or seizures (Calabrese et al. 2007). Angiography can show a picture identical to that seen in primary CNS vasculitis with beading of involved arteries, while MRI can reveal infarcts, hemorrhagic (cortical or subarachnoid), and edematous lesions (Calabrese et al. 2007). CSF analysis is usually normal. The clinical course of RCVS is benign with reversal of the vasoconstriction in the first 3 months after presentation.

A diverse number of infectious, autoimmune, neoplastic, or noninflammatory disorders can cause either a secondary CNS vasculitis or mimic CNS vasculitis (Table 2). As mentioned earlier, a thorough diagnostic work-up utilizing appropriate diagnostic modalities in tertiary centers by experienced subspecialists (such as rheumatologists, radiologists, neurologists, infectious disease specialists, and/or pathologists) are needed in order to exclude these diseases and make the appropriate diagnosis.

Treatment

Earlier reports of patients with primary CNS vasculitis have described a dismal prognosis. Over the last few decades, a number of studies have shown that immunosuppressive therapy is associated with a better outcome (Salvarani et al. 2007). Treatment of primary CNS vasculitis remains empirical since no controlled studies have ever been performed.

Therapy is usually initiated by high-dose corticosteroids followed in resistant cases with agents such as cyclophosphamide. The treatment is given until clinical remission is achieved (usually for 3–6 months). Assessing the response to therapy and differentiating between residual active disease and permanent damage is not an easy task. Serial imaging studies may be warranted. Once patients have reached clinical remission or stabilization of their condition, maintenance therapy with azathioprine or mycophenolate mofetil is started. Using this therapeutic approach, an initial response to treatment is observed in approximately 80 % of cases; relapses occur in approximately one-quarter of the patients (Salvarani et al. 2007). The 5- and 10-year survival rate of patients with primary CNS vasculitis is decreased compared to the general population (~60 %), indicating the need for novel therapies for this disease (Salvarani et al. 2007).

Primary Sclerosing Cholangitis: Clinical and Systemic Manifestations and Treatment

Emma Weeding[1], Mohamad Imam[1] and Keith Lindor[2]
[1]Division of Gastroenterology and Hepatology, Mayo Clinic, Rochester, MN, USA
[2]Health Solutions, Arizona State University, Phoenix, AZ, USA

Definition

Primary sclerosing cholangitis (PSC) is a chronic cholestatic liver disease characterized by progressive inflammation, fibrosis, and destruction of the intrahepatic and extrahepatic bile ducts, eventually resulting in biliary cirrhosis and end-stage liver disease (Chapman et al. 2010).

Clinical Manifestations

Patients with primary sclerosing cholangitis generally present with abnormally elevated liver tests, specifically an elevated alkaline phosphatase level. Common symptoms include fatigue and pruritus, as well as jaundice in patients with advanced disease. Fever, chills, and right upper quadrant pain may arise in patients with concurrent bacterial cholangitis.

PSC is diagnosed by establishing specific features of the disease via cholangiography after exclusion of secondary causes such as bacterial cholangitis, autoimmune pancreatitis, cholangiopathies, and malignancies (Berstad et al. 2006). The most important feature of PSC is the stricturing and dilation of both intrahepatic and extrahepatic bile ducts. Isolated stricturing of the extrahepatic or intrahepatic bile ducts may also be present. Patients with early-stage disease may have only shallow ulcerations of the bile ducts, and stricturing can develop as the disease progresses. Presence of stricturing is most commonly observed via magnetic resonance cholangiography. Endoscopic resonance cholangiography was once the standard course of action, but it is being used less frequently in diagnosis, as it leads to complications requiring hospitalization in over 10 % of PSC patients who undergo the procedure (Bangarulingam et al. 2009). Liver biopsy is not required in patients with characteristic cholangiographic findings but is advised in patients with suspected small-duct PSC and normal cholangiographies (Dave et al. 2010). Histologic features of PSC have low specificity. The most specific finding is destruction of the bile ducts and substitution thereof by connective tissue, which may extend into the liver parenchyma as the disease advances (Ludwig et al. 1981). Histologic findings allow staging of PSC as shown in Table 1.

Primary Sclerosing Cholangitis: Clinical and Systemic Manifestations and Treatment, Table 1 Staging of PSC

PSC stages	Finding
Stage 1	Inflammation of the portal triads with mononuclear infiltration and piecemeal necrosis
Stage 2	Fibrosis expanding into the parenchyma with dilation of the portal triads
Stage 3	Bridging fibrosis
Stage 4	Cirrhosis

Liver biochemistries may fluctuate in patients with primary sclerosing cholangitis, although elevation of alkaline phosphatase is usually the predominant pattern. Aminotransferases are moderately elevated and albumin levels may be decreased, especially in patients with inflammatory bowel disease. Altered prothrombin time and albumin level in a patient's serum reflect disease progression (Wiesner et al. 1989). Patients may also have elevated levels of gamma globulins, serum immunoglobulin M (IgM), and serum

immunoglobulin G4 (IgG4) levels (Mendes et al. 2006). Autoantibodies present in patients with primary sclerosing cholangitis include antismooth, antinuclear, and anticardiolipin antibodies. Anticardiolipin antibodies correlate with Mayo risk score, whereas other antibodies are of little prognostic significance (Angulo et al. 2000).

Systemic Complications

Primary sclerosing cholangitis has a strong association with inflammatory bowel disease (IBD). The prevalence of IBD in PSC has been reported as 60–80 % (Chapman et al. 2010). Patients with primary sclerosing cholangitis and inflammatory bowel disease are also at an increased risk of colonic neoplasia (Soetikno et al. 2002).

The most dreaded complication of PSC is cholangiocarcinoma (CCA), with an annual incidence of around 0.5–1.5 % and a lifetime risk of 10–15 % in PSC patients (Fevery et al. 2007). The presence of CCA denotes a poor prognosis. In one report, only 10 % of patients survived during the first 2 years of follow-up (Wiesner 1994). This high rate of morality is in part due to the difficulty of diagnosis of CCA. Presentation is usually nonspecific and highly variable, and hence the disease is often already at an advanced tumor stage by the time it is diagnosed. Patients developing CCA may present with weight loss, jaundice, abdominal discomfort, and quick clinical deterioration which can lead to its discovery. Diagnosis of cholangiocarcinoma in patients with PSC is established via some combination of ultrasound computed tomography, magnetic resonance imaging, brush cytology, endobiliary biopsy, and serum carbohydrate antigen 19–9 (CA 19–9) level (Rosen et al. 1991). Diagnosis via visual methods alone is unreliable as the appearance of CCA is similar to that of biliary strictures common in PSC patients. Additionally, there have historically been no clinically useful predictive factors for CCA, although several have been suspected, including alcohol consumption, presence of dominant strictures, variceal bleeding, cirrhosis, and presence of inflammatory bowel disease (Wiesner 1994). Screening criteria for CCA are being developed and are discussed later in this entry.

There are several other complications associated with PSC. One such complication is the development of dominant biliary strictures. Dominant biliary strictures develop in 45–58 % of PSC patients and may occur anywhere along the common hepatic or common bile duct (Chapman et al. 2010). Exclusion of malignancy is essential upon identifying a dominant stricture, as they are difficult to distinguish from cholangiocarcinoma. This is done by endoscopic biopsy and/or brush cytology (Chapman et al. 2010). Another complication of PSC is bacterial cholangitis. Patients with PSC may develop bacterial cholangitis spontaneously, especially if they have bile duct stones or strictures. The risk is increased in patients undergoing a liver biopsy or endoscopic and surgical manipulation (Porayko et al. 1991).

Other complications include hepatic osteodystrophy (osteopenia or osteoporosis), portal hypertension (PHT), and gallbladder disease. Hepatic osteodystrophy is associated with many chronic liver disorders and commonly develops in patients with advanced PSC. Risk factors for these conditions include age greater than 54 years, body mass index of 24 kg/m^2 or less, and presence of inflammatory bowel disease for 19 years or more (Angulo et al. 2011). PHT gradually develops in PSC patients with cirrhosis, as it does in all patients with cirrhosis. Finally, 30 % of patients with PSC may develop cholelithiasis and choledocolithiasis due to cholesterol or pigment stones (Mack 1995).

Treatment of Primary Sclerosing Cholangitis

There is currently no proven treatment which slows the progression of primary sclerosing cholangitis. A variety of anti-inflammatory and immunosuppressive agents, among others, have been tested, but with limited success (Poropat et al. 2011). Thus, the primary focus of treatment is on management of symptoms and

complications associated with PSC. This includes regular screening for cancers which commonly arise in the setting of PSC. For patients who have progressed to advanced disease, good outcomes can be achieved with liver transplantation (Graziadei et al. 1999). An overview of management of progressive disease is presented below.

Drug Therapy with Ursodeoxycholic Acid

The most extensively studied treatment for PSC is ursodeoxycholic acid (UDCA), a hydrophilic dihydroxy bile acid. UDCA is generally well tolerated and currently used as an effective treatment for primary biliary cirrhosis (PBC), a cholestatic liver disorder with some similarities to PSC (Lindor et al. 2009). Unfortunately, although UDCA has been shown to significantly improve liver biochemistries in PSC patients, it appears to have no proven beneficial effect on clinical endpoints, such as death or need for liver transplantation. It also has no significant effect on liver histology or clinical symptoms, including fatigue and pruritus (Poropat et al. 2011). High doses (28–30 mg/kg/day) are associated with worse clinical outcomes compared to placebo, especially in patients with early-stage disease and normal serum bilirubin levels. Nevertheless, UDCA is still prescribed for PSC patients due to its historical importance, as well as suspicions that the dosage and/or timing of treatment may play a role in the progression of PSC. There have been several studies to this end, but the full picture is only beginning to emerge.

Management of Symptoms and Complications

As there is no treatment for PSC, the primary goal of care is managing associated symptoms and complications. One common symptom is pruritus. Bile acid sequestrants, such as cholestyramine, are generally the treatment of choice. Similar to managing pruritus in patients with primary biliary cirrhosis, rifampicin or oral opiate antagonists may be prescribed if cholestyramine fails to relieve symptoms (Lindor et al. 2009; Chapman et al. 2010).

Pruritus can be perpetrated by dominant strictures, which can lead to other symptoms (e.g., cholangitis, jaundice) and impaired liver function. Existence of such strictures should be considered before beginning antipruritic drug therapy, particularly in patients with a worsening clinical presentation. As for treatment, various endoscopic and percutaneous approaches are available. The most common is usage of endoscopic retrograde cholangiopancreatography (ERCP) to further investigate and treat strictures with endoscopic techniques, primarily balloon dilation. However, it is recommended to perform brush cytology and/or endoscopic biopsy to exclude cholangiocarcinoma, which has an appearance very similar to benign biliary strictures, while pursuing endoscopic therapy. Occasionally, neither treatment of dominant strictures nor drug therapy is effective in alleviating a patient's pruritus. In these cases, liver transplantation may be indicated (Chapman et al. 2010). Bacterial cholangitis can also arise from dominant strictures. Specifically, biliary obstruction can lead to bacterial colonization of bile, resulting in secondary cholangitis. In general, patients respond well to drainage of the obstruction, plus antibiotics. For patients with recurrent bacterial cholangitis, the American Association for the Study of Liver Diseases (AASLD) recommends the use of prophylactic long-term antibiotics. As with pruritus, severe bacterial cholangitis may also be an indication for liver transplant (Chapman et al. 2010).

Other notable complications of PSC include the aforementioned hepatic osteodystrophy and portal hypertension. For the former, the AASLD recommends bone density examinations at diagnosis of PSC and at 2–3-year intervals afterwards. Treatment for PSC patients with osteopenia or osteoporosis includes calcium and vitamin D supplements and occasionally bisphosphonates as well depending on disease severity. As for PHT, treatment in patients with PSC is the same as for those without PSC.

This entails medications, endoscopic therapy, surgery, and radiologic procedures (Chapman et al. 2010).

Associated Malignancies and Screening

Primary sclerosing cholangitis is considered a premalignant condition, as patients with PSC have an increased risk of hepatic and extrahepatic malignancies. As discussed previously, the most grave of these is cholangiocarcinoma. Screening criteria for CCA and the optimal selection of patients for screening are yet to be determined. One suggestion is that all PSC patients undergo annual ultrasound or magnetic resonance imaging (MRI) with magnetic resonance cholangiopancreatography (MRCP), plus CA 19–9 determination (Razumilava et al. 2011). Regardless of the ongoing debate over screening and surveillance for CCA, the AASLD recommends that PSC patients who experience rapid clinical deterioration, such as weight loss or development of jaundice, should be evaluated for CCA (Chapman et al. 2010).

Due to the difficulty of diagnosis, cholangiocarcinoma is typically diagnosed at an advanced tumor stage, significantly limiting treatment options. Those who are diagnosed with advanced disease generally can only be given palliative care. Potentially curative resection is only an option for patients without cirrhosis, multifocal disease, or other advanced presentation, but even for such patients, the 3-year survival rate is less than 20 % (Chapman et al. 2010). The best outcomes are experienced by patients with early-stage cholangiocarcinoma who successfully undergo liver transplantation preceded by a thorough workup including neoadjuvant therapy. However, this course of action requires careful candidate screening and involves a complicated treatment regimen.

Primary sclerosing cholangitis is also associated with gallbladder cancer (GBC) and gallbladder disease in general. One study found the prevalence of all gallbladder abnormalities in PSC patients to be approximately 40 % (Said et al. 2008). The prevalence of gallbladder mass lesions is 3–14 % (Razumilava et al. 2011). The AASLD recommends annual ultrasound to detect such lesions in the gallbladder (Chapman et al. 2010). The general consensus historically has been to remove any gallbladder lesions in PSC patients regardless of size, but this has been challenged by recent examinations of early and long-term postoperative outcomes, as well as predictors of malignancy in PSC patients with gallbladder polyps. New data suggest that removal via cholecystectomy should be performed for polyps $\geq$0.8 cm, and it may be considered for smaller polyps if the patient's liver function is good. Any small polyps found but not removed should be monitored on a more regular basis, such as every 3–6 months instead of annually (Razumilava et al. 2011).

Yet another cancer known to be associated with PSC is hepatocellular carcinoma (HCC). Nearly all causes of cirrhosis correspond to an increased risk of HCC, and PSC is no exception. The incidence of HCC in PSC patients has not been well studied, however, and may be too low to warrant a separate screening regimen. Annual imaging studies for CCA and GBC surveillance may nonetheless assist in the detection of HCC as well (Razumilava et al. 2011).

Another malignancy associated with PSC, specifically in PSC patients who also have IBD, is colorectal cancer (CRC). In patients with both PSC and ulcerative colitis (UC), the cumulative incidence of CRC approaches 50 % after 25 years of colitis (Torres et al. 2011). Such patients are at a higher risk of CRC and dysplasia compared to patients with UC alone (Soetikno et al. 2002). Additionally, for patients with IBD, there is on average only a short-time interval between PSC diagnosis and development of CRC. As such, colonoscopy with biopsies at 1- to 2-year intervals is strongly recommended for patients with confirmed PSC and IBD (Graziadei et al. 1999; Soetikno et al. 2002; Chapman et al. 2010). For patients with PSC but no previous history of IBD, a full colonoscopy with biopsies is recommended upon PSC diagnosis. In most cases, however, IBD diagnosis precedes PSC diagnosis. Regarding management of IBD and

CRC, treatment of PSC patients is largely the same as treatment of non-PSC patients (Chapman et al. 2010).

Liver Transplantation

In the long term, the only life-prolonging treatment for primary sclerosing cholangitis is liver transplantation. Indications for transplantation for patients with PSC are similar to those for other chronic liver diseases; chronic liver failure and significantly reduced quality of life are two examples. Indications particular to PSC include intractable pruritus, recurrent bacterial cholangitis, and, in some cases, cholangiocarcinoma. As discussed previously, patients with early-stage cholangiocarcinoma can experience good outcomes with liver transplant, provided they are carefully selected and undergo neoadjuvant therapy beforehand (Chapman et al. 2010). Those with more advanced disease are not viable candidates for transplant, as cholangiocarcinoma has been shown to recur quickly in the vast majority of these cases (Graziadei et al. 1999).

In general, liver transplantation for PSC is successful, with roughly 85 % of patients surviving at least 5 years posttransplant. Disease recurrence is possible, however, and occurs in approximately one fifth to one fourth of patients within 5–10 years (Graziadei et al. 1999).

Conclusion

Primary sclerosing cholangitis is a chronic cholestatic liver disease that presents via elevated liver tests and eventually progresses to end-stage liver disease. PSC is commonly accompanied by IBD and is associated with several short- and long-term complications. The mainstay of treatment remains obscure, with no current treatment, other than liver transplantation, that improves outcomes, despite the positive effect of UDCA on improving liver biochemistries. Timely management of complications and the institution of recommended screening may prove beneficial in improving long-term outcomes for PSC patients.

Synonyms

Intrahepatic T-cell activation

Definition

Naïve T cells are normally activated in secondary lymphoid organs (lymph nodes and spleen) by professional antigen-presenting cells. The liver is the only nonlymphoid compartment where primary T-cell activation occurs. This intrahepatic activation is generally mediated by nonprofessional antigen-presenting cells and is thus governed by different rules than those existing in lymphoid tissues. Understanding the parameters influencing intrahepatic T-cell activation is thus critical to understanding how the liver influences immune responses to hepatic pathogens.

Introduction

Lymphocytes circulating via the blood are not generally able to directly contact parenchymal cells in most tissues. Endothelial cells and the tissue basal membrane form an effective physical barrier that excludes any contact between the two cell types. Thus, to access tissues and to overcome the strong shear force created by blood flow, lymphocytes need to express a range of molecules that promote strong adhesion, migration, and degradation of plasma membrane proteins. Due to its unique architecture and pattern of blood follow (vide infra), the liver is an exception to this rule of lymphocyte trafficking, allowing different liver cells to establish direct contact with blood lymphocytes and, if they express the relevant peptide/major histocompatibility complexes (p/MHC), to induce activation of T cells. The physiological role, significance, and consequence of this liver-specific direct T-cell activation are still the subject of current research, but there is no doubt that this alternative pathway of activation would have a deep influence on the immune response to liver-specific pathogens and to liver-expressed self-antigens during autoimmunity. This entry will discuss the evidence for direct T-cell activation in the liver, the characteristics of different hepatic antigen-presenting cells (APC), and the fate of these T cells.

The Liver Influences T-Cell Circulation

T cells develop in the thymus and recirculate via the blood and the lymph in an immature state. These resting or naïve T cells lack many molecules expressed by effector cells, including those that are required to adhere to the endothelium of most capillaries. However, they do express L-selectin, a molecule that facilitates adhesion to the high endothelial venules of the lymph nodes. Entry into the lymph nodes allows naïve T cells to scan for foreign antigens presented by dendritic cells (DCs) in the form of p/MHC. Primary T-cell activation by DCs allows blast formation, cytokine secretion, proliferation, and differentiation into cells endowed with effector function and the capacity for trans-endothelial migration. The ability of naïve T cells to be activated solely in lymphoid tissues is an immunological paradigm that has been experimentally proven in many organs but with one exception: the liver.

The most convincing evidence of this hepatic property comes from studies using transgenic mouse models: naïve T-cell receptor (TCR) transgenic $CD8^+$ T cells adoptively transferred into transgenic mice with expression of the cognate p/MHC restricted to the liver were retained within 1 h of transfer in this organ and underwent activation in situ (Bertolino et al. 2001; Bowen et al. 2004). No sign of activation was observed in lymphoid organs or other tissues, demonstrating that the liver is a site of primary activation independent of lymphoid tissues. More recently in a murine model, primary T-cell activation was also observed in liver transplants in the absence of extrahepatic T-cell activation in the recipients (Klein and Crispe 2006).

Primary T-cell activation in a solid organ is unique to the liver: when the same transgenic radiolabelled naïve T cells were adoptively transferred into transgenic mice ubiquitously expressing the cognate p/MHC, the liver was the only organ that retained the donor cells at 1 h post-adoptive transfer in an antigen-specific manner (Bowen et al. 2002; Bertolino et al. 2005). Lymphoid organs contained a much lower proportion of transferred radioactivity at this early time point, suggesting that the liver and secondary lymphoid tissues are the only sites contributing and competing for primary T-cell activation (Bowen et al. 2002; Bertolino et al. 2005). This intrahepatic retention has been shown to be mostly dependent on p-MHC/TCR and ICAM-1/LFA-1 interactions (Bertolino et al. 2005).

The liver also affects the circulation of activated/effector CD4 and CD8 T cells. When anti-hepatitis B surface antigen (anti-HBsAg) polyclonal CTL lines were adoptively transferred into transgenic mice ubiquitously expressing HBsAg, infiltration and tissue damage occurred only within the liver, despite similar antigen expression in other sites. Cytopathic damage to renal tubules in the kidney and choroid plexus epithelial cells in the brain did not occur unless CTL were injected beneath the kidney capsule or intracerebrally (Ando et al. 1994). Unlike naïve T cells that are only intrahepatically retained upon recognition of their cognate antigen, retention of effector cells in the liver is antigen independent. ICAM-1/LFA-1 interactions have been shown to play a key role in this adhesion (Mehal et al. 1999). It is likely that this "retention" reflects a slow transit of effector cells in the narrow sinusoids, rather than cells establishing permanent residency in the organ (Klugewitz et al. 2004).

The role of the liver in supporting primary T-cell activation has only been shown for CD8 T cells so far, due to the difficulty of restricting MHC class II expression and antigen to MHC class II liver APCs. Whether naïve CD4 T cells can be activated in the liver is still a matter of debate.

The Hepatic Sinusoids

The structure and cellular composition of the liver sinusoids (▶ Ultrastructure of the Liver Sinusoid) are key to understand its role in intrahepatic T-cell retention. These capillaries have an average diameter of about 10 μm and are lined by endothelial cells. Due to the narrow size of the sinusoids, interactions between T lymphocytes and liver endothelial cells occur under conditions of low velocity blood flow,

a property that is important in favoring leukocyte recruitment within the liver, which has been shown to occur in the absence of selectins (Wong et al. 1997; Bowen et al. 2004). Flow of arterial blood in the sinusoids is also intermittent due to the contraction of contractile smooth muscle sphincters in the walls of hepatic arterioles (MacPhee et al. 1995; MacSween and Scothorne 1979). Kupffer cells patrolling the sinusoids also obstruct the lumen of these capillaries and contribute to intermittent blood flow (McCuskey and Reilly 1993). Liver sinusoidal endothelial cells (LSEC) possess unusual properties; unlike other endothelial cells, they do not form tight junctions with adjacent endothelial cells but form an incomplete barrier between the sinusoidal lumen and the perivascular parenchymal tissue. Furthermore, these cells are perforated by several holes, or fenestrae, up to 120 nm in diameter (Wisse et al. 1985). These fenestrae are grouped in clusters forming sieve plates and behave as dynamic structures that dilate or contract to facilitate solute exchange between the plasma and hepatocytes (Wisse et al. 1985). Both hepatocytes and stellate cells are located under the endothelial cell layer. The liver also contains a significant number of immature dendritic cells, consistent with frequencies in other tissues. Although some DCs have been shown to transit the sinusoids (Matsuno et al. 1996), they appear to reside mostly within the portal tracts.

Antigen-Presenting Cells in the Liver

The liver receives up to 25 % of the cardiac output. Thus, every T cell in the body passes through the liver multiple times during its life and has the opportunity to interact with liver cells in the sinusoids. There has been extensive debate in the literature about the contribution of various liver APCs to intrahepatic T-cell activation. Experimental evidence has demonstrated that they can all act as APCs in vitro (reviewed in Bertolino et al. 2002). In vivo, two parameters would restrict activation: physical access to T cells and antigen expression. KC and LSEC are located in the lumen of the sinusoids and are the most accessible cells to blood lymphocytes. Hepatocytes and stellate cells are located underneath the endothelial barrier and are thus less accessible. However, electron microscopy micrographs have demonstrated that hepatocytes establish contact with leukocytes through LSEC fenestrations (Warren et al. 2006). Although not experimentally demonstrated, it is likely that similar contacts occur between stellate cells and leukocytes. There is no data in the literature indicating that DCs and BECs can induce primary T-cell activation within the liver. Whether liver DCs interact with circulating T lymphocytes has not been shown; however, if most DCs reside in the portal tracts as suggested by the literature, they would not be accessible to naïve T cells. Likewise, biliary epithelial cells (BECs) are located in portal tracts and are unlikely to play an important role in primary T-cell activation. Consistent with the above, the main liver cell types shown to play a role in primary activation are LSEC, KC, stellate cells, and hepatocytes, and their role will be briefly reviewed below.

Kupffer cells (▶ Kupffer Cells in Immune Tolerance) rest on LSEC and occasionally within gaps separating adjacent LSEC. Recent studies using intravital spinning disk and multiphoton microscopy have demonstrated that they are able to efficiently capture pathogens circulating in the sinusoids, such as *Borrelia burgdorferi* (Lee et al. 2010), and contribute to the formation hepatic granulomas in *Leishmania donovani* (Beattie et al. 2010) and *Mycobacterium bovis* BCG (Egen et al. 2008) infections. They express MHC class I and II molecules, ICAM-1, CD86, and CD80 and function as APCs for naïve CD8 T cells and CD4 T cells in vitro. In vivo, there is now data showing that liver bone marrow-derived cells (that include both KC and DC) are able to efficiently retain adoptively transferred naïve TCR transgenic CD8 T-cell mice in an antigen-specific manner (Bowen et al. 2002; Holz et al. 2012). This retention leads to the rapid activation of the transgenic T cells in situ. The fate of CD8 T cells activated by KC has not been fully studied, but recent results suggest that in the absence of inflammation, this activation leads to CD8 T-cell deletion (Holz et al. 2012). The role of KC in shaping CD4 and CD8 T-cell

responses is reviewed in a different entry of this encyclopedia (▶ Kupffer Cells in Immune Tolerance).

LSEC (▶ Liver Sinusoidal Endothelial Cells: Role in Immunity and Tolerance) are scavenger cells strategically located in the sinusoids to enable their extraction of blood-borne material, as demonstrated by their ability to clear low-density lipoprotein (LDL) and capture particulate antigens and immune complexes. This uptake is mediated by mannose receptor, and has been shown to be more efficient than KC, suggesting that these cells specialize in this function. LSEC constitutively express both MHC class I and class II molecules, low levels of CD86, as well as adhesion molecules including ICAM-1, VCAM-1, and dendritic cell-specific intercellular adhesion molecule 3-grabbing nonintegrin (DC-SIGN). They have been shown to be efficient APCs to both naïve CD4 and CD8 T cells in vitro (Knolle et al. 1999). More importantly, LSEC have also been shown to be capable of cross-presentation of soluble antigens on MHC class I molecules to CD8 T cells (Limmer et al. 2000), a property that is shared only by some subsets of DCs. In addition to their immunological properties, LSEC possess fenestrations that act as a portal between T cells and cells underlying the endothelial layer (hepatocytes and stellate cells) (Warren et al. 2006). The role of LSEC in shaping CD4 and CD8 T-cell responses is reviewed in a different entry of this encyclopedia (▶ Liver Sinusoidal Endothelial Cells: Role in Immunity and Tolerance).

Hepatocytes are the principal cell of the liver, comprising 75 % of hepatic cells. They are large polyhedral, often binucleated cells involved in the synthesis and secretion of a wide variety of biologically crucial molecules, as well as the metabolism and excretion of an extensive range of both endogenous and xenobiotic substances. In the absence of liver inflammation, hepatocytes express MHC class I molecules, CD1, and ICAM-1; MHC class II molecules, CD40L, and costimulatory molecules such as CD80 and CD86 are not constitutively expressed (Bertolino et al. 1998; Holz et al. 2012), however can be upregulated following inflammation. Since they normally lack MHC class II expression, resting hepatocytes may therefore only act as APCs for CD1 and MHC class I restricted T cells. Primary hepatocytes are able to drive efficient activation and proliferation of TCR transgenic naïve CD8 T cells in vitro (Bertolino et al. 1998). Although separated from leukocytes by an endothelial barrier, several studies have shown that hepatocytes interact with and activate TCR transgenic naïve CD8 T cells circulating via the blood in vivo (Bertolino et al. 2001; Bowen et al. 2004; Derkow et al. 2007; Klein and Crispe 2006). These contacts seem to occur via LSEC fenestrations and to require ICAM-1/LFA-1 interactions. Hepatocytes are not able to cross-present antigen like LSEC (Limmer et al. 2000).

The functional outcome of T-cell activation by hepatocytes remains controversial. In some studies, CD8 T cells activated by hepatocytes proliferated but were deleted within the first days postactivation, without developing significant cytotoxic activity. In those studies, most CD8 T cells were rapidly deleted within the first few hours postactivation as a result of invading hepatocytes and degradation into lysosomal compartments (Benseler et al. 2011). Some T cells surviving this process proliferated but subsequently died as a result of primary activation in the absence of costimulatory molecules. This "death by neglect" was associated with low expression of cytokines and high expression of the proapoptotic molecule Bim (Holz et al. 2008; Holz et al. 2012). In contrast to these studies suggesting that hepatocytes induce T-cell deletion and tolerance, several studies have suggested that CD8 T cells activated by hepatocytes survived and became effective CTLs (Derkow et al. 2007; Klein and Crispe 2006; Wuensch et al. 2006). The reason for such opposing outcomes has not yet been elucidated but might be related to the use of TCR transgenic T cells with different affinities, antigen persistence, or even the frequency of antigen-expressing hepatocytes.

Although hepatocytes are not as accessible to circulating T cells as LSEC and KC, they might play an important role in presenting self-antigens to the immune system and inducing tolerance.

Primary T-Cell Activation in Liver, Table 1 Summary of the different immune molecules expressed by the different sinusoidal liver cells

Molecules	Hepatocytes	LSEC	KC	Liver cDCs	HSC
MHC I	+	+	+	+	+
MHCII	-	+	+	+	+
CD1d	+	+	+	+	+
CD80/CD86	-	+	+	+	+
CD40	-	+	?	+	+ (act)
B7H1	+	+	NA	+	+
TLRs (reported)	2, 3 and 4	1, 2, 3, 4, 6, 9	Most TLRs	most TLRs	2 (act), 4, 9

Please note that the list of TLRs is not exhaustive due to discrepancies in the literature.
Act activated stellate cells

In addition, it is likely that they would be the first cells to present viral antigens to T cells during infections by hepatotropic viruses (such as the hepatitis B and hepatitis C viruses). Thus, activation by hepatocytes might play an important role in shaping the initial antiviral immune response.

Stellate cells (*HSC*), also known as Ito cells, are located between LSEC and hepatocytes. Following liver damage and regeneration, they secrete the extracellular matrix that is critical for tissue repair. However, this process is also responsible for the development of fibrosis. In a non-inflamed liver, these cells play a role in regulating blood flow by constricting the diameter of the sinusoids (Rockey 2001). Cultured HSC express MHC class I and II, CD1, and low levels of CD80 and CD86 (Winau et al. 2007). Contact between HSC and T cells has not been directly observed; however, it is likely that they occur via LSEC fenestrations as demonstrated for hepatocytes. Although the role of these cells in intrahepatic T-cell activation has been largely ignored, recent studies have demonstrated that HSCs are also able to activate naïve CD8 T cells in situ (Winau et al. 2007).

Table 1 summarizes some of the immune molecules expressed by the different sinusoidal liver cells.

Physiological Role for Intrahepatic Primary T-Cell Activation

It is not clear why the liver has evolved the ability to activate the cellular adaptive immune response. The liver processes and excretes a wide variety of toxins and is exposed to pathogens and proteins circulating via the blood. An important function of the liver might thus be to trap blood-borne pathogens and to induce a local and rapid innate immune response that would eliminate the pathogen without requiring secondary lymphoid tissues. It is possible that KC play a role in this process.

The function of the liver in tolerance induction in transplantation and other settings is also puzzling and unresolved. This function might be related to the unusual location and drainage of this organ: in addition to the blood supply provided by the hepatic artery, the liver also receives venous blood from the gut and spleen carrying food antigens. This unique blood drainage has led investigators to speculate that the liver plays a critical role in oral tolerance. This hypothesis has been supported by experiments showing that an immune response against food was elicited when blood originating from the gut was surgically diverted to the systemic circulation, bypassing the liver. This possible role of the liver in oral tolerance remains to be verified.

Conclusion

The liver is an unusual immunological organ characterized by a unique blood flow and architecture that facilitates the interaction of liver resident cells with circulating leukocytes. Under low blood flow conditions, liver cells expressing p/MHC are able to retain and activate

naïve CD8 T cells in the absence of selectins. This property is unique among the solid organs. Although the outcome of such activation is controversial, it is likely that it will depend on the type of liver APC involved in the activation, the avidity of the interaction, and the presence or absence of inflammation.

Synonyms

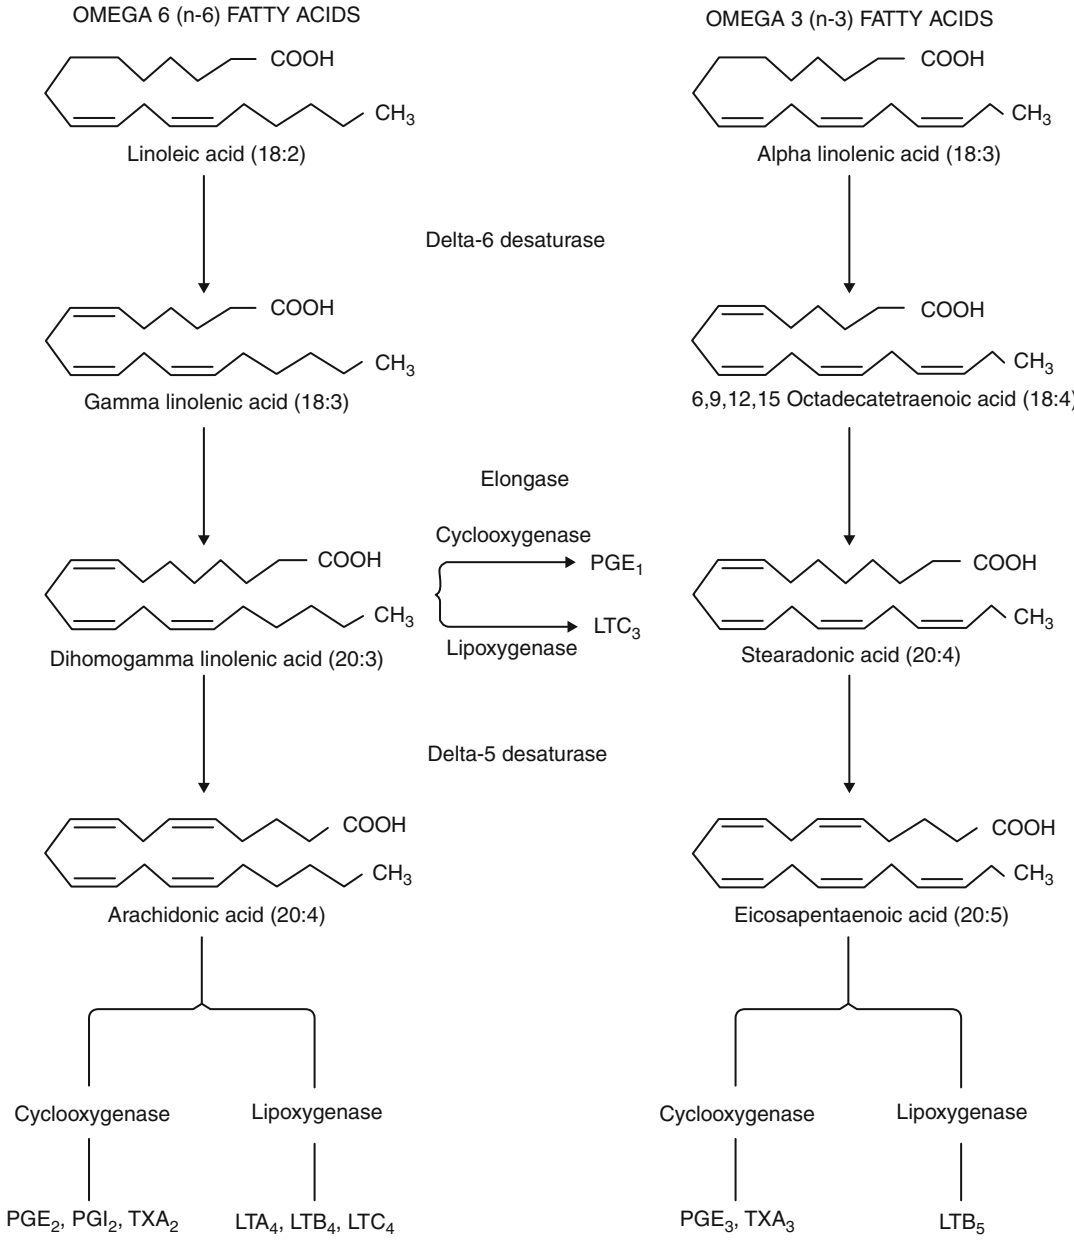
Eicosanoids

Definition

Over 80 years ago, it was observed that human myometrium exhibits rhythmic contraction and relaxation when incubated with fresh human seminal fluid. The active principle was then identified as an acidic lipid. Believing the lipid was produced in the prostate gland, von Euler named it *prostaglandin*. Eliasson later showed that seminal fluid prostaglandin in fact derives from the seminal vesicles. It was then determined that the active component in seminal fluid is not a single substance but several closely related compounds.

It is the oxygenation of several 20-carbon polyunsaturated fatty acids (arachidonic, dihomogammalinolenic, eicosapentaenoic) in nearly all human cell types that results in formation of several classes of bioactive products (Fig. 1) termed *eicosanoids* (eicosa = 20). These include prostaglandins (PGs), prostacyclin (PGI), thromboxanes (TX), leukotrienes (LT), and lipoxins (LX). All of these compounds are crucial to the regulation of immunity and inflammation, among other physiologic and pathologic processes.

Two groups of fatty acids are essential to the body: the omega-6 series derived from linoleic acid (18:2 n-6) and the omega-3 series derived from α-linolenic acid (18:3 n-3). The n refers to the number of carbon atoms from the methyl (omega) end of the fatty acid chain to the first double bond (i.e., omega-3 and omega-6 designations). Using this notation, 18 refers to the number of carbon atoms in the fatty acid. The degree of unsaturation (the number of double carbon-carbon bonds) follows the number of carbon atoms. Fatty acids are metabolized by an alternating sequence of desaturation (removal of two hydrogens) and elongation (addition of two carbons). Membrane phospholipids, the main storage site for polyunsaturated fatty acids, are particularly rich in eicosanoid precursors, which are located at the sn-2 position (Fig. 2). Because mammalian cells cannot interconvert n-3 and n-6 fatty acids, the composition of membrane phospholipids is determined by exogenous sources of fatty acids (Zurier 2009).

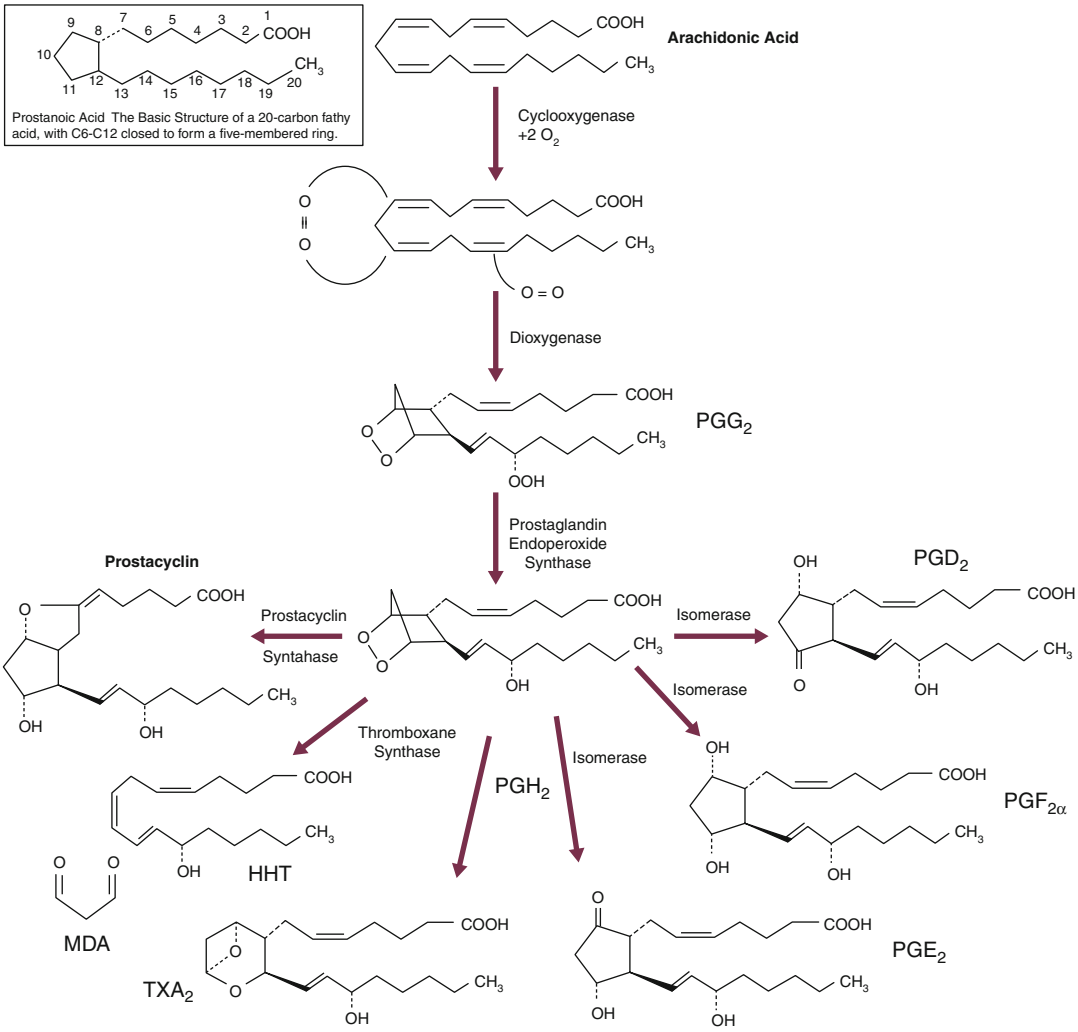


Prostaglandins, Leukotrienes, and Related Compounds, Fig. 1 Metabolic pathways of essential fatty acids. The pathways are ones of progressive desaturation alternating with elongation. Eicosanoid precursors include dihomogammalinolenic acid, arachidonic acid, and eicosapentaenoic acid. PG, prostaglandins; LT, leukotriene; TX, thromboxane

Biosynthesis of Eicosanoids

Phospholipases

Phospholipase A_2 (PLA_2) in lysosomes or bound to cell membranes catalyzes the breaking of the sn-2 bond, facilitating release of AA or other polyunsaturated fatty acids. The enzyme is crucial to regulation of eicosanoid synthesis because it is in the nonesterified state that the polyunsaturated precursors enter into the

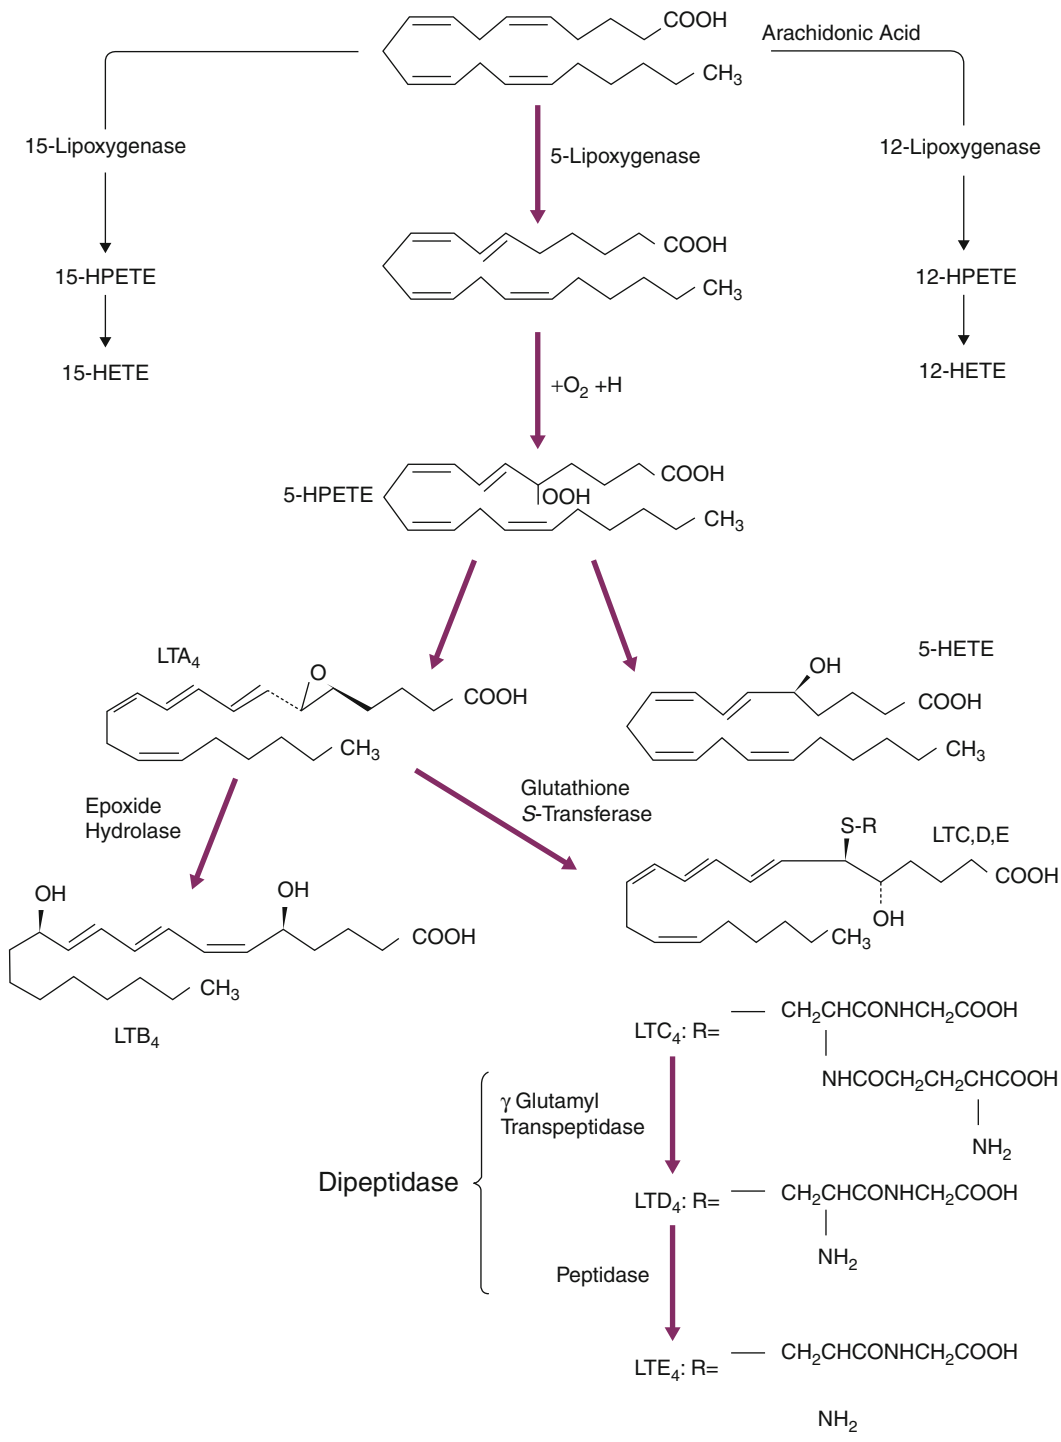


Prostaglandins, Leukotrienes, and Related Compounds, Fig. 2 Cyclooxygenase pathway of arachidonic acid metabolism. PG prostaglandin, MDA malondialdehyde, TX thromboxane

cascades leading to eicosanoid formation (Burke and Dennis 2009).

Under basal conditions, AA is liberated by $iPLA_2$, then reincorporated into cell membranes (reacylated), and is unavailable for appreciable eicosanoid biosynthesis. The acylase enzymes competitively inhibit the cyclooxygenase (COX) isoenzymes. After receptor activation and cell stimulation, intracellular Ca^{2+} levels increase, and the Ca^{2+}-dependent $cPLA_2$ liberates arachidonate at a rate that exceeds the rate of reacylation, leading to arachidonate metabolism by COX isoenzymes and by lipoxygenases.

The tetraenoic precursor (AA) is the most abundant of the three precursor fatty acids in cells of individuals who eat usual Western-style diets. Metabolites of AA constitute the "2" series (dienoic) PGs (two double bonds in the molecule), and the metabolic pathway has acquired the familiar name "arachidonic acid cascade." However, diets enriched in eicosapentaenoic or gamma-linolenic acid, the other eicosanoid precursors, lead to formation of different eicosanoids. The COX and 5-lipoxygenase pathways of the cascade are illustrated in Figs. 2 and 3, respectively.



Prostaglandins, Leukotrienes, and Related Compounds, Fig. 3 5-Lipoxygenase pathway of arachidonic acid metabolism. LT leukotriene, HETE hydroxyeicosatetraenoic acid, HPETE hydroperoxyeicosatetraenoic acid

Cyclooxygenase Pathway

The first step in the biosynthesis of the "prostanoids" (e.g., PGs, TXs, PGI) is catalyzed by the bifunctional PG endoperoxide synthase isozymes PGHS-1 (COX-1) and PGHS-2 (COX-2). To form the characteristic five-carbon ring structure (TXs contain a six-member ring), the precursor fatty acids must have double bonds at carbons 8, 11, and 14 (numbering from the carboxyl group). When a molecule of oxygen is inserted across carbons 9 and 11, ring closure occurs enzymatically across C8 and C12, creating the unstable PG endoperoxide PGG. Subsequent peroxidation yields PGH with formation of the cyclopentane ring. PGH serves as the common precursor for PGs, prostacyclin, and TXs that are formed under the influence of terminal synthases.

PGHS, the well-known target of nonsteroidal anti-inflammatory drugs (NSAIDs), exists in two isoforms. The localization of COX-1 in nearly all tissues under basal conditions suggests that its major function is to provide eicosanoids for physiologic regulation. This is seen clearly in platelets that do not have nuclei and cannot produce an inducible enzyme on activation. Rather, TXs are produced constitutively so that platelet aggregation can be completed (Rouzer and Marnett 2009).

The regulated formation of eicosanoids implies that cells have an appreciable ability to amplify the rate and amount of eicosanoid synthesis. Factors that regulate COX-2 expression are specific for the physiologic processes involved.

COX-1 and COX-2 effect a balance in several physiologic and pathologic situations. Of particular interest are their actions in kidney and stomach. During times of low blood volume, the kidney releases angiotensin and other factors to maintain blood pressure by systemic vasoconstriction. Angiotensin also provokes PG synthesis in the kidney. COX-1, expressed in vessels, glomeruli, and collecting ducts, produces vasodilating PGs, which maintain renal plasma flow and glomerular filtration during conditions of systemic vasoconstriction. In the antrum of the stomach, COX-1 leads to production of PGs, which increase gastric blood flow and mucus secretion. Inhibition of COX-1 by NSAIDs prevents these protective mechanisms and results in renal ischemia and damage and gastric ulcers (mainly antral) in susceptible individuals. These observations have led to development of NSAIDs that selectively inhibit COX-2 and spare COX-1. AA gains access to the active site of the COX via a hydrophobic channel, and access is blocked by insertion of an acetyl residue on Ser 530 in COX-1 and Ser 516 in COX-2. The irreversibility of the interaction and the unique expression of COX-1 in the anucleate platelet is the reason for the clinical efficacy of low-dose aspirin.

The major adverse effects of NSAIDs, gastroduodenal injury, impaired renal function, and induction of myocardial infarction and stroke are caused by inhibition of COX-1, whereas the analgesic and anti-inflammatory activities of NSAIDs rest in part on their ability to inhibit COX-2. COX-2 also seems to have a regulating role, however, in renal, brain, gastrointestinal, ovarian, and bone function. COX-2 also is expressed in endothelial cells, and its inhibition suppresses prostacyclin synthesis by endothelial cells. COX-2 acts in the initiation and the resolution of inflammation. Later in the response, COX-2 is expressed at even higher levels, leading to synthesis of PGD_2 and its dehydration product 15-deoxy-δ12,14-PGJ_2 (15δPGJ_2). Early expression of COX-2 is associated with production of inflammatory PGs, whereas the later peak results in production of PGs that suppress inflammation (Serhan 2011).

Acetaminophen, similar to NSAIDs, suppresses pain and fever. It is not an anti-inflammatory agent, and its mechanism of action – despite its extensive use – has not been apparent. The finding that acetaminophen inhibits COX activity more in canine brain homogenates than in spleen homogenates gave rise to the concept that variants of the COX enzyme (in addition to COX-1 and COX-2) exist that are differentially sensitive to acetaminophen. **COX-3** is a splice variant of COX-1.

COX-3 enzyme protein has been identified in human tissues, most abundantly in cerebral cortex and heart (Botting 2010).

Prostaglandin Synthases

Conversion of the endoperoxide intermediate PGH_2 to PGs requires the activity of specific terminal synthases: Hematopoietic PGD synthase (H-PGDS) catalyzes the isomerization of PGH_2 to PGD_2 in immune and inflammatory cells, cytosolic PGE synthase (cPGES) is responsible for constitutive expression of PGE_2, and microsomal PGE synthase (mPGES-1) induces PGE in response to inflammatory stimuli. Suppression of PG synthase activity might be considered as an alternative strategy that would fall between global blockade by inhibition of COX and blockade of a single eicosanoid receptor. Thus, efforts have been directed at development of drugs which inhibit mPGES-1, rather than COX-2, thereby suppressing PGE2 production while sparing production of prostacyclin (Claveau et al. 2003).

Products of the Cyclooxygenase Pathway

Prostaglandins

The basic structure of all PGs is a "prostanoic acid" skeleton, a 20-carbon fatty acid with a five-membered ring at C8 through C12 (Fig. 2, *inset*). The term *prostaglandins* is employed widely but should be used to describe only the oxygenation products that contain the five-membered carbon ring. The alphabetic PG nomenclature (e.g., PGE, PGF, PGD) is related to the chemical architecture of the cyclopentane ring. PGE and PGF differ only in the presence of a ketone or hydroxyl function at C9 (Fig. 2). These compounds are made by a variety of cells (e.g., PGE_2 and PGD_2 by isomerases, $PGF_{2\alpha}$ by a reductase). In the nomenclature, a subscript numeral after the letters indicates the degree of unsaturation in the alkyl and carboxylic acid side chains. The numeral *1* indicates the presence of a double bond at C13–C14 (PGE_1), *2* marks the presence of an additional double bond at C5–C6 (PGE_2), and *3* denotes a third double bond at C17–C18 (PGE_3).

PGs are produced on demand and seem to exert their effects on the cell of origin or nearby structures. Although lipophilic, the PGs do not leave the cell simply by diffusion. Rather, their release is mediated by the PG transporter, multidrug resistant protein 4 (MRP4), a member of the ATP-binding cassette transporter superfamily. They are not stored in cells and are degraded rapidly in vivo by 15-hydroxyprostaglandin dehydrogenase (PGDH) during one passage through the lungs. Abundant experimental evidence supports the view that PGs participate in development of the inflammatory response. PGs are probably better at potentiating the effects of other mediators of inflammation than they are at inducing inflammation directly. PGE compounds and intermediate hydroperoxides of AA increase pain sensitivity to bradykinin and histamine. The effects of PGE are cumulative, depending on concentration and time. Even very small amounts of PGs, if allowed to persist at the site of injury, may in time cause pain (Zurier 2009).

PGE_2 stimulates bone resorption (Blackwell et al. 2010), and its 13,14-dihydro derivative is nearly as potent, which is of interest because derivatives of the biologically active PGs are usually assumed not to be of functional significance. The observation that PGE_1 can stimulate bone formation suggests that PGs physiologically participate in coordination of bone formation and resorption.

PGD_2, the major PG formed by mast cells, also can mediate histamine release from mast cells exposed to anti-IgE antibody. PGJ_2, formed from the dehydration of PGD_2, seems to function as a brake on the inflammatory response. It reduces macrophage activation, reduces nitric oxide production from stimulated cells, and induces apoptosis in tumor cell lines. PGJ_2 is metabolized to 15-deoxy-δ12,14 PGJ_2 and δ12 PGJ_2, which also are biologically active (Zurier 2009).

Prostacyclin

Prostacyclin has been purified, and the cDNA for prostacyclin synthase has been cloned. In addition to a cyclopentane ring, a second ring

is formed by an oxygen bridge between carbons 6 and 9. It is generated from PGH_2 by a distinct prostacyclin synthase, a 56-kD member of the cytochrome P-450 superfamily of enzymes found predominantly in endothelial and vascular smooth muscle cells (Rouzer and Marnett 2009). Production of prostacyclin can be stimulated by thrombin or generated by transfer of PGH_2 from platelets (the endoperoxide steal), contact with activated leukocytes, or stretching of the arterial wall. It is a powerful vasodilator and inhibits platelet aggregation through activation of adenylate cyclase, which leads to an increase in intracellular cAMP. It is metabolized rapidly (half-life in plasma is less than one circulation time) to the more stable, less biologically active 6-keto-$PGF_{1\alpha}$. The enzymatic products of its conversion – 2,3-dinor-6 keto-$PGF_{1\alpha}$ and 6,15-di-keto- 2,3-dinor $PGF_{1\alpha}$ – also are chemically stable and have very little biologic activity. They are the major metabolites of prostacyclin excreted in urine, in which they can be assayed as indicators of prostacyclin generation.

Prostacyclin generated in the vessel wall has antiplatelet and vasodilator actions, whereas TXA_2 generated by platelets from the same precursors induces platelet aggregation and vasoconstriction. These two eicosanoids represent biologically opposite poles of a mechanism for regulating the interaction between platelets and the vessel wall and of formation of hemostatic plugs and intra-arterial thrombi. Given the central role of platelets in inflammatory reactions, an appropriate prostacyclin-TX balance is important to regulation of inflammation (Gryglewski and Mackiewicz 2010).

Thromboxanes

The endoperoxide PGH_2 can be converted into TXs after the action of the enzyme TX synthase, a microsomal 60-kD member of the cytochrome P-450 family, which is quite active in the platelet. The gene that encodes the enzyme has been cloned. TXs contain a six-member oxane ring instead of the cyclopentane ring of the PGs. TX synthase converts PGH_2 into equal amounts of TXA_2 and 12 L-hydroxy-5,8,10-heptadecatrienoic acid. TXA_2 stimulates platelet activation, contributes to intravascular aggregation of platelets, and contracts arteriolar and bronchiolar smooth muscles. It is hydrolyzed rapidly (half-life is 30 s) to the inactive, stable, measurable product, TXB_2; its actions are limited to the microenvironment of its release.

The extraordinary rapidity with which platelets adhere to damaged tissue, aggregate, and release potent biologically active materials suggests that the platelet is well suited to be a cellular trigger for the inflammatory process. Efforts directed at suppression of TX synthesis and platelet aggregation may result in limitation of inflammatory responses, especially in coronary arteries. Inhibition of platelet aggregation may be important to the anti-inflammatory effects of aspirin and other NSAIDs. Long-term administration of low doses of aspirin (40 mg/day – the lowest dose predicted to cause total inhibition of TX formation in serum, according to mathematic modeling) has inhibitory effects on platelet function ex vivo that are indistinguishable from the effects caused by giving 325 mg/day of aspirin. Aspirin acetylation of COX in platelets occurs in the portal vein where the aspirin concentration is high before it is metabolized in the liver, which explains why the 81 mg dose of aspirin is so effective in prevention of heart attacks and strokes. Platelets lose their ability to aggregate until new platelets are formed in about a week.

Selective inhibition of TX synthase represents an approach that can suppress TXA2 synthesis without depressing prostacyclin formation. Antagonists of the receptors shared by endoperoxide and TXA_2 have been developed, and these agents inhibit platelet aggregation in patients who are recalcitrant to TX synthase inhibition. Novel agents targeting TX receptors and TX synthase have improved treatment of vasculitis and cardiovascular and renal diseases (Zurier 2009; Rafferty and Walters 2010).

Lipoxygenase Pathways

In contrast to the COX pathway, in which stable products have three atoms of oxygen covalently attached to AA from 2 mol of molecular oxygen, lipoxygenases insert a single oxygen atom

into the molecular structure of AA. Separate lipoxygenases exist in certain cells and have strict structural requirements for their substrates. Six major mammalian lipoxygenases exist that insert their oxygen atoms into the 5, 12, or 15 position of AA, with formation of a new double bond and hydroperoxy group. Lipoxygenases that act on AA are found in the cytosol fraction of cells.

The human 5-lipoxygenase (5-LO) gene has been isolated and characterized and produces a 78-kD enzyme. In myeloid cells, the 5-lipoxygenase pathway leads to formation of the biologically active leukotrienes (LTs) (Fig. 3) that were originally found in leukocytes and that contain three conjugated double bonds (trienes). Cell activation leads to translocation of 5-lipoxygenase from cytosol to the nuclear membrane, where it encounters the 18-kD, 5-lipoxygenase-activating protein (FLAP). AA also is translocated to FLAP for presentation to 5-lipoxygenase (5-LO), In addition, upon cell stimulation, cPLA2 is activated and also associates with the nuclear membrane, close to FLAP. The ability of macrophages and dendritic cells to respond appropriately during innate immune responses is likely regulated by 5-LO and 12-LO.

The unstable HPETE is the initial metabolite of each lipoxygenase pathway. HPETE is reduced to the more stable HETE or is converted by 5-LO to LTA_4. LTA_4 can be converted to LTB_4 (in neutrophils and macrophages) or conjugated with reduced glutathione to form LTC_4 (in eosinophils, mast cells, endothelial cells, and macrophages). In contrast to lipoxygenase, which is mainly distributed in myeloid cells, LTA_4 hydrolase (5,12-dihydroxy-eicosatetraenoic acid), a zinc-requiring enzyme that converts LTA_4 to LTB_4, is widely distributed. From the cDNA sequence, it was suggested that mRNA for LTA_4 may have a short half-life, which could account for the properties of extremely rapid production and shutdown of LTB_4 and other eicosanoid biosynthesis.

LTA_4 can be exported from the cell of origin and converted in other cells by LTA_4 hydrolase to LTB_4. This transcellular metabolism also applies to conversion of LTA_4 to LTC_4 by LTC_4 synthase, a glutathione-*S*-transferase. LTD_4 and LTE_4 arise from LTC_4 after sequential removal of γ-glutamic acid and glycine from LTC_4. The enzyme γ-glutamyl transpeptidase is present in many cells as part of a complex enzymatic system involved in glutathione biosynthesis and amino acid transport. In many systems, the major sulfidopeptide LT has been reported to be LTD_4, rather than the precursor LTC_4. Removal of glycine from LTD_4 results in LTE_4 with concomitant loss of a significant amount of biologic activity (Radmark and Samuelsson 2010).

Products of the Lipoxygenase Pathways

The biologic effects of compounds produced in the lipoxygenase pathway indicate their importance in inflammatory diseases (Brash 1999). They are the major mediators of inflammation formed by the oxygenation of AA and are implicated as key mediators in several diseases, including inflammatory bowel disease, psoriasis, bronchial asthma, and RA.

5-HETE and 5-HPETE stimulate the generation of superoxide in human neutrophils. These compounds also augment intracellular calcium levels, facilitating PKC-dependent activation of a superoxide generating system of neutrophils. LTB_4 increases adherence of leukocytes to endothelial cells, a response that is augmented by exposure of the endothelial cells to TNF-α. LTB_4 does not seem to have a direct vascular contractile action because it is inactive in the hamster cheek pouch preparation and several other microvasculature systems. In rabbit skin, administration of LTB_4 with a vasodilator PG induces plasma exudation, which suggests that LTB_4 may facilitate enhanced vascular permeability. Increased venule permeability does occur in response to LTC_4, LTD_4, and LTE_4. LTB_4 is a potent chemotactic factor for neutrophils and is weakly chemotactic for eosinophils. LTB_4 and, to a lesser extent, 5-HETE enhance migration of T lymphocytes in vitro. LTB_4 also serves an immunoregulatory function. It stimulates differentiation of competent $CD8^+$ T lymphocytes from precursors lacking the CD8

marker. LTB_4 also stimulates interferon-γ and IL-2 production by T cells and biosynthesis of IL-1 by monocytes.

Strategies for inhibiting production or antagonizing the actions of LTs include development of selective LT receptor antagonists and inhibition of the production of LT by blocking the action of 5-lipoxygenase. Inhibition of enzymes distal in the LT cascade, such as LTA_4 hydrolase, also is a promising strategy for development of anti-inflammatory drugs. The existing agents may be aiming at the wrong target. Fibroblasts do not make much LTB_4, but they do make 12-HETE, which is a growth factor, through a cytochrome P-450 pathway. Cytochrome P-450 inhibitors may be more to the therapeutic point. Some inhibitors are more effective when activated by exposure to light. These inhibitors might prove useful as topical agents for treatment of inflammatory skin disease.

Lipoxygenase activities do not lead solely to production of mediators of inflammation. DGLA is converted by 15-lipoxygenase into 15-HETE, which is incorporated into diacylglyceride (DAG) and exerts anti-inflammatory effects partly by interfering with PKC-β activity. A lipoxygenase product of linoleic acid, 13-hydroxyoctadecadienoic acid, also suppresses inflammation and cell proliferation by means of a similar mechanism. EPA is converted by lipoxygenase into 15-hydroxyeicosapentaenoic acid, which also exhibits anti-inflammatory properties (Zurier 2009; Noguchi and Okubo 2011).

Lipoxins and Resolvins

(See ▶ Resolution of Inflammation)

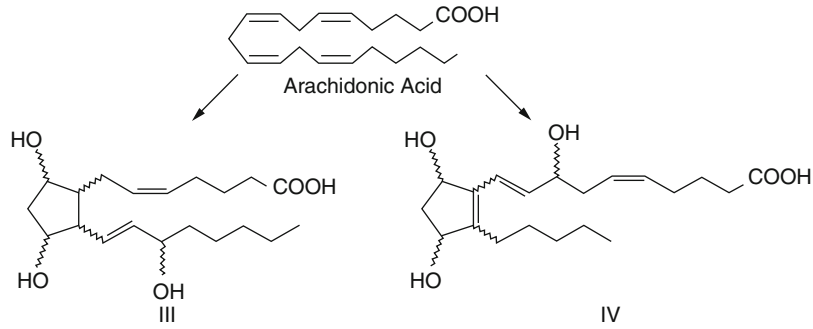
Isoeicosanoids

Isoeicosanoids, isomers of enzymatically derived eicosanoids, are derived from the free radical-mediated peroxidation of polyunsaturated fatty acids, including omega-3 fatty acids. They include members of the F, D, and E isoprostanes, isothromboxanes, and isoleukotrienes. Analysis of the isoprostanes (IsoP) indicates that they reflect lipid peroxidation in vivo. One F-type isoprostane, isoprostane F2α III (formerly 8-isoprostaglandin F2α) has been studied in detail because of its biologic activity in vitro. Isoprostane F2α III (Fig. 4) is a potent vasoconstrictor, with actions that are blocked by TX receptor antagonists. Although isoprostanes may act as ligands at TX or PG receptors (8,12-isoprostane F2α III activates the PGF2α receptor), they also may activate specific isoprostane receptors.

What all isoprostanes have in common, and what distinguishes them from the PGs, is the fact that the top (α) and the bottom (ω) side chains are always syn – that is, crowded together on the same face of the cyclopentane ring. In contrast to conventional, enzymatically derived PGs that are formed intracellularly and released immediately, isoprostanes are formed in the cell membrane where they remain until cleaved by phospholipases, circulate in plasma, and are excreted in urine. As stable end products of lipid peroxidation, endogenously formed IsoP are useful markers of oxidative stress and independent risk markers of coronary artery disease (Durand et al. 2010).

Endocannabinoids

Groups of naturally occurring members of the eicosanoid superfamily that can activate cannabinoid receptors and are derivatives of long-chain fatty acids have been referred to as endocannabinoids. They are not stored in cells. Rather, they are synthesized rapidly in the manner of PGs and LTs from lipid precursors and are released from – among other cells – cells of the immune system during immune/inflammatory responses. They can then activate cannabinoid receptors on the same or adjacent cells and are metabolized rapidly by the specific serine hydrolase, fatty acid amide hydrolase (FAAH), or by monoglyceride lipase or N-acylethanolamine. Thus, inhibition of FAAH offers a strategy for treatment of chronic inflammatory pain (Naidu et al. 2010). One of the most important endocannabinoids is anandamide (from the Sanskrit word for "bliss"), the amide conjugate of AA and ethanolamine (arachidonoyl ethanolamide).



Prostaglandins, Leukotrienes, and Related Compounds, Fig. 4 Isoprostane F2a structures. *Jagged lines* indicate that stereochemistry is uncertain

Anandamides and other endocannabinoids, such as 2-arachidonoylglycerol and virodhamine, are involved in a wide range of regulatory functions including pain perception and modulation of immune responses, actions mediated via cannabinoid 1 (CB1) and CB2 receptor subtypes, resulting in activation of G proteins of the G(i/o) family.

Acid congeners of anandamides are lipoamino acids (elmiric acids) that exist as endogenous substances, regulate tissue levels of anandamide, and exhibit anti-inflammatory effects and the capacity to facilitate resolution of inflammation. One such compound, N-arachidonoyl glycine (NAGly), is found in many tissues at higher concentrations than anandamide. It has analgesic actions similar to those reported for anandamide but does not exhibit psychotropic action. A library of elmiric acids (Burstein 1999) (n-3 and n-6) has been synthesized. Several of these compounds exhibit anti-inflammatory activity, likely in part by increasing production of PGJ2. That anandamide can enhance its own synthesis in macrophages suggests the presence of a rapid response to counter excessive inflammatory or immune responses. Anandamide is converted by COX-2 (but not by COX-1) into PGE_2 or $PGF_{2\alpha}$ ethanolamide directly, without going through free AA. These novel PGs ("prostamides") are pharmacologically active. Because anandamide is a substrate for COX-2, inhibitors of COX-2 may reduce anandamide metabolism with a subsequent increase in concentration of the anandamide. A combination of anandamide with ibuprofen produces synergistic analgesia in rats (Guindon et al. 2006).

Eicosanoid Receptors

For many years, it was thought that the lipophilic eicosanoids – in contrast to the peptide molecules for which receptors were characterized routinely – simply "diffused" into cell membranes or were carried in by a binding protein. The isolation and cloning of eicosanoid receptors changed that thinking.

Prostaglandin Receptors exert most of their actions through G protein-coupled receptors. Receptors for the COX products are designated P receptors, depending on the prostanoid that has most affinity for them. These receptors include the PGD receptors (DP), four subtypes of the PGE receptor (EP1 through EP4), the PGF receptor (FP), the PGI2 receptor (IP), and the TX receptor (TP). The IP, DP, EP2, and EP4 receptors mediate increases in cellular cyclic AMP, whereas TP, FP, and EP1 receptors induce calcium mobilization. EP2, EP4, and IP regulate macrophage cytokine production in a similar manner. As might be expected, signaling through these receptors is more complicated (Ricciotti and Fitzgerald 2011; Shimizu 2009).

Leukotriene Receptors

Surface receptors for LTB_4 denoted BLT1 and BLT2 and for the cysteinyl LTs also exert their actions through transmembrane-spanning G protein-coupled protein receptors. High-affinity LTB_4 receptors transduce chemotaxis and adhesion

responses, whereas low-affinity receptors are responsible for secretion of granule contents and superoxide generation. A COX-1 derived ligand 12(S)-hydroxyheptadeca-5Z,8E,10E-trienoic acid (12-HHT), produced during thromboxane synthesis, is an endogenous high-affinity ligand for BLT2 (now called BLT2/HHTR), another example of a connection between the LO and COX pathways. The cysteinyl LTs are recognized by at least two GPCR denoted CysLT1 and CysLT2. CysTL1 mediates calcium mobilization and inhibition of adenylate cyclase, whereas CysTL2 mediates calcium mobilization and increased cyclic AMP concentrations. The preferred ligands for CysLT1 are LTD4 > LTC4 > LTE4. CysLT2 binds LTC4 and LTD4 equally, whereas LTE4 exhibits low affinity for the receptor. Both receptors have wide tissue and cellular distribution, including a presence in cells which participate in immune responses. More than a dozen chemically distinct, specific, and selective antagonist drugs that block the binding of LT to $CysLT_1$ have been identified. Clinical use of these compounds has mainly been in the treatment of asthma (Mathis et al. 2010).

Lipoxin Receptors

Lipoxins can act at their own specific receptors for LXA_4 and LXB_4, and LXA_4 can interact with a subtype of LTD_4 receptors. Lipoxins also can act at intracellular targets within their cell of origin or after uptake by another cell. The monocyte and neutrophil LXA_4 receptors are identical at the cDNA level, but they evoke different responses, and the LXA_4 receptor on endothelial cells seems to be a structurally distinct form. LXA4 also binds to the human orphan receptor GPR32, a member of the chemoattractant receptor family (Chiang et al. 2006).

Nuclear Receptors

Nuclear receptors are a superfamily of ligand-regulated transcription factors that interact with other transcription factors and with co-regulators that either enhance (co-activators) or inhibit (corepressors) transcription. The major nuclear receptors involved in regulation of inflammation are the glucocorticoid receptor (GR), peroxisome proliferator-activated receptors, liver X receptors (LXR), and the orphan receptor nuclear receptor-related 1 protein (Nurr1). Other members of the nuclear receptor family which contribute to the regulation of inflammation include estrogen receptors, vitamin D receptor, and retinoic acid receptors (Huang and Glass 2010).

Platelet-Activating Factor

Platelet-activating factor (PAF, 1-0-alkyl-2-acetyl-sn-glycero-3-phosphocholine), is a potent mediator of inflammation that causes neutrophil activation, increased vascular permeability, vasodilation, and bronchoconstriction in addition to platelet activation. PAF is formed by a smaller number of cell types than the eicosanoids: mainly, leukocytes, platelets, and endothelial cells. Because of the extensive distribution of these cells, however, the actions of PAF can manifest in virtually every organ system. In contrast to the two long-chain acyl groups present in phosphatidylcholine, PAF contains a long-chain alkyl group joined to the glycerol backbone in an ether linkage at position 1 and an acetyl group at position 2. PAF represents a family of phospholipids (PAF-like lipids: PAF-LL) because the alkyl group at position 1 can vary in length from 12 to 18 carbons. PAF, similar to the eicosanoids, is not stored in cells. Rather, it is synthesized when cells are stimulated, at which time the composition of the alkyl group may change. The immediate effects of PAF are mediated through a cell surface G protein-coupled receptor PAFR. PAFR is coupled to Gi, Gq, and G12/13. Activation of PAFR results in inhibition of cyclic AMP, mobilization of calcium, and activation of mitogen-activated protein kinases.

The synthesis of PAF is tightly regulated, and a family of intra- and extracellular phospholipases A2 (PAF acetylhydrolases; PAF AH) degrades PAF and PAF-LL, thereby regulating their half-life and their engagement with the PAFR. In addition, receptor desensitization controls binding of PAF to its receptor (Yost et al. 2010).

Definitions

Hypertension is defined as blood pressure elevation to a level that places patients at risk for target organ damage including the kidneys, heart, and brain. The Joint National Committee on Hypertension defines hypertension for the general population as systolic blood pressure (SBP) greater than 140 mm Hg or diastolic blood pressure (DBP) greater than 90 mm Hg (Chobanian et al. 2003). Chronic kidney disease (CKD) is defined by the Kidney Disease Quality Outcome Initiative (K/DOQI) as either kidney damage or a glomerular filtration rate (GFR) of less than 60 ml/min/1.73 m^2 for 3 months or more irrespective of cause. Kidney damage refers to demonstrated pathologic abnormalities or the presence of makers of damage, including a urine albumin-to-creatinine ratio greater than 30 mg/g (Levey et al. 2004). In CKD, hypertension is considered to be a blood pressure greater than 130/80 mm Hg (Levey et al. 2004). In addition to a more stringent level of blood pressure control in CKD, the choice of antihypertensive medications is important as some classes not only reduce blood pressure but are also kidney protective. These themes are developed in this entry. To the best of our knowledge, there are no prospective randomized trials on the effect of blood pressure control in immune-mediated kidney diseases. Thus, our recommendations are based on the randomized trials for blood pressure control in other forms of CKD. Our experience in managing blood pressure in immunologic kidney disorders supports the notion that this is a valid extrapolation.

Introduction

Hypertension is a major modifiable risk factor for the development and progression of CKD. It is present in 85 % of patients with CKD and the prevalence of hypertension increases as glomerular filtration rate falls. Progressive kidney disease makes blood pressure more difficult to control. Also, hypertension superimposed on kidney disease promotes renal arteriolar nephrosclerosis and glomerular damage. This leads to a vicious cycle as kidney disease worsens hypertension and hypertension accelerates kidney disease (Sarafidis et al. 2007). Further, hypertension worsens proteinuria because it raises intraglomerular pressure. Proteinuria is the strongest single risk factor for CKD progression (progressive GFR decline). So, blood pressure control is essential to control proteinuria and slow CKD progression. Hypertension in immunologic kidney disorders such as glomerular disease is usually triggered by two factors: volume expansion and renal ischemia leading to activation of the renin-angiotensin-aldosterone system (RAAS). Unchecked upregulation of the RAAS leads to activation of several pathways deleterious to kidney function, including profibrotic growth factors, proinflammatory cytokines, and prothrombotic molecules.

CKD Progression

"Natural progression" of CKD refers to the decline in kidney function that is attributable to

mechanisms independent from those of the patient's original kidney disease. CKD patients are vulnerable to natural progression after they have sustained a GFR loss of greater than 50 % (Brown et al. 2010). The mechanisms of natural progression are largely related to overperfusion of the surviving glomeruli, which raises intraglomerular pressure and increases proteinuria. This mechanism, working in concert with metabolic derangements found in CKD such as hyperlipidemia, hyperuricosuria, and hyperphosphatemia, facilitates natural progression.

Another mechanism of GFR decline is that attributable to aging. This occurs in those with normal kidney function and causes GFR loss of about 1 ml/min/year starting after the age of 45 (Brown et al. 2010). In patients with CKD, it is likely that natural progression is additive to the progression due to aging.

Whether progression due to aging can be slowed is not clear. However, there is abundant evidence that natural progression can be slowed. Generally, natural progression is slow, so even small improvements in slowing natural progression can result in large delays in time to end-stage renal disease (ESRD) and need for dialysis.

Blood pressure control and reduction of proteinuria are critical to delay CKD progression. Four major trials provided blood pressure targets in CKD patients stratified by level of proteinuria (Klahr et al. 1994) (Wuhl et al. 2009; Wright 2002; Ruggenenti et al. 2005). Patients with proteinuric CKD (>1 g/day proteinuria) should have blood pressure controlled to less than 125/75 mm Hg. In addition, in patients with proteinuric kidney disease, the worse the proteinuria, the greater the benefit from aggressive blood pressure reduction on CKD progression. Those with less than 1 g/day proteinuria should continue to have blood pressure controlled to less than 130/80 mm Hg.

CKD Progression and the Renin-Angiotensin-Aldosterone System (RAAS)

Inhibition of the RAAS is of particular importance to delaying CKD progression. Protein excretion varies directly with intraglomerular pressure, and blockade of the RAAS decreases efferent arteriolar tone, thus decreasing glomerular capillary hydrostatic pressure (Yoshioka et al. 1987). The RAAS may also cause proteinuria by direct effects on podocytes (Durvasula et al. 2004). Intrarenal activation of the RAAS mediates podocyte apoptosis via angiotensin receptor 1 (ATR1) and may affect nephrin expression, disrupting slit diaphragm integrity on podocytes causing a loss in the ability to restrict protein filtration (Benigni et al. 2001; Bonnet et al. 2001). Furthermore, angiotensin II promotes glomerulosclerosis by promoting glomerular cell proliferation, altering growth factor expression and activating proinflammatory cytokines (Fogo 2006; Ruiz-Ortega et al. 2006). RAAS inhibition mitigates these maladaptive changes and helps restore podocyte health by reestablishing vascular endothelial growth factor (VEGF-A) and angiopoeitin-1 activity and inhibiting profibrotic factors, such as plasminogen activator inhibitor 1 (PAI-1) and transforming growth factor beta (TGF-β) (Table 1) (Brewster and Perazella 2004).

Angiotensin-Converting Enzyme Inhibitor (ACEi) Therapy

ACEi suppress the RAAS thus reducing blood pressure and proteinuria and restoring glomerular structure and function. Several large trials have validated the benefit of ACEi in proteinuric kidney disease (Lewis et al. 1993; The GISEN 1997; Maschio et al. 1996). Each trial demonstrated a significant reduction in proteinuria, rate of CKD progression, and onset of ESRD in patients treated with ACEi compared to placebo. A placebo-controlled trial of nondiabetics with CKD demonstrated a 53 % reduction in doubling of serum creatinine or need for dialysis after three years of follow-up in those receiving benazepril. The effect was greatest in those with proteinuria >1 g/day (Maschio et al. 1996).

In patients with proteinuric kidney disease, ACEi should be considered first-line therapy for hypertension and are also recommended in normotensive, proteinuric patients (Table 2). In both cases the ACEi should be titrated to the

maximum tolerated dose, as there is a dose-dependent increase in anti-proteinuric effect, and this will limit risk of aldosterone escape (increasing aldosterone levels during ACEi therapy), which can attenuate ACEi effect (Struthers 1995; MacFadyen et al. 1999; Hou et al. 2007). After initiation of ACEi therapy, an increase in serum creatinine may occur due to reduced filtration pressure from decreased efferent arteriolar tone. Patients must be monitored closely for progressive rise in serum creatinine and side effects such as hyperkalemia (Bakris and Weir 2000). ACEi should be held if acute kidney injury develops for any reason and 48 h before major surgery or iodinated contrast procedures.

Angiotensin Receptor Blocker (ARB)

While the action of ARBs appears to be similar to ACEi, there are some important differences. ARBs act on the angiotensin 1a receptor (ATR1a) in the kidney, inhibiting the effects of angiotensin II and thus do not increase bradykinin and have less effect on aldosterone (Tsouli et al. 2006). Two large, placebo-controlled randomized clinical trials confirmed the renoprotective benefits of ARBs in patients with type II diabetic nephropathy (Brenner et al. 2001; Lewis et al. 2001). ARBs were found to have similar antihypertensive and anti-proteinuric effects as ACEi in patients with diabetic nephropathy.

There are no large randomized trials of ARBs in nondiabetic kidney disease. However, given the best available evidence, ARBs may be used as an alternative to individuals intolerant of ACEi. As with ACEi, patients should be monitored closely for side effects such as hyperkalemia and progressive increase in serum creatinine while on ARB therapy.

Combination ACEi plus ARB Therapy

The addition of an ARB to ACEi may be more anti-proteinuric than either agent alone. Several small trials have found a significant reduction in proteinuria and rate of GFR decline compared to monotherapy MacKinnon et al. (2006); Kincaid-Smith et al. 2002; Luno et al. 2002; Wolf and Ritz 2005). However, a recent randomized, placebo-controlled trial which evaluated 25,620 individuals with vascular disease or diabetes found an *increased* risk of reaching all renal end points with combination therapy despite achieving a lower blood pressure than with either ACEi or ARB alone. There were also more adverse events with combination therapy (Messerli et al. 2008b). While this is contrary to the previous smaller studies, this report should not be taken lightly. This patient population likely had significant underlying vascular disease and, by extension, presumed renovascular disease. If so, it is understandable that lower blood pressures could have resulted in worse renal outcomes. Additionally, the trial did not demonstrate additional cardiovascular benefit with combination therapy. Another large trial also found no additional

Proteinuric Kidney Diseases: Importance of Blood Pressure Control, Table 2 Antihypertensive therapies and prevention of CKD progression

Intervention	Goals/comments
ACEi therapy	First-line therapy for hypertension in proteinuric kidney disease
ARB therapy	First choice for ACEi intolerance
Combination ACEi + ARB	May consider in patients with proteinuria > 3 g/day that cannot be controlled by a single agent. Avoid in patients with renovascular or cardiovascular disease
Aldosterone blockade	Anti-proteinuric effect at low doses. Slows progression of CKD. Consider as second-line agent for proteinuric kidney disease. Avoid if GFR < 30 ml/min/1.73 m^2
NDCAs	Anti-proteinuric effect. May be used in addition to ACEi/ARB to further reduce proteinuria and control blood pressure
Avoid DCAs	Not anti-proteinuric, may worsen proteinuria and promote kidney disease progression. Use only for refractory hypertension
Restrict NaCl intake	Goal 80–120 mmol/day (2–3 g/day) helps with blood pressure control and will optimize anti-proteinuric and antihypertensive therapies
Diuretics	Recommended use in conjunction with RAAS inhibition for salt-sensitive hypertension and in those with refractory high-salt diet or nephrotic syndrome
B-blockers	Concern for diabetic risk. Recommended in patients with cardiovascular disease or 4th-line agent for blood pressure control

cardiovascular benefit with combination therapy immediately post-myocardial infarction and instead showed increased adverse events (Pfeffer et al. 2003).

Combination therapy with ACEi and ARB must be used with caution. Combination therapy may still be warranted in those with heavy proteinuria (>3gm/day) after either drug alone has been maximized. Patients must be closely monitored for side effects and this regimen should generally be avoided in patients with atherosclerotic renal disease and cardiovascular disease.

Renin Inhibitors

Aliskiren is an agent that directly inhibits renin activity and is a therapy that is being used more commonly in clinical practice. Two large studies recently evaluated the efficacy of direct renin inhibition combined with ACEi or ARB (Parving et al. 2008; Peterson 2011). The results were conflicting and one study was stopped early due to increased renal and cardiovascular adverse events with combination therapy (Peterson 2011). Overall, the role of aliskiren in nondiabetic kidney disease is untested and it should not be used in place of ACEi/ARBs or in combination with ACEi/ARB.

Aldosterone Antagonism

Aldosterone plays an important role in the pathogenesis of renal injury. In addition to the adrenal glands, aldosterone is synthesized in endothelial and vascular smooth muscle cells (Hollenberg 2004). It functions in the kidney to maintain salt and water homeostasis and assist with excretion of potassium.

Aldosterone promotes fibroblast and/or myofibroblast growth and, through TGF-β, regulates collagen deposition in blood vessels and the heart (Brilla 2000) (Sun et al. 2000). Within the kidney, aldosterone mediates vascular remodeling, and excess aldosterone expression promotes tubulointerstitial fibrosis in patients with kidney damage (Sun et al. 2000). Aldosterone antagonists, even in low doses, have anti-proteinuric, antihypertensive, antifibrotic, and cardioprotective effects (Zannad et al. 2011; Pitt et al. 1999; Chrysostomou and Becker 2001; Sato et al. 2003). ACEi provide some blockade of aldosterone action and work synergistically with aldosterone antagonists (Chrysostomou and Becker 2001). Directly antagonizing aldosterone may therefore be important adjunctive therapy to primary RAAS inhibition in patients with kidney disease.

While there are no strong clinical trial data with hard end points like ESRD, the available data support the use of aldosterone antagonists in patients with CKD who have not met blood pressure or proteinuria goals with ACEi/ARBs. Patients with CKD on aldosterone antagonists must be monitored closely for hyperkalemia,

especially if on concomitant ACEI/ARB therapy. Further, aldosterone antagonists should not be used in patients with GFR < 30 ml/min/1.73 m^2 due to risk for hyperkalemia.

Diuretics and Salt

Sodium Restriction

Increased salt intake worsens hypertension and proteinuria in patients with CKD (Jones-Burton et al. 2006). A high-salt diet can also override the effects of anti-proteinuric and antihypertensive therapy (Heeg et al. 1989; Weir et al. 1998; Bakris and Smith 1996). The effect of lisinopril on reduction in proteinuria was found to be strongly dependent on dietary sodium intake in one study (Heeg et al. 1989). Similarly, the addition of salt restriction and diuretics to ARB therapy reduced proteinuria 25 % more than the ARB alone, and patients who did not initially respond to losartan monotherapy for proteinuria did so after the addition of salt restriction (Vogt et al. 2008). The average adult American diet contains about 170 mmol/d or 3.9 g/d of sodium. In individuals with glomerular disease and proteinuria/hypertension, sodium intake should be restricted to 80–120 mmol/day (2–3 g/day). Salt intake can be monitored by measuring sodium in a 24-h urine collection.

Diuretics

Diuretic therapy synergizes with RAAS inhibition to improve blood pressure and reduce proteinuria (Vogt et al. 2008). Diuretics alone have not been shown to reduce proteinuria beyond what is achieved by blood pressure control. Diuretics such as the thiazides have significant metabolic side effects such as hypokalemia, hyperglycemia, hyperuricemia, hyperlipidemia, hyponatremia, and stimulation of the RAAS. Most of these side effects are known to increase cardiovascular risk. However, if diuretics are used in conjunction with an ACEi or ARB, these metabolic effects are mitigated (Messerli et al. 2008a). For patients with nephrotic syndrome, who are prone to volume retention, diuretic therapy is beneficial, especially in combination with RAAS blockade (Messerli et al. 2008a). If the GFR is less than 30 ml/min/1.73 m^2, then a loop diuretic (e.g., furosemide) is preferred over thiazides. Electrolytes should be monitored closely.

Calcium Channel Blockers

Non-Dihydropyridine Calcium Channel Antagonists (NDCA)

The NDCAs, including verapamil and diltiazem, have been found to be anti-proteinuric. They have also been found to slow decline in kidney function (Bakris et al. 1996, 2004). In a study of patients with overt diabetic nephropathy, NDCAs had anti-proteinuric and antiprogression effects similar to lisinopril and superior to atenolol (Bakris et al. 1997). Individuals who remain hypertensive with persistent proteinuria despite adequate RAAS inhibition may benefit from the addition of NDCAs, particularly if the GFR < 30 ml/min.

Dihydropyridine Calcium Channel Antagonists (DCA)

As opposed to NDCAs, DCAs, while extremely effective antihypertensive agents, decrease glomerular afferent arteriolar resistance and thus tend to increase glomerular capillary hydrostatic pressure. This can worsen proteinuria and accelerate loss of renal function (Bakris et al. 2004; Ruggenenti et al. 1998; Gashti and Bakris 2004; Hummel et al. 2010). A more recent study compared candesartan to amlodipine in hypertensive patients with moderate to advanced CKD. After a 3.2 year median follow-up, the candesartan group had slower progression of CKD, less new onset diabetes, and significantly less cardiovascular risk compared to the amlodipine group (Saruta et al. 2009). In patients with proteinuric kidney disease, these agents should be reserved for those with refractory hypertension.

Other Antihypertensives

Beta-Blockers

There is no evidence to suggest that β-blockers slow progression of CKD. β-blockers are

typically reserved for patients with underlying cardiac disease and are otherwise considered fourth-line therapy for blood pressure control. β-blockers may increase the risk for developing diabetes when used as monotherapy (Messerli et al. 2008a). β-blocker use is recommended for patients with underlying cardiac disease and may be considered in those with refractory hypertension.

Conclusions

Hypertension is common in immunologic kidney disease and is typically caused by prolonged tissue ischemia leading to RAAS activation and volume expansion. The objective of blood pressure control is to delay kidney disease progression and reduce cardiovascular risk. Proteinuria and blood pressure are linked as risk factors for CKD progression, and emphasis should be placed on treating hypertension with agents that are known to reduce proteinuria and slow progression of CKD. Inhibition of the RAAS is necessary to achieve these goals. ACEi are considered first-line therapy for hypertension in patients with proteinuric kidney disease with goal blood pressure less than 125/75 mm Hg, as tolerated. ARBs may be used if ACEi are not tolerated. Additional antihypertensive agents are often needed and those with kidney protective effects as described above should be added. Volume expansion as seen in those with nephrotic syndrome should be treated with salt restriction and diuretic therapy. In summary, blood pressure control is critical to maintaining renal function. It should be followed closely and treated aggressively to delay CKD progression and reduce cardiovascular risk.

Psoriasis vulgaris

Definition

Psoriasis is an inflammatory, immune-mediated disease which can involve the skin, nails, and joints. Its occurrence may be influenced by environmental factors (Menter et al. 2008).

Introduction

Psoriasis is an inflammatory, immune-mediated disease that can affect a variety of skin surfaces, joints, and nails. Currently, there are several treatments available for the disease. Modalities include topical treatments, systemic medications, and phototherapy treatment. Most recently, biologic treatments have been used which work through the immune system to provide therapeutic benefit.

Psoriasis was first described by Robert Willan in 1809. In 1841, Hebra distinguished psoriasis from leprosy. Toward the end of the nineteenth century, Heinrich Koebner depicted psoriatic plaques emerging in areas of trauma (van de Kerkhof and Schalkwijk 2008).

Epidemiology

Generally, psoriasis affects about 2 % of the population (Menter et al. 2008). Worldwide, the occurrence of psoriasis varies based on age and geographic location. In adults, the prevalence of psoriasis ranges from 0.91 % in the United States to 8.5 % in Norway. In children, the prevalence is between 0 % in Taiwan to 2.1 % in Italy. The occurrence of psoriasis is more frequent in nations further from the equator (Parisi et al. 2013).

The occurrence of psoriasis may take place at any age. There are two peaks in incidence of psoriasis; the first peak occurs in early adulthood and the second peak occurs between ages 50 and 60 (Cohen et al. 2012).

Pathophysiology/Immunology

Traditionally, psoriasis had been classified as a T-helper (Th)-1 cell-mediated disease (Cai et al. 2012). Observations in support of this included elevated numbers of CD4+ TH1 and CD8+ cytotoxic cells type 1 (Tc1) and increased levels of cytokines including interferon-gamma (IFN-gamma), tumor necrosis factor (TNF)-alpha, and interleukin (IL)-12 (Cai et al. 2012).

More recently, it has been observed that in psoriasis, there is expansion and stimulation of not only Th-1 cells but also Th-17 and Th-22 cell populations (Reich 2012). In turn, there is release of TNF-alpha, IL-17, and IL-22 (Reich 2012).

The IL-23/Th-17 pathway is critical in psoriasis pathogenesis. This pathway facilitates the inflammatory response of the skin by directing cytokine and chemoattractant secretion and cytokine production (Monteleone et al. 2011). IL-23, a heterodimeric cytokine, consists of subunits IL-23p19 and IL-12p40 and is a crucial cytokine necessary for Th-17 cell maintenance and development (Cai et al. 2012). In psoriatic lesional skin and circulation, observations of increased Th-17 cells and related downstream molecules including IL-17A, IL-17F, IL-22, IL-21, and TNF-alpha have been noted (Cai et al. 2012).

Presentation

Skin

Classically, psoriasis presents with erythematous distinct scaly plaques overlying knees and elbows. The scale is a micaceous silvery scale. When the scale is rubbed or picked off, bleeding can occur. This is also known as Auspitz sign. In addition, lesions can occur in sites of trauma. Lesions occur between 10 days and a few weeks after the injury (Cohen et al. 2012). This is known as the Koebner or isomorphic phenomenon. Psoriasis of the skin can also involve the scalp, the intergluteal cleft, the palms and soles, the groin, and axillary regions.

Different types of psoriasis exist, but many individuals can have multiple subtypes that overlap (Menter et al. 2008) (Table 1).

Psoriasis, Table 1 Subtypes of psoriasis

Subtype of psoriasis	Description
Plaque psoriasis	The most common form of psoriasis
	Well-demarcated, red plaques ranging in size from 1 cm and beyond with overlying micaceous scale
	Favors the extremities (elbows and knees), scalp, trunk, and buttocks (James et al. 2005; Menter et al. 2008)
Sebopsoriasis	Features overlap with seborrheic dermatitis
	Seen on the scalp, face, breasts, flexural surfaces, and axilla (James et al. 2005)
Inverse psoriasis	Seen mostly in folds such as axilla and groin (James et al. 2005; Menter et al. 2008)
Guttate psoriasis	Small drop-like lesions, ranging in size between 1 and 10 mm, scattered mostly on the trunk, may occur after streptococcal infection
	Often seen in individuals less than 30 years old
	Responds well to phototherapy (James et al. 2005; Menter et al. 2008)
Pustular psoriasis	May be generalized or localized
	The localized form consists of erythema and pustules occurring on the palms and soles
	The acute generalized form, also known as von Zumbusch type, is characterized by a background of erythema with overlying pustules and fevers and toxicity
	May occur after administration of systemic corticosteroids is complete
	Treatment of choice is acitretin (James et al. 2005; Menter et al. 2008)
Impetigo herpetiformis	This is a form of pustular psoriasis seen in pregnancy
	Treatment may include delivery of the baby or systemic corticosteroids (James et al. 2005)
Erythrodermic psoriasis	Characterized by generalized erythema
	Involves most of the body surface area
	Chills, hypothermia, fluid loss may occur due to altered thermoregulation
	Fevers and fatigue may be seen (James et al. 2005; Menter et al. 2008)

Nails

Up to 45 % of psoriasis patients and almost 90 % of patients with psoriatic arthritis may have nail manifestations of psoriasis (Tan et al. 2012). About 5 % of patients present with nail psoriasis and have no skin manifestations of the disease (Tan et al. 2012).

Patients with nail psoriasis may have a variety of clinical findings including onychodystrophy, subungual hyperkeratosis, discoloration of the nail bed, onycholysis, and pitting of the nail plate. The most common nail finding in psoriasis is pitting. Splinter hemorrhages, leukonychia, red spots in the lunula, and crumbling of the nail plate may also be seen (Tan et al. 2012).

Joints

Psoriatic arthritis may occur with or without skin involvement. In addition, psoriatic arthritis may be accompanied solely by nail or scalp lesions.

Psoriasis, Table 2 Subtypes of psoriatic arthritis

Subtypes of psoriatic arthritis	Characteristics
Assymetric oligoarthritis	Common pattern, seen in up to half of male patients
	Initially affects digits causing a "sausage" appearance
	At any given time, less than five joints are involved (Franks 2004)
Symmetric polyarthritis	Most common subtype in women
	Rheumatoid-like pattern with involvement of hands, feet, and ankles
	Distinguished by involvement of the distal interphalangeal (DIP) joint (Franks 2004)
DIP joint	Symmetric involvement of the joint occurs in fewer than 5 % patients
	Mostly seen in men
	When involvement is asymmetric may overlap with oligoarthritic or rheumatoid-like types
	Nail involvement may occur (Franks 2004)
Arthritis mutilans	Osteolysis or resorption of bone with loss of joint space may occur leading to "pencil-in-cup" deformity which may be observed in radiographs (Franks 2004)
Spondylitis	Involvement of the neck, thoracic, and lumbosacral spine may occur
	Asymmetric sacroiliitis is seen (Franks 2004)

Generally, skin involvement occurs before joint involvement (Franks 2004) (Table 2).

Enthesopathy may be seen by itself or in conjunction with another subtype of psoriatic arthritis. In diagnosing psoriatic arthritis, it is important to establish the absence of rheumatoid factor. However, some patients may have both psoriatic arthritis and rheumatoid arthritis or may be part of the 5 % of the general population which is seropositive (Franks 2004).

Associations

Factors Which Exacerbate Psoriasis

Psoriasis may be exacerbated by a variety of factors. These include stress, high alcohol consumption, cold weather, skin trauma, and medications. Certain medications may exacerbate existing psoriatic disease, induce psoriatic lesions in patients with a history of psoriasis on skin that was previously uninvolved, or trigger new onset psoriasis (Dika et al. 2006). Drugs that are highly implicated include beta blockers, lithium, synthetic antimalarials, nonsteroidal anti-inflammatory drugs (NSAIDs), and tetracyclines. Medications that may possibly exacerbate psoriasis include ACE-inhibitors, terbinafine, and interferons (Dika et al. 2006).

Psoriasis and Metabolic Syndrome

There appear to be associations between psoriasis, psoriatic arthritis, cardiovascular disease, obesity diabetes, and non-alcoholic fatty liver disease. These associations have implications in terms of potential screening in patients with psoriasis and psoriatic arthritis (Johnsson et al. 2012). The prevalence of the metabolic syndrome in US adults with psoriasis is higher than the prevalence of metabolic syndrome in US adults without psoriasis; 40 % of psoriatics were found to have the metabolic syndrome versus 23 % of non-psoriatics who were determined to have the metabolic syndrome (Love et al. 2011).

Psoriasis and Infection

Guttate psoriasis has been linked to streptococcal infection. Specifically, it has been noted that tonsillar Streptococcus pyogenes infection may precede the onset of guttate psoriasis (Fry and Baker 2007). Colonization of the skin and/or gut with Staphylococcus aureus, Malassezia, and Candida albicans has been associated with disease exacerbation (Fry and Baker 2007).

HIV-associated psoriasis may be severe and difficult to treat. The severity of psoriasis in a patient with HIV may vary with the degree of immunosuppression. Guttate, inverse, and erythrodermic psoriasis are the most common subtypes of psoriasis in patients with HIV. In this population, psoriatic arthritis is more frequent and has greater severity. Treatment of psoriasis in HIV patients may be challenging as therapeutic choices may be limited and have the ability to cause more complications (Menon et al. 2010).

Diagnosis

Psoriasis may be diagnosed on the basis of patient history and clinical presentation. Biopsies of the skin may be done for confirmation of skin disease. X-rays may be helpful in diagnosing psoriatic arthritis.

The histology of psoriasis reveals confluent parakeratosis, Munro microabscesses, which consist of neutrophils in the stratum corneum, and spongiform pustules of Kogoj which are neutrophils in the stratum spinosum. Additional features include epidermal thinning above dermal papillae, hypogranulosis, acanthosis, dilation of capillaries in dermal papillae, and lymphocytes located perivascularly (Rapini 2005).

Treatment and Management

There are many treatments for psoriasis. Appropriate therapy depends on type and extent of disease. Patient comorbidities also affect the choice of therapy.

Topical and Local Treatments

For limited localized disease, topical therapy is often the first line of treatment. Topical agents can be used in mild to moderate disease. They can also be used in conjunction with ultraviolet (UV) light or systemic agents in resistant lesions. There are several different types of vehicles available. The vehicle can be adjusted based on body surface affected and patient preference. Topical agents may also be used in combination (Menter et al. 2009a).

Topical corticosteroids are frequently the mainstay of therapy in psoriatic patients. Topical steroids are recommended in psoriasis that involves less than or equal to 10 % body surface area (Paul et al. 2012). They are vasoconstrictive, immunosuppressive, antiproliferative, and anti-inflammatory (Menter et al. 2009a). Corticosteroids bind to intracellular receptors and regulate the transcription of genes coding for inflammatory cytokines (Menter et al. 2009a).

Mid to high potency topical steroids may be used as induction therapy in adults with psoriatic lesions on the trunk and extremities. In infants and young children and in adults with lesions on the face and intertriginous areas, lower potency topical steroids are used (Menter et al. 2009a). Side effects of topical corticosteroids generally occur only locally. Telangiectasias, striae, atrophy of the skin, purpura, ecchymosis, and acneiform eruptions can occur. Systemic side effects are very uncommon but are more of a risk with use of high and ultrahigh potency topical corticosteroids. Concerns include cataracts, glaucoma, Cushing's syndrome, and osteonecrosis of the femoral head and hypothalamic-pituitary-adrenal axis suppression (Menter et al. 2009a). Intralesional corticosteroid treatment may be used for thicker psoriatic plaques and has a similar side effect profile to ultrahigh potency topical steroid therapy.

Vitamin D analogues such as calcipotriene are believed to bind to vitamin D receptors inhibiting the proliferation of keratinocytes and promoting the differentiation of keratinocytes. They may be used in conjunction with topical corticosteroids in the induction phase of treatment and may be used as monotherapy in the maintenance phase of treatment (Menter et al. 2009a). As with topical corticosteroids, local side effects are more common. Redness, itch, edema, burning, peeling, and xerosis may occur. Systemic side effects are rare but can potentially include hypercalcemia and suppression of parathyroid hormone. UVA inactivates calcipotriene so patients are advised to apply the medication after exposure (Menter et al. 2009a).

Calcineurin inhibitors are another topical option. They include tacrolimus and pimecrolimus. They inhibit inflammatory cytokine synthesis and are particularly helpful in the treatment of psoriasis on the face and intertriginous areas since they are not known to cause skin atrophy. In addition, they are helpful in the maintenance phase of treatment. Burning and pruritus are common side effects. There is a black box warning on these medications due to potential risk of malignancies and deficient long-term safety data (Menter et al. 2009a).

Other topical options include the combination of calcipotriene and betamethasone propionate ointment, salicylic acid, anthralin, and coal tar.

Tazarotene and salicylic acid are helpful in treating resistant plaques (Paul et al. 2012).

Phototherapy

Phototherapy is indicated for patients with involvement of large body surface areas, mostly located on the trunk and the extremities. The options for phototherapy include PUVA (psoralen + UVA light) and NB-UVB (narrowband UVB light). PUVA is more effective. However, NB-UVB is preferred due to convenience and the increased risk of skin cancer associated with PUVA. It is recommended that patients undergoing phototherapy use ocular protection to prevent cataracts and use facial protection to prevent photoaging and lentigines. Phototherapy sessions should take place 2–3 times per week. Usually, clearance of psoriatic lesions occurs between 20 and 30 treatments (Paul et al. 2012).

Systemic Medications

There are many systemic therapies available for the treatment of psoriasis. Treatment choice depends on the type and extent of psoriasis. Patient comorbidities and characteristics affect the choice of therapy as well.

Methotrexate has been used in the treatment of psoriasis for several years. It is used in both severe psoriasis and psoriatic arthritis. It inhibits dihydrofolate reductase which reduces tetrahydrofolate synthesis. Tetrahydrofolate is a cofactor necessary in the synthesis of DNA and RNA. The effects of methotrexate in psoriasis are largely believed to be immunosuppressive; it inhibits the proliferation of lymphoid tissue (Callen et al. 2007). Methotrexate is administered once weekly either orally or parenterally. Prior to therapy, a test dose may be given to check for bone marrow suppression. Weekly dosages range between 7.5 and 25 mg (Menter et al. 2009b). Initial clinical response occurs within 4 weeks of initiating therapy, while full therapeutic effects often take between 2 and 3 months to occur (Callen et al. 2007). Folate supplementation may be helpful in preventing gastrointestinal side effects and bone marrow toxicity. More common side effects include stomatitis, anorexia, nausea, and fatigue. Major side effects include myelosuppression, pancytopenia, pulmonary toxicity, hepatotoxicity, lymphomas with Epstein-Barr virus, and renal toxicity (Callen et al. 2007). Patients require careful lab monitoring and diligent follow-up of the liver. Methotrexate is contraindicated in pregnant and nursing women. Men and women should wait 3 months after stopping the medication prior to trying to conceive (Menter et al. 2009b).

Cyclosporine is used as a short-term medication for the clearance of severe recalcitrant psoriasis. It may be used in patients who have failed other treatments, are experiencing a new flare of disease, or need clearance for a short period of time for a life event. Cyclosporine may be helpful in erythrodermic or pustular psoriasis, as well. Cyclosporine inhibits interleukin-2 (IL-2) produced by T lymphocytes through the inhibition of calcineurin by way of a complex formed between cyclosporine and cyclophilin. Decreased IL-2 production causes reduced numbers of CD4 and CD8 cells (Lee and Koo 2007). It is dosed between 2.5 and 5 mg/kg/day. Adverse effects include renal toxicity and hypertension. In addition, tremors, headaches, paresthesias, and hyperesthesias may be reported. Hypertrichosis and gingival hyperplasia may occur. Labs should be checked regularly as hyperkalemia, hyperuricemia, hypomagnesemia, and hyperlipidemia may develop. Gastrointestinal and musculoskeletal side effects may also occur. Cyclosporine is pregnancy category C (Lee and Koo 2007).

The retinoids are another group of oral medications which are used in the treatment of psoriasis. The exact mechanism of retinoids in psoriasis has not been elucidated. However, this group of medications affects cell differentiation and growth. In addition, retinoids work against inflammation and may be immunomodulatory. Acitretin is currently the retinoid most commonly used in psoriasis. It may be used in chronic plaque psoriasis and pustular psoriasis (Menter et al. 2009b). It may also be effective in treating nails that are affected by psoriasis. Acitretin can be

dosed from 10 to 50 mg and higher once nightly. Acitretin is useful in treating severe psoriasis in patients with HIV. Common side effects include dry skin, dry eyes, cheilitis, epistaxis, alopecia, brittle nails, and sticky or burning skin. In addition, lipid abnormalities, particularly increased triglycerides, and increased liver function tests may be seen. Acitretin is teratogenic and generally should not be given to women with childbearing potential (Menter et al. 2009b). Alcohol should be avoided as ethanol converts acitretin to etretinate which has a half-life to 168 days. Combination treatment with acitretin and NBUVB or PUVA is even more effective (Menter et al. 2009b).

Other systemic options include azathioprine, fumarates, hydroxyurea, leflunomide, mycophenolate mofetil, sulfasalazine, tacrolimus, and 6-thioguanine (Menter et al. 2009b).

Biologic Medications

One of the newest groups of systemic medications used in the treatment of psoriasis are the biologics. There are different types of biologic therapies, but they all target the immune system. Baseline screening includes complete blood cell count, liver function tests, hepatitis panel, and screening for tuberculosis (Kim et al. 2012).

The TNF-alpha inhibitors include etanercept, adalimumab, and infliximab. T cells and keratinocytes are sources of TNF-alpha which plays a crucial role as an inflammatory cytokine in psoriasis. A transmembrane-bound precursor undergoes cleavage to yield TNF-alpha which subsequently binds TNF-alpha receptor. TNF-alpha inhibitors block this pathway thereby obstructing the inflammatory cascade (Laws and Young 2012). These medications increase the risk of infection, particularly upper respiratory infections. Other risks include lupus-like syndrome from autoantibody formation and worsening of demyelinating diseases. Other potential associated adverse effects include increased mortality in patients with congestive heart failure, risk for the development of lymphomas, and non-melanoma skin cancers. Causality of these adverse effects has not been established (Kim et al. 2012).

Etanercept, a fusion protein made up of a TNF-alpha receptor fused to the Fc portion of human immunoglobulin G (IgG), is used in psoriasis and psoriatic arthritis. It is dosed at 50 mg subcutaneously once or twice a week for 3 months. Subsequently, patients receive 50 mg subcutaneously once a week. Injection site reactions can occur (Kim et al. 2012).

Adalimumab, a recombinant human immunoglobulin monoclonal antibody with high-affinity binding to TNF-alpha, is a therapeutic option in psoriasis and psoriatic arthritis. A loading dose of 80 mg is given subcutaneously. This is followed by subcutaneous doses of 40 mg every other week (Kim et al. 2012).

Infliximab, a chimeric monoclonal antibody which binds human TNF-alpha, is used to treat psoriasis and psoriatic arthritis. Intravenous infusions of the medication dosed at 5 mg/kg are administered at weeks 0, 2, and 6. Subsequently, the medication is given every 8 weeks. Rarely, anaphylaxis-like infusion reaction can occur (Kim et al. 2012).

Recombinant DNA technology has been employed to obtain alefacept, a human fusion protein which binds to memory effector T cells via CD2. Through this mechanism, alefacept obstructs the activation of T cells. Alefacept is used to treat psoriasis and administered as a 15 mg intramuscular injection every week for 12 weeks. Subsequently, there is a medication-free interval of 12 weeks (Kim et al. 2012).

Ustekinumab is a monoclonal antibody to p40, a subunit of both IL-12 and IL-23. IL-12 is believed to play a role in the differentiation of T cells to T-helper lymphocyte (Th)-1 cells, while IL-23 is thought to promote the differentiation of naive T cells toward Th-17 cells. This medication is used to manage psoriasis and is dosed at 45 mg subcutaneously at weeks 0, 4, and subsequently every 12 weeks. Patients who weigh more than 100 kg may be given 90 mg subcutaneously instead (Laws and Young 2012; Kim et al. 2012).

Conclusion

Psoriasis, an inflammatory, immune-mediated disease, can affect a variety of skin surfaces, joints, and nails. There has been much new research regarding the immunopathogenesis of this disease. This has resulted in the introduction of many new therapies with the promise of many more to come in the future.

Synonyms

Lymphoid phosphatase, LYP; Lymphoid-specific protein tyrosine phosphatase; PEST-domain phosphatase; PEST-enriched phosphatase, Pep; Protein tyrosine phosphatase, non-receptor type 8; Tyrosine-protein phosphatase non-receptor type 22

Definition

PTPN22 – a gene encoding the lymphoid phosphatase, a classical non-receptor protein tyrosine phosphatase expressed in hematopoietic cells.

Discovery of *PTPN22*

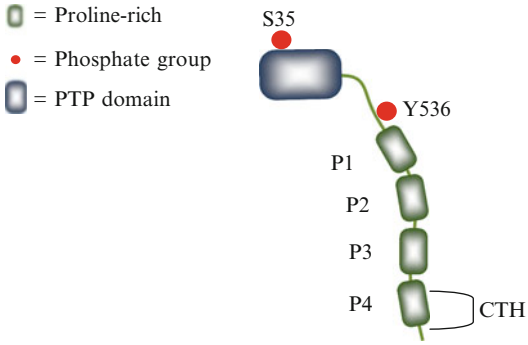
The human *PTPN22* gene is located on chromosome 1p13.3–13.1 and encodes the lymphoid phosphatase (LYP), a protein tyrosine phosphatase (PTP) cloned in 1999 by Chaim Roifman's laboratory (Stanford et al. 2010; Veillette et al. 2009). LYP shares 70 % sequence identity with the orthologous murine phosphatase Pep (PEST-enriched phosphatase), which had been cloned in 1992 by Matthew Thomas' laboratory and originally identified under the gene name *Ptpn8*. LYP/Pep belong to the PEST-enriched subfamily of non-receptor classical PTPs, which includes PTP-PEST (encoded by the *PTPN12* gene) and the brain-derived phosphatase 1 (BDP1, also known as the hematopoietic stem cell fraction phosphatase, PTP-HSCF, encoded by the *PTPN18* gene). As shown in Fig. 1, LYP and Pep are 105 kDa proteins containing three distinct regions: an N-terminal PTP catalytic domain, an interdomain region, and a C-terminal domain with four proline-rich motifs, termed P1–P4. The P4 motif is located within a carboxy-terminal homology (CTH) domain that is also found in BDP1 and PTP-PEST. Crystal structures of the catalytic domain of LYP have been solved and reveal a loop specific to the PEST-enriched PTPs. This region (amino acids 35–42) resides between the α1 and α2′ helices of the active site and participates in substrate binding (Orru et al. 2009; Yu et al. 2007).

LYP Expression in the Immune System

LYP/Pep is expressed only in hematopoietic cells. Three splice variants have been reported, designated LYP1, LYP2, and LYP3 (Burn et al. 2011). Additional shorter isoforms of LYP resulting from alternative splicing have been documented. Thus far, all functional studies have been performed on LYP1 (also designated LYP), the longest isoform of 807 amino acids. LYP2 was identified in resting T cells and contains a shorter C-terminus, which lacks the P2–P4 motifs and contains a unique tail of seven amino acids. LYP3 has a 28-amino acid deletion between the P1 and P2 motifs. No detailed expression surveys of the shorter isoforms, nor studies of putative shorter variants of Pep, have been reported. LYP1 is found in all hematopoietic cell lineages. At the mRNA level, the highest expression is found in natural killer cells and neutrophils, with lower expression in $CD8^+$ T cells, and the lowest in monocytes, dendritic cells (DCs), and $CD4^+$ T cells and B cells (Begovich et al. 2004). LYP/Pep is found in the cytoplasm, although Pep has been reported to localize to the nucleus and plasma membrane (Burn et al. 2011; Stanford et al. 2010; Veillette et al. 2009).

LYP Function in T Cells

The majority of studies on the function of LYP/Pep have been conducted in T cells (Stanford et al. 2010; Veillette et al. 2009). As shown in Fig. 2, LYP/Pep function as potent negative regulators of T cell activation through inhibition of key mediators of signal transduction downstream the T cell receptor (TCR).

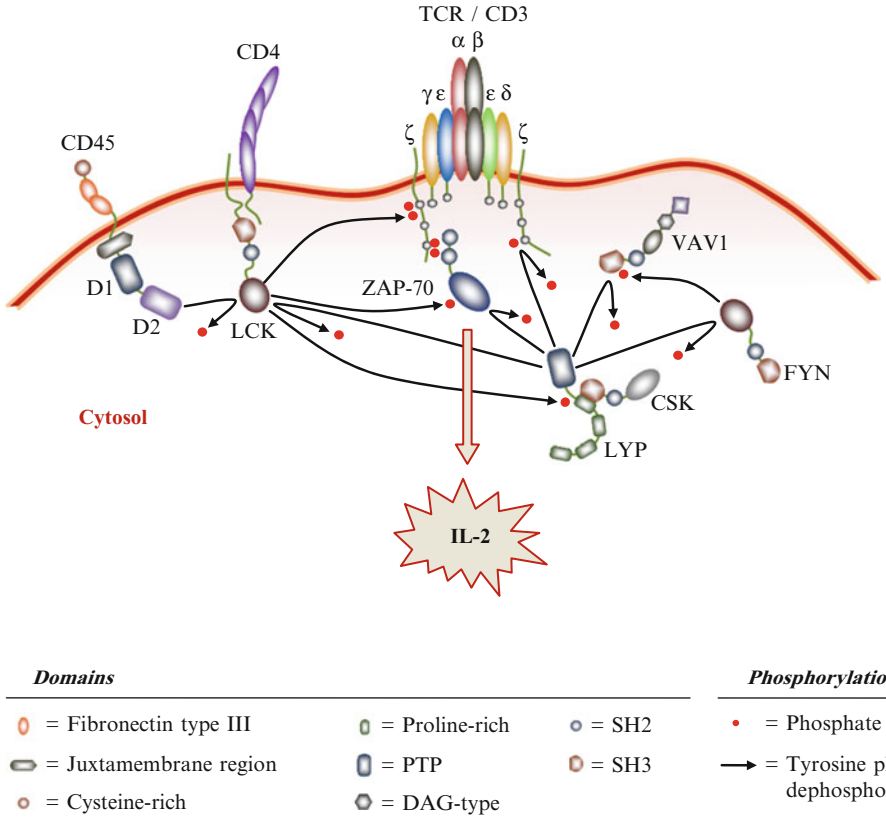


PTPN22, Fig. 1 Schematic representation of the LYP protein. LYP contains an N-terminal catalytic PTP domain, an interdomain region, and a C-terminal domain containing four proline-rich motifs, designated P1–P4, and a CTH domain. Reported sites of phosphorylation on serine (S) and tyrosine (Y) are shown

Through a combination of overexpression studies, substrate-trapping techniques, and studies using Pep-deficient mice, the substrates of LYP/Pep in T cells have been identified as the positive regulatory tyrosine residues in the activation loop of the Src family kinases (SFKs), lymphocyte-specific protein tyrosine kinase (LCK, Y394), and oncogene related to SRC, FGR, and YES (FYN, Y417) and the Syk family kinase zeta-chain (TCR)-associated protein kinase 70 kDa (ZAP-70, Y493); immunoreceptor tyrosine-based activation motifs (ITAMs) in the CD3ζ-chains; as well as phosphotyrosine residues in CD3ε, vav 1 guanine nucleotide exchange factor (Vav1), and valosin-containing protein (Vcp). Through dephosphorylation of these early mediators of signaling, LYP/Pep inhibits potentiation of the wave of tyrosine phosphorylation needed for early T cell activation and thus regulates signaling proximal to the TCR.

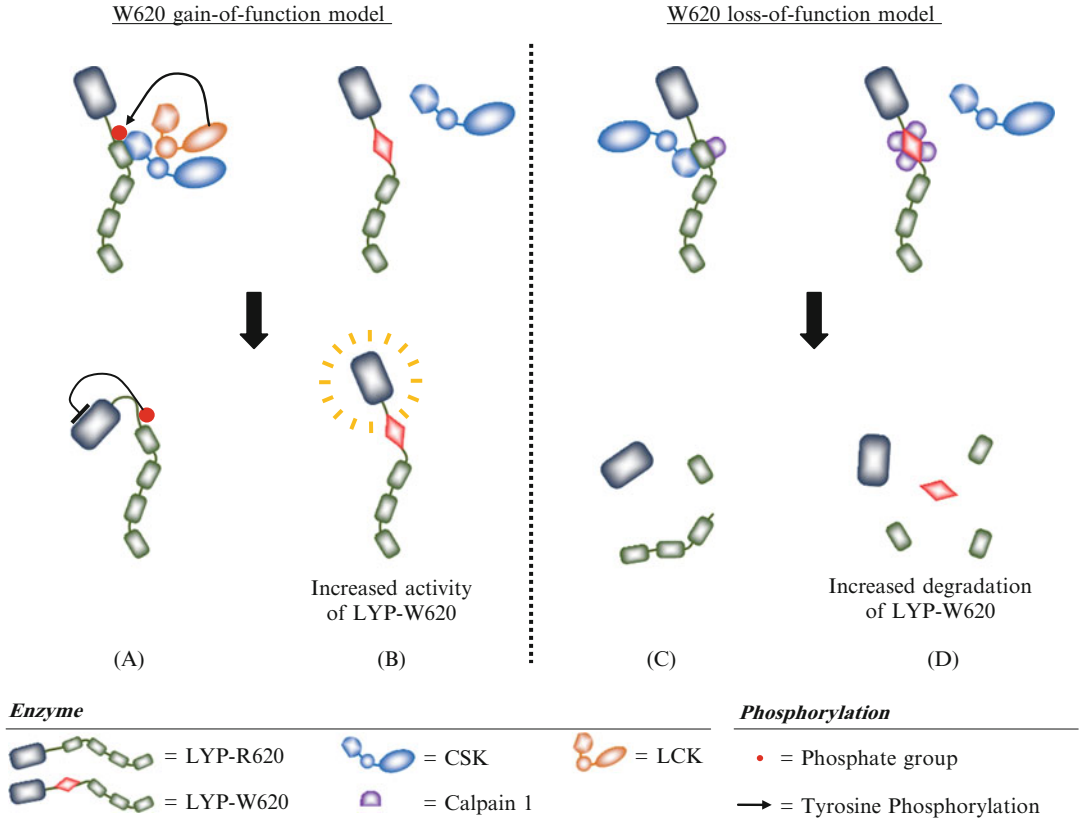
As demonstrated by Andrew Chan's group, in vivo deletion of Pep leads to increased T cell activation (Stanford et al. 2010; Veillette et al. 2009). T cells from *Ptpn22*$^{-/-}$ mice show enhanced TCR signaling, as evidenced by increased positive selection in the thymus, increased numbers of effector/memory CD4^{+} and CD8^{+} T cells, and increased responsiveness of effector/memory cells to TCR engagement. Naïve T cells from these mice show no difference in response to TCR stimulation, correlating with the expression pattern of LYP in T cells, which is high in thymocytes, low in naïve T cells, and high in mature and/or activated T cells. *Ptpn22*$^{-/-}$ mice also exhibit spontaneous germinal center formation in the spleen and Peyer's patches of aging mice, which have been attributed to an increase in T cell help. No spontaneous pathological phenotype has been found in these mice. Crossing of the *Ptpn22*$^{-/-}$ mouse with the CD45 E613R "wedge" model exacerbated the autoimmunity caused by the wedge mutation, indicating the importance of the threshold of lymphocyte signaling in maintaining immune homeostasis (Zikherman et al. 2009).

LYP contains four proline-rich motifs (P1–P4) that are potential binding sites for proteins containing SH3 domains. A well-documented interaction in T cells is that between the P1 motif of LYP/Pep and the SH3 domain of the negative regulatory tyrosine kinase C-terminal Src kinase (CSK) (Veillette et al. 2009). CSK is a potent inhibitor of TCR signaling through phosphorylation of the inhibitory tyrosine residue of the SFKs LCK and FYN. A proposed model for the function of the LYP-CSK complex is that it plays a dual role in controlling the threshold of TCR signaling. On one hand, the complex inhibits TCR signaling through synergistic repression of SFK activity by bringing LYP and CSK into close proximity to their SFK substrates. The phosphorylation of the inhibitory tyrosine by CSK, together with dephosphorylation of the activating phosphotyrosine by LYP, inactivates the SFKs and inhibits TCR signaling. On the other hand, it has been recently proposed that the complex between LYP and CSK also functions to sustain TCR signaling by tempering the activity of LYP upon TCR engagement. CSK recruits LCK to LYP, facilitating the phosphorylation of LYP by LCK on the inhibitory residue Y536 (see Fig. 3a). Phosphorylation on this site inhibits the enzymatic activity of LYP, allowing LCK to remain in an activated state to promote signaling through the TCR. According to this model, the strength and duration of TCR signaling is finely tuned by the feedback loop between LYP, CSK, and LCK to maintain T cells in the proper activation state (Fiorillo et al. 2010).



PTPN22, Fig. 2 LYP inhibits early TCR signaling. LYP acts as a gatekeeper of T cell activation through dephosphorylation of key mediators of signaling downstream the TCR. Upon ligand engagement of the TCR, a wave of tyrosine phosphorylation events occurs, which signals the response of the T cell. Key signaling mediators for this process are the SFKs LCK and FYN, the Syk family kinase ZAP-70, and downstream adaptor proteins. Upon TCR engagement, the SFKs become activated by phosphorylation in their activation motifs (Y394 of LCK and Y417 of FYN). The SFKs then phosphorylate the tandem tyrosine residues of the ITAMS of the TCR-associated CD3ζ-chain, which provide docking sites for the SH2 domains of ZAP-70. Once recruited to the TCR, ZAP-70 is phosphorylated and activated by LCK. ZAP-70 subsequently phosphorylates downstream adaptor proteins which nucleate signaling complexes to potentiate the wave of phosphorylation needed to transmit the TCR stimulation signal to the T cell nucleus. This signaling cascade leads to a myriad of responses by the T cell, which leads to T cell activation and, ultimately, production of IL-2, an autocrine growth factor for T cells. LYP inhibits this process through dephosphorylation of the activating tyrosine of the SFKs and ZAP-70, the ITAMs of the CD3ζ-chain, Vav1, and other mediators of signaling. Within this signaling cascade, LYP forms a high stoichiometry complex with CSK, a kinase that inhibits SFKs by phosphorylation on their negative regulatory tyrosine residue

Combined molecular and functional studies in T cells indicate that the activity of LYP is also regulated by intramolecular interactions and additional posttranslational modifications. Protein kinase C was shown by Zhong-Yin Zhang's laboratory to phosphorylate S35 in the LYP-specific loop of the catalytic domain, resulting in inhibition of the phosphatase activity (Yu et al. 2007). PTP-PEST is also inhibited by phosphorylation on the homologous residue, S39. Disulfide bond formation between the catalytic cysteine (C227) and a cysteine residue located outside the signature motif (C129) was reported to inhibit the phosphatase activity of LYP through a reversible oxidation mechanism. An intramolecular interaction between the catalytic



PTPN22, Fig. 3 Current models describing the molecular effect of the LYP-R620W polymorphism in T cells. (**a, b**) LYP-W620 gain-of-function model. (**a**) *Upper panel*, LYP-R620 binds CSK via the P1 motif of LYP-R620 and the SH3 domain of CSK. CSK recruits LCK to LYP-R620 through a currently unknown mechanism. LCK then phosphorylates LYP-R620 on Y536 in the interdomain region. *Lower panel*, phosphorylation of LYP-R620 at this site reduces the phosphatase activity of LYP-R620, leading to decreased inhibition of TCR signaling. (**b**) *Upper panel*, the W620 amino acid substitution in the P1 motif of LYP impairs the interaction between LYP and CSK. The CSK-dependent recruitment of LCK to LYP is reduced, and thus LYP-W620 undergoes less phosphorylation on the inhibitory Y536 residue. *Lower panel*, LYP-W620 is more enzymatically active, leading to gain-of-function inhibition of TCR signaling. (**c, d**) LYP-W620 loss-of-function model. (**c**) *Upper panel*, LYP-R620 binds to calpain through an unknown mechanism. *Lower panel*, binding of LYP to calpain leads to proteolysis of LYP. (**d**) *Upper panel*, LYP-W620 has increased interaction with calpain, possibly due to impaired interaction with CSK. *Lower panel*, LYP-W620 undergoes increased calpain-dependent proteolysis, leading to decreased expression of LYP-W620 and loss-of-function inhibition of TCR signaling

domain and the proximal interdomain region of LYP was also shown to regulate the enzymatic activity of the phosphatase (Stanford et al. 2010).

Little characterization of the regulation of the stability of LYP/Pep at the RNA or protein level has been reported. Pep expression was shown to be downregulated in T cells at the mRNA level by miRNA-181a (Veillette et al. 2009). At the protein level, LYP/Pep was reported to bind calpain, a Ca^{++}-dependent protease, through an interaction that promotes calpain- and proteasome-mediated degradation of the phosphatase (Zhang et al. 2011).

LYP Function in B Cells

Although LYP is highly expressed in other immune cell lineages, to date, little is known about its function outside of T cells. Several studies by Jane Buckner's laboratory in primary B cells from carriers of a functional variant of

LYP (R620W, see below) indicate that LYP inhibits human B cell receptor (BCR) signaling and possibly regulates selection of the B cell repertoire (Habib et al. 2012). Partial knockdown of Pep expression in an immature mouse B cell line was shown to inhibit BCR-triggered responses, suggesting a role for Pep as a positive regulator of BCR signaling in immature B cells. However, substrates of LYP/Pep in B cells have not yet been reported, and in vivo deletion of Pep showed no effect on BCR signaling. Whether this is due to compensation phenomena after knockdown/knockout of the phosphatase, to functional differences between the human and mouse proteins, or to another effect remains to be clarified (Veillette et al. 2009).

LYP Function in Myeloid Cells

A myeloid phenotype of the *Ptpn22*$^{-/-}$ mouse was recently reported (Obiri et al. 2012). This study indicates that Pep promotes mast cell degranulation through positive regulation of PLCγ1 and Ca^{++} signaling. Mice deficient in Pep showed impaired PLCϒ1 phosphorylation and Ca^{++} mobilization, defective mast cell degranulation, and decreased susceptibility to antigen-induced anaphylaxis. Additionally, a knock-in mouse carrying a functional variant of PTPN22 (Pep-W619) was reported to show increased numbers of splenic DCs, increased responsiveness of DCs to LPS stimulation, and increased T cell priming (Zhang et al. 2011). In humans, the presence of this same functional variant affects responsiveness of patients to imatinib treatment for chronic myeloid leukemia. These findings suggest a role for LYP in the signaling and/or function of myeloid cells, and further studies are warranted to understand the effect of LYP in these pathways and to determine if LYP is involved in homeostasis of the innate immune system.

PTPN22 in Human Disease

A role for *PTPN22* in human disease was identified in 2004 when a single-nucleotide polymorphism (SNP) in the gene, C1858T, was found by candidate gene approach to increase the risk of type 1 diabetes (T1D) in two independent populations (Bottini et al. 2004). That same year, two additional groups reported associations of the same SNP with rheumatoid arthritis (RA) (Begovich et al. 2004) and systemic lupus erythematosus (SLE) (Kyogoku et al. 2004). Since then, numerous studies have confirmed the T1858 allele to be a susceptibility locus for multiple, but not all, autoimmune diseases (Table 1) (Burn et al. 2011; Chung and Criswell 2007; Gregersen and Olsson 2009; Stanford et al. 2010). A smaller number of more recent studies have suggested that additional functional SNPs in the gene also regulate predisposition toward autoimmunity and have suggested a broader role for the *PTPN22* gene in regulating immune homeostasis. An overview of these polymorphisms, and their effect on human disease, is described below.

C1858T/R620W (rs2476601): This SNP encodes an R620W substitution in the P1 motif of LYP, disrupting the interaction of the phosphatase with CSK. The T1858 allele is a causal, population-independent risk factor for numerous organ-specific and systemic autoimmune diseases and has been identified as a general autoimmunity gene. The variant behaves as a codominant allele, conferring risk of disease in heterozygous carriers, and more so when present in both copies. The risk associated with the allele is variable among diseases and is the highest for RA and T1D. Indeed, *PTPN22* ranks the second most significant genetic risk factor for RA and the third most significant one for T1D. Interestingly, the T1858 allele does not increase risk for all autoimmune diseases and even acts as a protective variant for some, suggesting there may be shared pathogenic mechanisms among subsets of autoimmune diseases. There initially was reported no association with Crohn's disease, but recent studies have shown a protective effect, while there is no effect in ulcerative colitis (Burn et al. 2011; Chung and Criswell 2007; Gregersen and Olsson 2009; Stanford et al. 2010).

The T1858 allele also associates with increased risk of endometriosis, a disease characterized by autoimmune-like features, atherosclerosis, a disease with a strong inflammatory component, and bilateral Meniere's disease.

PTPN22, Table 1 ***PTPN22*** **associations with human autoimmunity.** Table denotes associations of *PTPN22* SNPs C1858T, G788A, and G-1123C with autoimmune diseases (Burn et al. 2011; Chung and Criswell 2007; Diaz-Gallo et al. 2011a, b; Gregersen and Olsson 2009; Stanford et al. 2010)

Autoimmune disease	Association of *PTPN22* allelic variants
RA	T1858: increased risk
	A788: decreased risk

Vitiligo	T1858: increased risk
Pemphigus vulgaris	T1858: none
Myasthenia gravis	T1858: increased risk
Acute anterior uveitis	T1858: none
Multiple sclerosis	T1858: none
Psoriasis	T1858: none

Carriers of the T1858 allele are significantly more likely to experience failure to respond to imatinib treatment for chronic myeloid leukemia than noncarriers, suggesting a role for LYP in regulating signaling downstream BCR-ABL in myeloid cells.

The T1858 allele frequency varies among populations, occurring most commonly in Scandinavians (greater than 10 % frequency), with lower frequency in Western Europeans (7–8 %), and even lower in Southern Europeans (2–3 %). The allele is extremely rare in African and Asian populations. In US and Australian Caucasians, it occurs at a frequency of 6–9 %, while it occurs at a frequency of 4–5 % in Hispanic populations. The reason for this geographical gradient is not yet clear, but evidence of positive selection at the *PTPN22* locus has been reported (Chung and Criswell 2007; Gregersen and Olsson 2009; Stanford et al. 2010).

To date, few studies have been conducted to investigate the role of *PTPN22* C1858T in infectious disease. The T1858 allele is protective against development of pulmonary tuberculosis (TB) and bacterial infections in immunocompromised transplant patients, but a risk factor for invasive pneumococcal infections, chronic mucocutaneous candidiasis and lepromatous and tuberculoid leprosy (Stanford et al. 2010). Thus far, the T1858 allele is shown to have no effect on hepatitis C infection outcome or susceptibility to *Trypanosoma cruzi* infection or brucellosis development (Burn et al. 2011). Further investigation of these diverging effects is likely, as with autoimmunity, to shed light on the functions of *PTPN22* in the immune system and in the pathogenesis of these disorders.

G788A/R263Q (rs33996649): This SNP lies within an exon encoding a segment of the catalytic domain, leading to an R263Q substitution that changes the conformation of the active site and reduces the enzymatic activity of the phosphatase. Carriers of this allele show reduced risk of developing several autoimmune diseases (Table 1), but increased risk of TB infection. This SNP segregates on different haplotypes than the C1858T SNP (Diaz-Gallo et al. 2011a; Orru et al. 2009; Stanford et al. 2010).

G-1123C (rs2488457): This SNP lies in the promoter region of *PTPN22* and has been shown to associate with several autoimmune diseases, particularly in Asian populations (Table 1). This SNP is in strict linkage disequilibrium with the C1858T SNP in Europeans and appears to have a minor effect in the presence of the C1858T SNP, but might be a significant risk factor in Asian populations (Burn et al. 2011; Stanford et al. 2010).

C1108A/H370N (rs72650671): This SNP is a rare variant encoding an H370N substitution in the interdomain region of the phosphatase and was recently found to increase risk of inflammatory bowel disease.

A10467572G (rs12730735): This SNP lies within intron 11 and was shown to associate with increased risk of Hashimoto's thyroiditis in a Korean population.

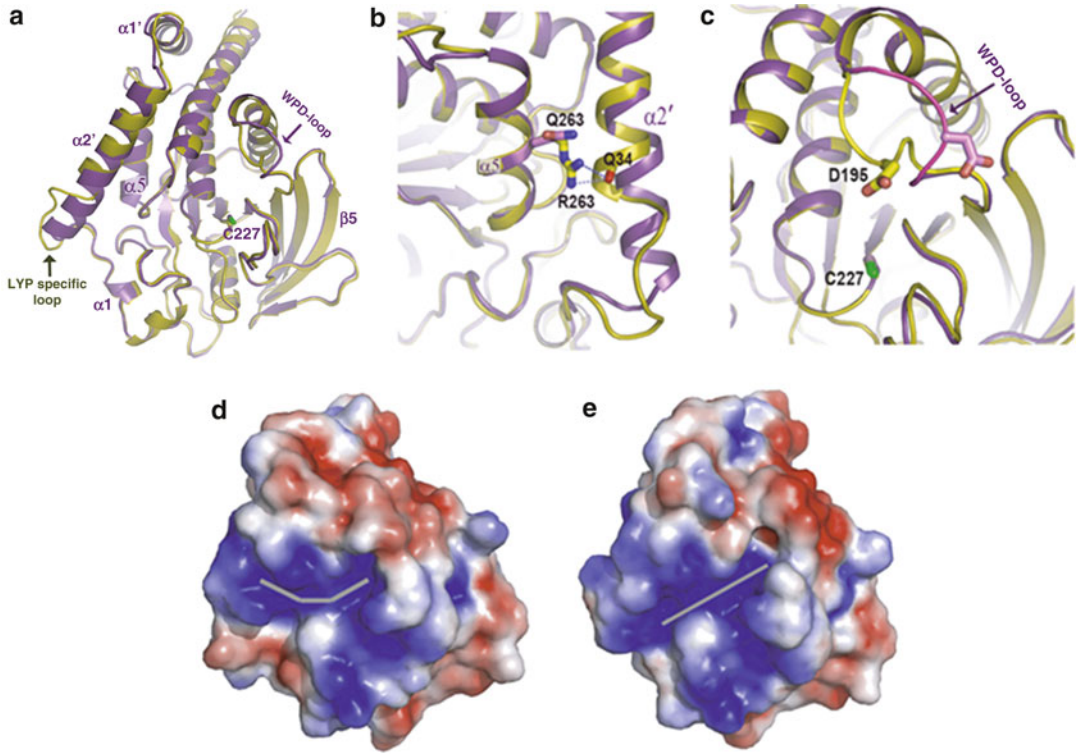
***PTPN22* Expression Levels and Autoimmune Disease**: Recent studies suggest that expression levels of *PTPN22* might also affect susceptibility to or prognosis of autoimmune disease. PTPN22 was shown to be expressed at higher levels in PBMC from patients with RA compared to controls. High *PTPN22* expression levels in $CD8^+$ T cells was shown to correlate with poor prognosis of antineutrophil cytoplasmic antibodies (ANCA)-associated vasculitis and SLE, suggesting PTPN22 might be a biomarker for prognosis for these or other autoimmune diseases.

Functional Genetics of the Disease-Associated PTPN22 Polymorphisms

The C1858T SNP encodes a substitution from arginine to tryptophan at amino acid 620 (R620W) of LYP, which strongly reduces the interaction between LYP and CSK. The functional effect of this variation is currently controversial. Some groups suggest that LYP-W620 is a gain-of-function form of the phosphatase. In support of this are reports that (1) T cells from T1D patients homozygous for the T1858 allele showed decreased TCR-induced Ca^{++} mobilization and IL-2 secretion (Rieck et al. 2007; Vang et al. 2005), (2) memory T cells from heterozygous T1858 carriers showed reduced TCR-induced Ca^{++} mobilization and IL-10 secretion (Rieck et al. 2007), and (3) LYP-W620 showed increased inhibition of TCR signaling and T cell activation compared to LYP-R620 in overexpression studies comparing the two variants (Fiorillo et al. 2010; Vang et al. 2005). A model to explain this gain-of-function phenotype of LYP-W620 at the molecular level is that the R620W polymorphism leads to increased enzymatic activity of LYP (see Fig. 3a, b). According to this model, impaired binding of LYP to CSK leads to decreased CSK-dependent recruitment of LCK to LYP and subsequent reduced phosphorylation of LYP on the inhibitory residue Y536. LYP-W620 is therefore a more potent inhibitor of TCR signaling, due, at least in part, to increased phosphatase activity (Fiorillo et al. 2010).

In contrast is the model suggesting that the W620 variant is a loss-of-function form of the phosphatase. In support of this model are two recent reports that (1) LYP-R620 was a more potent inhibitor of TCR stimulation compared to LYP-W620 when both variants were co-transfected with CSK in an overexpression study (Zikherman et al. 2009) and (2) T cells from mice carrying the W619 knock-in mutation of Pep (the homologous site to LYP-W620) and PBMC from homozygous carriers of the T1858 allele showed increased responsiveness to TCR engagement (Zhang et al. 2011). A model to explain the loss-of-function phenotype of LYP-W620 at the molecular level is that the R620W polymorphism leads to increased degradation of LYP (see Fig. 3c, d). According to this model, binding of LYP to calpain is enhanced in the presence of the W620 variation, leading to increased calpain- and proteasome-mediated cleavage of LYP-W620. LYP-W620 is therefore a less potent inhibitor of TCR signaling, due to decreased protein expression (Zhang et al. 2011).

It is evident that additional studies are necessary in order to explain the molecular effect of the R620W polymorphism on TCR signaling. No differences in transcription were observed between the two variants, suggesting that the molecular effect is at the protein level. At the systemic level, it is also not yet clear how



PTPN22, Fig. 4 Structural basis for the reduced activity of LYP-Q263. (**a**) Superimposed structures of the LYP-Q263 catalytic domain (Cat-Q263, shown in *purple*) on the LYP-R263 catalytic domain (Cat-R263, shown in *yellow*) show an open WPD loop and replacement of the LYP-specific loop with an extended helix in the mutant. The catalytic cysteine (C227) is shown in green. (**b**) The R263Q mutation in the LYP catalytic domain eliminates the contacts of R263 α5 helix to the α2' helix on the main-chain carbonyl oxygen of Q34. (**c**) Movement of the WPD loop to the open conformation in R263Q. (**d, e**) Surface electrostatics of the (**d**) Cat-R263 and (**e**) Cat-Q263 structures. The deep electropositive cleft stretches from the active site to the LYP-specific loop, which is marked by gray sticks. When the LYP-specific region adopts the helical conformation in Cat-Q263 and shifts away from residue 263, the cleft conformation changes, which may reduce the efficiency of substrate processing by the enzyme (This figure was reproduced from (Orrú et al. 2009) with permission from Oxford Journals)

the polymorphism abolishes immune tolerance to cause autoimmunity. Altered thresholds of TCR signaling could lead to (1) impaired deletion of autoreactive T cells during immune system development, (2) altered function of effector T cells, or (3) altered suppressive function of regulatory T cells, among others. Additionally, the role of LYP in B cells and in other immune cells also needs to be addressed. Carriers of the T1858 allele show decreased BCR signaling in circulating B cells and fewer memory B cells (Habib et al. 2012; Rieck et al. 2007). The B cell repertoire in these carriers seems to be skewed toward an increase in autoreactive T cells, suggesting that *PTPN22* might regulate B cell selection (Habib et al. 2012). The knock-in Pep-W619 mutation affects the DC phenotype in these mice, causing increased expansion of DCs and hyperresponsiveness of these cells to stimulation (Zhang et al. 2011). Further functional genetics of the role of the R620W polymorphism in both the adaptive and innate immune systems are necessary to clarify the pathogenesis of *PTPN22* in human disease.

Interestingly, the G788A polymorphism shows a disease association pattern quite distinct from the C1858T SNP (see Table 1). As shown in Fig. 4, this variation leads to an amino acid substitution in the catalytic domain of the phosphatase, changing the conformation of the LYP-specific loop of the active site (Orru et al. 2009). As this region participates in substrate binding, this variant shows reduced enzymatic activity and reduced inhibition of TCR signaling. To date, this SNP has not been shown to increase risk of any autoimmune disease but has been shown to confer protection against several. The A788 allele does, however, increase risk of TB, demonstrating an opposite effect to the T1858 allele (Diaz-Gallo et al. 2011a, b; Stanford et al. 2010).

Strategies to Inhibit LYP

An active area of research is the development of small molecule inhibitors of LYP. Due to the highly charged nature of the PTP active site, and because PTPs share a high degree of structural conservation near the active site, development of PTP inhibitors with cellular activity and selectivity over other PTPs is challenging. Several different strategies have been employed, yielding a few compounds with cellular activity. The first reported LYP inhibitor, called **I-C11**, is a salicylic acid-based compound developed by the Zhang group (Yu et al. 2007). **I-C11** was identified using a bidentate library screening approach, designed to identify ligands that bind to the active site of the enzyme and to an adjacent pocket. This binding mechanism was confirmed by structural analysis of **I-C11** co-crystallized with the catalytic domain of LYP. **I-C11** displays selectivity over a panel of PTPs and increases TCR signaling in a human cell line. Further optimization of this scaffold is ongoing and has successfully yielded additional compounds with activity in T cells (Barr 2010). Another approach used by the Barrios group has been to use Au(I)-phosphine complexes that bind covalently to cysteine residues in the catalytic domain. This strategy yielded a compound that shows increased TCR signaling in a human cell line and primary mouse T cells and shows high selectivity over the closely related PTP-PEST (Barr 2010). An in vivo study showed a Au(I)-phosphine complex effectively inhibited antigen-induced anaphylaxis in mice (Obiri et al. 2012). The first allosteric LYP inhibitor compound **4e** was identified from targeted screening of a small library of drug-like compounds to identify noncompetitive inhibitors. Structural studies indicate that this compound interacts with a hydrophobic patch located outside the active site of the enzyme. Treatment of a T cell line and primary T cells with compound **4e** and closely related analogs results in increased TCR signaling and T cell activation, and this compound shows some selectivity over the hematopoietic cell PTP, HePTP. All of these compounds inhibit LYP with an IC_{50} in the low micromolar range. In silico approaches led to the identification of compounds with sub-micromolar potency; however, selectivity or cellular activity of compounds identified in these studies has not yet been reported (Barr 2010).

Conclusion

The lymphoid phosphatase, LYP, is a hematopoietic non-receptor protein tyrosine phosphatase encoded by the *PTPN22* gene. LYP plays a key role as a gatekeeper of TCR signaling, and recent studies indicate that LYP is also involved in the signal transduction of multiple immune cell lineages and thus acts as a critical regulator of immune homeostasis. Functional variations in the *PTPN22* gene, in particular the R620W polymorphism, strongly affect susceptibility to multiple autoimmune diseases. This variant disrupts the interaction between LYP and CSK and results in increased risk of numerous autoimmune diseases and additional disorders and infections as well. While the mechanism of the pathogenesis of *PTPN22* in these disorders is not yet clear, it is evident that PTPN22 is a powerful gene that finely tunes the homeostasis of the immune system and immune tolerance.

Raynaud's Phenomenon

Jennifer Nashel
Department of Medicine, Division of Rheumatology, Beth Israel Deaconess Medical Center, Harvard University School of Medicine, Boston, MA, USA

Synonyms

Raynaud's disease; Raynaud's syndrome

Definition

Raynaud's phenomenon is an exaggerated response to cold characterized by reversible, intermittent vasospasm of acral (extremity) arteries and arterioles.

Introduction

Primary Raynaud's phenomenon (PRP) or Raynaud's disease indicates the absence of an associated disease, drug, or occupational trigger, whereas secondary Raynaud's phenomenon (SRP) refers to the vasospastic condition, which may accompany an underlying disorder such as a connective tissue disease. The classic description of RP is the occurrence of a triphasic color change to the digits starting with pallor (white) as a result of decreased blood flow, followed by cyanosis (blue) due to deoxygenation of static venous blood and finally rubor (red) from reperfusion hyperemia; however, many patients do not recall or report three distinct color changes. While this disorder was first described by Maurice Raynaud in 1862, more than 150 years later, many questions remain regarding the exact pathophysiology and ideal treatment.

Prevalence and Risk Factors

Population studies of RP estimate disease prevalence between 3 % and 9 % in the general population (Fraenkel et al. 1999; Harada et al. 1991). Gender, hormones, genetics, environment, body mass index, and occupational exposures may all contribute to disparity in prevalence across studies. Overall, there is a well-established female predominance in RP. Risk factors for RP may vary between genders. For example, emotional stress may be more predictive of Raynaud's development among women, whereas occupational exposure and smoking may be more prominent risk factors among men (Fraenkel 2002).

Estrogen, in particular, has been linked to development of RP and may explain the high rate of onset of PRP during puberty. Additionally, postmenopausal females receiving unopposed estrogen therapy had an odds ratio of developing RP of 2.5 compared with postmenopausal females not given HRT. Patients that use estrogen and progesterone in combination do not have an increased risk of RP (Fraenkel et al. 1998).

DOI 10.1007/978-0-387-84828-0, © Springer Science+Business Media New York 2014

The existence of genetic risk factors is supported by the increased prevalence of RP in patients who have family members with RP and differences between ethnic groups living in the same environment (Valter and Maricq 1998). Maricq et al. compared the prevalence of RP in 5 climates. There was a considerable difference in the rate of occurrence between warm and cold climates, suggesting that subclinical cold injury may be the predisposing factor for increased RP in the colder climates (Maricq et al. 1997). Lower BMI (or weight loss) may increase the risk of RP, especially among women (Roquelaure et al. 2012).

Disease Associations

Systemic sclerosis (SSc) is the connective tissue disease most commonly associated with SRP, with greater than 90 % of SSc patients developing RP during their disease course. RP is seen to a lesser extent in other autoimmune diseases including systemic lupus erythematosus, dermatomyositis and polymyositis, rheumatoid arthritis, undifferentiated connective tissue disease, and Sjogren's syndrome (Khan 1999). Other associations with RP include hypothyroidism, use of certain medications, and atherosclerotic disease (Table 1). Repetitive trauma (usually occupational exposure) to the superficial palmar branch of the ulnar artery causes hypothenar hammer syndrome, which may represent around 1 % of all Raynaud's presentations (Marie et al. 2007). This may be reversible with elimination of the trauma and conservative management.

Diagnosis of Primary and Secondary Raynaud's phenomenon

Raynaud's phenomenon is typically diagnosed by a clinical description of cold sensitivity in the digits with the observation of associated color changes. Confirmatory tests are not routinely performed in clinical practice. However, in the research realm, measurement of changes in digital systolic blood pressure before and after cooling the extremities in 15 °C water is a diagnostic tool. A drop in pressure greater than 20–25 mmHg may be indicative of RP (Galarraga et al. 2008). Other techniques for diagnosis include digital thermography and laser Doppler flowmetry.

It may be difficult to distinguish between PRP and SRP at the initial patient evaluation since RP may be the presenting symptom of an evolving connective tissue disease. A thorough history and physical examination (with particular attention to the skin, joints and muscles) are valuable in establishing a diagnosis of SRP. Several key features may be utilized for stratifying the risk of future development of a connective tissue disease. PRP tends to present in the second and third decades and has a milder disease course. Older age, rapid disease onset, and digital pits and ulcers are features of SRP. The occurrence of digital ulceration and tissue necrosis, rarely seen in PRP, should prompt a thorough evaluation for an underlying cause.

Autoantibody testing is also helpful for risk stratification at RP presentation. In a study of vascular studies and autoantibody testing, Landry et al. found that among patients with vasospasm who had negative RF and ANA tests, only 2 % progressed to connective tissue disease over 10 years while nearly 30 % of those with positive tests and arterial obstruction were ultimately diagnosed with a connective tissue disease (Landry et al. 1996). Similarly, Ziegler et al. found ANA was helpful for predicting progression to CTD whereas baseline ESR and CRP were not prognostic indicators (Ziegler et al. 2003).

In addition to baseline laboratory studies, nailfold capillaroscopy is useful in predicting which subset of Raynaud's patients will develop connective tissue diseases. In a 5-year prospective study, the finding of "scleroderma type" capillary changes – thickened and enlarged loops with capillary dropout – on initial evaluation was highly predictive for development of a connective tissue disease (systemic sclerosis, dermatomyositis, overlap syndrome, and mixed connective tissue disease) (Pavlov-Dolijanovic et al. 2012).

Pathophysiology

Although the pathophysiologic underpinnings of RP have not been fully elucidated, much is known about the mechanisms that contribute to this disorder. Because SRP, unlike PRP, is associated with such a diverse group of conditions and factors (see above), it is reasonable to infer that its causation involves different mechanisms, alone or in combination. Yet, there are certain distinct abnormalities which play a crucial role in the overt clinical manifestation of RP. These abnormalities may be broadly broken down into those involving the blood vessel wall, neural vascular control, and intravascular factors.

Abnormalities of the Blood Vessel

In PRP, the vascular defect is thought to be primarily functional in nature (Herrick 2005). Thus, while the blood vessels in these individuals are structurally intact, they demonstrate an exaggerated response to cold exposure and emotion. Cold triggers vasoconstriction through the effect of norepinephrine on the vascular smooth muscle. Therefore, the RP may be mediated by smooth muscle contraction as a result of increased sympathetic neural activity.

The vascular endothelium plays a crucial role both in vasoregulation and in controlling the growth of surrounding connective tissue (Limaye et al. 2007). When activated, endothelial cells produce a variety of cytokines which may contribute to structural vascular changes such as those seen in scleroderma and associated SRP. Among the more important of these cytokines is the vasoconstrictor, endothelin-1. Its overexpression is now well recognized as a key element in the pathogenesis of the microvascular abnormalities noted in scleroderma. Importantly, increased levels of endothelin-1 are also associated with SRP, especially when accompanied by digital ulcers. In pulmonary hypertension, which may complicate scleroderma, there is also increased expression of endothelin-1 in vascular endothelial cells and in the circulation (Giaid et al. 1993). This is the rationale for using bosentan, an endothelin-1 receptor antagonist, to treat both of these complications and its potential use for recalcitrant Raynaud's phenomenon (see below).

Neurovascular Dysregulation

The sympathetic nervous system plays a central role in the regulation of the peripheral circulation.

Vasoconstriction is mediated in part through the release of certain neuropeptides such as substance P and calcitonin gene–related peptide. Increased reactivity of alpha-2 adrenergic receptors in response to norepinephrine also contributes to the cold-induced vasospasm of PRP and SRP (Cooke and Marshall 2005). It is likely that an imbalance favoring vasoconstrictor over vasodilatory nerve activity results in reduced peripheral blood flow and what is recognized clinically as RP. Since calcitonin gene–related peptide released from sensory fibers is among the most important mediators of vasodilation, a reduction in number of these nerve fibers or damage to them would predispose to the development of a RP. Vibration-induced RP is well recognized in occupational medicine community. In this setting, neurovascular dysregulation appears to play a central role in the etiology of the vasospasm. Here, persistent exposure to vibratory tools causes direct injury to and depletion of the vasoregulatory nerves of the hands (Stoyneva et al. 2003).

Intravascular Abnormalities

A number of blood cellular elements and circulating factors may have important roles in the pathogenesis of RP associated with scleroderma. Increased levels of the vasoconstrictors thromboxane and serotonin attest to platelet activation in this condition (Herrick 2005). Furthermore, some scleroderma patients have been shown to have defective fibrinolysis. Fibrin deposition in smaller vessels can produce both compromised blood flow and microvascular occlusions (Ames et al. 1997).

Cryoglobulinemia and cryofibrinogenemia may be associated with RP, perhaps due to increased blood viscosity. Reduced red blood cell deformity also may contribute to impaired flow through peripheral vessels.

It is important to keep in mind that both vascular and neural factors play important roles in the pathogenesis of PRP and SRP. Since the control of peripheral blood flow is a complex interplay between central and local factors, perturbations in one or more of these regulatory mechanisms can trigger vasospasm.

Treatment

General Measures

The initial approach to managing RP is one of life-style modification. The emphasis should be on reducing cold exposure and sudden temperature change. When cold exposure is anticipated, the use of chemical or battery-powered warmers for gloves and socks may be helpful. In the workplace, patients should wear protective clothing with an emphasis on warming the extremities and maintaining core body temperature. For some individuals, a change in occupation may be necessary. It is also best to avoid drugs which may cause exacerbations of RP such as beta-blockers, amphetamines, and caffeine. Smoking cessation and avoidance of secondhand smoke is also advantageous. The use of behavioral therapy in RP is controversial. A meta-analysis of 5 studies utilizing biofeedback failed to demonstrate improvement in RP severity, frequency, or duration (Malenfant et al. 2009). In the case of SRP, treatment of the underlying condition is important as well.

Drug Therapy

Since RP appears to reflect an imbalance between vasodilation and vasoconstriction, pharmacologic treatment may be thought of broadly as the use of agents that promote vasodilation or those that inhibit vasoconstriction.

Vasodilators

- Calcium channel blockers (CCB): The most commonly utilized vasodilators are non-cardioselective calcium channel blockers. Inhibition of voltage-gated calcium channels leads to relaxation of vascular smooth muscle, causing vasodilation. A meta-analysis of PRP in 2005 showed a significant reduction in frequency (2.8 to 5.0 attacks less per week) and severity of attacks (33 % reduction) in the CCB treatment group versus placebo (Thompson and Pope 2005). The most commonly used CCB is nifedipine which is started at low doses and titrated upward as needed and tolerated. Other CCBs such as felodipine and amlodipine may also be of benefit. The use of

CCBs in patients with relative hypotension can be problematic and requires careful monitoring. Side effects including headache and lower extremity edema may limit tolerance of these medications. Unfortunately, the effect of CCBs tends to diminish over time.

- Topical Nitrates: Compounds such as glycerol trinitrate and 2 % nitroglycerin gel have been shown to improve RP and digital ulcer severity when applied topically (Franks 1982). They are typically utilized to improve blood flow to one digit, particularly when ulceration has occurred. Topical nitrate therapy for RP has been limited by the side effects of hypotension, headache, dizziness, and local skin irritation. A recent trial evaluating a new formulation of topical nitrate with faster absorption for local vasodilation was aimed at improving the side-effect profile of topical nitrates and is the largest placebo-controlled trial to date. While this study did show improvement in Raynaud's condition score, there were no statistically significant changes in Raynaud's frequency or severity (Chung et al. 2009).
- Phosphodiesterase type 5 inhibitors (sildenafil, vardenafil, and tadalifil): These agents have been used in RP in an attempt to improve peripheral circulation. They act by enhancing the effect of nitric oxide in promoting vascular smooth muscle relaxation. However, these drugs have had mixed results in mitigating recurrent attacks. One study of patients with severe RP reported a decrease in attacks and disease severity, and a tendency toward ulcer healing (Herrick et al. 2011). It has been suggested that this class of drugs is most effective when added to calcium channel blocker therapy.
- Prostaglandins: Both parenteral and oral prostaglandins have been utilized to decrease Raynaud's severity; in addition to vasodilation, they inhibit platelet aggregation and vascular proliferation. Intravenous formulations of prostaglandins analogues have been utilized in the setting of severe RP with digital ulcerations and digital necrosis. One placebo-controlled trial using a five-day course of 6-h intravenous infusions of iloprost showed a 39.1 % decrease in weekly number of Raynaud's attacks versus a 22 % decrease with placebo and an improved Raynaud's severity score (Wigley et al. 1994). Due to the difficulty of administration of the parental formulation, multiple cyclic schedules have been utilized for sustained effect. However, these have not been FDA approved for use in Raynaud's in the USA (Milio et al. 2006). Oral prostaglandins have not shown consistent benefit. A six-week trial of oral iloprost for management of Raynaud's in systemic sclerosis failed to show a reduction in frequency or duration of attacks compared to placebo (Wigley et al. 1998).

Inhibitors of vasoconstriction

- Angiotensin-converting enzyme (ACE) inhibitors and angiotensin receptor blockers (ARBs): ACE inhibitors and ARBs act as indirect vasodilators by inhibiting the effect of angiotensin II which is a powerful vasoconstrictor. The studies of ACE inhibitors in RP have generally been of short duration and have had mixed results and have not been shown to have a significant effect versus placebo (Gliddon et al. 2007). The ARB losartan when compared to the CCB nifedipine has shown a significant reduction in frequency and severity of Raynaud's attacks (Dziadzio et al. 1999).
- Endothelin receptor antagonists: These agents may be utilized as a second- or third-line treatment. Since endothelin-1 is a potent vasoconstrictor and is implicated in vascular remodeling, fibrosis, and inflammation, it is a potential target particularly in SRP with digital ulcerations. Treatment with the endothelin receptor antagonist bosentan was associated with a 48 % reduction in the mean number of new ulcers compared with placebo after 16 weeks of treatment (Korn et al. 2004). Another study utilizing bosentan over a 24-week course, compared to placebo, showed a 30 % reduction in occurrence of new digital ulcers; the reduction of new ulcers was more pronounced among patients with multiple ulcers (Matucci-Cerinic et al. 2011).

Other drugs

- Selective serotonin reuptake inhibitors (SSRIs) are another class of drugs that produce indirect vasodilation by blocking uptake of serotonin, a known vasoconstrictor. Thus, SSRIs provide one option for Raynaud's treatment in patients with relative hypotension. In a study utilizing fluoxetine 20 mg daily (versus a comparator group of nifedipine 40 mg daily), there was a statistically significant decrease in attack severity and frequency after 6 weeks of treatment (Coleiro 2001). Subgroup analysis showed the greatest effect in females with PRP.
- Anticoagulation is not routinely utilized in RP or for digital ulcerations but may be used during the acute phase of significant digital gangrene.

Sympathectomy

The disruption of the proximal or digital sympathetic nervous system can decrease the vasospastic response to cold. Sympathectomy may be either chemical or surgical. One tool for local chemical sympathectomy is injection of botulinum toxin A to block vasoconstriction of the digital arteries (Neumeister 2010). While case reports have shown significant improvement in healing of ulcers and a lessening of Raynaud's severity, there is a lack of randomized controlled data to support its use. In the setting of severe digital pain and vasospasm, a local digital or wrist block using lidocaine may be helpful.

Surgical sympathectomy may be performed proximally in the cervical region or at the digital level. Digital sympathectomy is usually preferred due to its less invasive nature and less severe side-effect profile. While a reduction in amputation for digital ischemia is reported in SRP, digital ulcerations following surgical digital sympathectomy may still occur (Wasserman and Brahn 2010).

Conclusion

Raynaud's phenomenon is a cold or emotion-induced vasospastic process affecting the digits. It is clear that the environment, hormones, and genetics play important roles in its pathogenesis. While RP is usually an isolated finding, it is important to keep in mind its important associations with connective tissue disease especially in patients who present with symptoms of obstructive arteriopathy, such as digital infarcts and ulceration. Despite major advances in understanding of the pathophysiology of RP, more effective treatments are needed for this condition.

Synonyms

B10 B cells; Bregs; Killer B cells; Suppressor B cells; T2-like Bregs

Definition

Regulatory B cells are $CD19^+$ lymphocytes that can inhibit inflammation in vivo or suppress the activation of immune cells in vitro or in vivo.

Introduction

The primary function of B cells is to participate in adaptive immune responses, acting as the precursor cells for immunoglobulin-producing plasma cells, presenting antigen to T cells and iNKT cells, and producing Th1 and Th2 cytokines that support the activation and differentiation of other lymphocytes. In certain circumstances, a particular subset, or subsets, of B cells, or a temporally/experimentally induced functional group of B cells, can play a role in controlling inflammation both in vivo and in vitro. These B cells have been named regulatory B cells (Bregs) (DiLillo et al. 2010; Mauri and Bosma 2012).

B cells with a regulatory function have been identified in a number of mouse models, primarily of autoimmunity but also infection, transplantation, and cancer, and have been ascribed a number of partially overlapping phenotypes (Mauri and Bosma 2012; Kalampokis et al. 2013). The factors involved in their generation and suppressive function vary according to the model used. In addition, regulatory B cells have been reported in human peripheral blood (Blair et al. 2010). At present, there is no equivalent of the regulatory T cell transcription factor Foxp3 that defines regulatory $CD4^+$ T cells (Tregs), to definitively discriminate Bregs from other B cells in either mice or humans, and the question of whether Bregs are a developmentally discrete subset or a functional classification that overlaps with previously defined B cell subsets is yet to be answered.

Historical Background

A suppressive capacity was first ascribed to B cells in the 1970s when it was found that adoptive transfer of B cell-depleted splenocytes was unable to prevent delayed-type hypersensitivity (DTH) skin reactions in guinea pigs in the way that adoptive transfer of B cell-replete splenocytes was able to. It was initially hypothesized that suppressor B cells might produce suppressive antibody that blocked the activity of cells responsible for DTH reactions (Katz et al. 1974). This hypothesis was later rejected when it was found that suppression of DTH could occur in the absence of detectable antibody production. The next reports of suppressive B cells were published in the mid-1980s when it was found that B cells were associated with the generation of antigen-specific T suppressor cells. However, the study of regulatory B cells did not begin in earnest until the late 1990s following the work of Charles Janeway who unexpectedly found that B cell-deficient mice were unable to recover from experimental autoimmune encephalomyelitis (EAE, a mouse model of multiple sclerosis) (Mann et al. 2012). The study of B cell-suppressive capacity then broadened to take in mouse models of rheumatoid arthritis, systemic lupus erythematosus (SLE), diabetes, inflammatory bowel diseases, and also studies of infection. The use of the term "regulatory B cell" to describe B cells that are able to suppress inflammation in vivo was first introduced in the early 2000s (Mizoguchi and Bhan 2006).

Subsets and Markers of Murine Regulatory B Cells

There is currently no consensus surface (cluster differentiation, CD) marker phenotype for murine regulatory B cells, and this phenotype has varied depending on the models studied. In the field of autoimmunity, two phenotypes that allow for the purification of functional regulatory B cells have achieved some prominence. $CD19^+$ $CD21^+$ $CD23^+$ $CD24^+$ IgM^+ IgD^+ B cells, termed T2-like Bregs, express surface markers consistent with belonging to an immature transitional-2 stage of development and have been reported to suppress T cell activation in vitro and to inhibit arthritis and lupus-like

disease in vivo upon adoptive transfer (Mauri and Bosma 2012). Similarly, adoptive transfers of CD1d^{hi} CD5^{+} B cells, termed B10 B cells for their ability to produce the immunoregulatory cytokine interleukin-10 (IL-10), have been reported to control DTH responses, EAE, and lupus-like disease (DiLillo et al. 2010). Although different CD markers are used to define T2-like Bregs and B10 B cells, there is some overlap in their phenotypes: both populations express CD19, CD21, CD24, and CD1d, and both can be isolated from naïve splenic B cells. It is possible that these phenotypes reflect the same population or developmentally related regulatory B cell subsets.

Other models of autoimmunity have produced partial phenotypes for regulatory B cells. A spontaneous colitis model resulting from the knockout of the α subunit of the T cell receptor (TCRα$^{-/-}$ model of colitis) suggested that the expression of CD1d, IgM, CD21, and CD23 may be associated with regulatory B cells. However, B cells purified based on this phenotype were not directly tested in suppression assays or by adoptive transfer. In models of rheumatoid arthritis and multiple sclerosis, marginal zone B cells and pre-plasma cell-like B cells have also been ascribed suppressive function (Mizoguchi and Bhan 2006).

Recently the study of transplantation has provided another possible marker for murine regulatory B cells (Ding et al. 2011). Treatment of mouse pancreatic islet transplant recipients with an antibody to T cell Ig domain and mucin domain protein 1 (TIM-1) induces the expansion of regulatory TIM-1^{+} B cells and tolerance to the allograft. The adoptive transfer of TIM-1^{+} B cells prolonged allograft survival. In contrast to the phenotypes defining T2-like Bregs and B10 Bregs, which appear to describe discrete B cell populations, TIM-1 is expressed by a wide range of developmentally distinct B cell subsets. This discrepancy highlights the fact that it is as yet unclear whether regulatory B cells are a developmentally discrete subset of B cells or whether many B cell subsets may contain potential regulatory B cells given the right immunological environment (Ding et al. 2011).

Human Regulatory B Cell Subsets

The study of regulatory B cells in humans is in its infancy. However, there is growing evidence that B cells with a CD19^{+} CD24^{hi} CD38^{hi} phenotype may comprise regulatory B cells. As with murine T2-like regulatory B cells, this phenotype is reminiscent of B cells at an immature transitional stage of development. The initial description of human regulatory B cells came from a study of multiple sclerosis patients who had concurrent helminth infections (Correale et al. 2008). Helminth infection correlated with lower numbers of relapses to disease with the induction of regulatory T cells, and it restored the ability of naïve CD27^{-}IgD^{+} B cells to produce IL-10 in response to CD40 stimulation. Purified B cells from helminth-infected patients could suppress the proliferation of, and IFN-γ production by, myelin-specific T cells in vitro. Shortly after this work, it was reported that CD19^{+} CD24^{hi} CD38^{hi} B cells purified from human healthy peripheral blood suppressed T cell activation in vitro. Again, this was a primarily CD40-driven IL-10-mediated suppression. Moreover CD19^{+} CD24^{hi} CD38^{hi} B cells shared the expression of CD1d and IgD with the B cells identified in multiple sclerosis patients and were also predominantly CD27^{-}(Blair et al. 2010).

CD19^{+} CD24^{hi} CD38^{hi} Bregs have been confirmed to be important clinically. In SLE, CD19^{+} CD24^{hi} CD38^{hi} Bregs are defective and lack the ability to of healthy Bregs to suppress T cell cytokine production in vitro (Blair et al. 2010). In rheumatoid arthritis, although these cells retain their suppressive capacity, they are reduced in number in the peripheral blood of patients with active disease (Flores-Borja et al. 2013). Interestingly, following treatment with the B cell-depleting anti-CD20 antibody Rituximab, remission from SLE correlates with the persistence of CD19^{+} CD24^{hi} CD38^{hi} B cells following B cell repopulation (Anolik 2011). In the field of transplantation, higher numbers of CD19^{+} CD24^{hi} CD38^{hi} B cells were detected in the peripheral blood of immunosuppressant-free tolerant recipients of a kidney transplant as compared to patients who required immunosuppression to

maintain graft function (Chong and Sciammas 2011). In contrast to their potentially beneficial role in autoimmunity and transplantation, $CD24^{hi}$ $CD38^{hi}$ Bregs may contribute to HIV-associated immune dysfunction of T cells: the frequency of PD-$L1^{+}$ $CD24^{hi}$ $CD38^{hi}$ B cells correlates with markers of HIV disease progression and may promote T cell dysfunction via the production of IL-10 (Siewe et al. 2013).

Other phenotypes for human regulatory B cells have been suggested. Human peripheral blood $CD24^{hi}$ $CD27^{+}$ B cells are described to produce the highest level of IL-10 in vitro following lipopolysaccharide (LPS) stimulation. It was hypothesized that these cells may be human equivalents of murine B10 Bregs. Functionally, these cells were able to inhibit TNF-α production by monocytes in vitro; however, this suppression was IL-10 independent. Clinically, $CD24^{hi}$ $CD27^{+}$ B cell numbers have not been reported to be decreased in patients with systemic or organ-specific autoimmune diseases. Moreover, IL-10 production in response to anti-CD40 and LPS or CpG stimulation was significantly increased in patient $CD24^{hi}$ $CD27^{+}$ B cells as compared to healthy controls (Iwata et al. 2011; Kalampokis et al. 2013).

Mechanisms of Suppression of Regulatory B Cells

At a cellular level, regulatory B cells can have multiple suppressive effects: they can (1) inhibit T cell cytokine production and proliferation, (2) convert Th1- to Th2-type immune responses, (3) inhibit the activation of antigen-presenting cells, (4) induce the generation of other regulatory cell subsets, or (5) cause the apoptosis of activated lymphocytes (Mauri and Bosma 2012).

The primary mechanism for the function of regulatory B cells has consistently been reported to be the production of the immunoregulatory cytokine IL-10. Studies of T2-like Bregs, B10 Bregs, and TIM-1^{+} Bregs have all found that if the regulatory B cell subsets are isolated from IL-10-deficient mice, or if IL-10 is blocked using monoclonal antibodies, then these cells are no longer able to inhibit autoimmune or alloimmune responses in vivo. It is hypothesized that IL-10 produced by B cells acts directly on T cells, or antigen-presenting cells, to suppress their activation. Similarly, in humans, the production of IL-10 appears to be a central feature of proposed regulatory B cell subsets, and IL-10 blockade can reverse their ability to suppress T cell cytokine production in vitro (DiLillo et al. 2010; Ding et al. 2011; Mauri and Bosma 2012).

IL-10 production is not the whole story, and different models of inflammation have identified different effector mechanisms for regulatory B cells. For instance, IL-10 production was initially found to be crucial for regulatory B cells to control inflammation in the $TCR\alpha^{-/-}$ model of colitis. It was subsequently found, however, that suppression also required IL-12-producing B cells, which may have been the cells that were directly mediating the inhibition of Th2 colitis (Sugimoto et al. 2007). In the NOD mouse model of diabetes, regulatory B cells have been shown to work via the production of transforming growth factor β (TGFβ), which induces apoptosis or anergy of $CD8^{+}$ diabetogenic T cells (Mauri and Bosma 2012). Similarly, schistosome infection can induce FASL expression on B cells, which can then go on to suppress $CD4^{+}$ T cell responses by FASL-FAS-induced cell death. These B cells were termed "killer B cells," although they may represent a type of regulatory B cell. Human B cells have also been reported to express FASL following mitogenic stimulation, although whether this has a role in suppression is as yet unclear (Klinker and Lundy 2012).

Antigen specificity is another feature of regulatory B cell function in mouse models. T2-like Bregs and B10 Bregs have both been shown to work in an antigen-specific manner in mouse models of arthritis and DTH, respectively. However, the clearest demonstration of regulatory B cell antigen specificity comes from the study of TIM-1^{+} regulatory B cells in transplantation. Here, TIM-1^{+} regulatory B cells isolated from mice that had been tolerized to pancreatic islet transplants from donors expressing the $H\text{-}2^{K}$ MHC haplotype were unable to prolong the

survival of pancreatic islet transplants from mice expressing the H-2^d MHC haplotype. In humans a requirement for antigen specificity has not yet been proven (Ding et al. 2011).

Regulatory B cells may mediate their suppressive effect through the induction of other regulatory cell subsets. In mouse models of arthritis, SLE, and multiple sclerosis, regulatory B cells have been shown to induce type 1 regulatory (Tr1) or $Foxp3^+$ regulatory T cells. In humans, $CD19^+$ $CD24^{hi}$ $CD38^{hi}$ regulatory B cells are able to convert $CD4^+$ $CD25^-$effector T cells into regulatory T cells (Mauri and Bosma 2012). In addition, it has been proposed that regulatory B cells may interact with invariant natural killer T cells (iNKT cells). iNKT cells are a subset of T cells that recognize lipid antigens presented by CD1d, a molecule expressed by the majority of murine and human regulatory B cell subsets. Although the recruitment of iNKT cells by regulatory B cells has not yet been formally proven, it has been demonstrated that CD1d expression is required for regulatory B cells to suppress colitis in mice, as B cells from CD1d knockout mice are unable to prevent intestinal inflammation (Mizoguchi and Bhan 2006).

A number of other cell surface receptors have been associated with regulatory B cell function. In particular, regulatory B cells that lack the expression of CD40 or CD86 are unable to control murine colitis. Similarly, in humans, blocking CD86 with monoclonal antibodies prevents $CD19^+$ $CD24^{hi}$ $CD38^{hi}$ regulatory B cells from suppressing T cell cytokine production in vitro. Both CD40 and CD86 expression by regulatory B cells may be important for their ability to interact with activated T cells that express their respective ligands, CD154 and CD28.

The Generation of Regulatory B Cells

While regulatory B cells can be isolated from naïve mice or directly from the peripheral blood of healthy individuals, it has been a consistent feature across most studies of regulatory B cells that their function can be enhanced, or their numbers expanded, by the presence of inflammation. T2-like regulatory B cells are empowered by the inflammation associated with collagen-induced arthritis; accordingly, inhibition of arthritis can be achieved by adoptively transferring half the number of these cells isolated from arthritic mice as compared to naïve mice (Mauri and Bosma 2012). Similarly, adoptive transfers of $TIM\text{-}1^+$ regulatory B cells can only prolong survival of pancreatic islet transplants if they are isolated from mice that have previously received islet allografts and been subject to transplant-associated inflammation (Ding et al. 2011).

Inflammation may induce regulatory B cell function through a number of pathways. First of all, signals from activated inflammatory T cells have been associated with the generation of regulatory B cells. For instance, activated $CD4^+$ T cells express CD154, the ligand for CD40, and ligation of CD40 using anti-CD40 antibodies can induce regulatory B cell IL-10 production and rescue suppressive function of defective Bregs. Both T2-like Bregs and B10 Bregs achieve their full potential for IL-10 production when stimulated in vitro via anti-CD40 (DiLillo et al. 2010; Mauri and Bosma 2012). In addition, T2-like Bregs isolated from lupus-prone MRL/*lpr* mice require in vitro stimulation with anti-CD40 to become regulatory as they are defective directly ex vivo. Cytokine production by activated T cells is equally important. Activated $CD4^+$ T cells produce IL-21 that enhances IL-10 production by regulatory B cells. Moreover, in vitro cultures of B cells with IL-21 and cells expressing CD154 and B cell-activating factor (BAFF) induce a potent $CD5^+$ regulatory B cell population that suppresses EAE development and can reverse established EAE (Yoshizaki et al. 2012).

In addition to signals from activated T cells, cognate interactions between B cells and antigen may be required for regulatory B cell development. It has been observed that mice deficient in CD19, a molecule that participates in B cell receptor (BCR) signal transduction, develop exacerbated EAE compared to wild-type mice, suggesting that BCR signals may be important in generating regulatory B cells. Similarly,

transgenic mice whose B cells all have BCRs specific for hen egg lysozyme, a protein not found in mice, have lower frequencies of IL-10^+ B cells. This suggests that B cells need to meet their cognate antigen for development of a regulatory IL-10 response (Mauri and Bosma 2012).

Regulatory B cell interaction with the innate immune system is another potential enhancer of regulatory B cell function. B cells express a number of receptors that are specific for bacterial fragments or innate danger signals, and several groups have found a requirement for signaling through these innate pattern recognition receptors for regulatory B cell function (Lampropoulou et al. 2010). For instance, B10 Bregs require stimulation with LPS, a ligand for Toll-like receptor (TLR) 4, to achieve full IL-10 production in vitro. Similarly, in humans and mice, it is well documented that CpG, an oligonucleotide ligand for TLR-9, can induce B cell IL-10 production. Treatment of mice with apoptotic cells can also generate regulatory B cells that are able to control collagen-induced arthritis. It has not been formally proven how this effect is mediated, but it could involve stimulation of B cells through TLRs as the recipient B cells pick up pieces of apoptotic material. Interestingly, one of the receptors for phosphatidyl serine, a molecule exposed on the membranes of apoptotic cells or vesicles, is TIM-1, which as described above is a marker of regulatory B cells in transplantation. Thus, apoptotic material may directly activate regulatory B cells through TIM-1. TIM-1 expression by regulatory B cells may in addition facilitate their interaction with innate immune cells such as monocytes or dendritic cells, both of which express one of its ligands, TIM-4 (Miyanishi et al. 2007).

Regulatory B cells can also be enhanced in vitro using vitamins or synthetic molecules. For instance, the active form of vitamin D, calcitriol, enhances B cell IL-10 production in vitro as compared to anti-CD40 and IL-4 stimulation alone. Functional regulatory B cells can be generated from mouse splenocytes cultured with a fusion protein GIFT15 constructed by coupling IL-15 to the cytokine granulocyte macrophage colony-stimulating factor (GM-CSF). GIFT15 generates IL-10-producing regulatory B cells that can suppress EAE development upon adoptive transfer (Deng and Galipeau 2012).

Conclusion

Regulatory B cells have been reported in a wide range of settings, mainly in the field of experimental autoimmunity. They exist in both rodents and humans and have been ascribed several phenotypes and modes of action, with IL-10 production being suggested as a primary function. Although they have been shown to be efficient suppressors of inflammation upon adoptive transfer, their role in the natural course of inflammation resolution is yet to be properly studied. Regulatory B cells appear to be generated by the process of inflammation itself and are much more potent when isolated from an inflammatory rather than naïve microenvironment. The ability to enhance regulatory B cell activity in vitro, and the findings that they can suppress inflammation following adoptive transfers in the mouse, has led some to suggest that, like regulatory T cells, regulatory B cells could one day be used for cellular therapy in humans.

Definition

Tregs: Regulatory T cells – Regulatory T cells, or suppressor T cells, are a distinct T cell population that downregulates the immune response. They play a central role in maintaining self tolerance and the prevention of autoimmunity. More recently, they have been shown to modulate many immune responses in infectious disease and cancer settings.

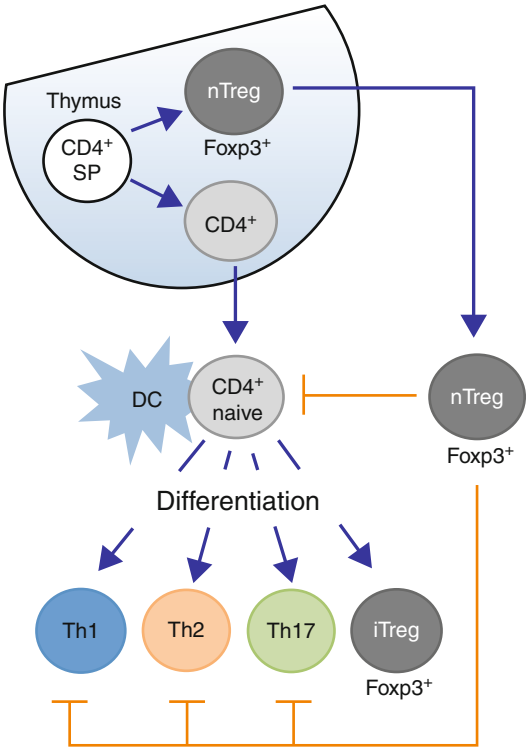
Historical Background

The immune system is tightly regulated to facilitate responses to infection while at the same time avoiding collateral damage of noninfected cells and avoiding immune activation to self-antigens that can result in autoimmunity. Cytokines made by effector T cells play a major role in activating and inhibiting immune functions, in essence making all immune cells regulatory in nature. However, since the 1970s, the idea of a specialized T cell whose primary function is to suppress immunity has been hotly debated and widely studied (Sakaguchi et al. 2008; Shevach 2000). The first breakthrough in defining Tregs was the identification of regulatory T cell suppressive function within a population of T cells expressing CD4 and CD25 (the interleukin-2 (IL-2) receptor α chain) (Sakaguchi et al. 1995). Depletion of CD25-expressing cells in the mouse led to autoimmunity that could be completely prevented by the transfer of $CD4^+CD25^+$ T cells from healthy donors (Sakaguchi et al. 1995). A second milestone came with the identification of the transcription factor Foxp3 (forkhead box P3) expressed only by $CD4^+CD25^+$ T cells in the steady state and which acts as a master regulator of Treg development and function (Josefowicz and Rudensky 2009). Naturally occurring mutations in the X chromosome-encoded *Foxp3* gene eliminate Treg generation in the thymus and lead to a lethal multiorgan autoimmune/inflammatory disease in mice (Scurfy) and human (IPEX) (Bennett et al. 2001; Brunkow et al. 2001). Thus, self-tolerance or homeostatic control of the immune system is dependent on regulation by thymically derived $CD4^+CD25^+Foxp3^+$ T cells that hold in check autoreactive T cells in the periphery. More recently, it has become evident that Tregs are an integral component of all adaptive immune responses being recruited and activated alongside effector T cells. The balance between Tregs and effectors has been shown to impact the quality or magnitude of immunity to many immune challenges including pathogens, tumors, transplantation, and vaccination.

Regulatory T Cell Subsets

Regulatory T cells can be divided into two main groups: thymically derived Tregs, which are generated in the thymus and seed the periphery as a functionally mature subset of T cells with regulatory function (natural Tregs or nTregs), and extrathymically derived Tregs, which can be induced from naïve T cells in the periphery following cognate antigen recognition (induced Tregs or iTregs) (Fig. 1). Both Treg populations express the Foxp3 gene that controls their development and function. Independent of Foxp3, a number of other T cells have been shown to be suppressive largely through the production of immune-suppressive cytokines such as IL-10 and TGF-β. These cells include suppressive Tr1 and Th3 $CD4^+$ cells, $CD8^+$ T cells, CD4-CD8- T cells and γδ T cells (Shevach 2006). These additional suppressive T cell subsets do not appear to play a critical role in self-tolerance but have been shown to impact the magnitude of the adaptive immune response in inflammatory settings. Of note, regulatory B cells expressing IL-10 have also been described, and their role in self-tolerance and immune regulation is currently of great interest.

Thymically Derived nTregs: The importance of the thymus in generating regulatory T cells has been appreciated for some 30 years. Early studies in the mouse demonstrated that thymectomy at day 3 of life resulted in organ-specific autoimmunity, while thymectomy on day 7 of life did not result in autoimmunity. Autoimmunity could be prevented in the day 3-thymectomized mice by the transfer of lymphocytes from adult thymus or spleen. Therefore, after 3 days of life, the thymus generates a population of T cells capable of controlling self-reactivity. The identification of Foxp3 as a Treg lineage-specific transcription factor fueled studies on the early development of regulatory T cells in the thymus (Josefowicz and Rudensky 2009). Similar to conventional $CD4^+$ and $CD8^+$ αβ T cell development in the thymus, Treg thymic development is a stepwise process that is dependent on signals through the TCR, CD28, and cytokine receptors.



Regulatory T Cell, Fig. 1 *Regulatory T cell development*. Regulatory T cells require the expression of the lineage specific transcription factor Foxp3 that controls Treg development, maintenance and function. Tregs can develop in the thymus (natural, nTregs) or be induced from conventional naive CD4 T cells in lymphoid tissues (induced, iTregs). (1) Bone marrow-derived single positive CD4+ T cells in the thymus are selected into the conventional CD4+ T cell lineage (T-helper-cells, Th) or into the CD4+Foxp3 + Regulatory T cell lineage. Signals for Treg development in the thymus include a limited antigen-specific niche, CD28 costimulation and interleukin-2 (IL-2). (2) In the peripheral lymphoid tissues, conventional naive CD4+ T cells are activated on encounter cognate ligand presented in the context of MHC Class II by dendritic cells (DC). The cytokine millieu at the time of initial activation drives the differentiation of naive T cells into effector T cells with specialized functions (Th1, for clearence of intracellular pathogens such as bacteria and viruses; Th2, for the clearance of large extracelluar parasites such as helminths; and Th17 for the clearance of some extracellular bacteria and fungi). In addition to effector T cells, naive T cells can differentiate into regulatory T cells (iTreg) by encounter with DCs in the presence of IL-2, TGFβ and retinoic acid. The gut-associated lymphoid tissues is a major site of iTreg generation. Tregs can inhibit the initial activation of naive T cells in the lymph nodes and their subsequent effector function in infected/inflamed tissues using a variety of mechanisms.

TCR specificity plays a critical role in determining Treg development in the thymus but not in a straightforward manner in which TCRs can be classified as being destined to induce Tregs or to induce conventional T cells. Rather, the ability of TCRs to facilitate Treg development appears to be controlled by limited antigen-specific niches, with the TCR clonal frequency needing to be below 1 % for efficient Treg selection (Lio and Hsieh 2011). Such a mechanism, although not fully understood, is likely to result in Treg TCRs recognizing rare tissue-specific antigens rather than ubiquitously expressed self-antigens and lead to a highly diverse TCR repertoire important for broad control of autoreactivity in the periphery. Along with TCR engagement, thymic development of Tregs requires signals from CD28 and the downstream activation of NF-κB, specifically c-Rel. Another critical signal for Treg differentiation is interleukin-2 (IL-2) mediated through the IL-2R and the signal transducer and activator of transcription 5 (STAT5). This combination of signals is thought to induce and/or stabilize Foxp3 gene expression during Treg differentiation but may also help to drive the expansion or survival of differentiated Tregs in the thymus. In the periphery, IL-2 produced by conventional T cells plays a key role in the maintenance of Foxp3 expression and in the activation, expansion, and survival of nTregs.

Peripherally Induced iTregs: The original studies of the Foxp3 gene demonstrated that ectopic expression of Foxp3 in nonregulatory T cells in vitro conferred regulatory functions, highlighting the fundamental role that Foxp3 plays in orchestrating the regulatory program. In vivo, naïve conventional T cells can be induced to express Foxp3 and gain regulatory function under distinct activation conditions. iTreg differentiation appears to be favored by interactions with dendritic cells (DCs) in the absence of inflammation leading to suboptimal TCR signaling or by activation in tolerogenic microenvironments such as the gut (Bilate and Lafaille 2012). In vitro, differentiation of naïve T cells into iTregs is dependent on antigen-specific activation by DCs in the presence of IL-2 and TGF-β and is

inhibited by IL-6. In contrast, TGF-β in combination with IL-6 promotes Th17 differentiation that is reciprocally inhibited by IL-2. The central role of TGF-β in driving both regulatory and effector populations suggests that iTregs and Th17 development are closely linked and that cofactors provided by the inflammatory milieu will dictate immune tolerance or activation. In vivo, the gastrointestinal tract represents a major site for iTreg development mediated through T cell activation by a particular retinoic acid producing $CD103^+$ DC subset in the gut-associated lymphoid tissue (GALT) (Siddiqui and Powrie 2008). Retinoic acid promotes iTreg differentiation by augmenting Foxp3 induction and inhibiting IL-6-dependent induction of Th17s. The induction of iTregs in the gut is thought to provide the mechanistic basis for tolerance/nonresponsiveness to orally administered antigens, known as oral tolerance. iTregs can also be generated in chronic inflammatory conditions such as allergic asthma, autoimmunity, and chronic infection. Induction of iTregs in inflammatory settings is still dependent on TGF-β but the antigen-presenting cell (APC) types and cytokine milieu that differentially drive effector and regulatory T cell differentiation in inflammation are not well defined. Kinetically, iTregs develop later than effector cells in an inflammatory immune response and are thought to limit the tissue damage caused by effector T cells.

Foxp3 and Treg Plasticity: In the past 10 years, the field of T cell differentiation has become heavily focused on stability of effector T cell subsets and the possibility of functional plasticity (Nakayamada et al. 2012). Th1 and Th2 cells were once thought to be stable "terminally differentiated" lineages by virtue of lineage-specific transcription factor-guided chromatin remodeling that opened up cytokine loci of the one program and repressed the cytokine loci of the reciprocal program. Technical advances in our ability to measure chromatin modifications have facilitated a detailed analysis of epigenetic marks in differentiated effector cells and have revealed that the lineage-specific transcription factors for the opposing lineage are poised for transcriptional activation. Indeed, otherwise stable, Th2 cells were shown to express Tbet and IFN-γ when activated in the context of interferons induced by viral infection. Therefore, Th effector populations can be functionally reprogrammed in particular inflammatory environments. For Tregs, the Foxp3 locus is heavily demethylated in nTregs indicating stability of the lineage (Miyara et al. 2009). In contrast, the Foxp3 locus of TGF-β-induced iTregs is more methylated implicating functional instability (Baron et al. 2007). Recent cell fate mapping studies using fluorescently tagged $Foxp3^+$ T cells have shown in certain circumstances that Foxp3 expression can be lost and that this loss coincides with the gain of effector function (Zhou et al. 2009), a study that remains controversial. The possibility of instability in the Treg lineage however and the ability of Tregs to gain effector function will need to be closely monitored as efforts to use Treg cell therapy for controlling inflammation and autoimmunity continue to be developed.

Of note, unlike mice, human conventional $CD4^+$ T cells express Foxp3 upon activation but do not acquire regulatory T cell phenotype or function. In this setting, Foxp3 is expressed at lower levels than nTregs and is transient and therefore may not be present in the cell long enough to make fundamental changes to effector function. Therefore, in humans, additional markers are needed to accurately distinguish between $Foxp3^+$ recently activated effector T cells and $Foxp3^+$ Tregs. The level of expression of the interleukin-7 receptor α, CD127, inversely correlates with Foxp3 expression and is widely used to distinguish Tregs from effector T cells, Tregs being $CD4^+CD25^{hi}Foxp3^{hi}CD127^{lo}$ (Miyara and Sakaguchi 2011).

Function

Regulatory T cells have been shown to regulate many immune cell types including $CD4^+$ T cells, $CD8^+$ T cells, B cells, NK cells, macrophages, mast cells, and dendritic cells. This broad spectrum of suppression is facilitated by the

Regulatory T Cell, Table 1

nTreg molecules	Regulatory mechanism
Cell surface	
CTLA-4	– Competes for co-stimulatory CD80/86 ligand binding on DC; reduces naive T cell activation – Removes CD80/86 from DC cell surface by endocytosis; reduces naïve T cell activation – Binding to CD80/86 induces IDO expression in DC, suppresses T cell activation by local depletion of tryptophan, induces a regulatory phenotype in the DC
CD25	Competes for the growth factor IL-2; limits naive T cell expansion/survival
LFA-1/ neuropilin	High Treg cell surface expression enhances Treg-DC adhesion; may physically limit naïve T cell interactions with DC
CD39/CD73	Ectoenzymes that degrade ATP and generate adenosine; limits availability of ATP needed for T cell activation signals, adenosine-mediated inhibition of cytokine transcription, role in metabolic inhibition
Surface TGF-β LAP	Broad immunoregulation; inhibits leukocyte activation and function; modulates DC function
LAG3	An MHC class II-binding CD4 homolog, implicated as a negative regulator; function unknown but LAG3-deficient Tregs have reduced suppressive function
Secreted	
IL-10	Broad immunoregulation; blocks effector cytokines such as IFN-γ at barrier surfaces; inhibits macrophage activation, suppresses Th1 responses
TGF-β	Broad immunoregulation; inhibits CD8 cytolytic function; supports DC generation of iTregs
IL-35	Heterodimeric regulatory cytokine composed of IL-12 p35 and Ebi3; inhibits T cell activation and cytokine production; can induce new IL-35-producing regulatory T cells
Perforin/ granzymes	Cytotoxic; can induce apoptosis in a variety of immune cells
cAMP	High intracellular levels in Tregs, delivered to T cell targets via gap junctions; inhibits T cell activation and cytokine production, role in metabolic inhibition

expression of a wide variety of adhesion molecules and chemokine receptors that enable Treg trafficking to lymphoid tissues, to inflamed tissues at infection and autoimmune sites, and to tumors (Campbell and Koch 2011). Tregs deficient in CD103 (αE integrin) failed to home to inflamed tissues and were functionally compromised. Thus, Tregs are localized for control of early events in immune activation in the lymph node (proliferation/expansion) and subsequent effector functions (cytokines, cytolytic) in inflamed/infected tissues. Multiple mechanisms for Treg suppressive function have been identified that fall into three main categories: cell-cell contact, secretion of soluble factors (cytokines), and competition for growth factors (Sojka et al. 2008; Tang and Bluestone 2008) (Table 1). The relative importance of each suppressive mechanism will likely depend on the type of target cell, its functional stage, and the activation milieu at the time of regulation. Recent advances in the ability to delete genes specifically in the Treg lineage will help to elucidate the role of specific regulatory components.

Cell-Cell Contact Dependent: The classic in vitro test of Treg function is a suppression assay in which conventional $CD4^+$ T cells are activated by anti-CD3 antibodies and APCs (T-depleted splenocytes) in the presence or absence of Tregs. In the presence of Tregs, $CD4^+$ T cells fail to sustain gene expression for IL-2 and do not proliferate. Suppression is lost if the Tregs and target $CD4^+$ T cells are physically separated using a transwell system. Therefore, cell-cell contact appears to be required for regulatory action, or, more precisely, the Treg and target T cells and/or antigen-presenting cells need to be in close proximity. A variety of different Treg mechanisms work through cell-cell contact, either Treg-APC or Treg-T conventional.

Cell contact between the Treg and the antigen-presenting cells, namely, DCs for naïve T cell activation, limits the stimulatory capacity of DC in a number of ways and hence limits T cell

activation. T cell activation is dependent on co-stimulation through CD28 on the T cell binding to CD80 and CD86 on the APC. CTLA-4 is a negative regulator of T cell activation that has a higher affinity for CD80/CD86 than CD28 and can outcompete CD28 for ligand binding and hence attenuate activation signals. Tregs constitutively express CTLA-4 on their surface and therefore can block conventional T cell access to DC CD80/CD86 co-stimulation and prevent activation of naïve T cells. It has also been reported that Tregs can limit co-stimulation by the physical removal of CD80/86 from the surface of the APC by CTLA-4-mediated trans-endocytosis. Tregs also express higher levels of adhesion molecules, such as LFA-1, and may dominantly interact with the DC at the expense of naïve T cells. Indeed, in vivo imaging studies have shown that Tregs inhibit stable contacts between the conventional T cells and DC. Tregs may also change the stimulatory properties of DC by inducing functional changes in the APC. Engagement of Treg CTLA-4 with CD80/86 on the DC initiates DC upregulation of indoleamine 2,3-dioxygenase (IDO). IDO is a tryptophan-catabolizing enzyme that suppresses T cell activation by local depletion of tryptophan and, independent of its catabolic functions, induces a regulatory phenotype in the DC.

Tregs can also directly interact with the T cells themselves to block activation. Tregs express high intracellular levels of cyclic AMP (cAMP) and have been shown to be able to directly deliver cAMP to the T cells via gap junctions. cAMP is a potent inhibitor of many cytokine genes in the T cells. In some settings, such as in the tumor microenvironment, the expression of the cytotoxic molecules granzyme and perforin by Tregs appears to limit antitumor immunity by inducing T cell and DC apoptosis. Although not directly cell-cell contact, Tregs can alter local concentrations of ATP through their surface expression of the ectoenzymes CD39 and CD73 that catalyze the generation of adenosine from ATP and ADP. Extracellular ATP is important for activated T cell signaling, and therefore, Treg-mediated degradation of ATP limits resources for efficient T cell activation. In addition, adenosine binds to A2A receptors on effector T cells and inhibits cytokine transcription via induction of cAMP.

Secretion of Soluble Factors: Tregs secrete a number of immunosuppressive cytokines including TGF-β, IL-10, and a newly described suppressive cytokine IL-35. Although not found to be required for the in vitro assays of Treg suppression of T cell proliferation, in vivo these cytokines clearly play a role in the regulatory function of Tregs. TGF-β is a key regulator of immune homeostasis and is made by many cell types including Tregs. Disruption of TGF-β signaling in T cells leads to a fatal lymphoproliferative disease similar to that seen with Foxp3 deficiency. TGF-β responsiveness by $CD8^+$ effector T cells was found to be key to Treg-mediated inhibition of cytolytic function. In addition to inhibiting immunity, TGF-β is also important for inducing and maintaining Foxp3 expression and thus positively regulates Tregs, both the generation of iTregs and the maintenance of nTregs. IL-10 is also produced by a range of immune cell types and can inhibit macrophage activation, induce tolerogenic DCs, and block Th17 generation. Treg-specific depletion of IL-10 revealed a nonredundant role for Treg IL-10 at barrier surfaces with the mice developing amplified lung, skin, and intestinal pathologies. Indeed, IL-10-deficient Tregs retained the ability to inhibit early T cell activation and proliferation in the lymph node but were unable to control IFN-γ production in the dermis. These studies highlight that although Tregs have a large arsenal of immunosuppressive tools, particular suppressive mechanisms will be critical in distinct locations or at specific time points in a developing immune response.

Competition: Regulatory T cells constitutively express a number of cell surface molecules that provide a competitive advantage for resources over conventional T cells where the molecules are not constitutively expressed but need to be induced following activation. CTLA-4 expression has been discussed earlier with respect to the ability of Tregs to outcompete naïve T cells for CD80/CD86 on DCs. IL-2 is fundamental to Treg survival and function but is not made by the Tregs themselves. Expression of the high-affinity

IL-2R, experimentally defined by the IL-2Rα chain CD25, facilitates the rapid utilization of exogenous IL-2 made largely by naïve T cells after activation. Tregs can therefore deprive conventional T cells of IL-2 and limit their proliferation and survival. Such a mechanism may be particularly important during early activation events in the lymph node where IL-2 is essential for antigen-specific T cell expansion.

Tregs in Disease

Mutations in the Foxp3 gene that result in loss of function lead to an early and fatal multiorgan autoimmune/inflammatory disease in mice and man (Bennett et al. 2001; Brunkow et al. 2001), demonstrating the importance of Treg control of self-tolerance and immune homeostasis. Therefore, there has been great interest in determining if a defect in Treg number or function can explain the loss of self-tolerance that defines autoimmune diseases. Acute deletion of Tregs in animal models can precipitate autoimmune disease, and the provision of additional Tregs can prevent disease. In humans, Treg functional defects have been described for type 1 diabetes (T1D), rheumatoid arthritis (RA), multiple sclerosis, and systemic lupus erythematosus (Buckner 2010). In RA, functional defects in Tregs may be caused by the inflammatory milieu of the disease (particularly TNF-α) and can be reversed by removing Tregs from the microenvironment or neutralizing the inflammatory cytokines. In T1D, in addition to Treg functional defects, the effector T cells from diabetic subjects appear to be more resistant to suppression adding another mechanistic layer to the immune dysregulation seen in autoimmunity. There is much excitement about the possibility of Treg therapy in autoimmune disease with efforts to define conditions in which to expand and/or induce antigen-specific Tregs for specific autoimmune diseases. However, successful Treg therapy will need to confront the functional plasticity of Treg populations and the nature of the inflammatory environment in which the Tregs will be required to function.

Tregs are also key to the control of immune responses to infection. By limiting the effector T cell response, Tregs prevent local immunopathology resulting from excessive cytokine production. Clearly, there is a fine balance between overcoming suppression sufficiently to mount a robust antimicrobial immune response and controlling collateral damage in the tissues. This balance is regulated at many levels with inflammatory signals that both inhibit Treg activity but also promote Treg specialization and enhance Treg function (Campbell and Koch 2011). Layered on top of this hematopoietic self-control is the ability of many pathogens to promote Treg recruitment and/or activation in infected tissues to repress pathogen-specific effector responses and promote/prolong microbial residency in the host (Maizels and Smith 2011). High levels of inflammatory cytokines such as TNF-α, IFN-γ and IL-6 have been shown to dampen nTreg activity and inhibit the generation of iTregs. In RA, anti-TNF-α treatment correlates with enhanced Treg activity. However, Tregs are also capable of responding to these same effector cytokines in a positive way to adapt to the inflammatory environment and provide better regulation. A series of recent studies have shown that, under effector T cell-polarizing conditions, Tregs acquire signaling and transcriptional components normally expressed by the effector T cells themselves (Campbell and Koch 2011). In a Th1-inducing environment, Tregs express Tbet which facilitates their recruitment to sites of Th1 inflammation. Similarly, in Th2 inflammation, Tregs appear to require expression of the Th2-associated transcription factor interferon regulatory factor 4 (IRF4) to curtail aberrant IgG1 and IgE production. For control of Th17 responses, Treg need STAT 3, a transcription factor downstream of the IL-6R. In all these cases, deletion of these molecules in Tregs compromised their ability to adapt to the environmental conditions and led to an inflammation-specific reduction in their regulatory capacity. Therefore, there is a complex relationship between inflammation and Treg activity, and the efficacy of Treg function in

a given inflammatory setting will likely be highly context dependent.

One unexpected negative consequence of Treg immune control has come from the study of tumor-infiltrating lymphocytes. Regulatory T cells expressing CCR4 are readily recruited to tumors by CCL22-producing tumor cells and tumor-infiltrating macrophages. The tumor can also promote iTreg generation through high TGF-β production and the induction of tolerogenic DCs. Tregs are highly activated in the tumor and can functionally dominate the tumor microenvironment preventing T cell activation. Indeed, an increased ratio of Tregs to $CD8^+$ T cells in the tumor correlates with poor prognosis in patients with breast, gastric, and ovarian cancers. Depletion of Tregs has been shown to lead to rapid T cell-mediated destruction of tumors and has prompted efforts to design therapies that block Treg activity in human tumor settings.

Summary

$Foxp3^+CD25^+CD4^+$ regulatory T cells are key modulators of immunity for immune tolerance and homeostasis and in response to infectious challenge. The Treg lineage is defined by the expression of the transcription factor Foxp3 that acts as a "master regulator" of Treg development and function. Tregs can limit the stimulatory capacity of DCs, outcompete naïve T cells for resources, inhibit effector cytokine production, and even kill immune cells. Mechanistically, Tregs express an array of immunosuppressive tools either on their cell surface such as CTLA-4 and CD25 which outcompete naïve T cells for activation signals or by secreted factors such as the immunosuppressive cytokines IL-10 and TGF-β. A loss of Treg function leads to a systemic autoimmune/inflammatory disease, highlighting their critical role in immune homeostasis and the prevention of autoimmunity. Tregs also play an integral role in immune responses to infection and other immune challenges such as allergens, vaccination, tumors, and transplantation. The balance between Treg and effector T cell responses is tightly regulated, and a number of therapeutic strategies are being developed to exploit this control mechanism to boost Treg activity in autoimmune and inflammatory diseases and inhibit Tregs for better tumor clearance.

Immunoglobulin repertoire

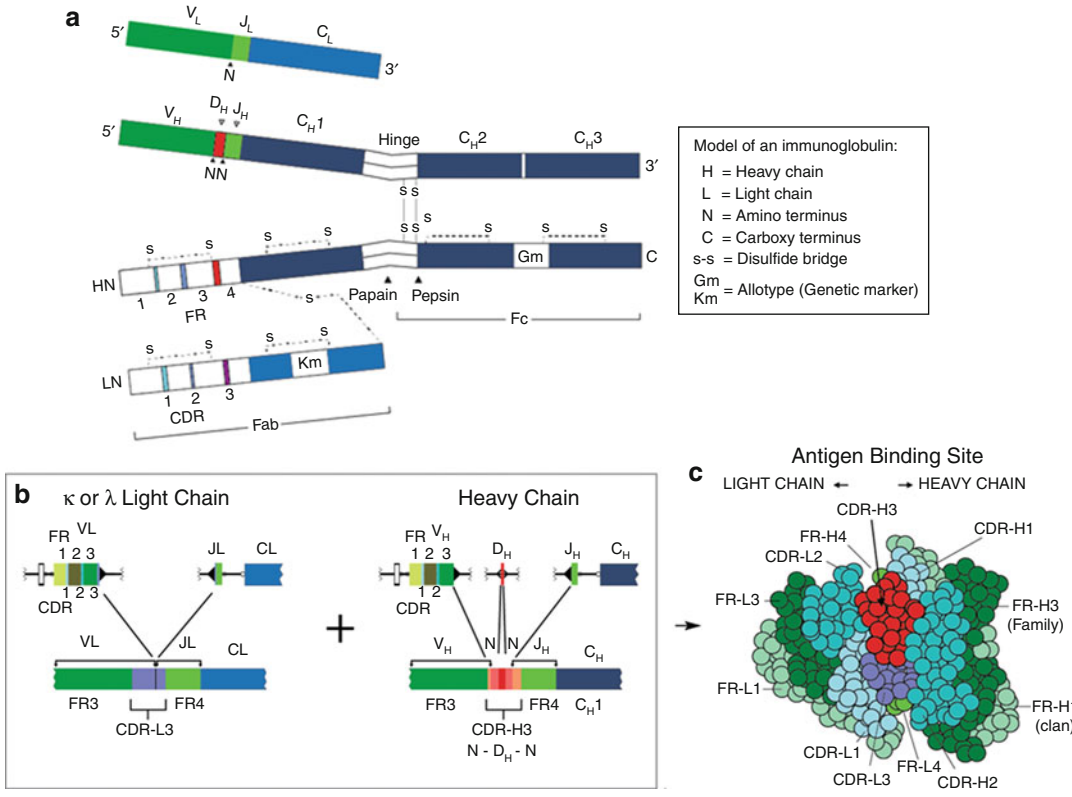
Definition

Repertoire selection is the process by which the antigen binding characteristics of the B cell receptor are used to maintain, activate, or expand B cell clones that make beneficial antibodies; and to suppress, sequester, or eliminate B cell clones that make ineffective or potentially pathogenic antibodies.

Introduction

Immunoglobulin (Ig), which in its membrane form functions as the B cell receptor (BCR) for antigen, is created by a complex process of clonal V(D)J rearrangement and N addition in developing B lineage cells. This process occurs in the bone marrow and fetal liver, both central lymphoid organs (Tonegawa 1983). Immunoglobulin belongs to the eponymous immunoglobulin superfamily (IgSF). They consist of two heavy (H) and two light (L) chains (Fig. 1), where the L chain can consist of either a κ or a λ chain (Schroeder and Cavacini 2010). Each component chain contains one NH_2-terminal "variable (V) IgSF domain and one or more COOH-terminal "constant" (C) IgSF domains, each of which consists of two sandwiched β pleated sheets "pinned" together by a disulfide bridge between two conserved cysteine residues. Each V or C domain consists of approximately 110–130 amino acids, averaging 12–13 kDa. L chains contain only one C domain, whereas H chains contain three or four. H chains with three C domains tend to include a spacer *hinge* region between the first (C_H1) and second (C_H2) domains. Considerable variability is allowed to the amino acids that populate the external surface of the IgSF domain and to the loops that link the β strands. These solvent-exposed surfaces offer multiple targets for docking with other molecules.

Following exposure to antigen in the periphery, B cells can induce further genetic modifications of their immunoglobulin through the process of somatic hypermutation (Kato et al. 2012). The collection of individual immunoglobulins is termed the antibody repertoire. As a result



Repertoire Selection, Fig. 1 *Immunoglobulin structure and derivation*. (**a**) Two-dimensional model of an IgG molecule. The H and L chains at the top deconstruct the antibody at a nucleotide level. The chains at the bottom deconstruct the protein sequence. (**b**) V(D)J rearrangement and N nucleotide addition create an extremely diverse Ig repertoire. (**c**) The antigen binding site is the product of a nested gradient of diversity. The view is looking into the binding site as an antigen would see the antigen binding site. This site is created by the juxtaposition of the three CDRs of the H chain and the three CDRs of the light chain. The VH domain is on the right side. The central location of CDR-H3, which due to N addition is the focus for repertoire diversity, is readily apparent

of these mechanisms of diversification, the antibody repertoire becomes large in size and extraordinarily diverse in content. The size and diversity of the repertoire creates immunoglobulins that have the potential to neutralize or protect against ancient or novel hazardous agents coming from inside or outside the body. Unfortunately, it also creates a repertoire with the potential to generate autoimmune disease (Durandy et al. 2013). This can occur when B cells produce Ig that binds inappropriately to self-antigens. Repertoire selection comprises a series of processes used by the immune system to control the composition of immunoglobulin in order to enhance protection and minimize the risk of pathogenic autoimmunity.

Darwinian Natural Selection of the Repertoire

The binding of a cell surface receptor to its ligand typically transduces a signal that affects the function or fate of the cell, including activation, mitosis, differentiation, or death. To maintain the specificity of these downstream effects, each receptor typically coevolves with its ligand. The B cell receptor would seem to be an exception because at first glance, its ligand (antigen) binding site appears to vary randomly in sequence and structure on a large scale (Tonegawa 1983). However, intra- and interspecies comparisons reveal evidence of conservation, or stereotypy, of germline VDJ

gene sequences and structures that may have a deterministic effect.

The term *natural selection* was used by Darwin to describe nature's analogy to *artificial selection*, a process by which animals and plants with traits considered desirable by human breeders are systematically favored for reproduction. Natural selection is considered to be the primary explanation for adaptive evolution. The structures encoded by the framework 1 (FR1) and framework 3 (FR3) of the V domain are more highly conserved within mammals than the constant domains, with certain FR3 structures conserved from shark to human (Kirkham and Schroeder 1994). Thus, the structures of these scaffolds for the antigen binding site appear to be preserved by natural selection.

Individual V gene sequences can be grouped into families sharing FR3's of similar sequence and structure. These stereotyped FR3's help shape and frame the antigen binding site (Kirkham and Schroeder 1994). V families can be grouped into clans based on the sequence and structure of FR1, which influences the nature of the elbow joint interaction between the V domain and the CH1 domain (Lesk and Chothia 1988). The antigen binding site is created by the juxtaposition of three hypervariable loops from the H chain, termed complementarity determining regions (CDRs), with three CDRs from the L chain. CDR1 and CDR2, which are completely encoded by the V gene segment and are juxtaposed to FR3, demonstrate conserved canonical structures with a nonrandom association of CDR1 structures with CDR2 structures (Chothia et al. 1992), influencing the binding properties of the outer edge of the antigen binding site. Even CDR-H3, which is created de novo by VDJ recombination and random N nucleotide addition, demonstrates evidence of stereotypy based on specific physicochemical properties that include enrichment for neutral amino acids such as tyrosine and depletion of highly charged amino acids (Ivanov et al. 2002).

Stereotypy in CDR-H3 is partly due to natural selection of JH and DH gene segment sequence coupled with control of DH reading frame usage (Schroeder et al. 2010). Thus, although the antibody repertoire is not identical between different individuals of the same or different species, there are physicochemical biases of sequence, structure, and hydrophobicity that are emphasized, and others that appear to be repressed. The sequence of individual germline-encoded V gene segments can also play a critical role in immune responses. Violation of these constraints can yield increased susceptibility to infectious agents.

Clonal (Somatic) Central Selection of the Repertoire

Generation of an immunoglobulin molecule in the bone marrow and fetal liver is typically viewed as a stepwise process that involves passage through a series of checkpoints that are used to test the stability of the H and L chains, and then the initial binding characteristics of the IgM they produce (Vale and Schroeder 2010). Passage through these checkpoints includes testing for physicochemical properties of the antigen binding site including hydrophobicity and structure. The initial requirement for the survival of a developing B cell is that it creates an H chain protein that can create a pre-B cell receptor in association with surrogate light chain (SLC), which consists of two L chain homologues termed VpreB and λ5. Failure of the H chain to bind a SLC results in cell death. Cells that survive this process repeatedly divide and then initiate L chain rearrangement. Production of a functional L chain permits creation of a complete IgM molecule by the immature B cell. Failure of the L chain to bind effectively to the H chain leads to additional rounds of VJ L chain rearrangement, with λ rearrangement typically occurring after κ rearrangements have failed. Immature B cells, which express only IgM on their cell surface, are tested for binding to self-antigens present in the serum or in their surroundings. Cells that bind too vigorously to self-antigens can be driven to apoptosis, become anergic and die by neglect, or return to a state where they undergo receptor editing, i.e., further rounds of L chain VJ

rearrangement or, less commonly, H chain V→V replacement until they create a more acceptable IgM.

Clonal (Somatic) Peripheral Selection of the Repertoire

B cells that survive this process leave the bone marrow or fetal liver and progress through transitional stages that precede their development into mature B cells, which circulate throughout the body (Vale and Schroeder 2010). The fate of these mature B cells depends both on antigen-by-antigen discrimination and on lineage. In the mouse, two lineages of B cells have been well-described. The B-1 lineage derives primarily from early fetal and neonatal progenitors and expresses a repertoire with fewer N nucleotides. Therefore, it is more highly dependent on germline sequence. B-1 cells pass through the spleen and most are then shunted into the peritoneal cavity where they will produce the majority of circulating IgM (Baumgarth 2011). This IgM is heavily enriched for natural autoantibodies that are polyreactive and bind with low affinity to many self-antigens, including altered self-antigens created by catabolism or environmental influences. These molecules aid in cellular homeostasis. Due to greater reliance on germline sequence, many of these B cells create antibodies with "public" antigen binding sites that can be found in many individuals of the same species.

Also present in the spleen are marginal zone (MZ) B cells which also tend to bind self-antigens with low affinity (Lopes-Carvalho et al. 2005). These cells are created by adult stem cells. Many of these cells produce immunoglobulins that bind common microbial constituents. They form an already active cohort of B cells that can respond to blood-borne microbial challenge very quickly. Among these MZ B cells, immunoglobulins bearing antigen binding sites with less common physicochemical properties, including a high frequency of hydrophobic or charged amino acids, are found more frequently. Both B-1 and MZ B cells tend primarily to produce IgM, and they typically do not require T cell help.

B cells in the follicles of the spleen, lymph nodes, and ectopic lymphoid aggregates associated with inflammatory responses typically require T cell help in order to develop into plasma cells or memory B cells (Shlomchik and Weisel 2012). High affinity for antigen or a high concentration of antigen permits follicular B cells to develop into short-lived plasma cells. A lower affinity or antigen concentration promotes creation and entry into a germinal center. In the germinal center, B cells undergo repeated cycles of antigen selection and somatic hypermutation, a process termed affinity maturation. Somatic hypermutation permits massive changes to the framework scaffolding that supports the antigen binding site as well as major changes to the structure and sequence of the antigen binding site itself.

Pathogenic autoreactive IgG antibodies are often highly mutated (Durandy et al. 2013). Engineering these molecules into a pre-mutated state often produces V domains that no longer bind the self-antigen, suggesting that somatic hypermutation has circumvented the mechanisms of somatic selection used to prevent initial production of autoreactive sequences. The mechanisms used to reduce the likelihood of the production of pathogenic autoantibodies by somatic hypermutation remain uncertain. It is possible that the less regulated structures created by ectopic lymphoid tissue that forms as a consequence of inflammation may be inherently less able to control repertoire diversification by hypermutation. These are areas of significant current scientific interest.

Biomarkers for the Evaluation of the Efficacy of Repertoire Selection

There are several means by which the efficacy of repertoire selection can be assessed. These range from gross measurements of antibody reactivity in the serum to single cell analyses.

Serologic analyses of autoantigen or antipathogen reactivities have a long history in clinical medicine. Examples of autoantigen reactivities include determination of dsDNA binding

titers or antinuclear antibody (ANA) titers in SLE, and of rheumatoid factor (RF) titers in rheumatoid arthritis (Riemekasten and Hahn 2005). Examples of anti-pathogen reactivities include anti-pneumococcal polysaccharide titers, anti-hemophilus influenza titers, and anti-influenza titers. However, these reactivities measure the final stage of antibody production and do not address particular stages where repertoire selection has acted.

Anti-idiotype or cross-reactive idiotype antibodies offer another means of testing where selection is occurring or has failed. For example, the V4-34 v_H gene segment contains a sequence in its frameworks and CDRs that facilitates binding to blood group antigens and other self-glycoproteins including CD45. An anti-idiotypic antibody, termed 9G4, exists that can stain cells using the V4-34 gene segment in its BCR. This antibody can be used in fluorescence-activated cell sorting studies to assess when use of this gene segment is suppressed. Some patients with autoimmune diseases fail to suppress use of this gene segment, which enables identification of the checkpoints at which tolerance has failed (Cappione et al. 2005). Labeled antigen can also be used to assess the frequency and subset of B cells with affinity for specific self- or auto-antigens.

High-throughput sequencing is a new tool that can be used to evaluate the actual composition of the repertoire in great detail (Weinstein et al. 2009). Sequencing studies, especially those focusing on sorted B cell subsets, have the potential to answer many questions about the precise details of repertoire selection. Coupling sequencing with single cell analyses makes it possible to directly link antigen specificity to molecular content (DeKosky et al. 2013). These types of studies will likely revolutionize our understanding of repertoire selection.

Catabasis; Lipid-mediator class switching

Definition

Resolution of inflammation is the termination of an inflammatory response.

Brief Overview

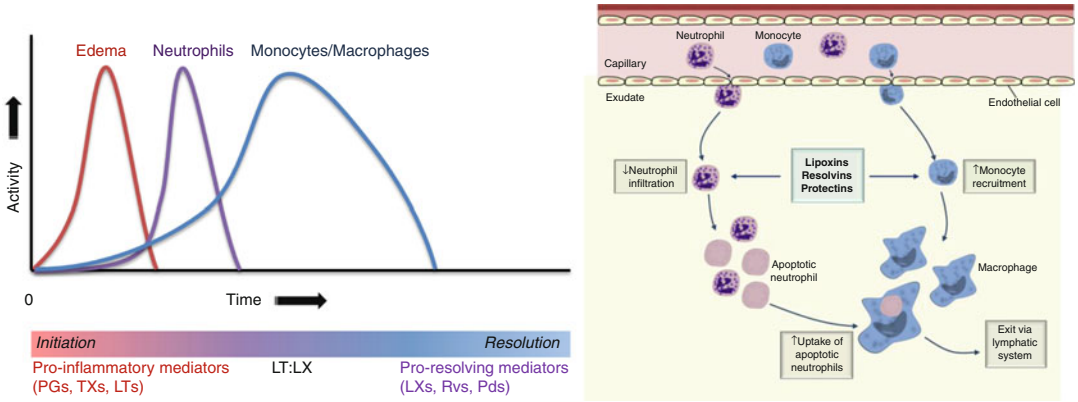
Acute inflammation is a protective response to invading microbes and tissue injury, and resolution is necessary for tissues to return to their normal state after the benefits of acute inflammation have been achieved. The resolution process is important for prevention of diseases characterized by chronic inflammation and tissue injury, such as atherosclerosis, cancer, inflammatory arthritis, and inflammatory bowel disease.

Resolution of inflammation is the coordinated, active termination of an inflammatory response. The term encompasses a switch in enzymatic activity and the biological actions of subsequently produced pro-resolving mediators, as well as the apoptosis and clearance of inflammatory cells (reviewed in Serhan 2007; Serhan et al. 2008). The process is typified by (1) the production of distinct lipid mediator classes: eicosanoids, resolvins, protectins, maresins, and anti-inflammatory cytokines; and (2) an active switch in cell types within the site of inflammation. Pro-resolution mediators signal termination of an inflammatory response by reducing ▶ neutrophil infiltration, activating ▶ neutrophil apoptosis, and recruitment of monocytes that mature into macrophages which clear apoptotic ▶ neutrophils and inflammatory debris. This process allows the tissue to return to homeostasis, a process also referred to as catabasis.

Temporal Actions and Lipid-Mediator Class Switching

Resolution of inflammation is characterized by an active switch in enzyme activity that produces the mediators predominating in inflammatory sites (Fig. 1). Initially, proinflammatory prostaglandins and leukotrienes activate and amplify inflammatory cascades. Next, prostaglandin (PG) E_2 and PGD_2, by inducing the production of key lipoxygenases, promote the synthesis of mediators that have both anti-inflammatory and pro-resolution activities. These include lipoxins, resolvins, protectins, and maresins (Fig. 1) (Serhan and Savill 2005). These families of specialized pro-resolution lipid mediators are not immunosuppressive, but instead function in the resolution of inflammation by activating specific mechanisms to promote homeostasis. Pro-resolution mediators stimulate and accelerate resolution by influencing the function of several cell types (Table 1). These lipid mediators provide potent signals that selectively stop ▶ neutrophil and eosinophil infiltration, stimulate non-phlogistic (noninflammatory) recruitment of monocytes, activate macrophage phagocytosis of microorganisms and apoptotic cells, and increase the exit of phagocytes from the inflamed site through the lymphatics.

Lipid-mediator class switching refers to the transition in enzyme activity from production of proinflammatory eicosanoids to pro-resolution lipid mediator classes (Fig. 1). During an inflammatory response, leukocytes rapidly biosynthesize PGs and leukotrienes via



Resolution of Inflammation, Fig. 1 Acute inflammation temporal actions. At the onset of inflammation, edema occurs by vascular leakage. Neutrophils appear first, followed by monocytes and macrophages. The switch in predominant cell types is driven by a shift in production of leukotrienes (*LT*) to the production of specialized pro-resolution lipid mediators including the arachidonic acid product, lipoxins (*LX*) (Adapted with permission, from Fredman and Serhan (2011) Biochem J. 437(2):185–97; and Serhan, Chiang, and Van Dyke (2008) Nat Rev Immunol. 8(5):349–61)

cyclooxygenase (COX) and 5-lipoxygenase (LOX) activity. As inflammation proceeds, the ▶ neutrophils stop producing chemoattractants (e.g., leukotriene B_4) and within hours begin to convert arachidonic acid into protective lipoxins (Fig. 1), thereby serving as agonists to actively terminate inflammation and promote resolution (Fredman and Serhan 2011). In contained exudates and inflamed tissues, both PGE_2 and PGD_2 have proinflammatory activities, but each can also promote a switch in the expression of biosynthetic enzymes produced by infiltrating ▶ neutrophils that changes their phenotype to a pro-resolution phenotype (Serhan and Savill 2005). The nonenzymatic degradation products of PGD_2 (i.e., 15-deoxy-delta-12,14-PGJ_2 and related cyclopentanones) can facilitate resolution by promoting leukocyte apoptosis and macrophage clearance from inflamed sites via inhibition of ▶ nuclear factor-κB (NFκB) activation.

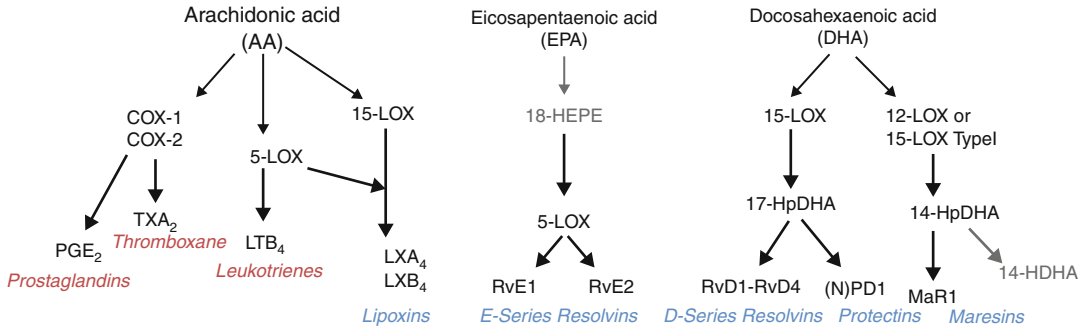
Lipoxins

Lipoxins, a large family of arachidonic acid metabolites, arise from the sequential action of 5-lipoxygenases and 15-lipoxygenases. Addition of 15-HPETE and 15-HETE to human leukocytes results in formation of a pair of oxygenated products containing a unique conjugated tetraene. One compound, lipoxin A4 (LXA4), was identified as 5,6,15L-trihydroxy-7,9,11,13 eicosatetraenoic acid, and the other proved to be its positional isomer (LXB4). Because both of these compounds can arise through an interaction between lipoxygenase pathways, the trivial name lipoxins (lipoxygenase interaction products) was introduced. Platelet 12-lipoxygenase can transform ▶ neutrophil leukotriene A4 (LTA4) to lipoxins. The complete stereochemistry and multiple routes of biosynthesis for the biologically active LXA4 and LXB4 – and their aspirin-triggered carbon 15-epimers (reviewed in (Serhan 2004)) – have been determined (Serhan et al. 2004). LXs generated by these cell–cell interactions stop ▶ neutrophil diapedesis and recruitment into the tissues and stimulate monocyte chemotaxis. LXs have additional effects on many cell types (Table 1).

In disease models, LXs and their aspirin-triggered epimers (stereoisomers that differ at only one site of chirality) have numerous effects (reviewed in Serhan et al. 2008). An abundance of literature documents the anti-inflammatory effects of LXs in rodent models of periodontitis, colitis, asthma, corneal disorders, glomerulonephritis, and pain.

Resolution of Inflammation, Table 1 Actions of specialized pro-resolution lipid mediators (Adapted with permission, from Serhan, Chiang, and Van Dyke (2008) Nat Rev Immunol 8(5):349–61)

Mediator	Target cell	Action(s)
Lipoxin A4 (*or aspirin-triggered lipoxin A4*)	Whole Blood leukocyte	Downregulates CD11b/CD18 expression
		Prevents shedding of L-selectin
		Reduces peroxynitrite generation on neutrophils, monocytes, and lymphocytes
	Neutrophil	Stops chemotaxis, adherence, and transmigration
		Stops neutrophil–epithelial cell and neutrophil–endothelial cell interactions
		Blocks superoxide anion generation
		Reduces CD11b/CD18 expression and $InsP_3$ formation
		Inhibits peroxynitrite generation
		Attenuates AP1, NF-κB accumulation, inhibits *IL8* gene expression
	Eosinophil	Stops migration and chemotaxis in vivo
		Inhibits generation of eotaxin and IL-5
	Monocyte	Stimulates chemotaxis and adhesion to laminin without increasing cytotoxicity
		Inhibits peroxynitrite generation
		Reduces IL-8 release by cells from individuals with asthma
	Macrophage	Stimulates non-phlogistic phagocytosis of apoptotic neutrophils
	T cell	Inhibits TNF secretion by blocking ERK activation
		Upregulates CCR5 expression
	Dendritic cell	Blocks IL-12 production
	Epithelial cell	Inhibits TNF-induced IL-8 expression and release in enterocytes
		Inhibits *Salmonella typhimurium*-induced IL-8 production by enterocytes
	Endothelial cell	Stimulates PKC-dependent prostacyclin formation
		Blocks the generation of reactive oxygen species
		Inhibits VEGF-induced endothelial cell migration
	Fibroblast	Inhibits IL-1β-induced IL-6, IL-8, and MMP3 production
		Inhibits CTGF-induced proliferation
Resolvin E1	Neutrophil	Stops transepithelial and transendothelial migration
	Macrophage	Stimulates non-phlogistic phagocytosis of apoptotic neutrophils
	Dendritic cell	Blocks IL-12 production
	T cell	Upregulates CCR5 expression
Resolvin D1	Microglia	Inhibits IL-1β expression
Aspirin-triggered resolvin D1	Neutrophil	Stops transmigration
Protectin D1	Neutrophil	Upregulates CCR5 expression
	Macrophage	Simulates non-phlogistic phagocytosis of apoptotic neutrophils
	T cell	Inhibits TNF and INFγ secretion and promotes apoptosis
		Upregulates CCR5 expression
	Microglia	Inhibits IL-1β expression
	Epithelial cell	Protects from oxidative stress-induced apoptosis in retinal pigment epithelial cells



Resolution of Inflammation, Fig. 2 Scheme of eicosanoid and specialized pro-resolution lipid mediators. *Red* indicates proinflammatory lipid mediators, and *blue* indicates pro-resolution lipid mediator classes (Reproduced with permission, from Fredman and Serhan (2011) Biochem J. 437(2):185–97)

Resolvins, Protectins, and Maresins

Resolvins, protectins, and maresins are synthesized from the marine-derived omega-3 fatty acids eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA) (Fig. 2). These pro-resolution products help explain the mechanisms whereby omega-3 fatty acids – which predominate in oily fish – reduce the severity of inflammatory diseases.

Resolvins

Resolvins are derived from both EPA and DHA as the E-series and D-series, respectively. Like LXs, resolvins are formed by transcellular biosynthesis and include aspirin-triggered epimers that differ only in the stereochemistry at one carbon. EPA is converted to E-series resolvins (RvE1 and RvE2) via initial production of 18R-hydroeicosapentaenoic acid (18-HEPE) that is subsequently transformed by ► neutrophil 5-LOX. DHA is converted to D-series resolvins (RvD1 through RvD4) via the initial production of 17-hydroxyDHA (17-HDHA). Similar to the pro-resolution effects of LXA_4, resolvin E1 exhibits anti-inflammatory effects in rodent models of periodontitis, peritonitis, retinopathy, and colitis (Serhan et al. 2008). Measurable levels of RvE1 are produced in human plasma following acute intake of EPA with or without aspirin.

Protectins

The 17-hydroxyDHA derived from docosahexaenoic acid (DHA) can be converted into the 10,17-dihydroxy compounds known as protectins, which are characterized by conjugated triene double bonds. When produced in neural tissues, the prefix neuro- is added to denote the site of synthesis. Protectins exhibit pro-resolution effects in rodent models of peritonitis, asthma, ischemia–reperfusion injury, retinopathy, and ischemic stroke (Serhan et al. 2008). Reduced concentrations of DHA – and thus (neuro)protectin D1 – have been demonstrated in the brain tissues of patients with Alzheimer's disease.

Maresins

DHA is also converted by macrophage lipoxygenases to 14-hydroxyDHA (14-HDHA) and subsequently to dihydroxy products termed "macrophage mediators in resolving inflammation," or maresins (Serhan et al. 2009). Maresins have pro-resolving properties that are similar to resolvins and protectins.

Aspirin-Triggered Products

Aspirin acetylates COX-2 and causes it to act as a 15-LOX. The combined actions of 5- and 15-LOX result in aspirin-triggered epimers

(stereoisomers that differ only by chirality at one site) of lipoxins, resolvins, and protectins (Serhan et al. 2004; Spite and Serhan 2010; Oh et al. 2011). These compounds differ in their stereochemistry at one carbon: the aspirin-produced compounds have an "R" configuration in contrast to the "S" configuration of the non-aspirin-produced epimers. Production of aspirin-induced resolution products requires sufficient substrate availability (i.e., arachidonic acid, EPA, and DHA). Thus, intake of appropriate fatty acids is also necessary for the optimum benefits of low-dose aspirin used to prevent fatal cardiovascular events (Investigators 1999).

Implications for Disease and Therapeutics

Uncontrolled inflammation drives the pathogenesis of many diseases including arthritis, atherosclerosis, cancer, asthma, neurological disorders (e.g., Alzheimer's disease), periodontal disease, and inflammatory bowel disease. Lipoxins, resolvins, and protectins promote resolution in animal models of oral, lung, ocular, kidney, skin, and gastrointestinal inflammation, as well as in ischemia–reperfusion injury and angiogenesis (Serhan et al. 2008). For example, in a rabbit model of periodontitis, topical treatment of the gums with resolvin E1 prevents alveolar bone destruction and reduces ▶ neutrophil infiltration. Genetic experiments also demonstrate increased production of pro-resolution mediators in association with improved outcomes in several inflammatory conditions.

The multiple potent biological actions of specialized pro-resolution lipid mediators have implications for drug development because pharmacological therapies can interfere with or facilitate resolution. Glucocorticoids and aspirin may enhance resolution, whereas COX-2 inhibitors hinder it. In addition, direct administration of pro-resolution mediators or stable derivatives may promote resolution of inflammation in patients with conditions in which resolution is impaired (Filep et al. 1999). Adverse events due to pro-resolution therapy have not been observed in animal models, which is striking, given the problems associated with treatment with current anti-inflammatory agents.

Biologic disease-modifying antirheumatic drugs; Biological agents

Definition

Biological therapeutics described a family of protein-based therapeutic agents that are designed to specifically target cell membrane expressed, or soluble targets. They may comprise monoclonal antibodies (e.g., fully human, humanized, chimeric, murine), Fab fragments of monoclonal antibodies, or engineered soluble receptors usually with the addition of an Fc fragment. Further chemical modifications may facilitate altered half-life or tissue penetration/retention capabilities, e.g., pegylation.

Pathogenesis of RA: The Starting Point for Biologic Therapeutics

The advent of biologic therapeutic agents in RA has been defined by the remarkable progress in understanding of disease pathogenesis over the last 30 years. The synovial inflammation, bone erosion, and deformity seen clinically in RA represent the end-stage of an ill-defined interplay of the innate and adaptive arms of the immune response, together with complex interactions with stromal cells including fibroblasts, chondrocytes, osteoclasts, endothelial cells, and mesenchymal stem cells. Environment-gene interactions particularly smoking, together with epigenetic alterations and dysregulation of the gastrointestinal and oral microbiome, result in autoimmune responses against altered self-proteins arising from posttranslational modification of arginine to citrulline residues (McInnes and Schett 2011). This transitions to chronic inflammation, leading to articular damage and wider impact including increased vascular risk, depression, to disability, and to significant socioeconomic costs. Increasingly, the critical inflammatory pathways, and the cells that mediate checkpoints in this process, have been identified and in turn become the substrate as targets for a variety of biological therapies.

Background Therapeutic Approach to RA

While new biologic agents have mediated a step change in the treatment of RA, they should not obscure the key foundations of management. It is imperative that RA be treated by a rheumatologist and that decisions made are shared by the patient and aim for best care (Smolen et al. 2010).

In the 1980s, due in no small part to questionable benefits and toxic effects of the available drugs, the management of RA was based upon a concept of working slowly up a treatment pyramid until disease control was achieved. Non-pharmacological measures comprised the first step of management, accompanied by symptomatic relief through prescription of NSAIDs, followed eventually by "trial and error" based introduction of monotherapy, or combinations of titrating doses of an eclectic mix of immune modulatory medications – now referred to as conventional disease-modifying antirheumatic drugs (DMARD). These agents included methotrexate, sulphasalazine, hydroxychloroquine, gold, D-penicillamine and on occasion necessitated use of cytotoxic agents such as azathioprine or even cyclophophosphamide in severe and resistant disease. Outcomes were poor and medications associated with substantial toxicities and attendant morbidity.

The paradigm of management has completely shifted with the acknowledgement that active disease is a sign of ongoing bone erosion and that such bone damage is a significant prognostic factor for future disability. The new imperative is that remission, or at least low disease activity (however measured), is achieved as quickly as possible. Thus, the current concept is one of "inverting the pyramid" (van Vollenhoven 2009), i.e., that the most effective drugs are used quickly to try to establish early remission. Thus, treatment is now driven by early and aggressive intervention with frequent monitoring of therapy, encapsulated in the notion of "Treat to Target." The caveat to this approach is that not all patients with RA require the most potent agent available to induce remission, and a process in which every patient was immediately placed on biologics would potentially expose a significant group of patients to unnecessary toxic and expensive medications with no beneficence (Chatzidionysiou and van Vollenhoven 2011). Thus, new patients with active RA should be placed quickly on a DMARD and monitored frequently (every month if necessary) with escalation of treatment as required.

Methotrexate is the initial DMARD of choice and is considered the "anchor drug" of RA (Smolen et al. 2010). This is because no other DMARD has shown to be superior in effectiveness to it; its long-term and widespread use has resulted in a well-known and acceptable safety profile; and its use in combination with biologic agents is superior to the use of either alone. If there are contraindications/ intolerance of methotrexate, leflunomide, sulfasalazine, or injectable gold can be used as these agents are not known to be less effective than methotrexate. It should also be acknowledged that these three DMARDs can be used in conjunction with methotrexate to attempt to induce remission, but this attempt should not delay the introduction of biologic agents, and combination of DMARD treatments has not been shown to be any more effective than monotherapy while increasing the risk of adverse events. Antimalarial drugs have been shown to be less effective than the other DMARDs, but may be used in combination with other treatments or if the patient has very mild disease and contraindication to all other treatment options. Glucocorticoids have been shown to have an additive disease-modifying benefit and are usually used with DMARDs; however, the appropriate dosing is unknown and their long-term use may lead to significant side effects (Smolen et al. 2010).

It is recognized that RA probably encompasses several different diseases with similar clinical features but different prognoses and responses to treatment. Presence of autoantibodies, a high disease activity measured clinically or by CRP or ESR, and early appearance of erosions, all result in a worse prognosis (Emery et al. 2008). Patients in whom remission has not been achieved within 3–6 months and have these poor prognosis factors should be started upon a biologic agent in addition to methotrexate use, this being more effective than monotherapy with either drug. Without these prognostic factors, a second DMARD may be tried if methotrexate has not produced a response, with a biologic agent started if remission has not been achieved in a further 3–6 months. This approach, however, remains unsatisfactory as it potentially exposes those patients who do not achieve remission on DMARDs to up to 12 months of poorly controlled joint inflammation and damage, which results in an adverse prognosis (Chatzidionysiou and van Vollenhoven 2011). Thus, patients with very active disease, early structural damage, or unfavorable prognostic indicators may be considered for immediate first-line treatment with DMARDs and biologic agents (Emery et al. 2008); however, there is uncertainty whether this provides any more benefit than starting with monotherapy DMARD and switching after 3 months to combination therapy with a biologic agent. The early identification and decision over treatment of these patients is one of the current major rheumatology controversies and challenges.

TNF Inhibitors

The original and most frequent biologic agents licensed for use in RA are those that target TNF. TNF is one of the major drivers of synovial

inflammation: upregulating cytokine and chemokine expression, endothelial cell adhesion molecules, angiogenesis and pain, protecting synovial fibroblasts, and downregulating regulatory T cells (McInnes and Schett 2011). The five anti-TNF agents currently licensed are adalimumab, etanercept, infliximab, certolizumab, and golimumab. All Anti-TNF agents have been shown to be significantly superior clinically, functionally, and radiographically to placebo in patients who fail to respond to methotrexate. Importantly, combination of methotrexate and an anti-TNF agent is superior to either methotrexate or anti-TNF monotherapy. Anti-TNF monotherapy is clinically equivocal to methotrexate monotherapy, and although superior radiographically, still inferior to combination therapy.

The anti-TNF agents are now over a decade old and so have the best-defined safety profile; thus, they are usually the first biologic agent of choice. There have been few comparisons between biologic agents. One of the few trials comparing anti-TNF agents with other biologics, however, found that abatacept (see below) was at least as efficacious and offered a satisfactory safety profile. Due to lack of efficacy or intolerance, approximately one third of patients will discontinue their first biologic agent within a year. There is little evidence that increasing the dose of a TNF inhibitor leads to any significant clinical improvement, while it may increase the risk of adverse effects, the cost, and, in theory, can introduce delay until a patient achieves benefit from another agent. In contrast, there is evidence that switching between biologics of distinct mode of action is effective, and so this should be the next step in management once a patient fails their initial biologic agent. Some advocate that patients that fail a TNF inhibitor for an adverse event, or from gradual loss of effect (e.g., through anti-drug antibodies forming) may benefit from a trial of a second TNF targeting agent.

Other Available Biologic Agents

The focus on pathogenesis lead discovery has facilitated introduction of biologic agents that target other molecular pathways that are active in the RA lesion. Three other biologic agents are currently widely accepted, whereas a fourth, that targets IL-1 (anakinra), is now rarely used. Thus, tocilizumab, abatacept, and rituximab comprise the newest additions to the RA therapeutic armamentarium. All three agents have been shown to be significantly effective compared with placebo in patients who have not responded to anti-TNF therapy (van Vollenhoven 2009).

Tocilizumab is an antibody that binds the IL-6 receptor. IL-6 is the second major cytokine that has so far been successfully targeted in RA. It is responsible for activation of leucocytes and production of autoantibodies, while mediating systemic effects promoting the acute phase response, anemia, lipid metabolism dysregulation, and cognitive dysfunction (Chatzidionysiou and van Vollenhoven 2011). Tocilizumab mediates outcomes that are broadly similar to those achieved with TNF inhibitors in terms of magnitude and frequency of response. Some initial trials appear to indicate that it may induce a higher rate of remission compared with anti-TNF agents (Smolen et al. 2010); there is also now evidence that it may serve as well given as monotherapy as when administered with methotrexate.

Abatacept disrupts the interaction of the innate and adaptive immune systems as it contains a recombinant form of CTLA4 that prevents costimulation of the T cell during antigen presentation. T cells of type 17 and type 1 subset derivation are abundant in the synovial tissue of an inflamed joint, and T cells against citrullinated self-proteins have been described, suggesting that such pathways may be of pathogenetic importance (McInnes and Schett 2011). Mature T cells can exert cytotoxic effects, but more importantly, Th1 and Th17 cells further stimulate the innate immune response and host target tissues, e.g., fibroblasts, chondrocytes, and osteoclasts through release of cascades of pro-inflammatory cytokines. Abatacept appears to have a slower onset of action than anti-TNF agents, but seems to be clinically equivocal to the anti-TNF drugs in terms of magnitude and frequency of response.

Rituximab is an antibody against B cells, targeting CD20; administration in two pulses separated by 14 days results in effective B cell and plasmablast depletion. B cells are found in

T-cell-B-cell aggregates in the synovium, and their derivatives, plasma cells and plasmablasts, are found throughout the synovium and bone marrow (McInnes and Schett 2011). Although classically thought to be predominantly involved in inflammation through antibody formation, their more significant role in RA may be for autoantigen presentation and the production of inflammatory cytokines. Plasma cells are typically CD20 negative and as such, these cells are spared in rituximab treated patients. Rituximab appears to have similar clinical efficacy to the anti-TNF agents.

While anakinra, which binds the IL-1 receptor, was designed to be one of the biologic agents for treatment of RA, it has not shown a high level of clinical efficacy despite the prevalence of IL-1 in the inflammatory process. This is thought to probably be due to functional redundancy of IL-1 driven pathways in the autoimmune process. Anakinra is therefore not recommended as a major biologic option in RA.

Adverse Effects of Biologic Agents

The most common adverse effects of the biologic agents comprise injection site reactions or infusion reactions. More important from a clinical perspective, their effects on suppressing the immune system can result in an increased frequency of infections, particularly in the first 1–2 tears of receipt of therapy with a given agent. They are thus contraindicated in active infection, and there is relative contraindication for those with recurrent infections (Chatzidionysiou and van Vollenhoven 2011). In particular, the anti-TNF agents have been shown to reactivate TB (Gomez-Reino et al. 2003) and a range of other mycobacterial species with potentially lethal consequences – this has subsequently been demonstrated to be due to the dissolution of the granuloma that encases mycobacterial species within a granuloma in quiescent TB. Thus, it is vital that tuberculous prophylaxis be offered in patients with latent TB before any of the biologic agents are initiated. Rituximab, due to its effects on B cells, can lead to the reactivation of viral infections, including hepatitis.

Due to the suppression of the immune system, there is the theoretical risk that the biologic agents may increase the risk of malignancy by decreasing immunosurveillance and the destruction of neoplastic cells. Current malignancy remains an absolute contraindication, and prior malignancy is a relative contraindication – use of the biologics is sometimes considered depending on the severity of arthritis (Chatzidionysiou and van Vollenhoven 2011).

There is also the potential for the anti-TNF agents to trigger psoriasis, or more rarely SLE-like syndromes and very rarely, demyelinating disease. The anti-TNF agents and tocilizumab are thus contraindicated in patients with demyelinating disease, although rituximab and abatacept may be used. Rituximab has been shown to cause a small number of cases of progressive multifocal leukoencephalopathy. Due in part to IL-6's systemic effects, tocilizumab can cause several biochemical abnormalities, including neutropenia, thrombocytopenia, transaminitis, and hyperlipidemia, and has rarely been found to cause gastrointestinal perforations. The hyperlipidemia is an increase in total LDL and HDL cholesterol, and does not appear to change the atherogenic index, although its long-term implications are unknown (Chatzidionysiou and van Vollenhoven 2011).

There is little information surrounding the teratogenicity of biologic agents, so they are currently contraindicated in pregnancy and lactation. The biologic agents, except for abatcept, are also contraindicated in moderate-severe heart failure despite a paucity of good data (Chatzidionysiou and van Vollenhoven 2011).

When Biologic Agents Should Be Withdrawn?

Due to the adverse event potential of the biologic agents, their cost, and the principle that no patient should necessarily be reliant upon life-long medication, the ultimate aim of treatment should be drug withdrawal when safe and feasible. One of the major challenges in rheumatology today is to identify those patients in which this is a reasonable and safe approach.

Conclusion

Biologic agents have dramatically improved the treatment of RA over the last few years, but this should not obscure some of the other underlying principles of management nor the role that other medications have to play, especially in combination with biologic agents. It must also be acknowledged that although biologic agents have made the remission the target for many patients, the majority will not achieve this. With the introduction of new biologic agents, and more information about the use of current biologic agents, this target should be achievable for more patients. When a biologic agent should be started, and which patients should receive it earlier; which biologic agent should be started first, which should be switched to if this fails, which is most efficacious with the lowest adverse events, and does this change with different patients; and can a biologic agent be stopped, all these are just some of the challenges that the introduction of biologic agents has posed for the next few decades to come.

Division of Clinical Immunology and Rheumatology, University of Alabama at Birmingham, Birmingham, AL, USA

Synonyms

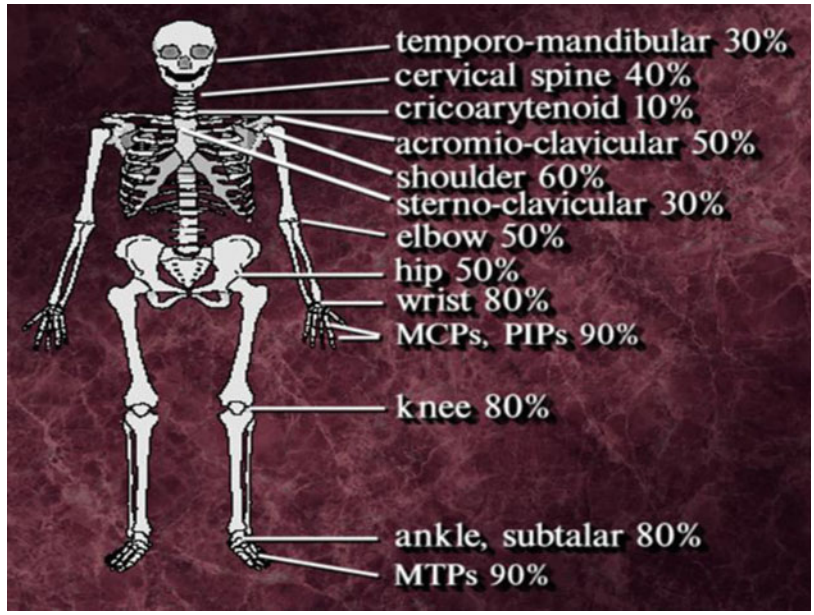
RA; Rheumatoid arthritis

Definition

Rheumatoid arthritis (RA) is a chronic, systemic, inflammatory disease of unknown etiology that affects the small and large joints in a symmetric fashion. Untreated, RA may lead to deformities and bony destruction of joints and the surrounding soft tissue structures in many patients. Subtypes of RA include patients who are seronegative for rheumatoid factor, lack joint erosions, and have a significantly better prognosis.

Introduction

RA is a systemic disease that predominately affects the joints but is a systemic illness leading to a number of extra-articular manifestations (see entry "▶ Rheumatoid Arthritis, Extra-articular Manifestations"). Patients with RA experience joint pain, swelling, stiffness, loss of mobility, decreased ability to perform activities of daily living (ADLs), as well as constitutional



Rheumatoid Arthritis, Clinical Features, Fig. 1 Joints distribution in RA. *MCP* metacarpophalangeal, *PIP* proximal phalangeal, *MTP* metatarsophalangeal

symptoms. This entry reviews the clinical features of this disease, particularly those affecting the joints and surrounding soft tissue structures.

Major Clinical Features

Constitutional Symptoms

Weakness, fatigue, weight loss, anorexia, and even low-grade fevers occur in patients with RA, particularly those with very active disease. These symptoms are nonspecific and can precede the onset of arthritis by months.

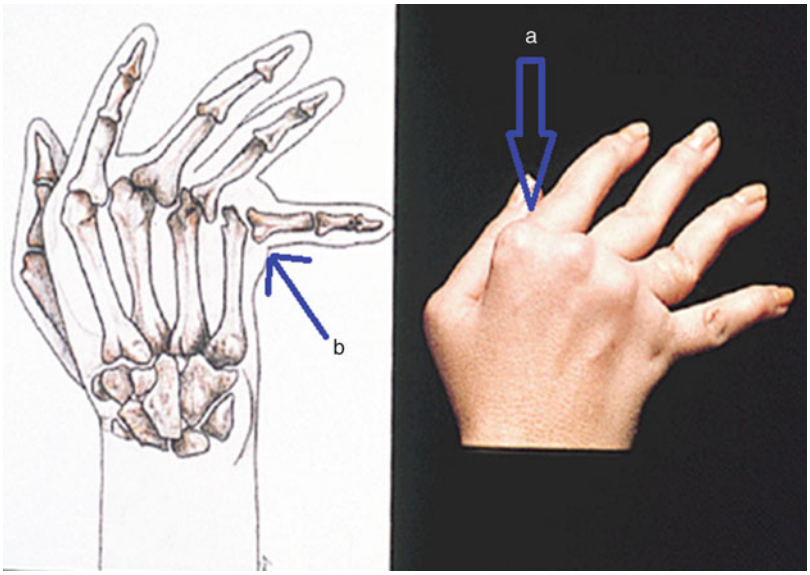
Stiffness

A hallmark feature of patients with active RA is generalized morning stiffness. Patients describe it as difficulty moving their joints after waking up, difficulty getting out of bed, and inability to start their morning activities. Morning stiffness in RA typically lasts for at least 1 hour when disease is active. This contrasts with the stiffness associated with osteoarthritis (OA), which is typically much more transient. Although it is rather subjective, the duration of morning stiffness may be useful in following RA disease activity (Lineker et al. 1999). Patients with RA also report "gelling" of their joints with inactivity, such as when sitting for an extended period of time. The key symptoms and physical signs based on the joints most commonly affected by RA will be described below.

Joint Manifestations

Rheumatoid arthritis typically affects peripheral diathrodial joints in a symmetric fashion. However, the symmetric joint involvement may be less evident early in the disease course.

RA may first manifest as a monoarthritis (involvement of one single joint), usually in a large joint. Monoarthritis tends to develop into polyarthritis within weeks or months, and ultimately RA affects small, medium, and large joints throughout the body (Fig. 1). RA causes pain, swelling, erythema (redness), and tenderness in the joints. The swelling occurs in the soft tissues around the joint (tenosynovitis) and/or in the joint space itself (synovium). Synovitis (inflammation of the normally thin lining of the joint) causes a "sponginess" or "bogginess" felt by the examiner and usually leads to pain when the joint is squeezed or moved. The joints also may feel warm on manual palpation. RA joint inflammation leads to a loss of mobility (range of motion) and a subsequent decline in ADLs and health-related quality of life. Although a trained



Rheumatoid Arthritis, Clinical Features, Fig. 2 Ligamentous laxity resulting in characteristic volar subluxation (*a*) and ulnar deviation (*b*) (© 2013 American College of Rheumatology. Used with permission)

examiner can usually identify joint swelling, tenderness, and painful range of motion, patients are often less accurate in differentiating joint swelling from tenderness, especially early in the disease course. This difficulty in differentiating pain alone from actual joint swelling (a hallmark of RA) often complicates or delays the diagnosis and assessment of disease activity. As RA progresses, particularly if inadequately treated, it may lead to fixed deformities in the joints.

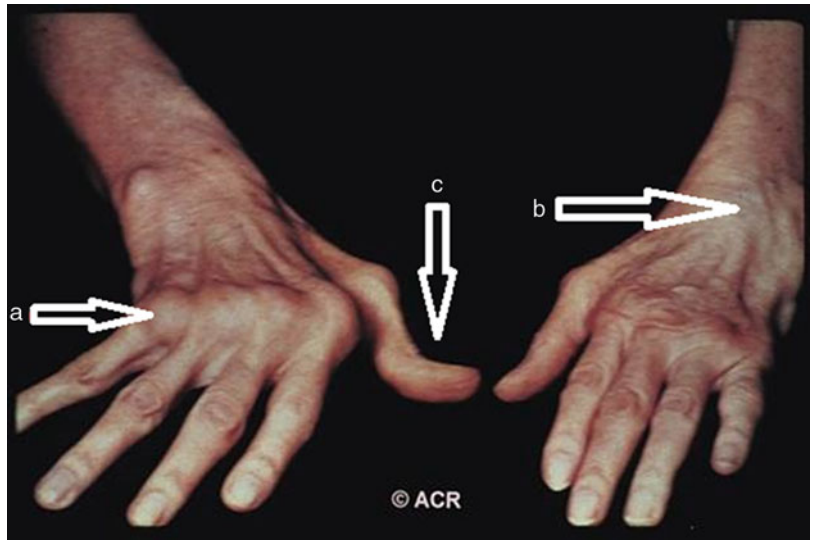
Hands and Wrist

The hands and wrists are affected in virtually all RA patients. The metacarpophalangeal (MCPs) and proximal interphalangeal (PIP) are involved in nearly all patients, whereas the distal interphalangeal (DIPs) joints are rarely involved. Swelling leads to diminished hand closure and grip strength coupled with pain and reduced ability to perform simple manual tasks such as eating, opening jars, and personal hygiene. Radial deviation at the wrist can occur with protracted inflammation. This is commonly associated with ulnar deviation of the digits (the metacarpal bones) (Fig. 2). This, along with palmar subluxation of the proximal phalanges, may lead to a "Z-deformity" of the thumb (Fig. 3). Other common deformities of the hands are volar (palmar) subluxation of the carpus bones on the wrist, bow string sign (prominence of the extensor tendons of the hands), swan-neck deformity of the digits (hyperextension of the proximal interphalangeal joints with compensatory flexion of the distal interphalangeal joints) (Fig. 4), boutonniere deformity (flexion contracture of the proximal interphalangeal joints and extension of the distal interphalangeal joints), and prominence of the ulnar styloid with hypermobility (piano key deformity).

RA complications in the hands include (1) carpal tunnel syndrome (this results from synovitis in the wrist, causing the median nerve to be compressed and leading to symptoms of numbness and tingling in digits 1–3 (and the radial aspect of the 4th digit) and eventual weakness in the hand (affecting the thenar eminence and the thumb)) and (2) extensor tendon rupture (this occurs in patients with significant dorsal tenosynovitis). Radiocarpal subluxation and tendon rupture lead to inability to extend the fourth and fifth digits (Fig. 5) (Fleming et al. 1976).

Knees

Inflammation of the knees causes swelling and pain. Knee symptoms are some of the most debilitating of RA due to their effects on standing and gait. Synovitis and a synovial joint effusion can usually be easily detected on physical



Rheumatoid Arthritis, Clinical Features, Fig. 3 Prominent ulnar deviation in the right hand, metacarpophalangeal (*MCPs*) (*a*), and proximal interphalangeal (*PIP*) swelling in both hands and synovitis of left wrist (*b*) and Z-deformity of the right thumb (*c*) (© 2013 American College of Rheumatology. examination and do not require advanced imaging in most cases. A fluid wave ("bulge sign") and a "ballotable" patella are key findings on the examination. A complication of a large or protracted knee effusion is a popliteal synovial cyst, also known as Baker's cyst. Baker's cysts manifest as swelling in the back of the knee and are not specific to RA. In RA, popliteal cysts occur secondary to knee joint inflammation and the popliteal space communicates with the articular space. Most popliteal cysts are small and asymptomatic, but they can lead to knee pain and stiffness and restricted mobility. If the cyst is big and compressing adjacent structures, it might resemble a deep venous thrombosis.

Feet and Ankles

Beyond the hands and knees, the small joints in the feet, particularly the metatarsophalangeal (MTP) joints, are affected in nearly all patients with RA (Fig. 1). This results in painful ambulation, and the sensation of "walking on marbles." MTP involvement can lead to "cock-up" deformities of the toes (Fig. 6). Other foot deformities include widening of the forefoot, hallux valgus,

lateral deviation, and dorsal subluxation at the toes (Fig. 7). The ankle and the talonavicular joints are also commonly affected in RA.

Hips

The hip joints are less commonly affected in RA than are the other large joints. When RA significantly affects the hip, it occurs later in the disease course. Earlier in RA, hip involvement is usually asymptomatic. An RA patient with significant hip involvement might experience groin pain, which further can be elicited on hip range of motion on physical examination (particularly a restriction in internal rotation). However, it is hard to detect synovial inflammation of the hip by physical examination alone.

Rheumatoid Arthritis, Clinical Features, Fig. 6 Cock-up toe deformities of the foot. (© 2013 American College of Rheumatology. Used with permission)

Shoulders

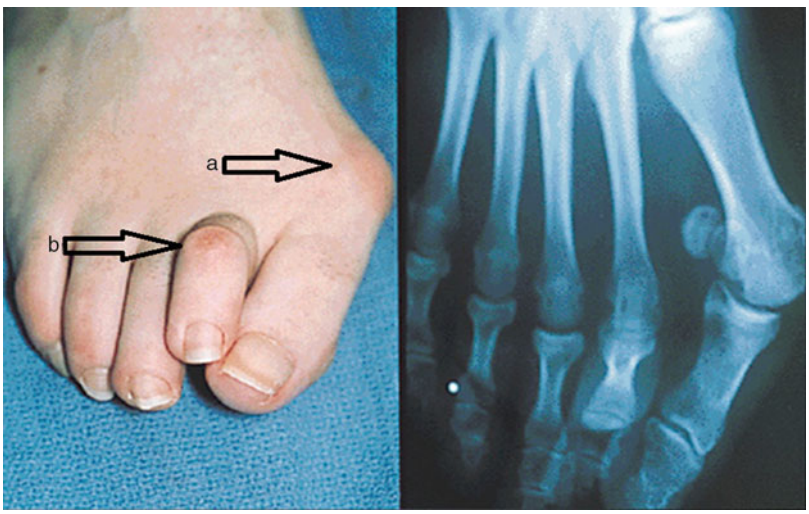
RA patients commonly experience pain and decreased range of motion in the shoulder region due to involvement of the glenohumeral joint. It is sometimes hard to appreciate a joint effusion on physical examination unless it is large, in which case a ballotable, anterior bulge may be appreciated.

Elbows

RA elbow involvement leads to pain, swelling, and loss of elbow flexion, extension, and pronation/supination. When the elbows are affected, it is usually appreciated on physical examination. Flexion deformities can develop later in the disease course and are manifest as inability to fully extend the elbows. Complications of RA elbow involvement include nerve entrapments around the elbow due to joint inflammation (leading to tingling, numbness, and weakness in the forearm and hand).

Cervical Spine

Axial skeletal involvement in RA is usually limited to the upper cervical spine. Typically, even moderate atlantoaxial RA is relatively asymptomatic and is seldom detected until neurologic



Rheumatoid Arthritis, Clinical Features, Fig. 7 Hallux valgus (first toe) (*a*) and hammer toe (second toe) (*b*). (© 2013 American College of Rheumatology. Used with permission)

symptoms develop (which may follow neck trauma). Symptoms of RA cervical involvement can include neck pain radiating to the occiput, sensory loss, and paresthesias (abnormal sensation such as tingling). Patients may describe a sensation of their head falling forward off their neck, if significant atlantoaxial laxity is present. RA neck disease is a potentially serious complication and it can lead to severe atlantoaxial subluxation (a misalignment of the first 2 cervical vertebrae). This complication can cause spinal cord compression (manifest as quadriparesis or paraparesis, sphincter dysfunction, sensory deficits, and/or transient ischemic attack due to compromise of the vertebral arteries) requiring immediate intervention (Neva et al. 2003).

Extra-articular Manifestations

Some of the most common extra-articular manifestations include rheumatoid nodules (subcutaneous nodules that are common on pressure points) (Fig. 8), skin ulcers due to vasculitis (inflammation of the vessels), eye involvement (e.g., episcleritis or scleritis, both of which are considered medical urgencies), Sjogren's syndrome (manifest as dry eyes and dry mouth), and RA lung involvement (interstitial and pleural lung disease). The extra-articular manifestations are discussed in more detail elsewhere (Sayah and English 2005).

RA Comorbidities

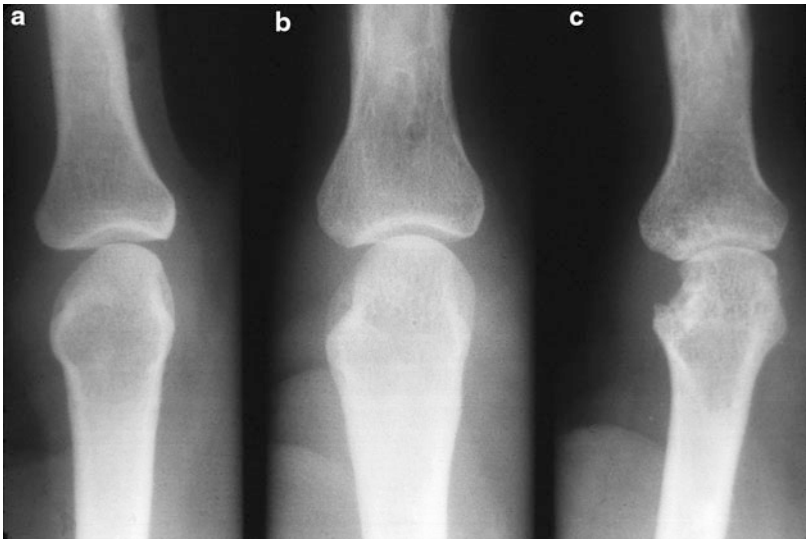
There is an increased risk of serious comorbidities in patients with RA. The most common conditions leading to the comorbidity of RA are:

(a) Infection: there is an increased risk of infection in patients with RA mediated in part by use of immunosuppressive medication as well as from immunosuppression by the disease itself (Doran et al. 2002).
(b) Cardiovascular disease: there is an increased risk of cardiovascular disease in patients with RA, mostly related to RA disease activity and chronicity (Gabriel 2010). Use of glucocorticoids may also play a role.
(c) Renal disease: this is uncommon but includes secondary amyloidosis, membranous nephropathy, NSAIDs (nonsteroidal anti-inflammatory drugs)-induced nephrotoxicity, and focal mesangial proliferative glomerulonephritis (Helin et al. 1995).
(d) Lymphoproliferative disorders: there is an increased incidence of lymphoma and leukemia in patients with RA. The most common type of lymphoma is diffuse large B cell type (Baecklund et al. 2006).

Rheumatoid Arthritis, Clinical Features, Fig. 8 Subcutaneous rheumatoid nodules at the elbow (© 2013 American College of Rheumatology. Used with permission)

Radiological Features

Early in the disease course, radiologic findings mostly reflect findings on physical examination: soft tissue swelling and joint effusions. With RA disease progression, radiologic findings include joint space narrowing due to loss of articular cartilage, which can be seen quite characteristically in the digits (Fig. 9), juxtaarticular osteopenia (loss of bone density around the joint), and bone erosions, which are usually marginal and can be seen in the digits (Fig. 9) and ulnar styloid (Fig. 10). Advanced RA disease in the hands is shown radiographically in Fig. 11. In the knees, cartilage loss affects both medial and



Rheumatoid Arthritis, Clinical Features, Fig. 9 (**a**) Soft tissue swelling. (**b**) Thinning of the radial side of the cortex with minimal joint space narrowing. lateral compartments equally leading to joint space narrowing; this helps distinguish it from cartilage loss due to OA, which more commonly affects medial compartment first (Fig. 12). In the hip there is an axial or medial migration of the femoral head into the acetabulum. Atlantoaxial subluxation (described above) and cranial settling can be seen on a cervical spine radiograph (flexion/extension view), but cervical magnetic resonance imaging (MRI) or computerized tomography (CT) may be required to assess more carefully.

Classification Criteria

Because there is not one unique symptom, physical examination finding, or laboratory test that is the sine qua non of the RA diagnosis, classification criteria are useful for considering the key features of RA that constitute a case definition useful for clinical research studies. Although these criteria are largely for the purposes of clinical trials, they may also serve as a guide for clinical diagnosis. The American College of Rheumatology (ACR) and European League

Against Rheumatism (EULAR) developed revised criteria in 2010 for the classification of RA. In order to classify patients with RA, a patient should have at least one joint with synovitis (as long as there is no alternative explanation for the synovitis) and a total score of at least 6 out of 10 from four categories: joint number and distribution, serology, symptom duration, and acute phase reactants (Table 1) (Aletaha et al. 2010).

Differential Diagnosis

Many conditions should be considered in the differential diagnosis of RA. The most common is OA and factors that help differentiate RA from OA are listed in Table 2. Other conditions that may mimic RA and ways to distinguish them from RA (in parenthesis) include acute viral polyarthritis (most commonly due to rubella, parvovirus B19, HBV, and HCV and usually self-limiting), systemic lupus erythematosus (does not cause joints erosions and has more systemic extra-articular manifestations), inflammatory bowel disease-associated arthritis (patients have either Crohn's disease or ulcerative colitis and the arthritis typically affects the spine and sacroiliac joints, mostly large joints, and is often asymmetric), psoriatic arthritis (patients have psoriatic skin lesions, nail pitting, sausage digits, and sometimes spinal involvement), Lyme arthritis (a late manifestation of Lyme disease, usually presents as monoarthritis of the knee and typically does not cause joint destruction and there should be a history of tick exposure and an antecedent rash), gout and pseudogout (crystals are seen under polarized microscope in affected joints, serum urate is usually elevated, and polyarthritis is proceeded by a protracted period of episodic mono or oligoarthritis in gout), septic arthritis (usually monoarticular, especially

Large joints: shoulders, elbows, hips, knees, and ankles; small joints: metacarpophalangeal joints, proximal interphalangeal joints, second through fifth metatarsophalangeal joints, thumb interphalangeal joints, and wrists; *RF* rheumatoid factor, *CCP* cyclic citrullinated peptide, *ESR* erythrocyte sedimentation rate, *CRP* C-reactive protein

In order to classify patients with RA, they should have at least one joint with synovitis (as long as there is no alternative explanation for the synovitis) and a total score of at least 6 out of 10 points

involving the knee, with fevers, more significant constitutional symptoms, and commonly an infectious prodrome), and polymyalgia rheumatica (in older adults with acute and profound muscle pain in the shoulders and hip girdle) (Pease et al. 2009; Smith et al. 1987).

Assessment of Disease Activity

There are a variety of well-tested measures that are used in research and, increasingly, in clinical practice to quantitate the extent of disease activity and its response to treatment. Patients should be evaluated with the same disease activity measure at each visit. Some of these measures include (1) Disease Activity Score (DAS) 28 (this measure calculates the number of swollen and tender joints out of total 28 joints and uses either C-reactive protein or erythrocyte sedimentation rate in the calculation) (Table 3 shows DAS28 scores and corresponding disease activity), (2) Simplified Disease Activity Index (SDAI) (uses the C-reactive protein in the calculation), and (3) Clinical Disease Activity Index (CDAI) (a more simplified SDAI version and does not require an acute phase reactant in the calculation). The goal for each RA patient should be low disease activity or remission. In ideal

Rheumatoid Arthritis, Clinical Features, Table 2 Differentiating rheumatoid arthritis (*RA*) from osteoarthritis (*OA*)

	RA	OA
Age of onset	Starts in early adulthood; peak incidence within the fourth and fifth decades	Increases with age
Risk factors	HLA DR4, smoking	Trauma, sports injury, orthopedic procedures (post -arthroscopy), age
Early symptoms	Morning stiffness	Pain increases with use and as day progresses
Joints involved	MCPs, PIPs, wrists; not usually DIPs	DIPs, PIPs, base of thumb (CMCs), knees, hips, L-spine, C-spine
Physical exam findings	Soft tissue swelling, warmth, synovitis, tenderness	Osteophytes, bony enlargement, often nontender
Radiographic findings	Periarticular osteopenia, erosions	Osteophytes, subchondral sclerosis, asymmetrical joint space narrowing
Laboratory findings	Increase in ESR and CRP, rheumatoid factor (RF), white blood cell count, and anti-CCP antibodies; anemia	Normal results

HLA human leukocyte antigen, *MCP* metacarpophalangeal, *PIP* proximal interphalangeal, *DIP* distal interphalangeal, *CMC* carpal metacarpal, *ESR* erythrocyte sedimentation rate, *CCP* cyclic citrullinated peptide

Rheumatoid Arthritis, Clinical Features, Table 3 Disease Activity Score (*DAS*) 28 score and corresponding disease activity

	DAS28
High disease activity	>5.1
Moderate disease activity	3.2–5.1
Low disease activity	2.6–3.2
Remission	<2.6

The equation includes swollen joint count (0–28), tender joint count (0–28), erythrocyte sedimentation rate (*ESR*) or C-reactive protein (*CRP*), and visual analogue scale (*VAS*) for general health assessment (0–100 mm)
Joints involved in the equation are shoulders, elbows, wrists, metacarpophalangeal, proximal interphalangeal, and knees

circumstances, RA remission should be the target of therapy, but in others, low disease activity may be an acceptable target. A joint ACR/EULAR task force defined remission as a tender joint count, swollen joint count, C-reactive protein (mg/dl) level, and patient global assessment of $\leq$1 each or a simplified Disease Activity Score of $\leq$3.3 (Felson et al. 2011).

Prognosis

The course of RA is highly variable and difficult to predict. Historically, there has been an increase in mortality rate and a reduced median life expectancy of patients with RA if the disease is untreated, estimated at between 8 and 10 years of reduced life expectancy (Erhardt et al. 1989). RA itself accounts for 30 % of this increased mortality, while the remainder is due to other factors, particularly infection and gastrointestinal bleeding. If the disease is untreated, joint damage caused by RA can lead to functional disability and, in many cases, the inability to perform ADLs or work tasks.

The presence of one or more of the following implies a poor prognosis: (1) the presence of >20 inflamed joints, (2) radiographic evidence of bone erosions, (3) rheumatoid nodules, (4) high titers of serum rheumatoid factor or anti-CCP, and (5) older age (Saag et al. 2008). Additional factors that also have been linked to worse outcomes defined by early disability and morbidity include (1) female sex, (2) presence of the shared epitope (HLA DR-B1), (3) poor results on the Health Assessment Questionnaire (HAQ), and (4) cigarette smoking. A plethora of effective treatment options (see entry "▶ Rheumatoid Arthritis, Treatment") has significantly modified the natural history of RA leading to improved short- and longer-term outcomes.

Rheumatoid Arthritis, Extra-articular Manifestations

Dimitrios A. Pappas and Joan M. Bathon
Department of Medicine, Division of Rheumatology, Columbia University Medical Center College of Physicians and Surgeons, New York, NY, USA

Synonyms

RA complications; RA extra-articular features; RA extra-articular signs; Extra-articular involvement of RA; Nonarticular manifestations of RA, Systemic manifestations of RA

Definition

The term "extra-articular manifestations of rheumatoid arthritis" refers to involvement with disease of tissues and organs outside the joints. It is believed that the same or similar cytokine pathway that drives synovitis may be the culprit for the involvement of extra-articular structures. Extra-articular involvement usually occurs in active, severe, and long-standing articular involvement.

Introduction

Rheumatoid arthritis (RA) is an inflammatory disease manifesting primarily with joint inflammation which if not treated early and aggressively leads to articular destruction and decreased functionality.

Less commonly RA is complicated by involvement of organ systems other than the skeletal. Most organ systems may be affected to the degree that RA could be viewed not as a "purely" joint disease but as a multisystem entity. Some of these extra-articular manifestations have a significant impact on overall prognosis, are associated with more active articular disease, and correlate with worse morbidity and higher mortality.

Traditional reference textbooks would provide an extensive list of extra-articular RA manifestations spanning from most common to the rare ones. In this entry, an exhaustive description of each individual extra-articular manifestation reported in the literature will not be attempted. Instead, the most frequently encountered and the ones associated with grave prognosis and worse overall outcomes will be described. While overall the occurrence of extra-articular manifestations has not declined in the recent years (Turesson et al. 2004), there is evidence that more aggressive therapy of rheumatoid arthritis may have contributed to a lower incidence of the most serious ones (Bartels et al. 2010).

Rheumatoid Nodules

Rheumatoid nodules are the most common cutaneous manifestation in patients with rheumatoid arthritis (Turesson and Jacobsson 2004). They manifest as subcutaneous firm growths on the extensor surface of extremities or joints (olecranon, extensor surface of forearm, achille tendon) and at pressure points (sacrum or occiput). Contrary to tophaceous growths, they are attached to the underlying periosteum. Rheumatoid nodules are almost exclusively encountered in patients with seropositive disease and associate with active erosive disease, smoking, and a higher likelihood of development of other extra-articular manifestations (Nyhall-Wahlin et al. 2011). Occasionally, they can appear in internal organs such as the lungs but also in other tissues (heart, meninges, and larynx).

Pathologically, they represent granulomata with fibrinoid necrosis in the center – frequently with evidence of small vessel vasculitis – surrounded by palisading macrophages and lymphocytes (Palmer et al. 1987).

Treatment with methotrexate – and less frequently other DMARDs – can occasionally be associated with new nodules or an increase in number and/or size of nodules –a condition called methotrexate-induced accelerated nodulosis – but a causality link has not been established with certainty (Patatanian and Thompson 2002). It can occur even after response of polyarthritis to therapy and also in seronegative patients (Kerstens et al. 1992).

Hematologic Abnormalities

Anemia of chronic disease – also referred to as "anemia of (chronic) inflammation"– is frequently encountered in patients with active articular disease along with frequent reactive thrombocytosis. Both abnormalities can improve with treatment of joint disease with anti-inflammatory and disease-modifying anti-rheumatic drugs (DMARDs).

Leucocytosis may accompany steroid treatment or be indicative of underlying infection in this frequently immunocompromised population. Cytopenias may represent bone marrow suppression due to DMARD treatment.

Felty's syndrome consists of neutropenia usually with detectable splenomegaly and occasionally accompanied by lower extremity skin ulcerations or concurrent thrombocytopenia. It is only rarely encountered – less than 1% – and is usually seen in long-standing seropositive nodular erosive disease (Goldberg and Pinals 1980) and much less frequently at RA presentation or with inactive or "burned out" disease (Balint and Balint 2004). It is associated with a higher risk for the development of other extra-articular manifestations (Goldberg and Pinals1980). The major concern when Felty's syndrome occurs is infections due to neutropenia.

Multiple possible mechanisms may participate in the pathogenesis of neutropenia in Felty's syndrome ranging from impaired granulopoiesis (due to antibody-mediated inhibition of granulocyte colony–stimulating factor, a maturation arrest in the bone marrow) to increased destruction of neutrophils in the periphery (due to immune complex–mediated reduced survival of neutrophils, or destruction via anti-granulocyte antibodies and sequestration in the spleen) (Rosenstein and Kramer 1991). Bone marrow examination usually demonstrates normal myeloid cellularity with maturation arrest in most of the cases (Rosenstein and Kramer 1991). HLA DR4 antigen is present in higher frequency in patients with Felty's syndrome than it is for the general RA population (Dinant et al. 1980).

Treatment for Felty's syndrome consists of treatment with DMARDs in the same manner active joint disease would be treated, which in most of the cases is simultaneously present with Felty's. Methotrexate is the most frequently used agent while other agents have been used such as leflunomide, sulfasalazine, plaquenil, or gold (Rashba et al. 1996). Steroids have and can be used but the concern of increasing the risk of an infection or further immunosuppressing already infected patients may complicate the therapeutic approach. In cases of significantly low neutrophils and fear of or recurrent infections, granulocyte colony–stimulating factor (G-CSF) can be attempted (Krishnaswamy et al. 1996) although reports mention an increased risk for a flare in articular disease. Resistant cases can be treated with splenectomy. Newer biologic therapies have been tried in case reports and series but have not been proven to be consistently effective (Narvaez et al. 2012).

Large granular lymphocyte syndrome (LGL) is an entity with several similarities to Felty's syndrome– sometimes called pseudo-Felty's syndrome – but also with distinct differences. In LGL, an expansion of a clonal cytotoxic T-lymphocyte – or less commonly natural killer cells (Loughran et al. 1993) – expressing a distinct set of surface markers is present and is accompanied by neutropenia and splenomegaly. There is peripheral lymphocytosis in contrast to Felty's syndrome, and frequently, the total WBC count is normal. The bone marrow is infiltrated

with lymphocytes, and anemia and thrombocytopenia are common. LGL is not associated with erosive arthritis or other extra-articular manifestations, and it frequently presents concurrently with RA. Due to neutropenia, recurrent infections are common. Patients may die from lymphoproliferative disease/leukemia (Lamy et al. 2003). While splenectomy is a therapeutic modality for Felty's syndrome, it can exacerbate LGL. Treatment for LGL syndrome is otherwise similar to this for Felty's syndrome (Rosenstein and Kramer 1991).

Patients with RA are at increased risk for lymphoproliferative malignancies and in particular non-Hodgkin's lymphoma – most commonly large-cell B-cell lymphoma – compared to the general population (Wolfe et al. 2004). The question as to whether the disease itself or treatment with nonbiologic or biologic DMARDs is responsible for this increased risk is still being debated (Wolfe et al. 2004).

Eye Involvement

The most frequent manifestation of RA in the eye is xerophthalmia resulting in keratoconjunctivitis sicca. Patients complain of dry eyes, a sensation of foreign body in the eye, burning, and possibly photophobia. The severity of isolated dry eyes does not seem to correlate with RA disease activity. However, secondary Sjogren's syndrome (sicca accompanied by xerostomia) is most frequently encountered in patients with active uncontrolled RA (Fujita et al. 2005).

Diagnosis of sicca is assisted by slit lamp examination and a Schirmer's test. In cases where keratoconjunctivitis sicca is not associated with active RA, symptomatic treatment with artificial tears or oral cholinergic/muscarinic agents is beneficial. Topical cyclosporine is also used although it may take several weeks before the effect becomes apparent (Barber et al. 2005). In resistant cases, punctal occlusion is offered as a therapeutic option. In the cases of secondary Sjogren's associated with active RA, treatment directed to controlling synovial inflammation may offer control of xerophthalmia symptoms.

Episcleritis presents in less than 1 % of the RA patients and manifests with a red eye accompanied by a dull orbital ache but usually with preserved vision. In contrast with scleritis – described below – episcleritis is a benign and usually self-limited entity which may be treated with topical or oral anti-inflammatory agents or steroids.

Scleritis is seen less commonly but is a serious ocular manifestation associated with grave prognosis as it may threaten the vision. It is usually associated with uncontrolled articular inflammation and sometimes with the coexistence of other extra-articular manifestations including vasculitis (Watson and Hayreh 1976). It frequently presents bilaterally which is in contrast with scleritis in the general non-RA population (Fujita et al. 2005). Patients have severe pain, a red eye, and photophobia. If left untreated, scleritis may lead to severe damage of the sclera and scleromalacia. Treatment for scleritis consists of topical anti-inflammatory and steroid agents in combination with systemic steroid-sparing agents. For mild cases, oral NSAIDs can be used but frequently an increase in the dose of methotrexate or initiation of more potent agents such as cyclophosphamide with high dose steroids may be needed. Multiple other agents have been employed in the treatment of scleritis including the newer biologic agents such as TNF-α inhibitors (Theodossiadis et al. 2007).

Less frequent eye manifestations comprise a wide spectrum of diseases including uveitis, ulcerative keratitis, scleromalacia perforans (a condition of necrotizing scleritis without inflammation which leads to thinning of the sclera without symptoms or redness), and also complications relating to treatment with hydroxychloroquine which can cause both retinopathy and keratopathy or steroids which may increase the intraocular pressure leading to glaucoma or cataracts.

Vasculitis

Rheumatoid vasculitis (RV) is the most serious extra-articular manifestation of RA. In fact

a vasculitic process is assumed to possibly underlie several other extra-articular manifestations such as the rheumatoid nodules and scleritis/episcleritis.

While early autopsy investigations reported the prevalence of RV to more than 15% and the lifetime risk to 2% (Suzuki et al. 1994), more recent evidence shows a decline in incidence especially after the year 2000 (Bartels et al. 2009), suggesting an association with the availability of newer agents to treat RA and the overall trend to treat articular disease more aggressively.

RV is associated with RA of long duration, severe destructive disease, seropositivity for rheumatoid factor and/or anti-CCP, and also nodules, certain HLA alleles, and smoking (Voskuyl et al. 1996).

Small and medium vessels may be affected and biopsy shows leucocytoclasis or pauci-immune lesions. Essentially, every tissue may be affected, but most commonly the skin and peripheral nerves are targeted in RV. Mesenteric, cardiac, and renal involvement is rare. Patients may present with systemic symptoms of fatigue, fever, and weight loss, but concurrent active articular disease may confound the association of these symptoms with underlying or evolving vasculitis. Skin involvement may be in the form of palpable purpura or more commonly manifest as nail-fold infarcts and leg ulcerations. Occasionally digital ischemia leading to gangrene may be seen. A sensory or mixed sensory motor neuropathy indicates peripheral nerve involvement. Mononeuritis multiplex is a common presentation and patients may develop a foot or wrist drop in an acute fashion.

A solid diagnosis will require a skin or nerve biopsy to exclude atheromatous disease accounting for ischemia or extremity ulcerations, or other conditions such neutrophilic dermatoses that may also be encountered in patients with RA and account for ulcerations.

Treatment is usually tailored to the severity of RV. Traditionally nail-fold infarcts have been considered a benign manifestation which may respond to accelerated DMARD treatment for the underlying articular disease. Small skin ulcerations that do not expand may also be treated with low dose prednisone or DMARDs. However, digital ischemia and peripheral nerve involvement are considered more ominous manifestations that will require high dose steroids and usually cyclophosphamide. Newer biologic agents have also been reported to be beneficial in the treatment of rheumatoid vasculitis (Puechal et al. 2008).

Recently, an association of vasculitis with treatment with TNF-α inhibitors has been reported in case reports and case series. In most cases, vasculitis responded to discontinuation of the TNF-α inhibitor therapy and in some cases recurred upon reinstitution of treatment (Ramos-Casals et al. 2007; Guignard et al. 2707). In most of the reported cases, only the skin was involved. However, other reports show that TNF-α inhibitors have been used successfully to treat RV (Puechal et al. 2008). Whether there is indeed an increased risk for development of vasculitis after treatment with TNF-α inhibitors and the role of these agents in the treatment of RV is an area of uncertainty.

Cachexia: Body Composition Changes

RA is associated with altered anthropometric characteristics. A low BMI – in the underweight range – is common in patients with RA, with some studies reporting a prevalence of more than 10% (Munro and Capell 1997). A lower BMI has been associated with radiologic progression and higher levels of disease activity (Westhoff et al. 2007). This association of low BMI with adverse outcomes in RA has in fact been reported to be stronger than that of the shared epitope with the same outcomes (Kaufmann et al. 2003). A lower BMI has also been associated with higher risk for disability, all cause mortality and CV associated mortality (Summers et al. 2008).

Rheumatoid cachexia is a state of loss of lean body mass and is reported to occur in up to 50% of patients (Summers et al. 2008). Cachectic obesity is a condition – also commonly encountered in RA – in which loss of lean body mass is

accompanied by gain in adipose tissue, thus maintaining "normal BMI." Both conditions are correlated with higher morbidity and mortality (Summers et al. 2008; Giles et al. 2008; 2010). These conditions seem to be associated with the altered cytokine milieu in RA and especially with higher levels of TNF-α (also called cachectin) (Giles et al. 2010). Excess adipose tissue in RA is reported to have a predilection for accumulation in the visceral fatty beds, thus contributing to higher prevalence of central obesity especially in men, thus increasing the risk for cardiovascular disease (Giles et al. 2010). Beyond the loss in lean mass, there is evidence that muscle density is lower in RA than controls, presumably due to fatty infiltration, and possibly related to reduced number of contractile units and decreased strength (Kramer et al. 2012). While the research field of anthropometry and body composition alterations in RA was a largely uncharted territory until several years ago, it has attracted more attention recently and more light should be shed soon. Evidence suggests that TNF-α inhibition may reverse some of the effects of RA on body composition and resulting cachexia (Summers et al. 2008).

Pulmonary Involvement

Lung involvement is common in RA and may involve virtually every part of the respiratory apparatus including the upper and lower airways, the parenchyma, and the pleura. The prevalence of different forms of respiratory involvement is difficult to assess due to the frequency of subclinical disease, the variable sensitivity of detection methods, and the confounding influences of medications and infections. In this section, we will elaborate on the most common forms of respiratory involvement in RA that impact the most on morbidity and mortality.

Interstitial lung disease (ILD) is the most common and most serious form of parenchymal lung involvement in RA. It is reported to be the second highest cause of mortality in this patient population (Gabriel 2008). It may remain asymptomatic and detectable only with imaging or pulmonary function testing (PFT) for long periods of time, but once symptoms manifest, a progressive course usually ensues, leading to early mortality (Gabriel 2008). The lifetime risk for ILD has been reported to be more than 7% in subjects with RA versus less than 1% in the general population (Bongartz et al. 2010). Male patients who are older at the time of RA onset and with severe articular involvement are at higher risk (Anaya et al. 1995). The mortality associated with ILD in RA is nearly three times higher compared to the general population.

Once clinically manifested by cough and dyspnea, imaging generally demonstrates reticular, ground glass or honeycombing opacities, and PFT reveals restriction and a decrease in diffusion capacity.

Biopsy in RA-associated ILD – often necessary to differentiate between RA related ILD, infection, or medication toxicity – usually reveals patterns consistent with nonspecific or usual interstitial pneumonia (NSIP and UIP respectively), less commonly bronchiolitis obliterans organizing pneumonia (BOOP), and more rarely lymphocytic or desquamative interstitial pneumonia (LIP and DIP respectively) (Lee et al. 2005). Between NSIP and UIP, the former is considered to be more responsive to immune suppression with steroids (Flaherty et al. 2001).

BOOP is more dramatic in presentation with systemic features of inflammation (fatigue, fever, increased inflammatory markers) and, on imaging, has a characteristic appearance with patchy peripheral consolidations. It often has a less grave prognosis with favorable response to treatment with steroids.

The first line of therapy for this condition involves steroids in most of the times. In the absence of randomized clinical trials for the treatment of RA-related ILD, an inadequate response to steroids is usually followed by the addition of immunosuppressives such as azathioprine.

Pleural involvement is reported to be very common in RA often as an asymptomatic bystander. Small effusions or histologically detected pleural involvement may be present, but patients complain of symptoms rarely (Balbir-Gurman et al. 2006). It frequently occurs in patients with active

nodular disease and may be an incidental imaging finding or present with dyspnea.

Thoracentesis reveals an exudative effusion with typical characteristics being a low glucose level, a high LDH concentration, and the presence of giant multinucleated cells.

Therapy of the articular disease may alleviate pulmonary effusions or additional treatment with steroids or pleurodesis, and other invasive methods may be necessary.

Chronic obstructive pulmonary disease (COPD)/emphysema may also occur frequently in patients with RA. Difficulty in assessing its exact prevalence relates to the confounding effect of smoking and also to the fact that prevalent PFT abnormalities in patients with RA have been argued as being overall stable over time and not of significant clinical relevance (Hassan et al. 1994; Fuld et al. 2003).

Apart from the above, the respiratory system may be affected in several other ways. Upper airway involvement while frequently present with diagnostic methods only on occasion will cause symptoms such as hoarseness or odynophagia (Geterud et al. 1986). Laryngoscopy will assist in diagnosis and PFT may show characteristic changes in expiratory flow volumes. Obliterative bronchiolitis usually is accompanied by systemic manifestations and has a poor prognosis (Devouassoux et al. 2009). Bronchiectasis is frequently encountered with CT imaging (Remy-Jardin et al. 1994) but less commonly presents with symptoms. Rheumatoid nodules may be present in the lung parenchyma as mentioned earlier and when they are encountered in patients with pneumoconiosis constitute the Caplan syndrome which is only rarely recognized nowadays.

As alluded to earlier, lung involvement may be an extra-articular manifestation of RA but the differential diagnosis should always include infections, malignancies, and medication toxicity. Among the latter we will only mention here methotrexate-induced hypersensitivity acute pneumonitis, which usually has a rapid onset and is accompanied by fever and bilateral infiltrates in association with new and often severe respiratory symptoms (Dawson et al. 2002).

Cardiovascular Involvement

Cardiovascular involvement in RA is of particular importance, given the fact that it is recognized as the leading cause of mortality in this patient population (Myasoedova et al. 2010). Recently, research has demonstrated the RA-related inflammation might be an independent risk factor for the development of atherosclerotic disease, and subclinical diastolic dysfunction (Nicola et al. 2005; Arslan et al. 2006). Patients with RA are considered to be at increased risk for myocardial infarctions, strokes, and heart failure even after adjustment for smoking and other traditional cardiovascular risk factors (Crowson et al. 2005). Medications used to treat articular disease – such as TNF-α inhibitors – may mitigate this risk (Listing et al. 2008). Coronary vasculitis only rarely causes ischemic myocardial events in RA and usually only in patients with full-blown rheumatoid vasculitis and severe and active joint disease (Morris et al. 1986). Current guidelines advocate annual cardiovascular risk evaluation for patients with rheumatoid arthritis and tight control of articular disease activity and conventional cardiovascular risk factors (Peters et al. 2010).

Beyond the above, a plethora of other cardiac manifestations may be encountered in patients with RA, including pericarditis, myocarditis, and valvular disease as well as rheumatoid nodules interfering with valvular or conduction system function (Voskuyl 2006).

Pericardial disease is the most common cardiovascular manifestation. In most cases, it is clinically asymptomatic and only detected by echocardiography or in autopsy series with prevalence ranges estimated to more than 30 %. Clinically evident disease is usually seen in patients with active RA, and management of the articular disease may also improve the pericardial involvement (Voskuyl 2006).

Myocarditis apparently directly related to RA inflammation is increasingly recognized with MRI and PET imaging in a percentage of patients as a possible cause of heart failure (HF) in patients with RA (Voskuyl 2006). Two major pathologic patterns are encountered: either

a granulomatous pattern similar to rheumatoid nodules, or a nonspecific form (Lebowitz 1963). Both forms of RA myocarditis are considered putative causes for HF in RA.

The articular inflammation of RA when active and longstanding may lead to secondary (AA) amyloidosis (Husby 1985). Such a condition is rarely encountered today as RA arthritis medications can sufficiently render the articular inflammation into remission in the majority of patients. In the rare cases of myocardial involvement by amyloidosis, renal involvement is usually also present and a restrictive physiology may be seen on echocardiography with a characteristic sparkling pattern (Voskuyl 2006).

Patients with RA may have frequent cardiac atrial and ventricular arrhythmias. Cardiovascular autonomic dysfunction, defined by decreased heart rate variability and increased QT dispersion, also reportedly increased in RA, may also contribute to the increased risk of CV disease in RA (Stojanovich et al. 2007).

Other Organs' Involvement

As already mentioned, neurologic involvement in RA may be encountered in the context of rheumatoid vasculitis. However, a common non-vasculitic neurological complication of RA is peripheral nerve entrapment syndrome, most typically affecting the median nerve and manifesting as carpal tunnel syndrome. Local synovitis compressing the nerve is usually the culprit and treatment of synovitis may improve symptoms, reserving surgical intervention only for resistant cases.

Muscle weakness due to disuse atrophy is encountered in patients with RA usually with active disease that interfere with exercise and deconditioning. Cachexia and loss of muscle density and the possible association with decreased strength is mentioned in a different section in this entry. Although autopsy series have reported low grade inflammation in muscles of RA patients, clinically evident primary inflammation is rare. In the case of clinically profound weakness, the clinician should always consider medication toxicity such as hydroxychloroquine steroid or statin-induced myopathy.

Renal involvement is also rare in rheumatoid arthritis. Biopsies have shown mild mesangioproliferative glomerulonephritis in a small percentage of patients. Nephrotic syndrome is only rarely encountered nowadays, given the low incidence of secondary amyloidosis in RA. NSAID-related kidney toxicity is probably the most frequent renal manifestation in patients with RA.

Definition

A discipline of science to clarify the contribution of genes in the etiology and pathophysiology of rheumatoid arthritis.

Genetic Factors in Rheumatoid Arthritis (RA)

RA is a systemic autoimmune disease that predominantly accompanies chronic synovial inflammation, which results in joint destruction and deformity. Approximately 1 % of the world population suffers from RA. It is widely accepted that both environmental and genetic factors contribute to the etiology of RA. Twin studies have revealed that genetic factors play a substantial role in the development of RA. For example, concordance rate for RA in monozygotic twins is four times larger than in dizygotic twins (MacGregor et al. 2000). Accordingly, overall contribution of genetic factors to RA is estimated to be 50–60 % (MacGregor et al. 2000; Seldin et al. 1999).

RA is heterogeneous in clinical manifestation and may have multiple causes (Aletaha et al. 2010; Arnett et al., 1988. Recent attempts to subclassify RA have shown that the presence of anti-citrullinated protein antibody (ACPA) has significant clinical relevance with the development of RA. ACPA is reasonably sensitive (68 %) and highly specific (98 %) for RA (Schellekens et al. 2000). ACPA is predictive for the development of RA: 75 % of patients with ACPA and undifferentiated arthritis would develop RA within 3 years (van Gaalen et al. 2004a). RA patients with ACPA exhibit more severe forms of the disease than those without ACPA (van Gaalen et al. 2004b). In addition, genetic risk profiles are different between ACPA-positive and -negative RA (D'Amato et al. 2010), suggesting differences in pathogenetic mechanisms between ACPA-positive and -negative RA. Recent genetic studies have analyzed not only clinically evident RA but also RA subtypes, for example, classified by the presence or absence of ACPA, as discussed below.

HLA (Human Leukocyte Antigen)-DRB1

Among multiple RA-susceptible alleles revealed so far, HLA-DRB1 risk alleles are most strongly associated with RA susceptibility (Plenge 2009; Raychaudhuri et al. 2010; Deighton et al. 1989). In the 1980s, it was discovered that multiple RA risk alleles in the HLA-DRB1 gene shared a common amino acid sequence, QKRAA, QRRAA, or RRRAA, which was designated "shared epitope" (SE) (Gregersen et al. 1987).

The SE is in the third hypervariable region of the DRB1 chain and situated in the α-helix of the peptide-binding groove (Gregersen et al. 1987). SE may therefore influence the species of peptides binding to the HLA molecule, hence the presentation of the peptides to T-cells; for example, arthritogenic peptides may be specifically bound to SE and interact with autoreactive T-cell receptors (TCRs) to activate arthritogenic CD (cluster of differentiation) 4^+ T-cells.

Notably, the association between SE allele and RA was only observed with ACPA-positive RA (Huizinga et al. 2005). Genetic risk factors associated with ACPA-negative RA appear to be much fewer than those associated with ACPA-positive RA partly because the cohorts analyzed so far mainly consist of ACPA-positive RA patients. Yet, one recent report showed that both ACPA-positive and ACPA-negative RA were equally heritable with approximately 65 % heritability for both diseases (van der Woude et al. 2009). However, only 2.4 % of the

heritability of ACPA-negative RA was due to SE, whereas 18 % of heritability of ACPA-positive RA was attributed to SE.

For ACPA-positive RA patients, smoking has been suggested as an important environmental risk factor, especially in those with one or two copies of the SE alleles (Kallberg et al. 2011; Linn-Rasker et al. 2006). In addition, enhanced expression of citrullinated proteins, as a result of induced expression of peptidylarginine deiminase-2, was found in the lungs of smokers (Makrygiannakis et al. 2008). It is thus plausible that smoking (an environmental factor) and SE (a genetic factor) cooperatively contribute to RA development. Certain autoantigens targeted in RA would be citrullinated as a result of smoking, thus acquiring a higher binding affinity for DRB1 molecule with SE; these citrullinated autoantigens displayed on SE are then recognized by autoreactive $CD4^+$ T-cells.

A recent genotype imputation approach has revealed variations of three amino acids at positions 11, 71, and 74 in HLA-DRB1 and single-amino-acid polymorphisms in HLA-B at position 9, which altogether could explain the HLA association with ACPA-positive RA (Raychaudhuri et al. 2012). The positions 71 and 74 are within an SE allele, and the position 11 is encoded by DNA (deoxyribonucleic acid) sequences approximately 200 base pairs away from those encoding the SE; all of these three amino acids are located within the peptide-binding groove of HLA-DRB1. Thus, peptides binding to the groove with SE may be presented for the activation of arthritogenic T-cells.

RA Risk Alleles Other Than HLA

Besides HLA, approximately 50 genes have been reported to have RA-associated risk alleles during last decade (Table 1), mainly as a result of the application of genome-wide association study (GWAS) for RA genetics. GWAS made it possible to conduct genetic studies of common variants across the entire human genome. Although exact causal mutations or genes are yet to be determined for most RA risk loci, it is of note that some RA risk alleles are common with other autoimmune diseases, and that there are substantial ethnic differences in RA risk alleles.

RA Risk Alleles Shared with Other Autoimmune Diseases

Many of RA risk loci (e.g., HLA-DR4, PTPN22 (Protein tyrosine phosphatase, non-receptor type 22), CTLA4 (Cytotoxic T-Lymphocyte Antigen 4), STAT4 (Signal Transducer and Activator of Transcription 4), IL2RA (interleukin 2 receptor alpha)) predispose to more than one autoimmune disease, including type 1 diabetes (T1D), celiac disease, systemic lupus erythematosus (SLE), inflammatory bowel disease, and multiple sclerosis. For example, PTPN22 is shared with T1D, SLE, and autoimmune thyroiditis (Begovich et al. 2004; Bottini et al. 2004; Criswell et al. 2005; Lee et al. 2007b; Orozco et al. 2005; Raychaudhuri et al. 2008). In most cases, the same allele is associated with these diseases. In addition, there are some gene loci that have several autoimmune alleles (e.g., TNFAIP3 (Tumor necrosis factor, alpha-induced protein 3) locus in RA, SLE, and T1D) (Fung et al. 2009; Graham et al. 2008; Musone et al. 2008; Plenge et al. 2007a; Thomson et al. 2007). The results suggest a common pathogenetic basis for autoimmune diseases.

Ethnic Differences

RA genetic studies so far conducted mainly on the populations of Caucasian and Asian populations have revealed clear ethnic differences in genetic predisposition to RA. For example, the peptidylarginine deiminase 4 (PADI4) gene is associated in several Asian populations in multiple studies (Ikari et al. 2005; Kang et al. 2006; Suzuki et al. 2003) and also in meta-analysis (Lee et al. 2007a). In contrast, it is not associated with RA susceptibility in Caucasians (Lee et al., 2007a; Plenge et al., 2005). Similarly, Fc receptor-like 3 (FCRL3)

gene is associated with RA in Japanese populations (Ikari et al. 2006; Kochi et al. 2005), but not in Caucasian descents (Hu et al. 2006; Martinez et al. 2006). In contrast, PTPN22 (Begovich et al. 2004; Lee et al. 2007b; Plenge et al. 2005), TRAF (TNF receptor associated factors)/C (Complement) 5 (Kurreeman et al. 2007; Plenge et al. 2007b; Raychaudhuri et al. 2008), and TNFAIP3 (Plenge et al. 2007a; Raychaudhuri et al. 2008; Thomson et al. 2007) are susceptibility genes in European, but not Asian, populations. The reason for these ethnic differences is not clear and could be distinct with each gene.

Mechanisms of Rheumatoid Arthritis Implicated by Genetic Studies

Because the number of newly identified RA risk alleles is rapidly growing, it is difficult to draw an integrated picture of RA pathogenesis by simply taking all these risk alleles into consideration. Most of RA risk genes are related to immune function and could be involved in three possible pathways or steps for RA development:

1. T-cell activation by antigen presenting cells (MHC class II region, PTPN22, STAT4, CD28, CTLA4, CD83, UBASH3A (Ubiquitin-associated and SH3 domain-containing protein A), CD247, SH2B3 (SH2B adapter protein 3), CD2, and CD58)
2. CD40 signaling pathway and downstream activation of nuclear factor-KB (NF-KB) signaling pathway (CD40, TRAF1, TRAF6, TNFSF (Tumor necrosis factor superfamily) 14, TNFAIP3, REL, and NFKBIE (Nuclear factor of kappa light polypeptide gene enhancer in B-cells inhibitor, epsilon))
3. IL-2 signaling pathway (IL2RA, IL2RB (Interleukin-2 receptor beta), and IL (Interleukin) 2/IL21)

Understanding how genetic variations in the function of these molecules contribute to RA development remains a challenge for future study.

Summary

To date, nearly 50 risk alleles have been described as associated with RA susceptibility. Among them, HLA-DRB1 risk alleles show the strongest association. Detailed analyses indicate that responsible polymorphisms are located within the peptide-binding grooves of HLA-DRB1 and possibly influence the display of self- or non-self-peptides that shape an arthritogenic TCR repertoire or activate arthritogenic T-cells. RA risk alleles other than HLA-DRB1 may affect immune regulation of the formation or activation of arthritogenic T-cells. The number of reported genetic risk alleles for RA is rapidly increasing mainly because of the application of GWAS. Hopefully, they will further elucidate the etiology and pathophysiology of RA.

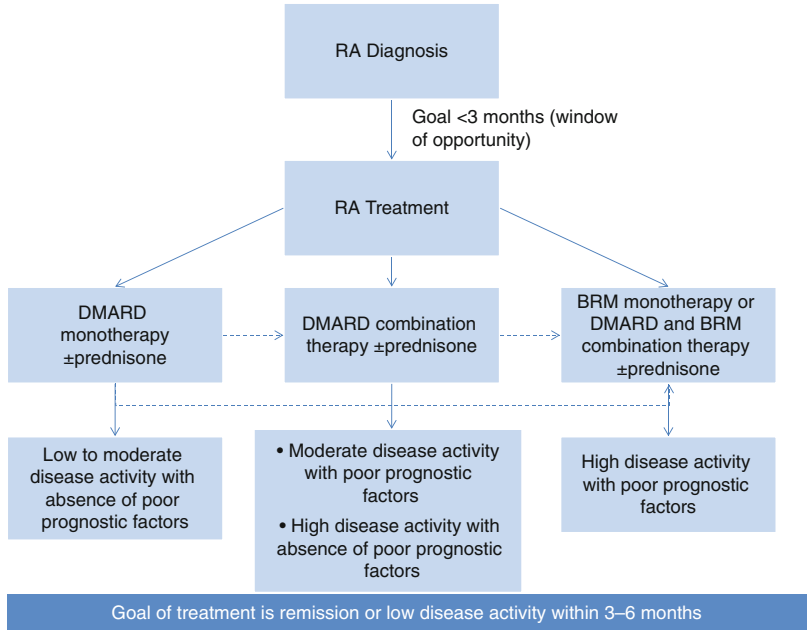
Definition

Rheumatoid arthritis treatment pertains to the medical management of one of the most common autoimmune rheumatic diseases. Various therapeutic strategies exist and multiple different classes of medications have emerged and will be critically reviewed.

Introduction

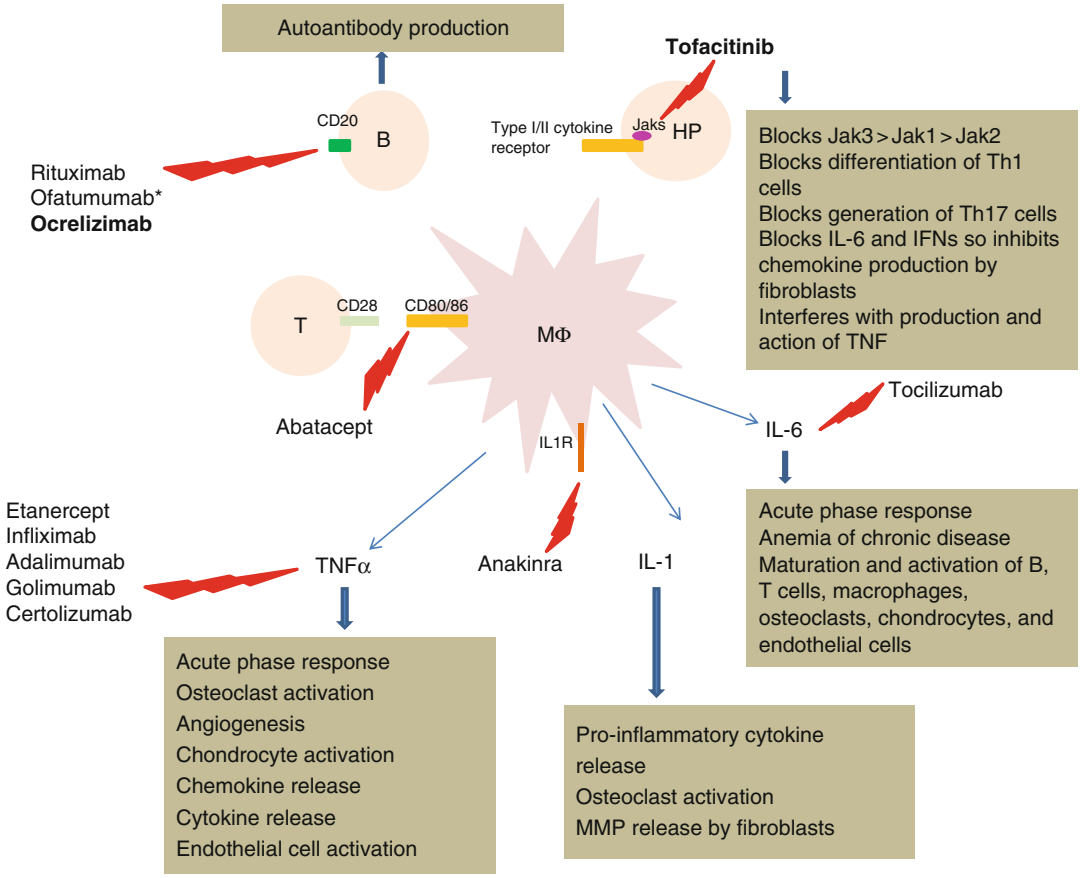
Since the mid-1990s, rheumatoid arthritis (RA) treatment has been revolutionized with the advent of molecular biology and the development of novel targeted biologic treatments, i.e., cytokine and cytokine receptor inhibitors. The therapeutic



Rheumatoid Arthritis, Treatment, Fig. 1 RA treatment algorithm. Ideally treatment should start within 3 months of diagnosis also known as window of opportunity. The goal is disease remission or minimal disease activity within 3–6 months form diagnosis. Different strategies exist depending on disease activity and patient prognostic factors. *BRM* Biologic Response Modifier, *DMARD* Disease-Modifying Antirheumatic Drug. **Disease activity:** Classified as low, moderate, and high, according to validated common scales such as Disease Activity Score in 28 joints (DAS-28) Remission: <2.6, Low activity: >2.6 to <3.2, Moderate activity: >3.2 to <5.1, High activity: >5.1. Other scales include the Patient Activity Scale (PAS) or PAS-II, Routine Assessment of Patient Index Data 3, Clinical Disease Activity Index, and the Simplified Disease Activity Index. **Poor prognostic factors:** extra-articular manifestations (rheumatoid nodules, Felty's syndrome, RA vasculitis), rheumatoid factor and/or anticyclic citrullinated peptide positivity, impaired functional ability (measured by Health Assessment Questionnaire (HAQ) or other validated tools), bone erosions by radiographs. *Dashed arrows* represent escalation of therapy in the absence of remission or significant improvement at 3-month re-assessment intervals

paradigm has been shifted from symptomatic relief toward earlier identification of disease and prompt initiation of disease-modifying treatment, aiming at structural preservation of the joints and improvement in function and quality of life. Traditional disease-modifying antirheumatic drugs (DMARDs) remain first-line agents in RA, with methotrexate (MTX) widely considered as the "anchor" drug. Other commonly prescribed DMARDs include leflunomide, sulfasalazine, and hydroxychloroquine. In an effort to achieve remission, current treatments target a variety of inflammatory pathways.

Combination regimens include multiple traditional DMARDs or combinations of a DMARD and a biologic response modifier (BRM). Different treatment strategies exist and, currently, sequential monotherapy and/or the step-up approach may be substituted with combination treatment, often including a BRM, in specific patient subsets with adverse prognostic factors (Fig. 1). Currently, different classes of BRMs exist, targeting a distinct niche of RA immunopathology, including cytokine inhibitors (TNF, IL-1, IL-6), B-cell-depleting agents (rituximab), T-cell co-stimulation inhibitors (abatacept), and small molecule tyrosine kinase (JAK, SYK) inhibitors in development (Fig. 2). However, even though modern RA treatment has drastically improved the natural course of the disease, achieving remission remains elusive in the majority of patients, underscoring the unmet need for further research that may lead to novel agents and/or strategies.



Rheumatoid Arthritis, Treatment, Fig. 2 Therapeutic targets in RA include cytokines such as TNF, IL-1, IL-6, B cells, T-cell co-stimulation, and kinases. Cytokines exert pleiotropic effects, predicting the beneficial action of cytokine blockers. Tofacitinib and fostamatinib targeting JAK3/JAK1 and SYK kinases exert their beneficial actions through different mechanisms shown above

Traditional Disease-Modifying Antirheumatic Drugs (DMARDs)

Corticosteroids and nonsteroid anti-inflammatory agents (NSAIDs) were the mainstay of RA treatment before the institution of current DMARD therapy, which is proven to delay disease progression by reducing joint destruction. Even though corticosteroids are shown to impede radiographic progression (Kirwan 1995), they are currently used at the lowest possible dose for short-term periods, as adjunct agents for symptomatic relief, in view of their well-established long-term side-effect profile including osteoporosis, impaired glucose tolerance, cataract induction, and hypertension.

The most commonly recommended DMARDs include MTX, hydroxychloroquine, sulfasalazine, and leflunomide. Historically, other DMARDs have been used, such as azathioprine, penicillamine, gold salts, minocycline, doxycycline, and cyclosporine; however, their use has been largely abandoned due to increased toxicity and/or lack of efficacy. DMARD choice depends on patients' prognostic features, comorbidities, and preferences, individual tolerance to the respective medication and the drug safety profile. Concurrently, adverse prognostic factors such as presence of radiographic progression (erosions, joint space narrowing), presence of the shared epitope, presence of anti-CCP antibodies, and rheumatoid factor could dictate an earlier and

more aggressive approach, often requiring combination therapy with DMARDs (usually MTX) and a BRM (Markatseli et al. 2010).

Methotrexate

MTX is a potent anti-inflammatory and antiproliferative agent. It exerts its effects by virtue of increased levels of adenosine and through inhibition of transmethylation reactions. MTX is a folate analogue, which rapidly enters dividing cells though a folate receptor. Intracellularly, MTX is polyglutamated interfering with enzymes ultimately leading to increased levels of adenosine. Adenosine has potent anti-inflammatory properties and it is shown to inhibit the pro-inflammatory action of many key cytokines (Canella and O'Dell 2008).

MTX is the cornerstone of DMARD therapy in RA and is indicated for patients who have moderate to severe disease and radiologic evidence of joint erosions. Once MTX efficacy and safety was established as monotherapy, it was quickly realized that its combination with other traditional DMARDs such as hydroxychloroquine and sulfasalazine (triple therapy) could be even more effective (Coury and Weinblatt 2010). Initial combination therapy as a therapeutic strategy was formally tested within the BeST trial, where 4 different approaches were compared: monotherapy, step-up combination with traditional DMARDs, step-down therapy or initial combination therapy with MTX and infliximab, a TNF-α inhibitor. Although, all strategies showed clinical efficacy at 1 year, combination therapies led to earlier clinical remission and less structural damage (Goekoop-Ruiterman et al. 2005). In a series of randomized control trials in MTX-naive patients with early RA (onset of symptoms within 3 years), the combination of MTX and an anti-TNF-α agent (either infliximab, etanercept or adalimumab) or abatacept, a T-cell co-stimulation blocker, was superior to MTX alone in terms of disease activity, radiographic progression, and functional outcomes (Coury and Weinblatt 2010). MTX has also been efficacious in combination with rituximab, a peripheral B-cell depletor, at the dose of 1000 mg, given twice, at a 2-week interval.

MTX can be administered either orally or subcutaneously at initially low doses of 7.5 mg to 10 mg weekly escalating to 20–25 mg weekly. Concurrent folic acid administration at a dose of 1–3 mg daily may decrease the incidence of gastrointestinal and hematologic side effects stemming from its mechanism of action.

Side effects frequently result from folate depletion and may be reversible with folic acid replacement. Nausea, dyspepsia, and oral ulcers are common. Elevation of liver function tests is dose dependent and can be more severe in patients with HBV or HCV and in patients consuming excessive alcohol (which are situations in which methotrexate is contraindicated). Cytopenias secondary to bone marrow toxicity are relatively rare and caution should be exercised in patients with impaired renal function because MTX metabolites are renally excreted. Folinic acid (leucovorin) administration can be given as rescue in cases of severe bone marrow toxicity. Pulmonary toxicity can present as hypersensitivity pneumonitis necessitating discontinuation of MTX and administration of systemic corticosteroids once other causes (e.g., infections) are ruled out. Interstitial lung disease has been rarely reported in cases where high cumulative doses are given long term. Associations of MTX with malignancies especially lymphoma have been reported, but no causative link has been established in RA, given the increased risk of lymphoma in RA, even in untreated patients (Wolfe and Michaud 2004).

Hydroxychloroquine

Hydroxychloroquine is an antimalarial agent with anti-inflammatory and immunomodulatory properties. As a lipophilic weak base, it enters lysosomes raising pH and therefore interfering with protein processing. Consequently, antigen presentation as well as cell-mediated cytotoxicity is impaired. Decrease of auto-reactive lymphocytes is reported as a result of upregulated apoptosis. More recently, hydroxychloroquine has been found to inhibit intracellular Toll-like receptors such as TLR-9, modulating innate immune responses and antigen presentation (Katz and Russell 2011).

Hydroxychloroquine has demonstrated modest efficacy in RA and it is typically reserved for

mild disease with few or no adverse prognostic factors and as part of combination treatment, such as triple therapy together with sulfasalazine and methotrexate (Gaujoux-Viala et al. 2010).

Hydroxychloroquine is administered orally at a maximum dose of 6.5 mg/kg of ideal body weight and has a large distribution volume. Its long half-life renders hydroxychloroquine a slow-acting drug. It has a favorable safety profile, including in pregnant and lactating women, with retinal toxicity being the most serious complication, albeit rare and usually reversible upon discontinuation. Due to the agent's accumulation in melanin-storing cells, skin can also be affected, causing rash and hair depigmentation. Other common side effects are nausea, vomiting, diarrhea, and hypoglycemia, especially in diabetic patients already on glucose-lowering medications and tight diabetes control. Rarely, neuromuscular toxicity is reported manifesting with indolent proximal weakness and normal creatine kinase.

Sulfasalazine

Sulfasalazine consists of two moieties: 5-aminosalicylic acid (5-ASA) possessing anti-inflammatory properties and the antibacterial sulfapyridine. Although sulfasalazine has been one of the first drugs to be specifically employed for RA, its full mechanism of action in vivo is yet to be understood. It is suggested to inhibit arachidonic acid cascade and increase adenosine levels by inhibiting intracellular enzymes similarly to MTX (Canella and O'Dell 2008).

Its use in RA is typically restricted to those with mild disease, as an alternative to MTX where contraindicated or combined with hydroxychloroquine and MTX. It is also considered relatively safe along with hydroxychloroquine for women contemplating pregnancy. It is administered orally initially at doses 500 mg daily escalating up to 1,500–3,000 mg daily as tolerated.

The most common side effects are nausea, epigastric discomfort, headache, and dizziness. Hematologic abnormalities usually occur within the first 3 months of therapy and may include leukopenia, rarely agranulocytosis, and hemolytic anemia in patients with glucose-6-phosphate dehydrogenase deficiency. Photosensitive rash has been reported and patients should be cautioned against taking sulfonamide-containing drugs (Canella and O'Dell 2008).

Leflunomide

Leflunomide is a prodrug which is rapidly converted to its active metabolite in the liver. It is considered to be a T-cell immunomodulator by inhibiting pyrimidine synthesis via reversible inhibition of the enzyme dihydroorotate dehydrogenase. Moreover, it acts as a tyrosine kinase inhibitor, interfering with signal transduction which is critical in immune cell growth and metabolism (Canella and O'Dell 2008).

Leflunomide has a 2-week half-life and it may be detected long after it has been discontinued. Given that it is teratogenic, patients contemplating pregnancy should have levels of its active metabolite measured and if higher than 0.02 mg/L, an elimination procedure with cholestyramine (2 g three times daily for 8 days) is recommended and levels rechecked for acceptable levels at least twice, in 2-week intervals (Canella and O'Dell 2008).

Leflunomide is an effective agent with onset of response seen within 4–12 weeks. A loading dose of 100 mg daily for 3 days is followed by a maintenance dose of 10–20 mg per day. Some expert clinicians advocate against the loading dose, in order to prevent adverse effects leading to attrition such as diarrhea, nausea, and abnormal liver function tests. Leflunomide is shown to retard radiographic progression and is considered to be a second-line agent in patients who are intolerant or failed MTX. Experience with leflunomide as a combination therapy is not as extensive as with MTX and frequent monitoring for toxicity is warranted (Maddison, Kiely et al. 2005). Side effects also include hypertension, hypercholesterolemia, weight loss, rash, interstitial lung disease, and, rarely, pancytopenia (Canella and O'Dell 2008).

Biological Response Modifiers (BRMs)

Biologic response modifiers have revolutionized the practice of rheumatology by improving

clinical outcomes and quality of life, arresting disease progression and preventing disability in a significant percentage of patients. The first class of BRMs that entered the clinic was the TNF-α inhibitors. Subsequently, advances in our understanding of RA immunopathophysiology allowed for additional target identification, including cytokines (IL-1, IL-6), B- and T-cells as well as signal transduction molecules.

Anti-TNFs

TNF-α has an established pivotal role as a driving cytokine in RA pathogenesis, mediating symptoms, and structural articular damage. TNF-α inhibitors have pleiotropic effects including complement-dependent cytotoxicity, antibody-dependent cellular cytotoxicity, reverse signaling, and cytokine suppression (Taylor 2010).

Currently, there are five anti-TNF drugs approved for moderate to severe RA resistant to DMARDs, such as MTX. Despite variable pharmacokinetic properties and distinctive differences in design, they have all shown similar efficacy in randomized controlled clinical trials. Given our significant experience with the entire class of anti-TNF agents in terms of efficacy and safety, the bar has been raised for novel candidate agents to be tested in RA. Anti-TNF therapies have been associated with rare, albeit serious and occasionally fatal complications, including the elevated infection risk (especially opportunistic infections such as tuberculosis), malignancies, heart failure, demyelinating disorders, and reactivation of hepatitis B (Aaltonen et al. 2012). Concurrent administration of MTX, even at low doses, has been shown to decrease the incidence of immunogenicity and production of auto-antibodies against these agents.

Infliximab

Infliximab is a chimeric (70 % human 30 % mouse) IgG1 monoclonal antibody that binds to cell-bound and circulating TNF-alpha with high affinity. Its half-life is 8–10 days. It is administered intravenously (iv) at a dose of 3 mg/kg, followed by repeat dosing at 2 and 6 weeks (loading) and thereafter every 8 weeks (maintenance). Unresponsive patients might benefit from increasing the dose (up to 10 mg/kg) or by increasing the infusion frequency to a maximal frequency of every 4 weeks.

Infliximab's efficacy in RA has been demonstrated in combination with MTX in multiple double-blind, randomized, placebo-controlled trials, mostly in patients who had failed DMARDs (including MTX) (Aaltonen et al. 2012) (Table 1). Infliximab monotherapy was only initially tested at small open-label trials to demonstrate efficacy and safety. However, given the emerging data that combination with MTX may be clinically superior and may also decrease the risk of immunogenicity, all subsequent studies tested the combination of infliximab with MTX versus MTX alone (placebo). Infliximab has been tested both in long-standing disease and early RA (3 years or less of duration). Interestingly, in early RA, joint destruction was averted even in the absence of clinical improvement in a subset of patients, suggesting that there might be uncoupling of radiographic disease progression and clinical response (signs and symptoms).

Etanercept

Etanercept is a humanized, fusion protein generated by the linkage of two ligand binding regions of p75 TNF-α receptor and the Fc portion of human IgG1, and possesses the shortest half-life (3–4 days) of all the TNF-α inhibitors. Unlike other TNF-inhibitors, it binds both TNF-α and TNF-β.

Etanercept is administered subcutaneously (SC) weekly at a dose of 50 mg or twice weekly at a dose of 25 mg. It is approved both as monotherapy and in combination with MTX in moderate to severe RA (Table 1). Etanercept was the first anti-TNF to be tested as monotherapy in double-blind placebo-controlled randomized trials (Aaltonen et al. 2012). TEMPO trial was the first to demonstrate that the "add-on" trial design, at least in the case of etanercept, is not

reflective of pharmacokinetic interaction of the study agent and MTX but rather an effect that may be dependent on the agents' mechanism of action.

Adalimumab

Adalimumab is a recombinant human IgG1 monoclonal antibody against TNF-α with an estimated half-life of 6–14 days, which can be used as monotherapy or in combination with MTX for the treatment of RA. It is administered subcutaneously at a dose of 40 mg every 2 weeks and is often titrated up to weekly, if necessary (approved in this higher dosage if taken without MTX). As with etanercept, adalimumab was tested in MTX non-responders (ARMADA study) and in MTX naive patients with early RA (PREMIER study, disease duration less than 3 years). The combination with MTX was clinically superior, with less radiographic progression at years 1 and 2 compared to monotherapy with either MTX or adalimumab. Adalimumab monotherapy compared to MTX monotherapy was also effective in arresting radiographic outcomes with comparable clinical efficacy (Aaltonen et al. 2012) (Table 1).

Golimumab

Golimumab is a humanized TNFα blocker binding to both soluble and transmembrane forms of TNF-α given every 4 weeks by a subcutaneous injection at a dose of 50 mg. Efficacy of golimumab with MTX has been demonstrated in RA patients who were MTX-naive, MTX-inadequate responders, and, for the first time in a randomized controlled study, TNF-inhibitor-inadequate responders, supporting the current practice pattern of "cycling" different TNF-blockers in patients who have an inadequate response to one TNF-inhibitor (Boyce et al. 2010) (Table 1).

Certolizumab

Certolizumab pegol is the pegylated portion of the Fab' fragment derived from a TNF-α monoclonal antibody, given subcutaneously once every two weeks. It is the only sc TNF-inhibitor with a loading dose (400 mg at weeks 0, 2, 4) and, for maintenance, it can be administered either every 2 weeks (200 mg) or every 4 weeks (400 mg). The absence of Fc region renders the drug incapable of inducing complement- or antibody-dependent cell-mediated cytotoxicity, differentiating certolizumab from the other anti-TNFs. Furthermore, the lack of the Fc portion may translate in hindered active transfer through the placenta in pregnant women. Clinical trials have proven certolizumab to be efficacious, both as monotherapy and as an add-on therapy to MTX improving the signs and symptoms of RA as early as week 1 and inhibiting the progression of structural joint damage as early as 16 weeks (Mease 2011) (Table 1).

Interleukin-1 Blockade

Interleukin-1 belongs to the cytokine milieu known to drive the pathophysiology of RA. This is established in various preclinical RA models and in vitro where both IL-1α and IL1β are proven to induce cytokine production by synovial mononuclear cells and chondrocytes and also drive bone erosion following osteoclast activation.

Anakinra

Anakinra is the recombinant form of human IL-1 receptor antagonist (IL-1ra) that is currently approved by the US Food and Drug Administration (FDA) for moderate to severe RA that has been unresponsive to initial DMARD therapy. In Europe, this agent has been approved for the treatment of RA only in combination with MTX whereas in USA, monotherapy may also be instituted (Mertens and Singh 2009) (Table 2).

It is administered as a daily subcutaneous injection at a dose of 100 mg and adverse effects primarily include injection-site reactions and increased rate of serious infections, yet not statistically significant in randomized trials compared to placebo (Mertens and Singh 2009).

The fact that the absolute treatment benefit with anakinra does not reach that of anti-TNFs and the need for daily administration has led to its infrequent use in adults with RA. Longer acting IL-1 inhibitors, such as rilonacept and canakinumab, primarily used for

Rheumatoid Arthritis, Treatment, Table 2 Pivotal clinical trials of IL-1 inhibitors in rheumatoid arthritis

auto-inflammatory syndromes, have not been studied in RA (Mertens and Singh 2009).

Interleukin-6 Blockade

Interleukin-6 is known to play a critical role in RA pathogenesis, as evidenced by increased levels both in serum and synovial tissue which also significantly correlate with disease activity reflected in joint destruction and inflammatory markers. Preclinical models of IL-6 knockout mice were protected by collagen-induced arthritis laying the foundations for subsequent clinical development of an IL-6 inhibitor for RA.

Tocilizumab

Tocilizumab is a humanized IgG1 monoclonal antibody against the soluble and membrane-bound 80 kD component of the IL6 receptor, thereby inhibiting the homodimerization of gp130 and downstream signal transduction.

Tocilizumab has been approved for the treatment of RA in the USA after failure of at least one TNF-inhibitor, at a dose of 4 or 8 mg/kg given intravenously every 4 weeks, based on its efficacy in patients who had previously failed to respond to DMARDs or anti-TNF agents or both (Singh et al. 2011). Weekly or biweekly subcutaneous injections are being tested in early phase clinical trials. Overall, combination therapy of tocilizumab and MTX has resulted in superior efficacy than MTX alone with side effects being infusion-related reaction, increased frequency of infections, cytopenias, hyperlipidemia, and hypertension (Singh et al. 2011) (Table 3).

B-Cell-Depleting Agents

The presence of auto-reactive B cells resulting in the production of auto-antibodies highlights the key role of B-cell compartment in RA pathogenesis. It has also been convincingly shown that Bcells may also function as antigen-presenting cells, especially at the tissue level, and as cytokine secretors, driving the inflammatory process. Expression of CD20 on distinct stages of B-cell development was initially utilized to target peripheral B-cells in patients with non-Hodgkin lymphoma and the strategy was, more recently, tried in RA.

Rituximab

Rituximab is a chimeric human/mouse anti-CD20 antibody administered intravenously in two doses of 1000 mg, 2 weeks apart. Rituximab leads to apoptosis via antibody-dependent cytotoxicity and/or complement-dependent cytotoxicity. Pre-medication with steroids is indicated, especially prior to the first dose, to decrease the frequency and severity of infusion reactions. Rituximab induces a rapid depletion of CD20-expressing B-cells in the peripheral

blood, and levels remain low or undetectable for 2–6 months before returning to pretreatment levels at a mean of 8 months. Of note, hypogammaglobulinemia has not been consistently reported. In the USA, rituximab use is reserved for incomplete responders to TNF-inhibitors. It appears that clinical efficacy may be predicted by rheumatoid factor, albeit not anti-CCP, positivity (Benucci et al. 2010) (Table 4).

New-Generation Anti-CD20 Monoclonal Antibodies

In an effort to minimize infusion reactions, presumably due to the chimeric nature of rituximab, second-generation humanized anti-CD20 agents were developed. They also have the theoretical advantage of not triggering human anti-chimeric antibodies resulting in loss of efficacy similarly to anti-TNFs, although not yet reported with rituximab in RA. Ocrelizimab, which binds to a different epitope of CD20, was bedeviled in clinical trials by serious and opportunistic infections, especially at the higher doses where efficacy was seen, leading to suspension of phase III trials for RA. Ofatumumab, another humanized anti-CD20 monoclonal antibody, again binding to a different epitope, showed promise in phase I/II trials with no increase in safety signals (Buch and Emery 2011).

T-Cell c-Stimulation Blockade

T-cell activation is crucial in the induction of adaptive immunity in RA. Classically, T-cells are activated in a stepwise fashion during their interaction with the antigen-presenting cells (APCs). The first signal consists of presentation of the antigen loaded on major histocompatibility complex molecule to the T-cell receptor. Full T-cell activation requires a second co-stimulatory signal mediated by the interaction of APC surface molecules (CD80/CD86) and CD28 on T-cells. Although multiple co-stimulation mechanisms have been described, the CD80/86-CD28 pathway remains the best characterized.

Abatacept

Abatacept (CTLA4-Ig), a selective T-cell co-stimulation modulator, is administered as an intravenous infusion at week 0, 2, week 4, and every 4 weeks thereafter with the dose determined by body weight (500–1000 mg). It is also available on subcutaneous formulation with similar efficacy and safety profile with no evidence of immunogenicity. The subcutaneous injection is administered as a fixed dose (125 mg weekly) with or without an initial, weight-based, intravenous loading dose. Mechanistically, it binds to CD80 and CD86 blocking the co-stimulatory signal and optimal T-cell activation. This strategy has been employed for the treatment of solid tumors and hematological malignancies (Pham et al. 2012).

In RA, it is indicated as monotherapy or in combination with DMARDs (but not with other biologics) based on clinical and radiographic superior outcome compared to placebo in both

TNF-inhibitor naïve patients and in patients who had failed to respond to these agents. Abatacept's efficacy tends to be seen later compared to anti-TNFs enduring beyond 6 months of treatment (Pham et al. 2012) (Table 5).

No specific laboratory or immunological tests are needed to monitor abatacept therapy. Standard practice laboratory tests to include inflammatory markers and liver function tests in cases of concomitant MTX therapy are indicated every 2 to 3 months. In the absence of comorbidities, cytopenias are uncommon (Pham et al. 2012).

Tyrosine Kinase Inhibitors

Despite the great advances in therapeutics, 30–40 % of RA patients do not achieve remission, highlighting the need for drugs with novel mechanism of action. Tyrosine kinases comprise of 90 members, among which Janus activation kinases (Jaks) and Spleen tyrosine kinase (Syk) have been implicated in RA pathogenesis, as evidenced by the successful preclinical studies with tofacitinib and fostamatinib. Jaks compose of Tyk2, Jak1, Jak2, and Jak3 which bind to type I and II receptors in different combinations. Upon ligand binding, Jaks phosphorylate cytokine receptors, initiating a signal transduction cascade which leads to gene transcription modulation (Kontzias et al. 2012).

Syk is a non-receptor cytoplasmic tyrosine kinase involved in signaling and the activation of Fc gamma receptors in many cells which are key players in RA pathogenesis. Of note Syk is

highly expressed by all hematopoietic lineage cells. Many kinase inhibitors with different specificities are in the pipeline for various indications in the spectrum of auto-immunity and cancer. As of now, tofacitinib, is approved by the FDA for treatment of moderate to severe rheumatoid arthritis in patients who have had an inadequate response to, or who are intolerant of, methotrexate. Fostamatinib's efficacy was not proven to be efficacious in three randomized placebo-controlled phase II trials and one phase III trial so this agent is no longer a candidate for RA treatment.

Tofacitinib

Tofacitinib (formerly designated CP-690,550) is the first selective Jak inhibitor to be tested in humans potently inhibiting Jak3 and Jak1 and to a lesser extent Jak2. It efficiently blocks common γc cytokines including IL-2, IL-4, IL-15 and IL-21, but it also inhibits signaling by IFN-γ, IL-6, and to a lesser extent IL-12 and IL-23, therefore abrogating Th1 and Th17 cellular effects. In vivo tofacitinib mitigates the effects of IL-6 and type I interferons on synovial fibroblasts, inhibiting chemokine expression (Kontzias et al. 2012).

The efficacy of tofacitinib in RA was established in phase II and III trials both as monotherapy and combined with methotrexate in patients who failed DMARDs. Tofacitinib was compared head to head with adalimumab and was found to be non-inferior. Importantly, there was evidence to suggest that structural damage was also prevented in the higher dose (10 mg twice daily) (Kontzias et al. 2012) (Table 6).

Safety signals from long extension studies include infections usually upper respiratory and less commonly opportunistic, mild increase in creatinine, hyperlipidemia, LFT abnormalities, neutropenia, and anemia.

Conclusion

The field of therapeutics in RA has leapt forward over the last 15 years. The "revolution of biologics" sustained great impact in the natural history of the most common autoimmune disease. This coincided with the better understanding of its pathogenesis which provided the rationale to target specific molecules found to play a critical role in the disease process. This effort would not

Rheumatoid Arthritis, Treatment, Table 6 Pivotal clinical trials of Janus kinase inhibitors in rheumatoid arthritis

	Kanik et al.	384	6 months		DMARDS-IR	ACR20/50/70, DAS28
	Tanaka et al.	136	12 weeks		MTX-IR	ACR20/50/70

have been possible without the evolutionary tools of molecular biology. Multiple novel medications are in the pipeline targeting specific pathways with a great interest in those modulating signal transduction. Most of them are administered orally, potentially lowering the future health costs for the treatment of this chronic debilitating disease. Further comparative studies identifying predictors of response for subsets of patients are needed for a true tailored approach. It remains to be seen how RA's therapeutic algorithm will be changed in the future influenced by the currently established medications, the efficacy of novel drugs, and the future pharmacoeconomic environment.

Definition

This contribution provides a general overview about the biosynthesis cycle, regulatory mechanisms, and in vivo functions of Rho/Rac proteins, a large group of GTP-binding proteins belonging to the Ras superfamily, in both the immune system and immune-related diseases.

Historical Background

The first Rho/Rac family member (RhoA) was cloned serendipitously by R. Axel's group in 1985 while searching for human chorionic gonadotropin-like hormones in *Aplysia* using low-stringent cDNA library screenings. Rac1, Rac2, and Cdc42 were discovered in the 1989–1990 period using cDNA library screenings with degenerated oligonucleotides designed from peptides of the so-called G25K (Cdc42) GTPase. The rest of family members were discovered using a similar approach or, more recently, via the sequencing of the genomes of

Rho/Rac GTPases, Table 1 Rho/Rac GTPases

GTPase subfamily	Subfamily members
Rac	Rac1, Rac2, Rac3, RhoG
Rho	RhoA, RhoB, RhoC
Cdc42	Cdc42, RhoJ, RhoQ
RhoH	RhoH
RhoU/V	RhoU, RhoV
Rnd	Rnd1, Rnd2, Rnd3
RhoF	RhoD, RhoF

different species (Bustelo et al. 2007). Currently, this family is composed of 18 different genes that, by alternative splicing, can generate 22 proteins in humans (Bustelo et al. 2007). According to structural homology criteria, these proteins can be subclassified in seven different subfamilies (Table 1). Although some classifications include the three RhoBTB proteins (RhoBTB1, 2, and 3), they should not be considered bona fide members since they are quite different in terms of structure, function, and regulation.

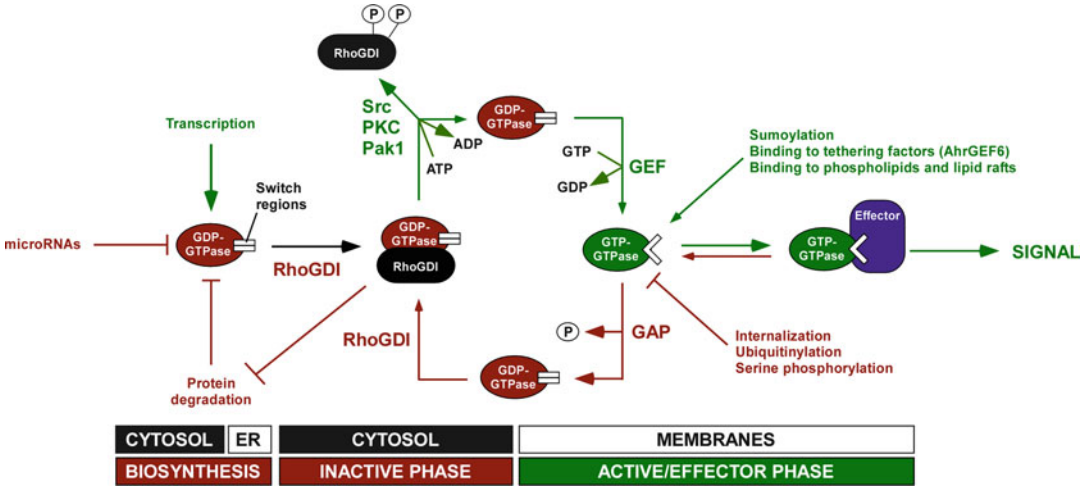
Like the majority of Ras superfamily proteins, the "conventional" Rho/Rac GTPases behave as molecular switches that fluctuate between inactive and active states depending on the signaling status of cells (Fig. 1). These states are modulated by the differential binding of GDP and GTP, two guanosine nucleotides that are essential for inducing the inactive and active state, respectively. When in the active state, these GTPases bind to a large collection of proximal elements (also referred to as "effector" molecules) that, in turn, promote the stimulation of downstream signaling cascades (Bustelo et al. 2007) (Fig. 1). However, a minority of "nonconventional" Rho/RacGTPases (i.e., Rnd subfamily members) are constitutively bound to GTP molecules and, therefore, are always present in a permanent active state. These proteins work as antagonists for conventional Rho/Rac GTPases (i.e., RhoA) (Chardin 2006). Conventional and nonconventional Rho/Rac GTPases control functions common to many cell types, including the regulation of the cytoskeletal structure, cell cycle transitions, cell survival, or vesicle trafficking (Bustelo et al. 2007; Chardin 2006). In addition, they are in charge of cell type-specific functions, including the differentiation, stimulation, migration, and chemotaxis of different immune cell types (Bokoch 2005; Bustelo 2002, 2007; Mulloy et al. 2010; Tybulewicz and Henderson 2009). In this entry, a brief discussion of the regulation and biological roles of this GTPase subfamily in specific cell lineages of the immune system will be presented. Such discussion includes information about (1) the biosynthetic cycle of Rho/Rac proteins, (2) the regulation of its GDP/GTP cycle, (3) the downstream effectors, (4) the biological routes controlled by them in immune cells that have been corroborated using animal models, (5) and the implication of these proteins in diseases related to the immune system. The implication of Rho/Rac proteins in other hematopoietic lineages and non-hematopoietic cells can be found elsewhere (Bokoch 2005; Bustelo et al. 2007; Mulloy et al. 2010).

Regulation

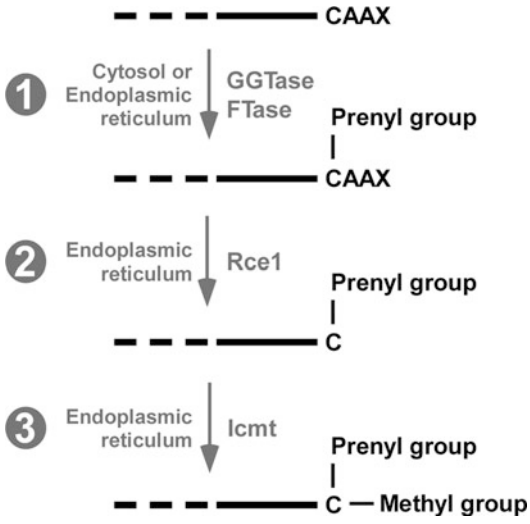
Rho/Rac GTPases are subjected to a complex array of regulatory mechanisms controlling their subcellular localization, activation level, and overall signaling output. Those include:

Posttranslational Modification of the C-Terminus. Most Rho/Rac proteins require the attachment to the plasma membrane and/or intracellular vesicles to carry out their biological functions. This step requires the posttranslational modification of Rho/Rac proteins in the four C-terminal amino acids that receive the collective name of "CAAX box" (where C is cysteine, A is any aliphatic amino acid, and X can be methionine, serine, alanine, or glutamine) (Bustelo et al. 2012, 2007). This modification takes place, depending on the GTPse involved, in three to four independent steps (Fig. 2):

(1) Incorporation of either a geranylgeranyl or a farnesyl group onto the cysteine residue of the CAAX box of the recently translated, cytosolic GTPase (Fig. 2, step 1). This process is catalyzed by either cytosolic type I geranylgeranyl transferases or endoplasmic-reticulum-localized farnesyl transferases. Geranylgeranylation is by far the



Rho/Rac GTPases, Fig. 1 *GTPase cycle*. Main regulatory mechanisms affecting the functional cycle of conventional Rho/Rac proteins. The GDP/GTP cycle as well as other regulatory steps mediated by the action of either effectors or other signaling elements is depicted in the figure. Activation and inactivation steps are indicated by *arrows* and *blunted lanes*, respectively. The subcellular localization and activation phases of the GTPase are indicated at the *bottom*. For the sake of simplicity, the regulatory cycle of a "conventional" Rho/Rac protein capable of undergoing GDP/GTP exchange has been only depicted. The regulatory steps for "nonconventional" Rho/Rac GTPases are similar, with the exception of the RhoGDI binding and GEF-/GAP-catalyzed steps. *ER* endoplasmic reticulum, *P* phosphate. Other abbreviations have been introduced in the main text



Rho/Rac GTPases, Fig. 2 *GTPase maturation*. C-terminal processing of Rho/Rac proteins. The palmitoylation step that some GTPases undergo upon C-terminal processing has not been depicted. See details in main text. *FTase* farnesyl transferase, *GGTase* geranylgeranyl transferase

most prevalent posttranslational event in Rho/Rac subfamily members, because farnesylation is only observed in RhoB, RhoJ, and RhoQ.

(2) Cleavage of the C-terminal AAX tripeptide at the endoplasmic reticulum by the action of Rce1, an isoprenyl, CAAX-specific endoprotease (Fig. 2, step 2).

(3) Methylation of the α-carboxyl group of the newly exposed C-terminal isoprenylcysteine residue of the GTPase at the endoplasmic reticulum, a process catalyzed by the carboxyl methyltransferase Icmt (Fig. 2, step 3).

(4) Some GTPases (i.e., Rac1, RhoB, RhoJ, RhoQ) are further modified by the addition of a palmitate group to cysteine residues situated immediately upstream of the CAAX motif. The enzyme responsible for this step is still uncharacterized in mammals.

Regulation by Rho GDP Dissociation Inhibitors (RhoGDIs). Once prenylated and processed at the endoplasmic reticulum, the mature

GDP-bound GTPases bind to RhoGDIs (Fig. 1). In fact, it is assumed that all the inactive pool of Rho/Rac GTPases is trapped in RhoGDI complexes. The main role of RhoGDIs is an inhibitory one, since they sequester the GTPases in the cytosol, restrict the release of GDP molecules from the bound GTPases, and extract the GTPases from membranes at the end of the stimulation cycle (Bustelo et al. 2012, 2007; DerMardirossian and Bokoch 2005) (Fig. 1). However, recent reports have revealed that RhoGDIs can also play positive roles in this route, favoring the translocation of these proteins during signal transduction and protecting the inactive GTPases from proteolytic degradation (Boulter et al. 2010; Bustelo et al. 2012; 2007; DerMardirossian and Bokoch 2005) (Fig. 1). Although the mechanism is not fully elucidated, it has been shown that the release of the GTPases from the RhoGDI complexes, a process required for the activation and membrane anchoring of the GTP-binding proteins, is mediated by the phosphorylation of RhoGDI by Src, protein kinase C, and Pak1 (Bustelo et al. 2012) (Fig. 1). There are three known RhoGDIs in vertebrates, all of them expressed in hematopoietic cells: RhoGDI1 (also known as RhoGDIα), RhoGDI2 (also known as D4/LyGDI/β), and RhoGDI3 (also referred to as RhoGDIγ) (DerMardirossian and Bokoch 2005).

Regulation of the GDP/GTP Cycle. The conventional members of the Rho/Rac family have to undergo GDP/GTP exchange in order to become activated during signal transduction. This process is catalyzed by enzymes known as Rho/Rac GDP/GTP exchange factors (GEFs) (Fig. 1). Depending on whether they contain Dbl-homology (DH) or Dock-homology catalytic domains, these GEFs are subclassified in Dbl and Dock subfamily proteins (Bos et al. 2007). Although mammals have nearly 70 proteins with this enzyme activity (Bos et al. 2007), the GEFs with specific roles in immune cells include, so far, only five Rac subfamily-specific GEF (Vav1, Vav2, Vav3, Tiam1, Dock2), a Rho subfamily-specific exchange factor (Lsc, also known as p115-RhoGEF and ArhGEF1), and a Rac1-/Cdc42-specific GEF (ArhGEF6, also known as α-Pix) (Tybulewicz and Henderson 2009). At the end of the activation cycle, the GTPases are inactivated by the action of the enzymes known as GTPase-activating proteins (GAPs). These proteins promote the hydrolysis of the GTPase-bound GTP molecules and, therefore, the transit back to the inactive, GDP-bound state of these GTPases (Bos et al. 2007) (Fig. 1). Similar to the Rho/Rac GEFs, there is a large number of GAPs in mammals (Bos et al. 2007), many of which are expressed in immune cells (Tybulewicz and Henderson 2009). However, few of them have been analyzed in the immune system using animal models (Tybulewicz and Henderson 2009).

Other Regulatory Steps. Recent work has been shown that the active GTPases can be regulated by additional mechanisms, including tethering to specific subcellular localizations, protein/protein interactions, ubiquitinylation, sumoylation, C-terminal phosphorylation, internalization/recycling using the vesicle trafficking machinery, transcriptional activation of their genes and microRNA-mediated degradation of GTPase-encoding transcripts (Fig. 1). Some of these mechanisms have been recently reviewed (Boulter et al. 2012; Bustelo et al. 2012, 2007; Chardin 2006).

Downstream Effectors

The activation of Rho/Rac proteins leads to their association with effector molecules responsible for the assembly of specific signaling cascades. To date, around 60 potential effectors have been identified for RhoA, Rac1, and Cdc42 that participate in different signaling pathways (Bustelo et al. 2007) (Table 2). Although this list is very extensive and highly heterogeneous from a functional point of view, the Rho/Rac effectors can be divided in eight main subclasses: (1) direct regulators of the F-actin cytoskeleton (Was, Baiap2, formins, rhotekins); (2) serine/threonine kinases controlling cytoskeletal

Rho/Rac GTPases, Table 2 Examples of effectors of the most important Rho/Rac GTPases

GTPase	Effector[a]
Rac1	ArhGEF7; Arfip2; Baiap2; CybA; Cyfip2; Fhod1; IQGAP1,2; Ncf1,2; Nck1; mTor1,2; Pak1; Pak2; Pak3; PIK3R1; Stat3; Wasf1,2
RhoA	Citron; Diaph1,2; Rtkn1; Rtkn2; Rhpn1; Rhpn2; PI-4-p5K; Pld1; Pkn1,2; Rock1,2
Cdc42	Baiap2; CopG2; Cdc42BPGA,B; Cdc42SE1,2; Cdc42EP1,3,5; Dia2,3; IQGAP1,2; Mig6; Pard6A,G; PIK3R1; Stat3, Tnk2; Was; Wasf1,2; WasL

[a]Names are given following the consensus Human Genome Organization nomenclature

dynamics and other downstream biological responses (Pak, Citron, Rock, and Pkn families); (3) tyrosine kinases (Tnk2, also known as Ack); (4) enzymes involved in lipid biosynthesis (▶ PI3K, PI-5-p5K); (5) proteins involved in the regulation of multisubunit complexes such as the neutrophil NADPH oxidase (Ncf1 and CybA, also known as $p47^{Phox}$ and $p22^{Phox}$, respectively); (6) proteins involved in cell polarity (i.e., Pard6A and B); (7) molecules that tether Rho/Rac proteins to specific subcellular localizations (i.e., ArhGEF7, Nck, CopG2); (8) and a heterogeneous group of proteins including metabolic enzymes (i.e., ▶ mTORC) and transcriptional factors (Stat3). The exact interactomes of all members of the Rho/Rac family are still unknown, so it is possible that additional effector molecules may exist. It is also important to note that highly related Rho/Rac GTPases share overlapping, but not identical, spectra of binding proteins. For example, Rac1, but not Rac2 or RhoG, can bind to members of the Pak serine/threonine kinase family.

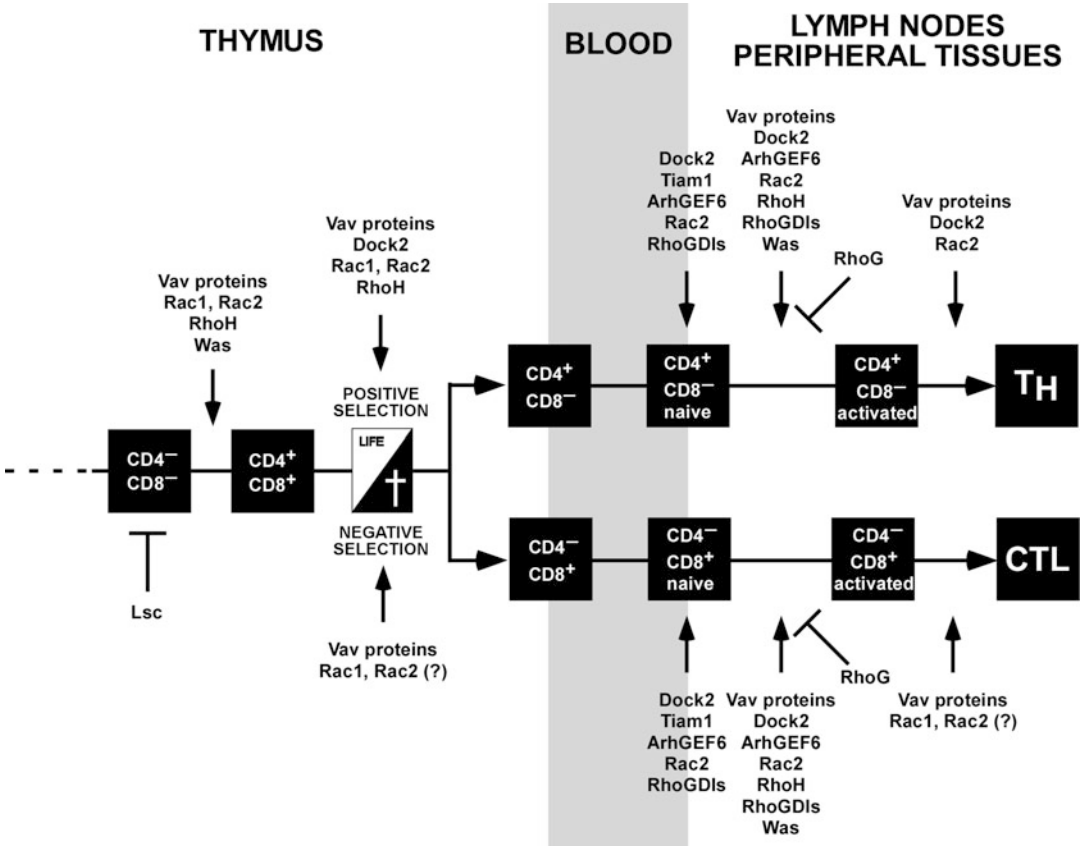
The interaction of Rho/Rac proteins with effectors is mediated by specific residues present in the switch I and switch II regions and, in some cases, further stabilized by interactions with other regions of the GTPase structure. This is consistent with the fact that the switch regions are the only parts of the GTPase molecule that undergo substantial conformational change upon the binding of guanosine nucleotides (Bustelo et al. 2007). However, in exceptional cases, the effectors can bind independently of the nucleotide-bound status of the GTPase. For example, mTorc1 and mTorc2, two signaling elements of the ▶ mTOR complex, can bind to indistinctly to the C-terminus of GDP- and GTP-bound Rac1 (Bustelo et al. 2012).

Upon binding, most of the effectors are activated (Bustelo et al. 2007). In the majority of cases, this is achieved by the induction of conformational changes that, in turn, favor the activation of the latent enzyme or biological activities of effectors (Bustelo et al. 2007). This is the case for the downstream enzymes belonging to the Pak, Rock, and Pkn families. In other cases, the activation step may relay exclusively in the tethering of the effector to specific subcellular localizations (Bustelo et al. 2007). Less frequently, Rho/Rac GTPases induce the release of inhibitors from a signaling complex (Bustelo et al. 2007). Thus, the activation of Wave1 by Rac1 is achieved by the indirect binding and release of Nap125 and Pir121 proteins from that complex. Finally, some interactions lead to the direct inhibition of the bound downstream effector (Bustelo et al. 2007; Chardin 2006). This is the case of Rnd3 that, by binding tightly to Rock, blocks the activation of this serine/threonine kinase by RhoA. The Cdc42-mediated inhibition of Borgs and the NADPH oxidase complex has also been described (Bustelo et al. 2007).

Biological Effects

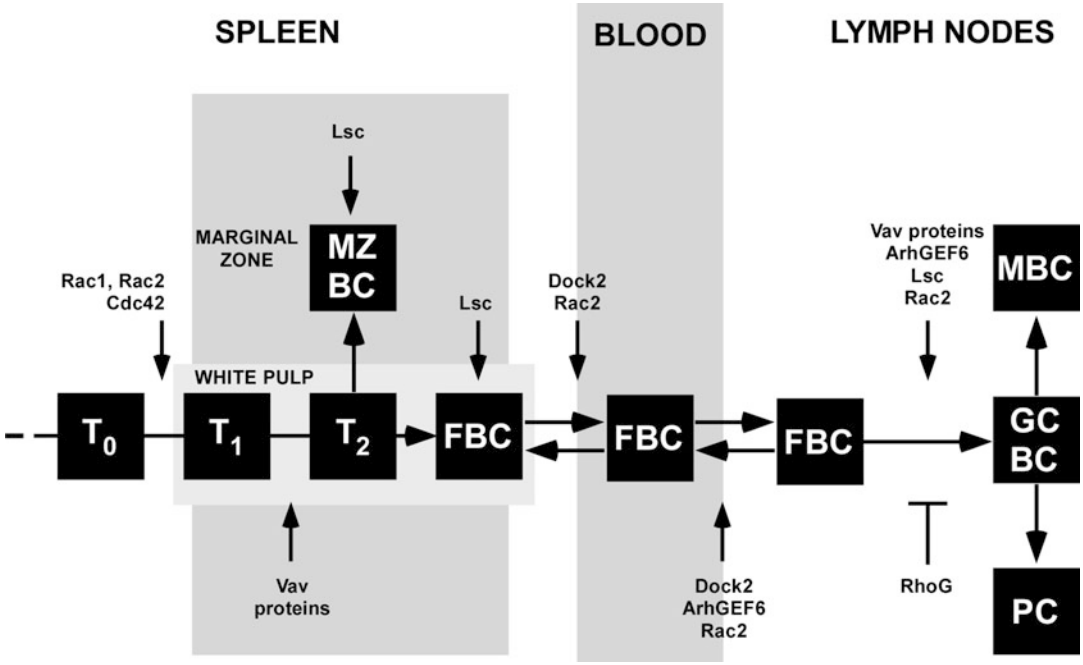
A wealth of information has been recently generated using knockout and knock-in animal models for specific signaling elements implicated in Rho-/Rac-dependent routes. The main biological processes controlled by those proteins in lymphocytes and myeloid cells are described below. The functions of Rho-/Rac-dependent routes in other hematopoietic cell types have been discussed in previous review articles (Bokoch 2005; Bustelo et al. 2007; Mulloy et al. 2010).

Rac Subfamily-Dependent Routes in T Lymphocytes. The most comprehensive characterization of the importance of Rac-dependent routes in this cell lineage has been done using animal



Rho/Rac GTPases, Fig. 3 *GTPases in T cells*. Schematic representation of T-cell development and the T-cell functions that are Rho/Rac GTPase dependent. Putative functions are indicated by a *question mark*. *CTL* cytotoxic T cell, *TH* helper T cell, ✞ cell death

models deficient in Vav family members. These proteins work as tyrosine phosphorylation-dependent Rac subfamily-specific GEFs (Bustelo 2000; Bustelo 2008, 2010, 2011; Bustelo and Couceiro 2008; Turner and Billadeau 2002). These analyses revealed that Vav proteins play essential roles in both the development and effector functions of T cells. In the former case, those functions include favoring pre-T-cell receptor (TCR) signals for the proper transition of double negative ($CD4^-CD8^-$) into double positive ($CD4^+CD8^+$) thymocytes and in the positive/negative selection of $CD4^+CD8^+$ T cells (Fig. 3). Vav proteins also control effector functions of mature T cells downstream of the TCR that include, among others, the TCR capping and F-actin polymerization; the formation of the immune synapse, proliferation, and cytokine production; the induction of cytotoxic-, helper-, and T-cell-dependent B-cell responses; and the homing of stimulated T cells into peripheral tissues (Fig. 3). In addition to the expected effects on the F-actin cytoskeleton, Vav proteins control the activation of ▶ PI3K and phospholipase C-γ1 (PLC-γ1) and, therefore, the optimal activation of Ca^{2+} dependent routes, the PLC-γ1/RasGRP1/Ras/Erk pathway as well as Akt-, protein kinase C- and protein kinase D-dependent routes downstream of the TCR. These proteins are also required for the optimal stimulation of transcriptional factors such as ▶ NFAT, ▶ NFκB, and Foxo1. These functions involve the use of both



Rho/Rac GTPases, Fig. 4 *GTPases in B cells*. Schematic representation of B-cell development and the B-cell functions that are Rho/Rac GTPase dependent. Proteins with positive and negative roles are indicated by arrows and blunted lanes, respectively. Rac GTPase-dependent and Rac GTPase-independent routes (Bustelo 2000, 2008, 2010; 2011; Bustelo and Couceiro 2008; Turner and Billadeau 2002; Tybulewicz and Henderson 2009). Other Rac subfamily exchange factors play more restricted roles in T cells. Thus, Dock2 has roles in the positive and negative selection of thymocytes and the TCR-triggered proliferation of mature T cells (Tybulewicz and Henderson 2009) (Fig. 3). It is possible that some of those functions are partially redundant to those engaged by Vav family proteins. Finally, the Rac subfamily-specific Tiam1 GEF favors the transendothelial migration of activated T lymphocytes (Tybulewicz and Henderson 2009) (Fig. 3).

The coordinated action of both Rac1 and Rac2 is required for T-cell development and positive selection. These roles are a copycat of those for the Vav family GEFs in the same developmental setting (Fig. 4). In mature T cells, the *Rac2* gene deficiency induces a similar although milder phenotype to that induced by the loss of the Vav GEF family. Finally, it has been shown that this GTPase is important for the differentiation of T-helper type 1 cells, probably by regulating the secretion of γ-interferon (Bustelo et al. 2007; Mulloy et al. 2010; Tybulewicz and Henderson 2009) (Fig. 3). Animals deficient in Rac1 and Rac2 have not been analyzed as yet in mature T cells, although it is predictable that the phenotype of those mice will result in the aggregation of defects previously detected in mice lacking expression of the aforementioned Rac GEFs. RhoG is dispensable for T-cell development, although its deficiency leads to slightly higher proliferation rates in stimulated T cells (Bustelo et al. 2007; Mulloy et al. 2010; Tybulewicz and Henderson 2009) (Fig. 3). RhoG has been also shown to be important for T-cell trogocytosis, a recently described biological process that promotes the internalization of large plasma membrane chunks of the antigen-presenting cell by the conjugated T cell (Martinez-Martin et al. 2011).

Rho- and Cdc42 Subfamily-Dependent Routes in T Lymphocytes. The function of Rho subfamily GTPases (RhoA, RhoB, RhoC) has not been analyzed comprehensively in T lymphocytes. The exception has been the characterization of mice deficient in Lsc, a Rho subfamily-specific GEF-activated downstream of G-coupled receptors. In contrast to Rac subfamily GEFs, the lack of Lsc leads to an increase in the total numbers of mature T cells, a phenotype that has been linked to deficient apoptosis of immature T cells downstream of the thromboxane receptor (Tybulewicz and Henderson 2009) (Fig. 3). The role of Cdc42 subfamily proteins in T cells has not been explored either. However, the Rac1-/Cdc42-specific ArhGEF6 has been shown to be important for the proper activation of the Pak family of serine/threonine kinases downstream of the T-cell receptor and for the formation of cell conjugates with dendritic cells (Tybulewicz and Henderson 2009). The analysis of mice lacking Was, a Cdc42 effector, has demonstrated that this protein is critical for the normal production of immature and mature T cells (Fig. 3). The reduced production of thymocytes is due to impaired progression from the $CD44^{-}CD25^{+}$ to the $CD44^{-}CD25^{-}$ differentiation stage (Bustelo et al. 2007). *Was*$^{-/-}$ thymocytes and mature T cells show impaired T-cell receptor capping and endocytosis, defective Ca^{2+} fluxes, and reduced F-actin levels. As a consequence, they proliferate poorly upon engagement of the T-cell receptor (Bustelo et al. 2007) (Fig. 3).

Role of other Rho/Rac GTPase Subfamilies in T Lymphocytes. The analysis of *Rhoh*$^{-/-}$ mice has shown that this GTPase has also roles in T-cell development. This role seems to be connected to an adaptor function that favors the translocation of Zap70, a tyrosine kinase that plays essential roles downstream of the T-cell receptor (Tybulewicz and Henderson 2009) (Fig. 3).

Rac Subfamily-Dependent Routes in B Lymphocytes. Vav proteins play roles in B-cell differentiation, in pre-B-cell receptor-triggered proliferation, and in many antigen receptor-induced mature B-cell responses (i.e., proliferation, immune synapse formation, adhesion, spreading, peripheral survival) (Fig. 4). Vav proteins also work downstream of the receptors for polysaccharide (LPS) and the CCL21, CXCL13, and CXCL12 ▶ chemokines (Bustelo 2000, 2008, 2010, 2011; Bustelo and Couceiro 2008; Turner and Billadeau 2002; Tybulewicz and Henderson 2009) (Fig. 4). Dock2 is important for chemokine-induced B-cell migration, leading to defective infiltration of B cells in lymph nodes and the splenic white pulp. It also favors the adhesion and transendothelial migration of B cells through lymph node capillaries as well as the migration out of lymph nodes in response to sphingosine-1-phosphate stimulation (Tybulewicz and Henderson 2009) (Fig. 4).

Mice lacking Rac1 and Rac2 proteins display a developmental block of B-cell development at very immature stages, a phenotype connected to the improper activation of Akt-dependent survival signals and the poor expression the antiapoptotic BAFF receptor and Bcl-x_L (Fig. 4). In addition, immature B cells lacking these two GTPases cannot migrate properly, leading to a defective infiltration of the splenic white pulp and further impairments of the survival and maturation of these cells (Bustelo et al. 2007; Tybulewicz and Henderson 2009) (Fig. 4). *Rhog*$^{-/-}$ B cells can develop normally. However, as in the case of T lymphocytes (see above), RhoG-deficient mature B cells hyperproliferate upon B-cell receptor stimulation when compared to control cells (Bustelo et al. 2007; Tybulewicz and Henderson 2009) (Fig. 4).

Rho- and Cdc42 Subfamily-Dependent Routes in B Lymphocytes. Little information is available regarding the role of Rho subfamily GTPases in this cell lineage. The only exception has been the analysis of Lsc-deficient mice, which has revealed an implication of this RhoA GEF in the generation of normal B-cell numbers, the engagement of T-cell-dependent B-cell responses, and the LPS-induced migration of B cells to follicles (Tybulewicz and Henderson 2009) (Fig. 4). In the case of Cdc42, the recent analysis of inducible Cdc42 knock-in mice has revealed that this GTPase is important for the development of B1a and conventional B cells, probably by regulating pro-survival signals downstream of the B-cell

receptor (Bustelo et al. 2007; Mulloy et al. 2010; Tybulewicz and Henderson 2009) (Fig. 4). The use of knockout mice for ArhGEF6 indicates that this protein is important for the migration of B cells to lymph nodes and B-cell receptor-triggered proliferation (Tybulewicz and Henderson 2009) (Fig. 4). Thus, the activation of Cdc42 in immature B cells is probably regulated by other Rho/Rac GEFs.

Rac Subfamily-Dependent Routes in Myeloid Cells. Vav proteins are important for integrin-dependent adhesion and spreading, phagocytosis, and the oxidative burst of neutrophils. These functions contribute to the optimal assembly of IgG-/FcγR-mediated hemorrhage and edema responses in lung and skin, the interstitial transit of those cells toward sites of bacterial infection, and the effective assembly of responses against nosocomial organisms (Bustelo 2008, 2010, 2011, Bustelo and Couceiro 2008; Mulloy et al. 2010). Rac1 and Rac2 play nonoverlapping roles in these cells. Thus, Rac2 is critical for the motility, chemotaxis, phagocytosis, and the activation of the NADPH oxidase complex. Rac1 seems to be only important for chemokine-dependent responses. Rac1 and RhoG also participate, although in a less significant manner than Rac2, in the activation of the NADPH oxidase complex (Bustelo et al. 2007; Mulloy et al. 2010; Tybulewicz and Henderson 2009).

In the case of macrophages, Vav1 and Vav3 are important for ROS production and, in addition, for complement-mediated phagocytosis. The latter role seems to be connected to the proper tethering of Arp2/3 complex and F-actin to the phagocytic cup (Bustelo 2008, 2010, 2011, Bustelo and Couceiro 2008; Mulloy et al. 2010). Rac2 is important for both migration and superoxide production and phagocytosis to some (i.e., FcγR stimulation, IgG-sensitized sheep red blood cells) stimuli. By contrast, Rac1 seems to be important for regulating macrophage cell morphology and lamellipodia formation (Bustelo et al. 2007; Mulloy et al. 2010; Tybulewicz and Henderson 2009).

Other Rho/Rac Subfamily-Dependent Routes in Myeloid Cells. Cdc42 is involved in neutrophil polarity, as inferred from recent data using both Cdc42- and Cdc42-GAP-deficient cells (Mulloy et al. 2010). In addition, Wasp-deficient neutrophils have reduced phagocytic activity (Bustelo et al. 2007). The role of other Rho/Rac GTPases in this cell lineage is still unknown.

Rho-/Rac-Dependent Routes in Human Immune Diseases

An inactivating mutation in Rac2 (Asp57→Asn) with a dominant negative effect has been associated with a severe neutrophilic immunodeficiency in humans, a disease phenotypically very similar to the phenotype of *Rac2*$^{-/-}$ mice in this cell lineage (Mulloy et al. 2010). Different mutations in the *Was* gene, a locus encoding the Cdc42 Was effector that plays critical roles in cytoskeletal architecture, are the molecular cause for the recessive X-linked Wiskott-Aldrich immunodeficiency syndrome (WAS) that affects lymphocyte and myeloid cell function. T and B cells from WAS patients have both altered and reduced numbers of microvilli in their surface and, in addition, display defective downstream signaling from antigen B- and T-cell receptors (Bustelo et al. 2007). In cancer, the *RHOH* locus is frequently involved in chromosomal translocations in cases of human multiple myeloma, non-Hodgkin lymphoma, and B-cell chronic lymphocytic leukemia (Mulloy et al. 2010). Rac subfamily proteins are important for the tumorigenic status of chronic myeloid and MML-AF9-derived leukemia, as assessed by the use of Rac family animal models and Rac-specific inhibitors (Mizukawa et al. 2011; Mulloy et al. 2010). Finally, it has been shown that the immunodeficiency virus (HIV) stimulates the Rac1 route to favor its infectivity cycle. To this end, HIV encodes a protein (Nef) that, upon expression in the infected T cells, promotes the activation of the Rac1/Pak1 route through the direct binding to Pak1 and Rac1 GEFs (Vav1 and Dock2) (Greenway et al. 2003).

Conclusion

The studies conducted so far have shown that Rho/Rac GTPases play critical roles in the

development, selection, differentiation, and function of many immune-related cells such as lymphocytes and myeloid cells. Information gathered during these years has also indicated that Rho-/Rac-dependent signaling elements could be potential therapeutic targets to deal with immune dysfunctions and immune-related neoplasias. However, this is probably just the tip of the iceberg, since only a very limited subset of Rho/Rac signaling elements have been characterized so far at the functional and genetic level in immune cells. Further work in this area will yield additional information about the role of this complex protein family in the development and functionality of the immune system.

Role of B Cells in Suppressing/Modulating Immune Function

Bregs

Definition Based on Function

Regulatory B cells are B lymphocytes that are capable of impairing or suppressing one or more components of an immune reaction (Mauri and Bosma 2011). B cell production of antibody subclasses with high affinity for inhibitory Fc receptors may be considered one suppressive function of B cells. However, the term regulatory B cell ("Breg") is most frequently reserved to describe antibody-independent mechanisms of suppression. Such suppressive activity can occur either directly by producing cytotoxic and suppressive soluble factors or indirectly by enabling other immune cells with suppressive properties.

One indirect mechanism is antigen presentation by normal naïve B cells to promote the development of regulatory T cells ("Tregs") (Redfield et al. 2011). Depleting Tregs in mice results in poor growth of transferred tumors, likely through enhanced responses of other T cells with inflammatory, antitumor properties (Tadmor et al. 2011). In this model, Treg-phenotype ($CD25^+Foxp3^+$) cell proliferative capacity and suppressive activity are suboptimal if the tumor recipients cannot produce B cells (Tadmor et al. 2011). Furthermore, B cells promote the accumulation of Treg-phenotype cells in the spleen, tumor-draining lymph node, and tumor bed, associated with reduced cytotoxic spleen cell activity, IFN-γ secretion, and enhanced growth of the injected tumor (Tadmor et al. 2011). This evidence collectively suggests that Bregs promote the differentiation and/or expansion of Tregs, which in turn suppress cytotoxic and inflammatory reactions that otherwise disable tumor growth. Thus, targeting the Breg-Treg axis may be a way to enhance immunotherapies against malignancy.

Direct suppressive mechanisms include the ability of B cell chronic lymphocytic leukemia cells to express the cytotoxic molecule granzyme B and kill other B-CLL cells in vitro (Jahrsdorfer et al. 2006). Additionally, normal (non-transformed) activated human B cells can reduce T cell division (Bouaziz et al. 2010). B cells can also secrete soluble factors that reduce expression of inflammatory cytokines by T cells. For example, supernatants of IFN-β-treated human B cells reduce *IL17* mRNA levels and IL17 protein secretion from activated T cells, an effect that can be reversed by neutralizing IL27 (Ramgolam et al. 2011). Therefore, IFN-β causes B cells to secrete something that inhibits T cell IL17 production in an IL27-dependent manner. Similarly, B cell suppression of the inflammatory cytokines TNF-α and IFN-γ in T cells can be reversed by neutralizing interleukin 10 (IL10) in culture (Blair et al. 2010; Bouaziz et al. 2010; Iwata et al. 2011). After *Salmonella* bacterial infection in vivo, mouse B cell IL10 can limit accumulation of TNF-α^+ neutrophils, IFN-γ^+ NK cells, IFN-γ^+ CD4 T cells, TNF-α^+ CD4 T cells, and IFN-γ^+ CD8 T cells in spleen as well as inflammatory foci in liver, correlating with inhibition of bacterial clearance and inhibition of mouse survival (Maseda et al. 2012). Collectively, these observations demonstrate that B cells have suppressive activity in vivo and suggest a mechanism in which such cells dampen inflammatory responses mediated by T cells as well as innate immune cells that otherwise protect from lethal pathology induced by microbial pathogens.

B Cell IL10 Induction

IL10 production is the most well-studied suppressive mechanism in human B cells, and its potential for resolving immune reactions is corroborated by evidence from mouse studies. Like many other cytokines, IL10 expression by B cells is undetectable directly ex vivo without additional stimulation. However, when human spleen, tonsil, adult blood, or cord blood mononuclear cells are cultured for ~5 h with toll-like receptor (TLR) ligands in the presence of PMA/ionomycin, ~0.5–3 % of the B cells become $IL10^+$ (Bouaziz et al. 2010; Iwata et al. 2011). Similar results are observed for mouse B cells (Yanaba et al. 2009). This readout is inferred to represent an immediate capacity to produce IL10 in vivo, such that Iwata et al. referred to the cells as the "B10" subset and distinguished "B10" from "B10 progenitor" to refer to cells that

produce the cytokine only after stimulation on the order of days (Iwata et al. 2011). In this case, a boost with stimuli such as PMA/ionomycin in the final few hours is essential (Iwata et al. 2011) and is included in the studies described hereafter. Caution should be noted, however, because the term "B10" is inconsistently used to indicate any $IL10^+$ B cell detected after such longer stimulations.

Human B cell IL10 production induced by TLR ligands like LPS or CpG can be further enhanced by signaling through CD40 (Iwata et al. 2011; Yanaba et al. 2009), and CD40 engagement by itself also stimulates a range of IL10 secretion from purified human B cells (Duddy et al. 2007). Thus, T cell-independent (TLR ligation) and T cell-derived (CD40 ligation) signals alone or in combination can promote B cell production of IL10.

Two human studies show that engaging the B cell receptor (BCR) before or during treatment with CD40L ± CpG can reduce IL10 production, but not IL10 production induced by CpG alone (Duddy et al. 2007; Iwata et al. 2011). However, another study showed that BCR engagement could synergize with CpG to increase IL10 secretion (Bouaziz et al. 2010). It remains to be determined whether technical differences such as the specific anti-BCR reagent or the readout of accumulated secreted cytokine in the latter study *versus* intracellular staining in the former accounts for this apparent discrepancy. Nonetheless, these observations suggest that IL10 production by B cells may be regulated by the co-stimulation available when the cell encounters its cognate antigen and by the circumstances of B cell receptor engagement.

Besides the stimuli described above, IL10 as well as IL27 and IL12 secretion by human B cells can be induced by IFN-β, a treatment that also decreases B cell IL1β and IL23 secretion (Ramgolam et al. 2011). IL10 production by individual human B cells in culture is typically mutually exclusive with that of other inflammatory cytokines including IFN-γ, IL6 (Amel Kashipaz et al. 2003), and lymphotoxin (Duddy et al. 2007). $IL10^+$ B cells from human CD19 transgenic mice do not have a substantial enrichment for any particular cytokine message besides IL10 (Yanaba et al. 2009). These observations collectively suggest that IL10 production by B cells occurs in a relatively polarized fashion in which co-expression of inflammatory cytokines (besides IL12) are disfavored. For this reason, "B10" B cells are commonly thought of as a distinct functional subset or collection of subsets.

Neonatal mice have larger proportions of IL10-competent B cells compared with adults (Yanaba et al. 2009). The importance of this difference for immune system development remains to be determined. Interestingly, IL10-competent B cells from unmanipulated adult mice have diverse immunoglobulin gene usage, ≥80 % of them lack immunoglobulin somatic hypermutations, and ~70 % are not antibody isotype switched (Maseda et al. 2012). Thus, at least in mice at steady state, many IL10-expressing cells may be induced without specific antigen selection or participation in organized germinal centers. Consistent with this conclusion, gnotobiotic mice have similar frequencies and numbers of IL10-competent B cells compared with mice raised in conventional facilities (Yanaba et al. 2009). Nonetheless, injecting mice with stimuli like LPS can increase the frequency of $IL10^+$ splenic B cells by 3 days (Maseda et al. 2012). Although studies of completely germ-free mice are needed to establish the true contribution of environmental microbial molecules in determining steady-state B10 numbers, the evidence thus far indicates that de novo microbial stimuli can trigger inducible IL10-competent B cells.

Mouse genetic studies have also helped define in vivo B cell IL10 regulation by host molecules. Activity of the mouse IL10 gene regulatory elements are unaffected by IL10 expression itself (Maseda et al. 2012). Thus, any feedback autocrine regulation of this cytokine does not appear to occur at the transcriptional level in mice. Optimal steady-state numbers of IL10-competent B cells do not require CD21, MHC class II, or CD40 (Yanaba et al. 2009), indicating that CD21 complement receptor signals and T cell help are dispensable. In fact, T cells as well as the B cell surface protein CD22 can limit IL10-competent

B cells detected in mouse lymphoid organs (Yanaba et al. 2009). It remains to be determined whether the apparent discrepancy between T cell signals (CD40 engagement) being able to induce IL10 in vitro and the limiting effect of T cells in vivo could be due to different T cell subsets providing differential regulation to distinct B cell subsets (discussed below) in various circumstances.

Optimal steady-state numbers of IL10-competent mouse B cells require an intact B cell receptor repertoire, the B cell receptor co-stimulatory molecule CD19, as well as expression of the TLR signaling molecule myd88 (Yanaba et al. 2009). Myd88 has multifaceted roles in antimicrobial responses. On one hand, mice globally deficient in myd88 demonstrate that this molecule is needed for protection from *Salmonella* infection (correlating with splenic neutrophil and IFN-γ^+ NK cell numbers) (Maseda et al. 2012). Myd88 in B cells is important for optimal kinetics of the antimicrobial B cell response (GC-phenotype cells, antibody titers, and long-lived plasma cells) (Maseda et al. 2012). However, B cell myd88 also suppresses inflammatory IFN-γ^+ CD4, TNF-α^+ CD4, and IFN-γ^+ CD8 T cell, TNF-α^+ neutrophils, and IFN-γ^+ NK cell accumulation in spleen, limits inflammatory foci in liver, and suppresses bacterial clearance and mouse survival (Maseda et al. 2012). Thus, TLR signaling in B cells appears to have a dual function of promoting antimicrobial responses as well as resolving the ensuing inflammation induced by the pathogen.

IL10-Competent B Cell Subsets

The observations described above demonstrate that suppressive activity and IL10 production by B cells are complex in their regulation. Optimally utilizing this information for therapeutic advantage could be enhanced by understanding specifically which phenotypic B cell subsets are responsible for these functions in different circumstances. Most commonly defined human B cell subsets (Anolik et al. 2009) are capable of producing IL10 (Blair et al. 2010; Bouaziz et al. 2010; Iwata et al. 2011). Nonetheless, considerable investment has been made in determining the relative capacity of these subsets for IL10 production in different situations.

Transitional B cells are defined as recent emigrants from bone marrow into peripheral circulation and secondary lymphoid organs where they complete maturation (Anolik et al. 2009). These B cells are enriched in neonatal humans and are often the first to repopulate the circulation of adults that have been therapeutically depleted of their B cells. Compared with more mature human B cell subsets, these cells co-express higher levels of CD24 and CD38 (Blair et al. 2010). In culture, $CD24^{high}CD38^{high}$ human B cells can inhibit T cell production of TNF-α by a mechanism involving IL10 secretion and CD80/86 interactions with T cells (Blair et al. 2010). This B cell fraction can also inhibit T cell production of IFN-γ by a CD80/86-mediated mechanism that appears to be less dependent on IL10 (Blair et al. 2010). Some groups have found that 5-h stimulation of human peripheral blood mononuclear cells with CpG yields the highest proportion of $IL10^+$ cells from the $CD24^{high}CD38^{high}$ fraction compared with other B cells (Bouaziz et al. 2010). Similar results were observed when the cells are sorted before 3-day stimulation through CD40 (Blair et al. 2010). Whether enrichment of transitional-phenotype B cells accounts for the high frequencies of IL10-competent B cells in neonatal mice and whether this is also the case for humans is unknown. Others have demonstrated that IL10 secretion after anti-CD40 (± anti-BCR) is enriched in the $CD27^{neg}$ B cell fraction (Duddy et al. 2007), known to contain both transitional and mature-naïve B cells. In fact, enhanced IL10 production from reconstituted B cells in neuromyelitis optica patients previously treated with B cell depletion therapy correlates with excess $CD27^{neg}$ B cells (Duddy et al. 2007). Collectively, these data show that B cells characteristic of early differentiation stages can be a source of IL10. It is not entirely clear if the common phenotype represents early B cells that are suppressive or if some suppressive B cells happen to

share a cell surface phenotype with early B cells. Nonetheless, the observation that early reconstitution of transitional-phenotype B cells correlates with long-term clinical remission in SLE patients previously treated with B cell depletion therapy (Anolik et al. 2007) suggests that the immunosuppressive potential of such cells could be harnessed through specialized therapies.

Human B cells positive for the activation/memory marker CD27 are also capable of producing IL10 (Bouaziz et al. 2010; Iwata et al. 2011) correlating with the ability to suppress T cell and monocyte TNF-α production (Blair et al. 2010). Reports appear to differ on whether such cells compared with the earlier phenotypic subsets are the most efficient IL10 producers. Whether the apparent discrepancies result from analytical variation or truly represent biological differences among subject groups and immunological circumstances remains to be resolved.

Evidence from mouse studies also suggests efficient IL10 production from activated B cells, as indicated by higher proportions of $IL10^+$ B cells expressing the marker CD43 (Maseda et al. 2012; Yanaba et al. 2009). A fraction of $CD43^+IL10^+$ mouse B cells are $GL7^+$ (Maseda et al. 2012), suggesting that germinal center B cells can express IL10. This may account for or at least contribute to the ~20 % of $IL10^+$ B cells with immunoglobulin somatic hypermutation and ~30 % that are isotype-switched (Maseda et al. 2012). The remaining $IL10^+$ cells may derive from locations and/or B cell fractions that are not in typical follicles associated with germinal center formation. Consistent with this suggestion, mouse $IL10^+$ cells have more CD5, CD1d, and CD19, but less CD23 compared with IL10-negative B cells (Maseda et al. 2012; Yanaba et al. 2009). This phenotype is characteristic of cells in the splenic marginal zone and also B1 B cells that are considered "innate-like" based on their rapid responsiveness to stimuli and use of germline B cell receptor sequences (Martin and Kearney 2002). $IL10^+$ B cells from adult T cell-deficient nude mice are all $CD1d^{high}CD5^+$, whereas in T cell-competent mice, it is only a 70 % majority (Yanaba et al. 2009). Thus, IL10 induced in innate-like phenotype B cells is T cell independent, whereas IL10 from other B cell subsets is likely influenced by signals from T cells.

Intriguingly, evidence from mice suggests that some IL10 production is from B cells that have differentiated to secrete antibody. At steady state, a fraction of $CD43^+IL10^+$ mouse B cells are $B220^{low}$ (Maseda et al. 2012), a characteristic of antibody-secreting cells. Similarly, 1 day after injecting IL10 mRNA reporter mice with LPS, IL10 reporter gene signal can be found in 16 % of cells with the plasma cell phenotype $B220^{low}CD138^+$ (Maseda et al. 2012). At the transcript level, purified mouse $CD1d^{high}CD5^+$ B cells are enriched for *IL10* as well as *blimp1* and *IRF4* mRNA when compared with $CD1d^{neg}CD5^{neg}$ B cells (Maseda et al. 2012). Another reporter model revealed that B cells capable of expressing IL10 are enriched for *blimp1* and *XBP1* mRNA, but *Pax5* and *Bcl6* levels are lower (Maseda et al. 2012). These gene expression profiles are characteristic of antibody-secreting plasma cells and plasmablasts. Functionally, mouse B cells expressing an IL10 mRNA reporter gene are more likely to secrete antibody in vitro and reconstitute antibody in lymphocyte-deficient mice in vivo compared with reporter gene-negative B cells (Maseda et al. 2012). IL10-expressing antibody-secreting cells can be induced by either immunization with haptenated protein or injection with attenuated *Salmonella* bacteria (Maseda et al. 2012). The true importance of this B cell functional multitasking remains to be fully understood. Differentiation of IgM secretion from $CD1d^{high}CD5^{neg}$ B cells after LPS treatment in vivo does not require IL10 expression (Maseda et al. 2012). However, IgM derived from IL10 reporter-positive B cells transferred into lymphocyte-deficient mice is polyreactive against TNP, dsDNA, ssDNA, and histones (Maseda et al. 2012). This was not the case for IgG derived from the same pool of IL10-competent cells. It remains to be determined at what level the regulation of this self-reactivity *versus* effector isotype is regulated, which cells are responding to IL10, and the overall contribution of this system to peripheral tolerance.

Bregs in Disease

B cell suppressive activity may be advantageous in dampening damaging inflammation once a pathogen is successfully cleared. However, this activity may also contribute to the pathogen's ultimate success (Maseda et al. 2012; Neves et al. 2010). Thus, vaccine design could benefit from trying to surpass such suppressive activity while enhancing protective reactions. Further elaboration of the in vitro and in vivo regulation of different B cell subsets with suppressive potential will be needed to catalyze this optimization.

Reciprocally, this knowledge may also be used to benefit individuals that suffer from self-targeted immune reactions. For example, helminth (parasitic worm) infection increases the number of $IL10^+$ B cells in mouse spleen (Amu et al. 2010). These B cells express high levels of CD1d, CD5, CD21, and IgM but low levels of CD23 (Amu et al. 2010), consistent with an innate-like marginal zone or B1 B cell phenotype. Interestingly, mice previously infected with the helminth are less susceptible to de novo or established ovalbumin-induced asthma (Amu et al. 2010), suggesting that the IL10-competent B cells in these mice could contribute to such protection. In fact, helminth-immune mouse B cells, especially $CD1d^{high}$ B cells, can transfer asthma suppression in a B cell-intrinsic IL10-dependent manner (Amu et al. 2010). This transferred suppression correlates with increased numbers of Treg-phenotype cells in the recipient lung, draining lymph node, and airways and, in fact, requires $CD25^+$ recipient cells (Amu et al. 2010). These observations collectively suggest that the Breg-Treg axis could be exploited for immunotherapy against asthma and hypersensitivity.

Additional evidence suggests that Bregs can help control autoimmune disease as well. In the TCR-α-deficient model of intestinal inflammation, B cells delay disease onset (Mizoguchi et al. 2002). This suppressive effect requires B cell expression of CD1d and IL10 (but not MHC II) and correlates with reduced expression of *IL1β* mRNA in the colonic mucosa (Mizoguchi et al. 2002). Paradoxically, IL10-competent B cell frequencies and numbers are increased in other autoimmune-prone mouse strains (Yanaba et al. 2009), and some autoimmune human patients have increased frequencies of IL10-competent B cells in circulation (Iwata et al. 2011). Human systemic lupus erythematosus (SLE) is an example of an autoimmune disease in which some patients show increased IL10 potential in the B cell compartment, most of which is reported to be in $CD5^+$ B cells (Amel Kashipaz et al. 2003). It is unknown whether this correlation reflects pro-inflammatory roles for IL10 or if IL10 is being produced in an attempt to dampen inflammation. Either possibility could be supported by the observations that the frequency of IL10-competent SLE B cells correlates with B cell lymphopenia and B cell-derived IL6 production (Amel Kashipaz et al. 2003). By contrast, $CD24^{high}CD38^{high}$ B cells from SLE patients have poor IL10 induction after CD40 engagement and also fail to limit IFN-γ production by activated CD4 T cells (Blair et al. 2010). Because increased IL10 from total SLE B cells and reduced IL10 from $CD24^{high}CD38^{high}$ SLE B cells were reported in separate studies, it is unknown whether the discrepancy can be explained by a shift in excessive IL10 production from B cells of other phenotypes. Resolving this issue would be highly informative for understanding IL10 in lupus and exploiting its suppressive capacity for therapeutic approaches.

Unlike lupus, total B cells from multiple sclerosis (MS) patients secrete less IL10 after in vitro stimulation through CD40 and the BCR (Duddy et al. 2007). However, after these patients are treated with the immunosuppressant mitoxantrone, their B cells are capable of IL10 production at normal levels (Duddy et al. 2007). This observation strongly suggests that poor IL10 production is an acquired, and not an intrinsic trait of MS B cells. In the mouse model of MS, experimental autoimmune encephalomyelitis (EAE), B cells are required for disease remission (Fillatreau et al. 2002; Wolf et al. 1996). B cell contribution to this remission correlates with suppressed IFN-γ production from antigen-restimulated splenocytes and requires the

B cells to express CD40 and to produce IL10 (Fillatreau et al. 2002). Antigen-reactive B cells in EAE-convalescent mice can produce IL10, and BCR reactivity is important for EAE remission (Fillatreau et al. 2002). These observations provide a very rational motivation for investigating the ability to manipulate Bregs to help induce remission in human MS.

Overall, the suppressive capacity of B cells is only beginning to be understood. Evidence from both human and mouse systems argue that further investigation could advance understanding of such cells in order to exploit their therapeutic potential in the context of cancer, infection, asthma, and autoimmunity. Other evidence indicates suppressive B cells in inhibiting graft rejection in mice (Redfield et al. 2011). Thus, multiple venues of disease can benefit from an understanding of Bregs.

Noncaseating granulomatosis

Definition

Sarcoidosis, a term derived from the Greek word *sarx* meaning "new flesh," is a disorder of unknown cause manifesting as granulomatous inflammation in affected organs. Any organ system can be affected; tissue lesions are characterized by the presence of granulomas without central necrosis (caseation).

Immunopathogenesis

No single trigger for the development of sarcoidosis has been identified. The inflammatory response in affected organs is characterized by a cell-mediated response and aggregation of CD4+ T lymphocytes. Studies demonstrating high levels of IL-12p40 in serum or BAL fluids derived from patients with active sarcoidosis may reflect enhanced secretion of either IL-12 and/or IL-23. In contrast to the presumed Th1 (or Th17) responses seen in other types of granulomatous inflammation, there is a state of peripheral anergy in sarcoidosis associated with increased circulating CD8+ suppressor T lymphocytes and Th2 cytokines.

Epidemiology

Sarcoidosis presents at any age, but initial manifestations most commonly occur between the second and fifth decades with a slight predominance in females (Costabel and Hunninghake 1999; Hosoda et al. 2002). The reported prevalence is higher in African Americans than in Northern Europeans (ACCESS Research Group 1999); the disorder is perceived to be less common in Asians.

Genetics

A role for genetic factors is supported by the observations of difference disease prevalence among ethnic groups and familial clustering (Sverrild et al. 2008). Genetic linkage analyses combined with sib pair and case–control association studies have identified disease susceptibility loci within the Annexin A11 gene (Hofmann et al. 2008) and BTNL2, a regulator of T cell co-stimulation (Valentonyte et al. 2005). Polymorphisms in CARD15/NO2, the gene coding the recognition protein for bacterial

peptidoglycans linked to constitutive NFκB activation, and the susceptibility gene for both Blau syndrome and perianal Crohn's disease, are associated with disease severity (Sato et al. 2010).

Clinical Features and Presentation

The respiratory system is thought to be involved at some point in almost all patients with sarcoidosis, but clinical manifestations may occur in any number of different organs with disease also initially becoming manifest as ocular, neurologic, or cutaneous abnormalities. Pulmonary presentations include non-productive cough, with or without dyspnea, in association with symmetric hilar/paratracheal adenopathy and variable degrees of interstitial parenchymal abnormalities on chest imaging. Chronic sinusitis due to involvement of the paranasal sinuses may be a presenting feature.

Cutaneous presentations most commonly include dermal pigmented papules and pannicular inflammation. Biopsy of suspect skin lesions confirms the presence of noncaseating granulomatous inflammation in the dermis. Septal panniculitis with erythema nodosum may be a presenting feature of sarcoidosis but almost always occurs in the context of other apparent disease manifestations. The presentation of fever, erythema nodosum, arthralgia, and symmetric hilar adenopathy (Lofgren's syndrome) is a characteristic acute presentation of sarcoidosis.

Up to 40 % of patients with sarcoidosis have musculoskeletal findings (Thelier et al. 2008; Zisman et al. 2002). Acute arthritis in sarcoidosis most commonly presents as an additive symmetrical oligoarthritis predominantly involving peripheral large joints; symmetrical polyarthritis and asymmetrical transient polyarthralgia have been described less frequently (Awada et al. 2003). The course of acute sarcoid arthropathy is typically benign, with spontaneous resolution of arthritis within a few weeks or months, although relapses may occur. Chronic sarcoid arthritis occurs less frequently but tends to follow a progressive course, causing erosive joint changes and deformity in a limited number of joints. Synovial fluid is inflammatory with lymphocytic predominance and protein elevation; synovial histology may show the typical noncaseating granuloma or nonspecific inflammatory synovitis (Torralba and Quismorio 2003). Axial arthritis is an uncommon manifestation of sarcoidosis, with sacroiliitis reported in 6 % or less of patients (Erb et al. 2005). Periarthritic inflammatory changes in the digits may present as soft-tissue swelling, tenosynovitis, and dactylitis.

Osseous lesions, manifest as punched-out areas of cortical as well as medullary bone, are most often asymptomatic and noted as incidental findings, occurring in 3–13 % of patients (Wilcox et al. 2000). The progression of bone destruction may be complicated by superimposed pathological fracture and/or arthropathy of adjacent joints.

Skeletal muscle involvement is common, occurring in up to 75 % of patients; symptoms are frequently absent but may include myalgia and symmetrical muscle weakness (Zisman et al. 2002; Awada et al. 2003; Le Roux et al. 2007). Nodular tumorous sarcoidosis is characterized by multiple intramuscular nodules that are palpable. Characteristic MRI findings demonstrate well-demarcated nodules with a central star-shaped area of hypointensity surrounded by areas of increased T2 signal; biopsy reveals dense central fibrosis surrounded by lymphocytes and epithelioid noncaseating granulomas with giant cells (Otake and Ishigaki 2001; Otake 1994). Acute sarcoid myositis is rare but most often occurs in the context of acute arthritis or periarthritis. Creatine kinase levels are typically elevated, EMG demonstrates a myopathic pattern, and focal areas of muscle edema may be identified on MRI; muscle biopsy reveals acute inflammation in the muscle fascicle and noncaseating granuloma formation (Otake and Ishigaki 2001; Otake 1994; Moore et al. 2005).

Ocular manifestations may involve the lacrimal glands, thereby giving rise to dry eyes and manifestations of keratoconjunctivitis sicca. Orbital myositis may accompany adnexal gland involvement, resulting in inflammatory pseudotumor of the orbit (Prabhakaran et al. 2007). Uveitis may be

insidious or present acutely involving one or both eyes. A distinguishing feature of sarcoid uveitis is that other ocular structures are commonly involved and may be associated with occult findings on high-resolution chest CT (Clement et al. 2010). The concomitant occurrence of uveitis with parotiditis and facial nerve palsy (Heerfordt's syndrome) is a distinct entity unique to sarcoidosis (James and Sharma 2000).

When present, central and/or peripheral nervous system manifestations are the presenting feature of sarcoidosis in up to half of involved cases (Joseph and Scolding 2009). Disease of the leptomeninges may present as an aseptic meningitis syndrome or as cranial neuropathy. Any of the cranial nerves may be affected but seventh nerve lesions are most frequent, followed by ocular and vestibular nerve complications. Hypothalamic and pituitary lesions may present as endocrine dysfunction. Cortical involvement is most commonly manifest as perivascular gray and white matter lesions, giving rise to a variety of focal deficits; peripheral cranial lesions can mimic a meningioma (Krejchi et al. 1998). Spinal cord myelopathy is often multifocal and may occur at any level. Peripheral neuropathy may occur as a consequence of sarcoid vasculitis or granulomatous inflammation of perineural tissues (Vital et al. 2008).

Myocardial involvement may be manifest as pericarditis, left and/or right heart failure, valvular disease, heart block, or arrhythmia. Delayed enhanced contrast MR imaging with gadolinium provides a sensitive means of detecting myocardial disease in sarcoidosis, 18F-fluorodeoxyglucose PET imaging offers an equally if not greater sensitive alternative for patients unsuitable for MR imaging (Ayyala et al. 2008). Potentially fatal arrhythmias are often refractory to medications and are usually best managed with an implantable defibrillating device (AICD) (Banba et al. 2007).

Vascular involvement with sarcoidosis may involve any caliber vessels resulting in aortitis, necrotizing arteritis of medium caliber vessels, and/or leukocytoclastic vasculitis. Necrotizing sarcoid granulomatosis (NSG) is a variant of sarcoid vasculitis presenting as large nodular lesions in the lung. The radiographic appearance may be similar to that seen in patients with ANCA-associated granulomatosis with polyangiitis, but the predominance of lymphoid aggregates with NSG and a paucity of neutrophils and eosinophils distinguish NSG from lung lesions due to ANCA-associated vasculitis.

Diagnosis

The diagnosis of sarcoidosis is best established by histological confirmation of the presence of noncaseating granulomas in biopsy material obtained from lymphoid, lung, dermal, salivary, lacrimal, or muscle tissue. Biopsy is usually not necessary in patients presenting with Lofgren's syndrome, provided histoloplasmosis is excluded with appropriate serologic studies. Clinical laboratory abnormalities including elevations of angiotensin-converting enzyme (ACE) level are nonspecific, not universally abnormal, and are unreliable for diagnostic purposes or as an indicator of disease activity. MRI is the most sensitive imaging modality used to detect active granulomas in bone, joint, and muscle (Moore et al. 2005; Judson 2008) and may be useful to guide biopsy of appropriate tissue to establish the diagnosis.

Treatment

Systemic corticosteroids are the mainstay of treatment for active sarcoidosis that involves musculoskeletal tissue and visceral organs. To avoid toxicity associated with prolonged corticosteroid use, steroid-sparing immune modulators including methotrexate (MTX), antimalarials, azathioprine, cyclosporine, and mycophenolate mofetil have been used with reported success in limited uncontrolled case series. TNF-α inhibitors (e.g., etanercept, infliximab, adalimumab, golimumab) have been used for patients with refractory or recalcitrant sarcoidosis (Sweiss et al. 2005) with reported success although studies to date do not suggest a consistent beneficial effect.

Definition

Scleroderma or systemic sclerosis (SSc) is a chronic autoimmune disorder with multi-organ system involvement. It has the highest overall morbidity and mortality of any connective tissue disease, and to date, there is no effective therapy.

Introduction

Scleroderma or systemic sclerosis (SSc) is a chronic fibrosing disorder with widespread systemic involvement and the highest overall morbidity and mortality of any connective tissue disease. The etiology of the disease is unknown; however, it is thought to arise from a combination of factors including autoimmunity, fibroblast proliferation, and endothelial cell dysfunction.

Disease Classification

SSc is heterogeneous and can be divided into various subsets – localized, limited, and diffuse. Localized scleroderma is a cutaneous fibrosing disorder that does not have systemic organ involvement. Patients with localized scleroderma develop skin thickening or hyperpigmentation of the skin in patches, described as morphea. Another form of localized SSc is linear scleroderma or en coupe de sabre, in which the skin is affected in a dermatomal pattern, usually on one side of the body.

The limited and diffuse scleroderma subsets are based on the degree and location of cutaneous involvement. Rarely, SSc without skin involvement (sine scleroderma) can occur, where visceral organs such as the lung, kidney, and heart are involved in the absence of cutaneous disease. In limited SSc, skin fibrosis or thickening is limited to the hands and the area distal to the elbows. Diffuse SSc is defined by skin involvement of the trunk, proximal arms, and legs. The face can be involved in either limited or diffuse disease. Diffuse SSc often has a worse prognosis with a higher rate of interstitial lung disease (ILD) and renal dysfunction, while limited SSc carries a higher rate of pulmonary artery hypertension (PAH) and a lower but still clinically significant risk of ILD than diffuse SSc. The key features of limited and diffuse SSc are outlined in Table 1.

Epidemiology, Genetics, and Environmental Exposures

The reported incidence and prevalence of SSc differs based on the geographic population studied, date of data acquisition, and methodological approaches to disease definition. Overall, the estimated prevalence is 276–658 cases per million with an incidence ranging from 13.9 to 21 cases per million/year in the United States and Canada, with lower rates noted in Europe and the lowest rates in Asian cohorts (Steen et al. 1997; Mayes et al. 2003). SSc occurs more frequently in women (4:1 female to male ratio) and the disease is more severe in African Americans and in those who develop the disease later in life.

While certain familial and ethnic groups may have increased susceptibility to SSc (i.e., Choctaw Native Americans), no clear familial or ethnic predisposition has been identified. The concordance rate for SSc among twins is low at 4.7 %. Specific risk-associated alleles have recently been identified that may predict increased risk for SSc, including HLA-DQA1*0501 in men, and HLA-DRB1*01 and HLA-DRB1*11 (Gorlova et al. 2011; Arnett et al. 2010). Recently, HLA DRB1*0407 and *1304 were found to be independent risk factors for scleroderma renal crisis (Nguyen et al. 2011). Associations of single nucleotide polymorphisms (SNP) with SSc are reported in genes encoding endothelin-1, various growth factors such as transforming growth factor (TGF-β) and connective tissue growth factor (CTGF), and various extracellular matrix proteins. These SNPs are associated with risk for the development of SSc.

Environmental exposures may be linked to the development of scleroderma, including silica, polyvinyl chloride, and organic solvents, though rigorous studies to link these exposures to clinical disease are lacking. In addition, numerous

Scleroderma (Systemic Sclerosis): Pathogenesis and Clinical Manifestations, Table 1 Clinical features of limited and diffuse SSc

Clinical and Laboratory Features	Limited SSc	Diffuse SSc
Autoantibodies	Anti-centromere	Anti-topoisomerase I (Scl-70), anti-RNA polymerase III
Cutaneous	Skin thickening limited to the distal extremities and face	Skin thickening of extremities, trunk, and face
	Calcinosis cutis	Calcinosis cutis
	Telangiectasias	Rapid progression
Vascular	Raynaud's phenomenon: usually prior to skin involvement and severe	Raynaud's phenomenon: coincides with skin thickening and mild
Cardiac	Rare involvement	Risk for myocarditis, pericardial effusion is highest early in disease onset
Pulmonary	ILD: infrequent, later in course	ILD: frequent, early in course of disease
	PAH: frequent, later in course	PAH: usually in association with ILD
Renal	Renal crisis rare or none	Risk of renal crisis within first 5 years of disease onset
Gastrointestinal	Gastroesophageal reflux, dysphagia	Gastroesophageal reflux, dysphagia
Musculoskeletal	Arthralgias	Arthralgias, muscle weakness, tendon friction rubs

drugs have been implicated in the development of SSc-like fibrosis including bleomycin, radiation, cocaine, and taxol, among others.

Laboratory Features

Antinuclear antibodies (ANAs) are detected in almost all SSc patients. The antibody profile can aid in disease classification. For example, the presence of certain antibodies can predict the clinical subset of scleroderma that may develop; in other instances, these antibodies, in the presence of specific clinical findings such as Raynaud's phenomenon and nailfold capillary changes, can aid in early diagnosis.

Patients with limited SSc typically have the anti-centromere pattern of ANA; these patients are at increased risk for the development of pulmonary hypertension. The development of ILD in this population is less common though not insubstantial, while the risk of renal crisis is low. The anti-topoisomerase antibody (Scl-70) is typically found in patients with diffuse SSc and is more commonly associated with ILD and occasionally with renal crisis. Patients with Scl-70 typically have reduced survival compared to patients with the anti-centromere pattern. A third antibody, RNA polymerase III, has been associated with diffuse skin disease and is associated with a higher risk of renal crisis. Other antibody profiles include anti-PM/Scl, which is associated with scleroderma and polymyositis. The anti-U1-RNP (ribonucleoprotein) antibody is associated with mixed connective tissue disease in which patients may have manifestations of various connective tissue diseases including systemic lupus erythematosus, dermatomyositis, and SSc. Two recently described antibodies, the anti-Th/To and anti-U3 RNP, are both specific for SSc and ILD, but are not commonly measured clinically.

Pathogenesis

The pathogenesis of SSc is multifactorial and incompletely understood. The disease is characterized by immune dysfunction, vasculopathy, and fibrosis. The earliest manifestations of SSc include autoimmune dysfunction, inflammation, and endothelial cell dysfunction affecting the vasculature.

Autoimmunity and Inflammation

The innate and adaptive immune system is activated in SSc. As in other rheumatologic diseases such as SLE, increased expression of interferon-responsive genes, for example, the Type I interferon signature, is also found in SSc (Assassi et al. 2010). Type I interferons are secreted through toll-like receptor (TLR) activation on dendritic cells. TLRs are the most widely studied pathogen recognition receptors of the innate immune system and these receptors initiate the immune response. The ligands for TLRs stimulate dendritic cells to produce IFN-α and IL-6, which, in turn, stimulate pro-fibrotic monocytes/macrophages. In addition, activated T cells are present in affected SSc tissue (Chizzolini and Truchetet 2011). Activated macrophages and T cells demonstrate a Th2 polarized immune response, which induces TGF-β and promotes collagen synthesis and a pro-fibrotic response.

Vasculopathy

Vascular injury is one of the initial insults in SSc pathogenesis, as evidenced by the early manifestation of Raynaud's phenomenon in SSc patients. The vasculopathy is associated with alteration in the autonomic and peripheral nervous systems with decreased vasodilatory neuropeptides and increased reactivity of smooth muscle adrenoreceptors (α2), resulting in vasoconstriction. Subsequent endothelial injury leads to dysregulated production of endothelium-derived, vasodilatory (nitric oxide), and vasoconstrictive (endothelin-1) substances. The vasculopathy affects all blood vessels including capillaries, arterioles, and large blood vessels, and ultimately impairs blood flow and tissue oxygenation. The persistent vessel and endothelial cell damage results in intimal hypertrophy and endothelial cell apoptosis with ultimate obliterative vasculopathy, the hallmark of SSc vascular damage.

Fibrosis

Fibrosis is the differentiating factor of scleroderma and sets it apart from other connective tissue diseases. Fibrosis characteristically follows the autoimmune and vascular changes that occur early in SSc and is the result of dysregulated synthesis and accumulation of collagen and extracellular matrix components. Fibroblasts are the main cell type implicated in fibrosis. Over time these fibroblasts acquire features of smooth muscle cells and become myofibroblasts. Myofibroblasts contribute to fibrosis through collagen accumulation and TGF-β production.

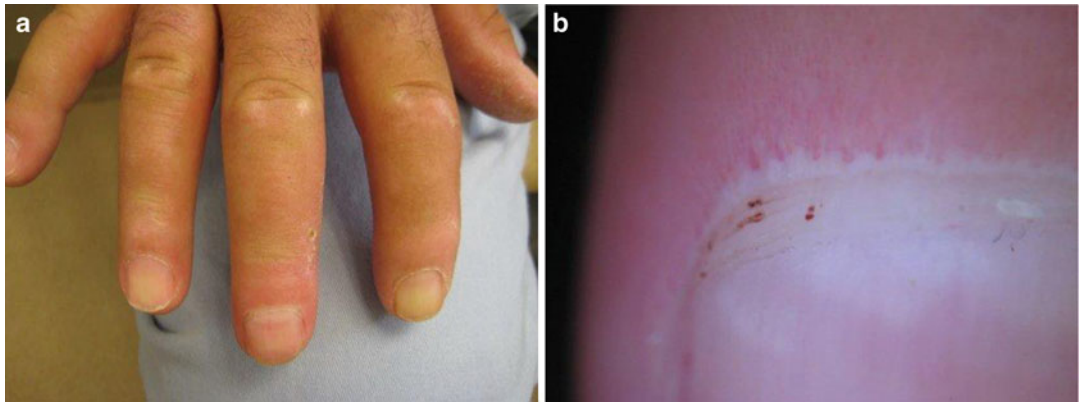
Among the pro-fibrotic cytokines, TGF-β is the central player orchestrating fibrosis. Other key players include CTGF and platelet-derived growth factor (PDGF). The key pathways through which these factors augment the fibroblast response and perpetuate fibrosis are still incompletely understood.

Clinical Features of SSc

Cutaneous Manifestations

Early in SSc, the skin develops edematous or inflammatory changes, which manifest as "puffy" digits with shiny skin. Over the course of several months, these edematous changes lead to skin thickening and fibrosis; in the hands, this is described as "sclerodactyly" (Fig. 1a). The skin usually becomes thickened in a distal to proximal manner. In limited SSc, the skin of the face, neck, and extremities (distal to the elbows) is primarily involved. In diffuse SSc, the skin is affected across multiple regions, including the face, proximal and distal extremities, and trunk. The modified Rodnan skin score (MRSS) is typically used to quantify skin thickness in clinical studies. The MRSS measures skin thickness or tightness in 17 separate body areas with a score of "0" indicating normal skin and a score of "3" indicating severe skin thickness.

Other cutaneous manifestations of SSc include telangiectasias or dilated capillaries, which primarily manifest along the face, oral mucosa, chest, nail beds, and palmar surfaces of the hands. Patients with both limited and diffuse SSc can also develop calcinosis or deposits of calcium hydroxyapatite along the palmar aspects of the digits and extensor surfaces of the extremities.



Scleroderma (Systemic Sclerosis): Pathogenesis and Clinical Manifestations, Fig. 1 (**a**) Sclerodactyly in a patient with limited SSc. Digits are thickened with evidence of early contractures and periungual erythema. (**b**). Nailfold capillary microscopy of a patient with limited SSc reveals capillary dropout with few giant capillary loops (Courtesy: Joseph Merola, M.D.)

These calcium deposits are difficult to treat and can occasionally drain or become infected.

Cardiovascular Manifestations

Raynaud's phenomenon is one of the first vascular manifestations to arise in SSc patients. Raynaud's phenomenon is a triphasic color change in the digits usually triggered by extremes in temperature. While classically described as a triphasic change, most patients do not report all three phases. Raynaud's phenomenon occurs secondary to vasospasm of the digits and results in sequential blanching or whitening of the digits on exposure to cold, followed by blue/purple changes secondary to ischemia, and then hyperemia or redness during reperfusion. In SSc, nail fold capillary microscopy can be helpful to evaluate for capillary dropout or giant capillary loops (Fig. 1b). These findings are usually seen with connective tissue diseases and are absent in patients with primary Raynaud's phenomenon.

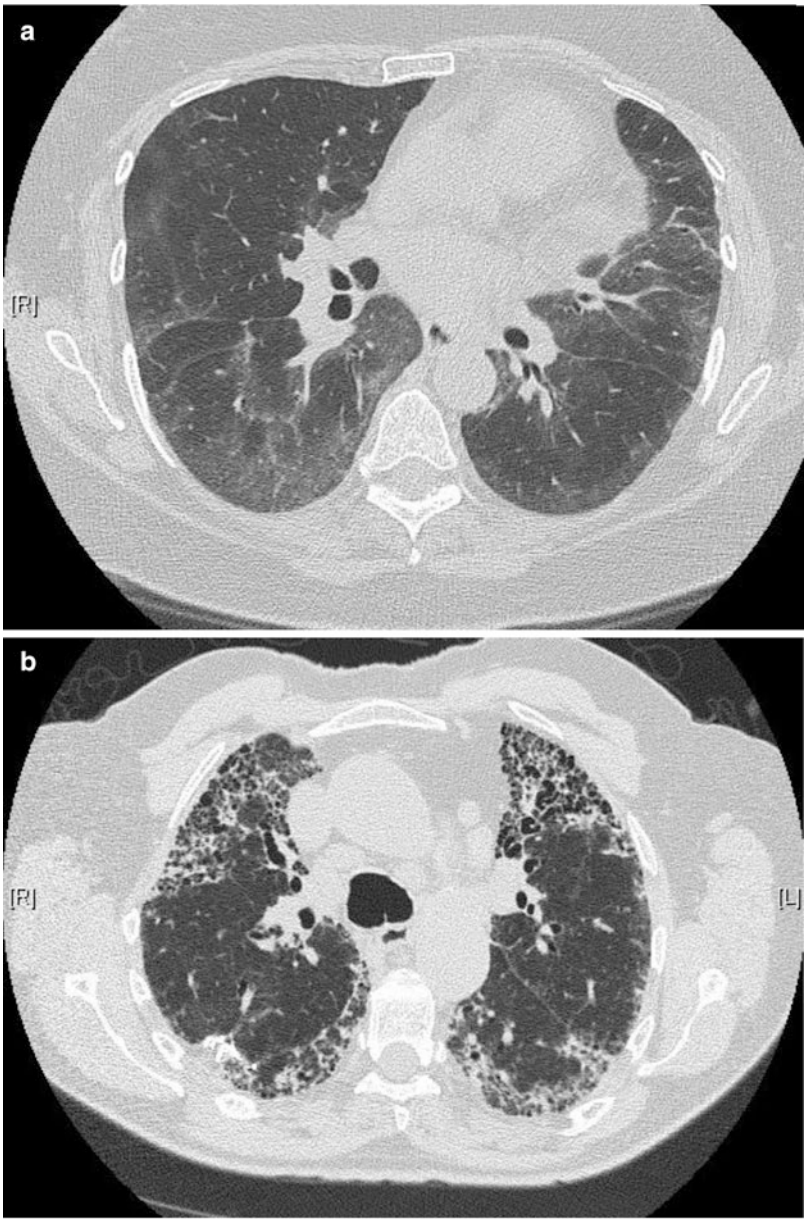
The primary cardiac abnormalities in SSc include contractile dysfunction secondary to myocardial fibrosis, arrhythmias secondary to conduction system fibrosis, coronary artery disease due to microvasculature changes, and pericardial disease (Desai et al. 2011). Additionally, cardiac manifestations can be secondary to pulmonary artery hypertension or interstitial lung disease. Evaluation for cardiac involvement is imperative; echocardiography is a common screening method used to estimate left ventricular function, and assess the pericardium for effusion.

Pulmonary

Interstitial Lung Disease

Pulmonary disease is a leading cause of death in SSc patients. Most patients with SSc have evidence of ILD by high-resolution computed tomography (HRCT) of the chest or at autopsy. Close to half develop clinically significant ILD. In a multi-ethnic study, the risk for ILD in SSc was greater in patients of African-American ethnicity, and those with more extensive skin and cardiac involvement (McNearney et al. 2007). Autoantibody expression is a predictor of internal organ involvement, particularly lung involvement. The presence of anti-topoisomerase antibodies (Scl-70) is strongly associated with development of significant ILD, while anti-centromere antibodies appear to be protective, though patients with limited SSc are not excluded from developing ILD (Kane et al. 1996). In a cohort of 3,656 SSc patients, ILD was present in 53 % with diffuse SSc and in 35 % with limited SSc (Walker et al. 2007).

Histologically, SSc-ILD is characterized by early pulmonary infiltration of inflammatory cells and subsequent fibrosis of the lung



Scleroderma (Systemic Sclerosis): Pathogenesis and Clinical Manifestations, Fig. 2 (**a**) Nonspecific interstitial pneumonia (*NSIP*) pattern on HRCT. (**b**) Usual interstitial pneumonia (*UIP*) pattern on HRCT with evidence of honeycombing

parenchyma. The most common histologic pattern seen in SSc-ILD is nonspecific interstitial pneumonia (NSIP); usual interstitial pneumonia (UIP)-pattern is less common (Fig. 2). Histologically, NSIP is characterized by varying degrees of inflammation and fibrosis. In contrast, UIP is characterized by dense patchy fibrosis with "honeycombing," primarily in a sub-pleural distribution.

To date, there is no cure or effective disease-modifying therapy for any form of SSc-ILD. Since there is evidence of inflammation in early-stage disease, current therapies for SSc-associated ILD target the inflammatory response. The immunosuppressive agents that are most widely used for this purpose are corticosteroids, cyclophosphamide, azathioprine, and mycophenolate mofetil.

Pulmonary Artery Hypertension

Pulmonary artery hypertension (PAH) can be a primary vasculopathy or secondary to underlying cardiac disease or ILD. PAH is defined as mean pulmonary artery pressure >25 mmHg with a pulmonary capillary wedge pressure <15 mmHg. Patients with PAH often present with dyspnea and fatigue. PAH is predominantly present in patients with limited SSc; however, it can also be present in patients with diffuse SSc and is sometimes secondary to underlying ILD.

Screening for PAH in SSc is recommended and often begins with pulmonary function tests (PFTs) including evaluation of diffusing capacity for carbon monoxide (DLCO) and echocardiography. In isolated PAH, PFTs will demonstrate a reduced DLCO with normal lung function. Echocardiogram can be helpful to approximate right ventricular systolic pressures as an indicator for PAH. If elevated >40 mmHg, right heart catherization is indicated to definitively diagnose PAH. Surrogate markers for PAH have recently been evaluated and serum levels of brain natriuretic peptide (BNP) have been found to correlate with severity of PAH in SSc (Fischer et al. 2012). Therefore, measurements of BNP may be useful for PAH screening in SSc patients.

Gastrointestinal

The gastrointestinal (GI) tract may be involved early in the course of SSc. In 10 % of cases, it is the presenting feature (Clements et al. 2003). The most frequent GI organ involved is the esophagus, followed by the small bowel (Gyger and Baron 2012). The pathogenesis of GI dysfunction stems from vascular changes to the mucosa with neural dysfunction and eventual smooth muscle atrophy.

Abnormal esophageal involvement is the most common GI manifestation in SSc patients with 70–90 % incidence noted depending on the study. Patients have esophageal dysmotility and decreased lower esophageal sphincter tone. While most patients are asymptomatic, therapy with a proton pump inhibitor should be considered for all patients with SSc.

Gastric manifestations of SSc include delayed gastric emptying, which can contribute to esophageal symptoms as well as early satiety and bloating. Other less common manifestations include gastric antral vascular ectasia (GAVE), described as "watermelon stomach," which manifests with severe bleeding. Intestinal dysmotility can lead to bloating, malabsorption, and eventual weight loss and malnutrition. Additionally, bacterial overgrowth of the bowel can result in alternating diarrhea and constipation.

Renal

Scleroderma renal crisis (SRC) is the main renal manifestation and occurs in 10–15 % of patients. It occurs early in the disease course and sometimes precedes the diagnosis of SSc. The classic presentation is new-onset hypertension with progressive renal insufficiency. Risk factors for SRC include diffuse SSc, RNA polymerase III antibody, African-American race, and male gender (Bussone et al. 2011). With the advent of angiotensin-converting enzyme (ACE) inhibitors for the treatment of SRC, the survival from SRC has improved dramatically.

Musculoskeletal

While SSc patients develop myalgias and arthralgias, inflammatory arthritis is less frequent. With progressive skin thickening, patients can develop flexion contractures along the digits, requiring splinting and occupational therapy. Other manifestations include tendon friction rubs, which present along tendon sheaths of the digits, elbows, knees, and ankles. These rubs occur secondary to inflammation and fibrosis of the tendon sheaths at the joint.

Muscle involvement can also occur in patients with SSc and this can be secondary to either deconditioning or malnutrition. SSc patients can additionally have an overlap with polymyositis and test positive for anti-PM/Scl antibody. Occasionally a non-inflammatory myopathy characterized by atrophy and fibrosis in the setting of normal muscle enzymes is seen in the later stages of SSc.

Course and Prognosis

The natural progression of SSc is variable and difficult to predict. Overall, patients with diffuse

disease have rapidly progressive disease with higher mortality, with limited SSc patients progressing slowly. SSc prognosis correlates with skin involvement. Compared to the general population, SSc has a five- to eight-fold higher mortality rate. Major causes of death include PAH, ILD, gastrointestinal involvement, and cardiac disease. While mortality from SRC has been reduced with the advent of ACE inhibitors, the treatment of SSc as a whole is still inadequate and further studies to develop effective therapies are warranted.

Definition

Scleroderma renal crisis (SRC) is a serious complication of systemic sclerosis. It is defined by malignant hypertension and acute kidney failure from prolonged renal ischemia. It is a medical emergency that if left untreated is life threatening and may lead to end-stage renal disease.

Introduction

Systemic sclerosis is a multisystem autoimmune disorder characterized by inflammation, skin

fibrosis, and vascular abnormalities and can manifest as a limited cutaneous or diffuse cutaneous form. Renal failure associated with systemic sclerosis was first described in 1863 (Steen 2003). In 1952 Moore and Sheehan described the renal lesion that was associated with significant morality in scleroderma (see below). SRC is a severe and significant complication of systemic sclerosis that is classically characterized by accelerated hypertension and acute kidney injury. It is prevalent in about 5–10 % of cases and predominantly affects women. SRC is most common with diffuse cutaneous disease but can occur in the limited form. Prior to the advent of angiotensin-converting enzyme inhibitors (ACEi), SRC was almost uniformly fatal. It remains an emergency and has a 5-year survival rate of 65 % (Bussone et al. 2011).

Pathogenesis

The proposed mechanism of SRC begins with endothelial injury followed by increased endothelial permeability and edema. Factors contributing to endothelial injury include vascular collagen accumulation, anti-endothelial cell antibodies, and overexpression of endothelin-1, a potent vasoconstrictor (Worda et al. 2003). This exposes the subendothelium to blood elements activating the coagulation cascade and causing thrombotic proliferative endarteropathy (onion-skin type lesion) (Batal et al. 2010). The renal ischemia that follows causes juxtaglomerular apparatus (JGA) hyperplasia and increased renin secretion leading to accelerated hypertension and kidney injury (Trostle et al. 1988). The end result is thrombotic microangiopathy with renal cortical necrosis.

Renal Pathology

While renal biopsy will confirm the diagnosis of SRC, it is often unnecessary as clinical manifestations are characteristic. Biopsy, however, may be helpful in determining prognosis. On renal biopsy, small-vessel thrombosis is more common than glomerular thrombotic microangiopathy classically seen in TTP/HUS. Prolonged renal ischemia due to vascular disease can lead to ischemic acute tubular necrosis, and if the disease remains unchecked, tubular atrophy and interstitial fibrosis will develop. In untreated disease, duplication of glomerular basement membrane, glomerulosclerosis, and ischemic glomerular collapse may occur (Batal et al. 2009). Severity of acute vascular injury is most predictive of poor outcome, but severe glomerular ischemic collapse and acute tubular necrosis also portend a poorer prognosis.

Clinical Features and Risk Factors

The clinical features of SRC are malignant hypertension and oliguric acute kidney failure. Urine evaluation typically shows microscopic hematuria and subnephrotic proteinuria (<3.5 g/day). Microangiopathic hemolytic anemia has been described in 50 % of cases and leads to abrupt onset of anemia with the presence of schistocytes on peripheral smear and associated thrombocytopenia. Platelet count rarely decreases to less than 50,000/mm^3 and recovers quickly with blood pressure control (Steen 2003). This process is not specific to SRC, and alternative diagnoses, such as disseminated intravascular coagulation (DIC) or thrombotic thrombocytopenic purpura/hemolytic uremic syndrome (TTP/HUS), must be ruled out. Other clinical findings include headache, blurry vision, and seizures related to hypertensive encephalopathy. Congestive heart failure related to the rapid rise in blood pressure is also possible.

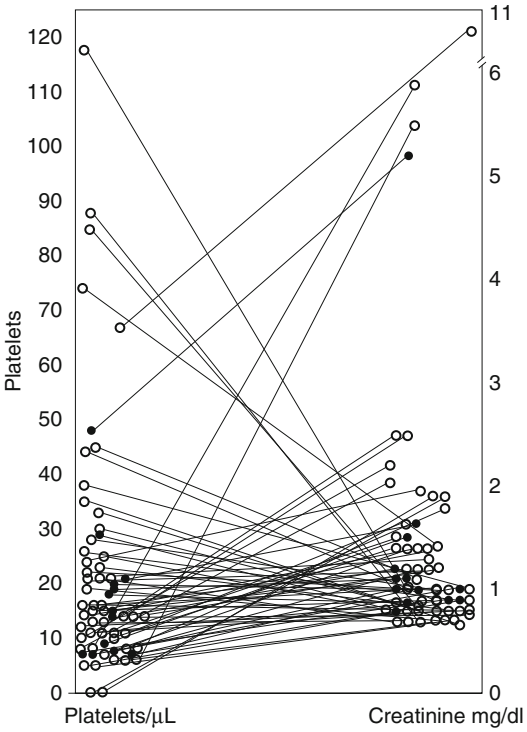
Patients with diffuse cutaneous disease and rapidly progressive skin thickening are at higher risk for SRC and should be monitored closely. In addition conditions that decrease renal perfusion such as new cardiac events or anemia are associated with increased risk for SRC (Steen 2003). Drugs such as systemic corticosteroids, cyclosporine, and cocaine have been associated with SRC. Cyclosporine is thus not recommended after renal transplantation in systemic sclerosis (Bussone et al. 2011). Corticosteroids are thought to inhibit prostacyclin activity and increase tissue ACE activity and may be the mechanism for

increased risk (Steen 2003). Male sex, older age, and *normotension* at diagnosis are thought to be poor prognostic factors (Penn et al. 2007). While vascular changes and hyperreninemia are common in SRC, they do not predict development of SRC and are present in asymptomatic individuals (Trostle et al. 1988). Antinuclear antibodies (ANA) are commonly found in SRC but are nonspecific. Type I and III anti-RNA polymerase antibodies are significantly associated with the development of SRC. Anti-Scl-70 and anti-U3 RNP antibodies have also been associated with SRC; however, anti-centromere antibodies which are commonly seen in limited cutaneous scleroderma have not been associated with SRC (Batal et al. 2010).

Treatment and Prognosis

Aggressive blood pressure control is the mainstay of therapy in SRC and has been shown to stabilize or improve renal function in 50–70 % of cases, if started before irreversible vascular damage has occurred. Inhibition of angiotensin II-mediated vasoconstriction with ACEi is the treatment of choice and significantly improves blood pressure in most patients (Fig. 1). When compared to other antihypertensive agents in SRC, ACEi have increased efficacy, better preserved renal function, and significantly improved survival (Zawada et al. 1981; Thurm and Alexander 1984). ACEi must be continued even if renal function deteriorates and should be titrated to maximum dose over 2–3 days with goal blood pressure of 130/80 mmHg. If blood pressure remains uncontrolled after maximum ACEi, then addition of vasodilator agents should be considered. Calcium channel blockers should be combined with ACEi for added benefit. Nitrates may be used for acute pulmonary edema (Denton and Black 2004). Diuretics should be used with caution as patients have relative hypovolemia in SRC.

If ACEi are not tolerated, angiotensin receptor blockers (ARBs) may be used although the clinical experience with these agents compared to ACEi has been variable and should be used with caution. Recently, a small open-label trial of six patients demonstrated improvement similar to that seen with ACEi after 6 months of therapy with the endothelin receptor antagonist bosentan (Dhaun et al. 2009).



Scleroderma Renal Crisis, Fig. 1 Treatment of scleroderma renal crisis (These agents have been used in smaller studies with variable benefit. Larger trials are warranted prior to recommending their use. ET receptor antagonists appear promising and have shown to have benefit in small trials. IV Prostacyclins have been used for SRC in Europe but there are no large randomized clinical trials to date)

Intravenous prostacyclin is thought to mitigate the microvascular lesion without causing hypotension and has been used at the onset of SRC in Europe (Bussone et al. 2011). However, there are no prospective trials demonstrating benefit. Hemodialysis may be a necessary supportive tool in patients with severe renal failure. With treatment, however, there is usually significant improvement in renal function over time and dialysis may be stopped. Kidney transplantation may be considered in patients who remain dialysis dependent (usually after 2 years) (Pham et al. 2005).

Kidney transplantation provides better outcomes compared to ongoing dialysis for end-stage kidney disease due to SRC. Graft survival, however, is reduced compared to the general renal transplant population and is likely due to recurrence of SRC (Pham et al. 2005).

Conclusion

SRC is a significant complication of systemic sclerosis characterized by accelerated hypertension and acute kidney injury. In SRC, endothelial injury causes thrombotic microangiopathy and renal cortical necrosis. It is a medical emergency, and early recognition is imperative. Aggressive treatment with ACEi and additional antihypertensive agents needed to achieve blood pressure control are necessary to preserve renal function and reduce mortality.

Definition

The treatment of systemic sclerosis, based on likely pathogenic mechanisms, is directed toward immune cell activation, pathways of collagen synthesis, and, in patients with vascular manifestations, vasoreactive pathways.

Background

Scleroderma (systemic sclerosis, SSc) is a complex disease characterized by (a) extensive ▶ fibrosis that affects the skin and internal organs and can lead to serious compromise of organ function, as in lung fibrosis (interstitial lung disease, ILD); (b) vasculopathy of small arteries (microvasculopathy) with vasospastic episodes (Raynaud's phenomenon) and fibrosis that can cause serious manifestations, such as pulmonary arterial hypertension (PAH), scleroderma renal crisis, and skin ulcers; and (c) activation of the immune system (macrophages, T cells, B cells, and eosinophils), with the production of autoantibodies (Sakkas et al. 2006).

Treatments of scleroderma are based on clinical manifestations and are directed at immune cells (T cells, B cells) and fibroblasts. Treatment directed at immune cells (immunotherapy) is based on evidence of the involvement of immune cells in the pathogenesis of the disease (Sakkas et al. 2006, 2012; Trojanowska and Varga 2007; Maurer and Distler 2011). In skin lesions there is evidence of an antigen-driven T cell activation and proliferation. This involves the interaction of T cell antigen receptor (TCR) on T cells with antigen/HLA complex on antigen-presenting cells, as well as the interaction of co-stimulatory molecules. T cells also help B cells in the production of IgG autoantibodies. A number of autoantibodies in SSc are profibrotic. In addition, T cells in scleroderma patients produce profibrotic soluble cytokine products, including interleukin (IL)-4, IL-13, and IL-17. Transforming growth factor-β (TGF-β) expression is also increased.

Much of the knowledge on human SSc comes from studies in mouse models of scleroderma, particularly bleomycin-induced scleroderma, the tight-skin mouse model of scleroderma, and chronic sclerodermatous graft-versus-host disease (GVHD). The latter develops after hematopoietic stem cell transplantation (HSCT) from one strain into another strain of mouse (allogeneic HSCT).

The treatment of serious clinical manifestations of SSc includes potentially toxic medications. Recommendations regarding treatments based on small nonrandomized studies should be regarded as preliminary until are validated by randomized controlled trials (RCTs). Vascular manifestations, such as skin ulcers, PAH, and scleroderma renal crisis, require additional therapeutic approach (Maurer and Distler 2011).

Immunotherapies

Immunotherapy includes general immunosuppression and therapies targeting specific molecules involved in T cell and B cell survival and function (targeted therapies). Immunotherapies tend to be more effective during early-phase disease. This is because the natural history of SSc, at least as is exemplified in the skin, is first infiltration with T cells, macrophages, B cells, mast cells, and eosinophils, then development of fibrosis with gradual disappearance of inflammatory infiltrates and finally dominance of fibrosis (Prescot et al. 1992; Sakkas et al. 2006). This may explain why immunotherapies may be less effective in late-phase disease.

Cyclophosphamide

Cyclophosphamide (CyP) is an alkylating and cytotoxic agent and, therefore, a general immunosuppressive drug. CyP can be administered either by oral route (e.g., 2 mg/Kg/day) or by intravenous infusions every 2–4 weeks for a maximum of 6 months followed by milder forms of immunosuppression, such as methotrexate or azathioprine. CyP has been used to treat SSc-associated interstitial lung disease (SSc-ILD) in randomized clinical trials. It stabilized if not slightly improved pulmonary function as measured by spirometry and diffusion capacity for carbon monoxide (Hoyles et al. 2006; Taskin et al. 2006; Nannini et al. 2008). It also improved skin score but had no efficacy on skin ulcers in an SSc-ILD study. CyP may improve microvascular damage, as seen by capillaroscopy of nail folds. Side effects of CyP include nausea and vomiting, bone marrow suppression, increased risk of infections, hemorrhagic cystitis, and bladder cancer.

Methotrexate

Methotrexate (MTX) inhibits dihydrofolate reductase, an enzyme needed for DNA synthesis.

It also causes extracellular release of adenosine that exerts immunomodulating effects. MTX, given orally or by subcutaneous injection (10–25 mg/week), is generally a standard, first choice of therapy for rheumatoid arthritis. In two small, randomized, controlled studies of early SSc, MTX improved skin score and hand function (van den Hoogen et al. 1996; Pope et al. 2001). Side effects of MTX include bone marrow suppression, gastrointestinal upset, hair loss, and liver fibrosis.

Mycophenolate Mofetil

Mycophenolate mofetil (MMF) is an inactive prodrug of mycophenolic acid that inhibits inosine monophosphate dehydrogenase and, therefore, the proliferation of both T cells and B cells. It is administered orally (e.g., 500–1,500 mg twice daily). MMF has been evaluated in small retrospective or open-label prospective studies in SSc and SSc-ILD. It improved skin score and stabilized pulmonary function. More importantly, it improved a 5-year survival (Nihtyanova et al. 2007; Liossis et al. 2006; Koutroumpas et al. 2010). Side effects of MMF include diarrhea, increased risk of infections, and bone marrow suppression.

Azathioprine

Azathioprine (AZA) is a purine analog that inhibits DNA synthesis. AZA has been used as maintenance therapy in SSc-ILD after initial therapy with CyP. In a randomized, open-label trial of oral AZA (2.5 mg/Kg/day) versus oral CyP in early diffuse cutaneous SSc, AZA showed no efficacy on skin thickness and pulmonary function (Nadashkevich et al. 2006). Side effects of AZA include bone marrow suppression and gastrointestinal upset.

Cyclosporin

Cyclosporin binds to cytoplasmic protein cyclophilin and inhibits calcineurin. Calcineurin is a calcium-dependent phosphatase that dephosphorylates nuclear factor of activated T cells (NFAT) that translocates to the nucleus and initiates the transcription of IL-2 and the IL-2 receptor. Therefore, cyclosporin inhibits T cell activation and proliferation. Cyclosporin (2.5 mg/Kg/day, orally) improved skin thickness scores and reduced serum levels of IL-6 in case reports and small open-label studies (Clemens et al. 1993; Filaci et al. 1999). Today, it is rarely used in SSc patients because of its renal side effects. Common effects of cyclosporin include hypertension, elevation in serum creatinine, hypertrichosis, and gingival hypertrophy.

Rapamycin

Rapamycin binds to FK-binding protein 12 and inhibits the mammalian target of rapamycin complex (▶ mTORC) 1, a key regulatory kinase of cell metabolism and proliferation. Rapamycin inhibits T cell activation and Th17 cell differentiation, as well as B cell activation. In TSK mice, rapamycin reduced skin fibrosis and serum levels of autoantibodies. In bleomycin-induced SSc model, administration of rapamycin prior to bleomycin reduced skin and lung fibrosis and skin inflammatory cell infiltrates, as well as the skin expression of IL-4, IL-6, IL-17, and TGF-β. Sirolimus and everolimus, mTORC inhibitors, had beneficial effects in chronic sclerodermatous GVHD. In a small randomized pilot study in patients with early diffuse cutaneous SSc, rapamycin improved skin score but was not superior to MTX. There was no efficacy on lung function (Yoshizaki et al. 2010; Jedlickova et al. 2011; Su et al. 2009). Side effects of rapamycin include gastrointestinal upset, bone marrow suppression, increased risk of infections, elevation in serum triglycerides, and interstitial pneumonitis.

Intravenous Immunoglobulin

Intravenous immunoglobulin derives from pooled plasma of thousands of healthy individuals. The mechanism of high-dose intravenous immunoglobulin (IVIg) remains unclear but probably works on several fronts. One proposed mechanism involves anti-idiotype antibodies directed against unique amino acid sequences on the variable region of immunoglobulins and TCRs that recognize antigens (idiotope). All immunoglobulins and TCRs that share an idiotope belong to one idiotype. Thus, IVIg

blocks the binding of serum immunoglobulins, B cell surface immunoglobulins, as well as TCRs on T cell surface to their respective antigens. Other proposed mechanisms include binding of sialylated IgG to dendritic cells and increasing the expression of their inhibitory receptors for IgG (FcγR) and inhibition of complement.

IVIg reduced skin fibrosis and inhibited IL-4 and TGF-β production in TSK mice (Blank et al. 2002). In two small open-label studies in patients with SSc, IVIg reduced histological skin fibrosis and joint pain and improved the hand function (Levy et al. 2004; Nacci et al. 2007).

Autologous Hematopoietic Stem Cell Transplantation

The process of hematopoietic stem cell transplantation (HSCT) eliminates autoreactive T cells and B cells. In autologous HSCT, hematopoietic stem cells (HSCs) are collected from a patient, who then receives strong immunosuppression, including cyclophosphamide, to destroy lymphocytes. Finally, the patient receives his own HSCs to repopulate his bone marrow. HSCT reverses the Th2 cell profile (producing the profibrotic IL-4 and IL-13) in SSc patients into Th1 cell profile (producing the antifibrotic interferon [IFN]γ) that lasts at least 3 years and is associated with skin improvement (Tsukamoto et al. 2011). A high-dose myeloablative regimen was associated with high frequency of early mortality, and therefore, less intense non-myeloablative regimen was used. In addition, myeloablative HSCT showed no superior efficacy compared to non-myeloablative HSCT (Tyndall and Saccardi 2005). In nonrandomized studies, autologous HSCT showed substantial efficacy in up to 90 % of patients improving skin score and histological fibrosis and stabilizing the internal organ function up to 7 years after the transplantation (Nash et al. 2007; Vonk et al. 2008). It may also regenerate capillaries and improve microcirculation, as seen on nail fold capillaroscopy and histochemistry (Fleming et al. 2009; Miniati et al. 2009). In an open-label randomized trial, autologous non-ablative HSCT was superior to monthly pulse CyP, improving skin score and lung function that persisted for up to 2 years (Burt et al. 2011). Side effects include early mortality, increased risk of infections, and the development of new (secondary) autoimmune diseases, such as myasthenia gravis. Secondary autoimmune diseases occur in about 3.9 % of HSCT cases.

Halofuginone

Halofuginone, a plant alkaloid, inhibits nuclear factor κB (NF-κB) and p38 mitogen-activated protein kinase (MAPK) in activated T cells and also Th17 differentiation. It also inhibits fibroblast collagen production, by inhibiting TGF-β signaling. Topical skin application of halofuginone in chronic GVHD, TSK/+ mice, and patients with SSc improved skin thickness (Pines et al. 2003).

Oral Administration of Type I Collagen

Type I collagen is the most abundant collagen in humans. Human type I collagen could be an autoantigen in SSc, activating T cells. For instance, peripheral blood mononuclear cells cocultured with human type I collagen are activated and express more immune-related genes in patients with early- than late-phase diffuse cutaneous SSc (Atamas et al. 2010). The rationale behind oral administration of bovine type I collagen is to induce tolerance to human type I collagen and that was based on the observation that bovine type I collagen reduced T cell activation and T cell reactivity to human type I collagen. In a randomized, double-blind, placebo-controlled trial, oral administration of bovine type I collagen improved skin score in late-phase SSc (Postlethwaite et al. 2008).

Inhibition of T Cells (Anti-CD25 Monoclonal Antibody)

CD25 is a high-affinity IL-2 receptor expressed on activated T cells and T regulatory cells (Tregs). Tregs, a subset of CD4+ T cells, are important in immune homeostasis because they prevent responses to one's own antigens (autoantigens). Basiliximab, an anti-CD25 monoclonal antibody, decreases the expression of CD25. In a small open-label study,

basiliximab-treated patients with SSc experienced significantly reduced skin thickness scores and stabilized lung function (Becker et al. 2011). A concern regarding basiliximab is that it may decrease Tregs, though this was not observed after short-term treatment in patients with kidney transplantation (Wang et al. 2009).

Inhibition of Co-stimulator Molecules

The activation of T cells by an antigen requires a second signal provided by the interaction of co-stimulatory molecules. The interaction of ▶ CD28 (on T cells) with B7(CD80/CD86) (on antigen-presenting cells) is the best studied such a co-stimulatory interaction. A recombinant ▶ CTLA4-Ig fusion protein consisting of the extracellular domain of CTLA4 and the Fc fragment of IgG1 (abatacept) binds to CD80/CD86 (on antigen-presenting cells), thus blocking CD28 binding to CD80/CD86. This block decreases T cell activation. Based on the significant role of T cells in SSc, a trial of abatacept in SSc has been carried out [www.clinicaltrials.gov. NCT00442611].

B Cell Depletion

B cells have CD20 on their surface. Administration of anti-CD20 monoclonal antibody that depletes B cells in TSK/+ mice before the development of the disease significantly reduces skin fibrosis and serum levels of autoantibodies (Hasegawa et al. 2006). It also reduced skin Th2 cells that produce the profibrotic IL-4 and increased Th1 cells that produce the antifibrotic interferon-γ (IFN-γ). However, anti-CD20 monoclonal antibody had no efficacy when administered after disease development in these mice. Rituximab is a chimeric (part human, part murine) IgG monoclonal antibody that binds CD20 and depletes B cells and has been licensed for use in B cell lymphoma and rheumatoid arthritis. In small open-label studies in SSc, Rituximab improved skin thickness score and reduced serum levels of IL-6 (Bosello et al. 2010). It also improved or stabilized lung function and reduced histological skin fibrosis (Daoussis et al. 2010; Smith et al. 2013). Rituximab may decrease skin fibrosis through attenuation of platelet-derived growth factor receptor expression (Daoussis et al. 2012). However, rituximab did not improve skin thickness score in one study (Lafyatis et al. 2009). A randomized controlled trial of rituximab in SSc-associated PAH is ongoing [ClinicalTrials.gov. NCT01086540].

Inhibition of B Cell Survival

B cell activating factor (BAFF) is a B cell modulator and maturation factor and is increased in SSc. Neutralization of BAFF with BAFF receptor-Ig fusion protein in TSK mice inhibited skin fibrosis and autoantibody production (Matsushita et al. 2007). Anti-BAFF monoclonal antibody (belimumab) is being evaluated in systemic lupus erythematosus.

Interferon-γ

Interferon-γ (IFN-γ) is a cytokine produced by Th1 cells. It inhibits collagen production both in vitro and in vivo in animal models. It also inhibits Th2 differentiation. Recombinant IFN-γ had no effect or slightly improved skin thickness score in small, open-label, single-arm (without comparator) studies (Freundlich et al. 1992; Hunzelmann et al. 1997) and had a mild beneficial effect on skin score in a small randomized controlled trial (Grassegger et al. 1998).

Inhibition of IL-13

Interleukin-13 (IL-13) is a profibrotic cytokine produced by Th2 cells. Inhibition of IL-13-receptor α2 (IL-13Rα2) signaling in bleomycin-induced lung fibrosis with IL-13Rα2-specific small interfering RNA (siRNA) markedly reduced lung fibrosis (Fichtner-Feigl et al. 2006). There are two trials ongoing in SSc-ILD and idiopathic pulmonary fibrosis with anti-IL-13 monoclonal antibody [www.clinicaltrials.gov, NCT00581997, NCT00532233].

Anti-IL-6 Receptor Monoclonal Antibody

IL-6 is a fibroblast growth factor and promotes Th17 differentiation. Treatment of two patients with SSc with anti-IL-6 receptor monoclonal antibody (tocilizumab) decreased skin fibrosis (Shima et al. 2010). A trial of

tocilizumab in SSc is ongoing [clinicaltrials.gov.NCT01532869].

Fibroblast-Directed Therapies

Fibroblasts are the final effector cells in fibrosis. They are activated into myofibroblasts (acquiring α-smooth muscle actin) and produce collagen and other extracellular matrix molecules. Apart from resident fibroblasts, other sources of myofibroblasts are circulating fibrocytes, which are bone marrow-derived mesenchymal cells carrying hematopoietic and stromal cell markers (CD34, CD45 procollagen-I), from pericytes, and from transition of epithelial cells, endothelial cells, and adipocytes into mesenchymal cells, capable of collagen production.

Neutralization of Transforming Growth Factor-β (TGF-β)

Transforming growth factor-β (TGF-β) is a major inducer of fibroblast activation and collagen production. After binding to its receptor, TGF-β activates Smad2 and Smad3 which then form heterotrimer with Smad4 that activates the transcription of target genes. More importantly, TGF-β is involved in the differentiation of epithelial cells, endothelial cells, and adipocytes into mesenchymal cells (transition). This transition involves the acquisition of stromal cell markers and the ability of collagen production (Trojanowska and Varga 2007). An anti-TGF-β polyclonal antibody prevented skin and lung fibrosis in sclerodermatous GVHD mouse model (McCormick et al. 1999). However, a recombinant human anti-TGFβ1 monoclonal antibody was not superior to placebo in a randomized controlled trial (Denton et al. 2007).

Tyrosine Kinase Inhibitors

Imatinib mesylate is a tyrosine kinase inhibitor of c-abl and of proto-oncogene c-kit and c-fms proteins and also of platelet-derived growth factor (PDGF) receptor. c-abl is a downstream mediator of TGF-β. Imatinib reduced fibroblast synthesis of collagen in culture, prevented skin thickness in TSK-1 mice, and reduced bleomycin-induced established skin fibrosis (Akhmetshima et al. 2009). Imatinib also modulates Th2 cytokines in vivo. In SSc-associated ILD, imatinib greatly reduced IL-4-producing T cells in bronchoalveolar lavage (Divekar et al. 2011).

In a patient with SSc, imatinib improved skin fibrosis. In a patient with SSc-associated PAH and right heart failure refractory to bosentan and sildenafil, the addition of imatinib significantly improved right ventricular function and exercise tolerance (Sfikakis et al. 2008; ten Freyhaus et al. 2009). Imatinib at a dose of 400 mg daily was not tolerated in a small, randomized, 6-month trial. In a 1-year, single-arm, open-label phase II trial, imatinib (400 mg/day) was tolerated by most patients and improved skin thickening and forced vital capacity. In another 1-year, phase I/IIa trial in patients with SSc-associated ILD, imatinib (up to 600 mg/day) showed a trend toward improvement of forced vital capacity and a modest improvement in skin score but was associated with frequent side effects. In an observational study of five patients with advanced SSc-associated ILD, a combination of imatinib (200 mg/day) with CyP (500 mg every 3 weeks, intravenously) was well tolerated but improved lung function in only one patient who had mild restrictive lung disease (Pope et al. 2011; Spiera et al. 2011; Khanna et al. 2011; Sabnani et al. 2009). Side effects of imatinib include fluid retention, nausea and vomiting, diarrhea, myalgias, alopecia, rash, and anemia.

Peroxisome Proliferator-Activated Receptor-γ

Peroxisome proliferator-activated receptor-γ (PPAR-γ) is a nuclear receptor. Upon binding to its ligand or a synthetic agonist, PPAR-γ activates the transcription of genes involved in lipid and glucose metabolism. PPAR-γ is also a negative regulator of collagen synthesis and thus an attractive target of antifibrotic treatment. PPAR-γ expression is reduced in SSc skin and also reduced by TGF-β in fibroblasts. Fibroblast-specific PPAR-γ deletion in bleomycin-induced SSc mice caused increased skin thickening, whereas synthetic PPAR-γ agonists, such as the synthetic cannabinoid ajulemic acid and the antidiabetic drug rosiglitazone, inhibited fibrosis in bleomycin-induced SSc mouse model (Wu et al. 2009; Gonzalez et al. 2012).

Relaxin

Relaxin is a physiologic protein produced by ovary and placenta during pregnancy and by the prostate gland. Relaxin reduces TGFβ1-induced fibroblast differentiation and collagen production. Recombinant human relaxin prevented bleomycin-induced lung fibrosis in mice (Unemori et al. 1996). In two randomized, double-blind, placebo-controlled trials in SSc, continuous subcutaneous administration of recombinant human relaxin (10 μg/Kg/day or 25 μm/Kg/day) gave conflicting results on skin thickness (Seibold et al. 2000; Khanna et al. 2009). Side effects of relaxin include elevation in serum creatinine and hypertension.

D-Penicillamine

D-penicillamine (DP) is a chelating agent for divalent cations, such as copper, but also inhibits the cross-linking of collagen. In a randomized trial of high-dose (1,000 mg/day) versus low-dose (125 mg/day) DP in diffuse cutaneous SSc of recent onset, there was improvement in skin thickness score in both groups, with no advantage of high dose over the less toxic low dose (Clemens et al. 1999). The authors interpreted these results as negative. However, DP (mean dose 750 mg/day) decreased skin involvement and improved visceral organ involvement in a retrospective study (Derk et al. 2008). Side effects of DP include membranous nephropathy with proteinuria, cytopenias, skin rash, pemphigus vulgaris, myasthenia gravis, and, rarely, Goodpasture's syndrome. Because of serious and frequent side effects and dubious efficacy, DP is rarely used in SSc today.

Therapies for Vascular Manifestations

Pulmonary Arterial Hypertension

The pharmacological management of SSc-associated pulmonary arterial hypertension (SSc-PAH) targets one or more of the three pathogenic pathways, namely, the increased vasoconstrictor endothelin-1 (ET-1) pathway and the decreased vasodilating pathways of prostacyclin and nitric oxide. Epoprostenol, iloprost, and treprostinil are prostacyclin analogs. Bosentan is an inhibitor of both ET-1 type A and ET-1 type B receptors, and ambrisentan and sitaxsentan are ET-1 type A receptor antagonists. Sildenafil (Revatio) and tadalafil inhibit phosphodiesterase 5, an enzyme that rapidly degrades cyclic guanosine monophosphate, a molecule that mediates the vasodilating effects of nitric oxide. All these agents improve exercise capacity, hemodynamics, and quality of life (Launay et al. 2010), and a treatment with two different mode agents modestly increases exercise capacity but does not appear to improve survival (Fox et al. 2011). Therefore, SSc-PAH still remains a condition with poor prognosis despite optimal treatment.

Scleroderma Renal Crisis

▶ Scleroderma renal crisis (SRC) is manifested by severe elevations in blood pressure, elevation in serum creatinine, and fragmented red cells in the peripheral blood. SRC is a serious condition that frequently leads to chronic renal failure. The treatment that changed the prognosis of SRC is based on angiotensin-converting enzyme (ACE) inhibitors (Steen et al. 1990; Penn et al. 2007; Guillevin et al. 2012). ACE converts angiotensin I into angiotensin II (Ang II), a potent vasopressor exerting its effect directly on arteriolar smooth muscle cells. Ang II binds to angiotensin II type 1 (AT1) receptor and activates connective tissue growth factor (CTGF) and collagen production via the Smad pathway and the p38 MAPK pathway. Ang II also affects immune cells. In Ang II-induced hypertension in mice, T cells have a major role in mediating accelerated microvascular thrombosis (Senchekova et al. 2011). Also, in Ang II-induced pulmonary hypertension in mice, there was vascular infiltration of T cells and increased activation of T cells of pulmonary arteries (Vinh et al. 2010). Furthermore, blocking the B7/CD28 co-stimulation with CTLA4-Ig protein construct decreased pulmonary arterial blood pressure and vascular infiltration of T cells and inhibited T cell activation (Vinh et al. 2010). It should be mentioned that stimulatory antibodies against AT1 receptors are detected in sera of patients with SSc (Riemekasten et al. 2011).

ACE inhibitor therapy has greatly improved the survival of patients with SRC. However, up to

44 % of patients may develop end-stage renal failure requiring hemodialysis.

Skin Ulcers

Iloprost, a prostacyclin analog, can be used for severe digital ischemia and dermal ulcers. Iloprost administration by a 6-h intravenous infusion (0.5–2 ng/Kg/min) for 6 sequential days has led to healing of digital ulcers (Wigley et al. 1994). Bosentan, a dual endothelin receptor antagonist, is used for prophylaxis against new ulcer development. In two RCTs, bosentan reduced the occurrence of new digital ulcers by 30–48 % but had no effect on ulcer healing (Korn et al. 2004; Matucci-Cerinic et al. 2011).

Raynaud's Phenomenon

Raynaud's phenomenon (RP) describes vasospastic episodes in which cold exposure or stress triggers a blanching of the digits due to impaired perfusion, then cyanosis due to ischemia, and finally red discoloration due to reperfusion. Treatment with dihydropyridine-type calcium channel antagonists (e.g., nifedipine) results in modest reduction of the frequency and severity of Raynaud's phenomenon (RP) (Thompson et al. 2001). Similar efficacy was demonstrated with angiotensin II receptor type 1 inhibitors (losartan), phosphodiesterase 5 inhibitors (tadalafil), and iloprost, the latter by intravenous infusion. Oral iloprost and bosentan had no efficacy on RP (Wigley et al. 1998; Herrick 2011).

Conclusion

SSc is a complex disease characterized by extensive fibrosis in tissues and blood vessels. The immune system is implicated in fibroblast activation in early-phase disease. In late-phase disease, the persistent activation of fibroblasts is less clear. Apart from general immunosuppression, pathways involved in immune cell activation and fibroblast activation have recently emerged as likely targets of therapy in SSc. In addition, vasoactive pathways may also affect immune function and are therapeutic targets of vascular manifestations of SSc.

Systemic sclerosis – genetics

Definition

This is a short entry on the recent advances in understanding the genetic basis of systemic sclerosis (scleroderma). The findings of case–control and genome-wide association studies in systemic sclerosis are discussed.

Background

Systemic sclerosis (SSc or scleroderma) is a rare multisystem disease characterized by immune dysregulation, obliterative vasculopathy, and widespread skin and internal organ fibrosis. SSc is associated with high morbidity and mortality. The standardized mortality ratio in patients with SSc is 3.5 (Elhai et al. 2012) which is higher than the mortality observed in patients with other rheumatic diseases, such as rheumatoid arthritis, systemic lupus erythematosus (SLE), or Sjögren's syndrome. The prevalence of SSc ranges from 24 to 44 cases per 100,000 in North America (Bernatsky et al. 2009; Mayes et al. 2003). SSc is subdivided clinically into limited and diffuse subtypes based on the extent of skin disease. It is also characterized by mutually exclusive and highly specific antinuclear autoantibodies that predict various disease manifestations (Steen 2005). Anti-centromere, anti-topoisomerase I, and anti-RNA polymerase III are the most common SSc-related autoantibodies.

The pathogenesis of SSc remains poorly understood. The disease is thought to result from the interplay of genetic and environmental factors. While the environmental triggers are not well studied, there have been significant advances in understanding the genetic basis of SSc in recent years. SSc recurs more commonly in families than expected. DNA samples collected from large numbers of SSc patients through multicenter, international collaborations, as well as advances in high-throughput gene mapping technology and more sophisticated statistical methods have resulted in identification of several robust genetic susceptibility loci in SSc.

Major Histocompatibility Complex (MHC) and SSc Genetics

The three recently completed genome-wide association studies (GWAS) in SSc (Zhou et al. 2009; Radstake et al. 2010; Allanore et al. 2011) have confirmed results of previous case–control studies that the MHC region (especially HLA Class II) represents the most prominent genetic susceptibility locus in SSc (Arnett et al. 2009; Gladman et al. 2005). MHC associations with SSc have been reported in white, Hispanic, African-American, and Asian patients, but the observed effect sizes are relatively weak. Considerably stronger associations have been observed with each of the SSc autoantibody subgroups studied thus far. For example, in a study examining HLA class II in 1,300 SSc cases, the *DRB1*11:04, DQA1*05:01, DQB1*03:01* haplotype and *DQB1* alleles encoding a non-leucine residue at position 26 were risk loci for SSc, while the *DRB1*07:01, DQA1*02:01, DQB1*02:02* haplotype and *DRB1*15:01* haplotype were negatively correlated and possibly "protective" in dominant and recessive models, respectively (Arnett et al. 2009). However, stronger associations were observed with autoantibody subgroups. *DPB1*13:01* was strongly associated with the anti-topoisomerase subgroup of SSc (odds ratio = 14). The anti-centromere positive subgroup was associated with *DQB1*05:01* (OR: 2.6) and *DQB1*26* epialleles while anti-RNA polymerase III positivity was related to *DRB1*04:04 (OR: 5.1), DRB1*11* and *DQB1*03* alleles in white and Hispanic subjects.

HLA associations have been also reported with less common SSc-related autoantibodies. In a study examining 278 African-American patients with SSc, *HLA-DRB1*08:04* was strongly associated with anti-fibrillarin autoantibodies compared to unaffected African-American controls (OR: 11.5) (Sharif et al. 2011). A GWAS follow-up study with 3,175 white SSc patients indicated that *HLA-DQB1*, *HLA-DPA1/B1*, and *NOTCH4* associations with SSc are likely confined to SSc-specific autoantibodies (Gorlova et al. 2011). Recently developed methods for imputation of HLA alleles based on GWAS data and sequencing will enable examination of specific MHC regions in large SSc patient populations in the near future.

Non-MHC SSc Susceptibility Loci

Case–control studies conducted by independent groups have led to the discovery of several robust

Scleroderma: Genetics, Table 1 Selected non-major histocompatibility complex susceptibility genes for systemic sclerosis which were confirmed in at least two independent studies

	Approximate OR	Potential Function
BANK1	0.6–0.8[a]	Lymphocyte activation – B-cells
BLK	1.2–1.5	Lymphocyte activation – B-cells
CD247	0.6–0.8[a]	Lymphocyte activation – T-cells
CD226	1.0–1.2	Lymphocyte activation – T-cells
IRF5	1.2–1.5	Innate immune signaling – Interferon pathway
MIF	1.0–1.2	Adhesion molecule on endothelial cells
PTPN22	1.2–1.5	Lymphocyte activation – T-cells
STAT4	1.2–1.5	Innate immune signaling and lymphocyte activation – T-cells
TNFSF4	1.2–1.5	Lymphocyte activation – T-cells and B-cells
TNIP1	1.2–1.5	Nuclear factor κB pathway

[a]The minor allele is protective.

susceptibility loci in SSc (reviewed in Martin et al. (2012), Mayes (2012)). The majority of these genes such as *IRF5* (Dieude et al. 2009a), *STAT4* (Rueda et al. 2009), *BANK1* (Dieude et al. 2009b), and *BLK* (Gourh et al. 2010) belong to pathways involved in innate and adaptive immunity.

Three recent GWAS studies in SSc have enabled an unbiased examination of the common genetic variants in the entire genome (Zhou et al. 2009; Radstake et al. 2010; Allanore et al. 2011). These studies have confirmed some of the previously reported associations and have led to discovery of novel susceptibility loci. When examined separately, these gene variants have only a small effect on the development of disease (OR < 1.5).

Table 1 summarizes a list of selected non-MHC susceptibility loci that have been confirmed at least by two independent groups. The majority of these loci belong to genes that are involved in immune regulation. For example, *CD247* encodes the T-cell receptor zeta subunit modulating T-cell activation, *IRF5* belongs to a family of transcription factors in the type I interferon pathway, while *TNIP1* is a negative regulator of the nuclear factor κB pathway. The majority of these risk genes are also susceptibility loci for other autoimmune diseases, especially for SLE, suggesting that individuals with SSc may share a common genetic background with several other autoimmune diseases. This supports the concept of quantitative thresholds in immune-cell signaling in which several genetic factors of relatively small effect may cumulatively create a state of susceptibility to autoimmune diseases (reviewed in (Cho and Gregersen 2011)). Self-reactive B- and T-cells are a normal component of the immune system; however, their effect is usually regulated by the appropriate mechanisms in the thymus, bone marrow, or peripheral blood. According to the concept of quantitative threshold, the implicated genetic variations cumulatively impair the necessary biological processes for regulating auto-reactivity, leading to development of autoimmunity. The validity of this concept in SSc is supported by the fact that several SSc genetic susceptibility loci overlap not only with SLE but also with other autoimmune diseases. For example, *STAT4* is also implicated in rheumatoid arthritis and primary biliary cirrhosis.

Several of the confirmed SSc susceptibility loci show a stronger association with its autoantibody or clinical subtypes (limited versus diffuse) than with the overall disease. For example, multiple non-MHC susceptibility genes, such as *BANK1*, *IRF8*, *SOX5*n *and IRF7*, are mainly associated with the SSc-related autoantibodies (e.g., anti-centromere or anti-topoisomerase I) or clinical subtypes of disease (Carmona et al. 2012).

It is important to point out that the majority of identified loci in GWAS studies merely tag the actual causal genetic variants that have yet to be identified by genetic fine-mapping approaches. Furthermore, the GWAS approach does not allow investigation of rare causal variants because the GWAS platforms provide only sufficient coverage (usually >80 %) for common polymorphisms in the human genome.

Genes do not operate in isolation and are usually involved in intertwined biological processes. Therefore, novel mathematical approaches might lead to discovery of gene-gene

interactions that have a significantly higher impact on the development of SSc in comparison to the effect of each susceptibility variant separately. Furthermore, future mechanistic studies are needed to elucidate the cross-talk of the immune susceptibility loci with the other two prominent pathological features of SSc, namely, vasculopathy and fibrosis.

Definition

Scleroderma is a systemic disease with the potential for sclerosis of multiple organ systems including the skin, lungs, kidneys, cardiovascular system, and GI tract (Firestein and Kelley 2009). Prior to modern medicine, the most obvious of these manifestations was the skin, and it is therefore named for this manifestation from the Greek (skleros = hard and derma = skin). However, scleroderma is not the only disease entity that can cause sclerosis or the phenotypically similar phenomenon of fibrosis of the skin. The diseases that show these phenotypes are termed "scleroderma-like conditions."

Historical Background

Other conditions that may present with skin stiffening include other autoimmune- or immune-mediated diseases such as overlap syndromes, eosinophilic fasciitis, lichen sclerosis et atrophicus, or graft-versus-host disease; depositional disorders such as lipodermatosclerosis, scleromyxedema, scleroderma, and systemic amyloidosis; reaction to exogenous agents whether occupational, iatrogenic, or a food contaminant (these include such things as aniline-denatured rapeseed oil, L-tryptophan, polyvinyl chloride, bleomycin, and silica); nephrogenic systemic fibrosis, genetic syndromes including certain subtypes of progeria; and stiff skin syndrome itself. This finding therefore has a wide differential. Despite this wide differential, each of these diseases has characteristic features and history, and if the correct information is elicited from the patient, it should therefore be easy to distinguish them. As the treatment and prognosis, and ongoing screening for associated complications, is dramatically different between diagnoses, it is of high importance to know the key differences between these conditions to differentiate them. The different subtypes of "scleroderma," namely, diffuse, localized, and limited scleroderma, are reviewed elsewhere in this volume. This review focuses on briefly reviewing the most common of the scleroderma-like conditions that would enter into the differential and that are most commonly mistaken for scleroderma by nonspecialists. This chapter does not review such things as bleomycin-induced fibrosis or graft-versus-host disease which should be obvious from a simple medical and medication history or localized fibrosing disorders such as scleroderma or lipodermatosclerosis which by distribution are easy to distinguish.

Scleromyxedema

Scleromyxedema is a rare systemic disease which often first presents with the finding of skin stiffening (Rongioletti and Rebora 2001). It may

present as either localized or diffuse forms. In the localized form, it is generally easily differentiated from scleroderma, as instead of skin stiffening, it consists of 1–3 mm asymptomatic or mildly pruritic dome-shaped papules on the skin. These range in color from waxy and skin colored to occasionally mildly erythematous or hyperpigmented. They are most commonly found on the dorsal hands, face, or extensor surfaces of the arms and legs. They can coalesce or occur in parallel ridges. In patients with the diffuse form, despite the more widespread involvement, like the localized form but unlike diffuse scleroderma, the skin is often still mildly papular or cobblestoned. In diffuse scleromyxedema the glabellar and postauricular areas are often targeted and may lead to "leonine facies," where facial ridges and facial folds become accentuated.

Scleromyxedema usually presents between ages 30 and 70. There is no gender or ethnic predilection.

Histology includes deposition of mucin in the dermis between extensive proliferations of plump stellate fibroblasts. Essential parts of work-up include skin biopsy and a serum protein immunoelectrophoresis. Typically patients have a monoclonal paraproteinemia most commonly of the 7S immunoglobulin G (IgG) with lambda light chain type. The pathologic significance, if any, of this is unknown. Less commonly patients may have an associated Waldenström macroglobulinemia or multiple myeloma, but if present this portends a poorer prognosis. Patients with cardiac or pulmonary involvement also have poor prognoses. Lab work-up including thyroid testing is usually otherwise normal unless systemic involvement has begun to affect other organ systems. Work-up is therefore often directed by history and symptoms and suspicion of organ system involvement.

As in scleroderma, in addition to skin stiffening, patients may have multiorgan involvement. Most common is GI dysmotility, but Raynaud's phenomenon and myopathy have also been reported. Neurologic involvement may range from peripheral neuropathy and carpal tunnel to central nervous system involvement resulting encephalopathy and seizures. Mortality may come either from cardiac and pulmonary involvement in the form of pulmonary hypertension, from complications of medications used in treatment, or from underlying malignancy.

Previously melphalan, an alkylating agent, provided the mainstay of treatment, but improvements were usually short lived, and this medication has been associated with significant morbidity and mortality in the form of sepsis and hematologic malignancies (Harris et al. 1979; Helm and Helm 1987). More recently IVIG has been gaining wider acceptance, and there are an increasing number of reports of significant and durable improvements with the use of this medication (Blum et al. 2008). A wide range of other treatments have also been tried, with varying responses including thalidomide (Jacob et al. 2006), which has the side effect of neuropathy which may exacerbate that found in the underlying disease, as well as NBUVB, PUVA, methotrexate, cyclosporine, azathioprine, and mycophenolate mofetil.

Eosinophilic Fasciitis

Originally reported by Schulman in 1974, this entity was described as peripheral eosinophilia with fasciitis leading to deep fibrosis (Shulman 1975). It is distinguished from scleroderma as it often lacks the systemic symptoms of scleroderma, has no Raynaud's or periungual nail fold capillary changes, involves the deep fascia rather than the dermis, and most commonly lacks sclerodactyly as it spares the digits. Classically, the skin is initially edematous but non-pitting, and patients complain of ache. The onset is often rapid, evolving over days to weeks, and in over half of the cases, a history of an immediately preceding strenuous exercise can be elicited. As the disease progresses, the skin becomes increasingly indurated, but due to the distribution of the fibrosis that tends to be deeper, the skin will often appear as a peau d'orange or dimpled appearance and vasculature on the arms and legs appear sunken giving the classic "groove sign."

Involvement is often symmetric and most body areas can be affected, but the face and hands are rarely involved.

EF onset is usually between the second and sixth decade (Lakhanpal et al. 1988). Although rare in pediatrics, when it does occur, it is more common in girls. In adults, in contrast to scleroderma, which like most autoimmune diseases is more common in women, EF occurs more frequently in men (2:1). It shows a predilection for Caucasians. Although EF generally lacks renal, pulmonary, or cardiac involvement, other than in occasional case reports, a symmetric inflammatory arthritis has been reported in about 40 % of cases and carpal tunnellike findings in 10–15 %.

Skin biopsy can be helpful in diagnosis. In early EF skin biopsy shows a mixed cell infiltrate in the deep fascia with lymphocytes, plasma cells, histiocytes, and eosinophils. Vascular cuffing with lymphocytes and plasma cells can also be seen. Of note distribution of the eosinophils in the fascia may be segmental and can sometimes therefore be missed on biopsy. In addition, in later lesions the inflammatory infiltrate is replaced by sclerosis and thickening of fascia and dermis, and biopsies can sometimes be misinterpreted as representing scleroderma or morphea (Barnes et al. 1979).

Sixty to eighty percent of patients have a peripheral blood eosinophilia which often reflects the degree of eosinophilia found in biopsies. The presence of hypergammaglobulinemia is variable occurring in anywhere from 20 % to 60 % of patients (Antic et al. 2006; Bischoff and Derk 2008). When present it is most often a polyclonal increase in immunoglobulin G. Given an association in a subset of patients with hematological malignancy, screening is appropriate and a basic work-up should also include at a minimum CBC and SPEP with immunofixation.

Imaging is rarely necessary, but MRI of involved areas can show fascial thickening, abnormal signal intensity, and contrast enhancement (Moulton et al. 2005).

For most patients the prognosis is good with around 30 % of patients showing spontaneous remission and up to 70 % of EF patients responding to oral corticosteroids. A small subset has therapy unresponsive and progressive disease, and these patients can also have significant morbidity with joint contractures. Due to the limited number of cases, prospective controlled trials comparing the efficacy of different therapeutics do not exist, but a wide range have been tried and reported in case reports to have varying success including hydroxychloroquine, chloroquine, azathioprine, cyclosporine, dapsone, infliximab, tacrolimus, methotrexate, D-penicillamine, griseofulvin, ketotifen, alpha interferon, IVIG, and antitumor necrosis factor (TNF)-alpha agents (Bischoff and Derk 2008; Khanna et al. 2010). Physical therapy, especially in those with contractures, remains an important adjunct to pharmacological intervention.

Nephrogenic Systemic Fibrosis

Nephrogenic systemic fibrosis (NSF) was first observed in 1997, but currently over 335 cases have been reported to the NSF registry (Cowper et al. 2000; Cowper Nephrogenic Systemic Fibrosis 2001–2009). Clinically patients resemble severe EF patients with rapid onset (days to weeks) of non-pitting edema. This most commonly is symmetric and affects the lower extremities followed by the upper extremities. Truncal involvement can occur, although more commonly only in advanced disease. Involvement of the extremities can result in contractures and affect joint flexion and extension. Early on skin is skin colored to mildly erythematous, but as the disease progresses, hyperpigmentation is not uncommon. Early edema evolves into woody induration and patients often complain of itch, burning, and pain.

Despite the clinical similarity to EF, histologically NSF more closely resembles scleromyxedema with spindled cells extending between fat lobules, fibroblast proliferation, thickened collagen bundles, and mucin deposition. Most of the spindle cells are CD34/procollagen dual-positive cells (Kucher et al. 2005).

All patients have some degree of renal dysfunction, and the vast majority has undergone some form of dialysis, although this latter condition is not true of every confirmed patient. Most have also had MRI with a Gadolinium-based contrast agent (GBCA). For this reason GBCA is highly suspected in etiology and can be found in the skin biopsies of many NSF patients (Boyd et al. 2007). This also explains the appearance of this condition in 1997, as this was when these agents first began to find widespread use in the USA. NSF can affect any age but occurs most commonly between 30 and 50 years of age. It shows no predilection by gender or ethnicity. Reports have occurred from North and South America, Europe, Asia, and Australia, but the majority of reports still remain in the United States likely reflecting the higher use of gadolinium contrast studies in that country.

Some, but not all, patients respond to improvement in their renal function, increased dialysis, or renal transplantation. Reports of treatment success with imatinib mesylate are continuing to increase, and this appears at present the most established treatment for this sometimes devastating disease (Kay and High 2008). Second-line treatments and isolated case reports of varying success have also been given with IVIG, extracorporeal photochemotherapy, UVA with or without psoralen, and alpha interferon, but poor success has been reported with methotrexate and cyclophosphamide.

SH2 Domain-containing Inositol Phosphatase-1 (SHIP)

Matthew D. Blunt and Stephen G. Ward
Department of Pharmacology, University of Bath, Bath, Somerset, UK

Synonyms

Inositol polyphosphate-5-phosphatase, 145 kDa; Inpp5d; SHIP; SH2 domain-containing inositol phosphatase

Definition

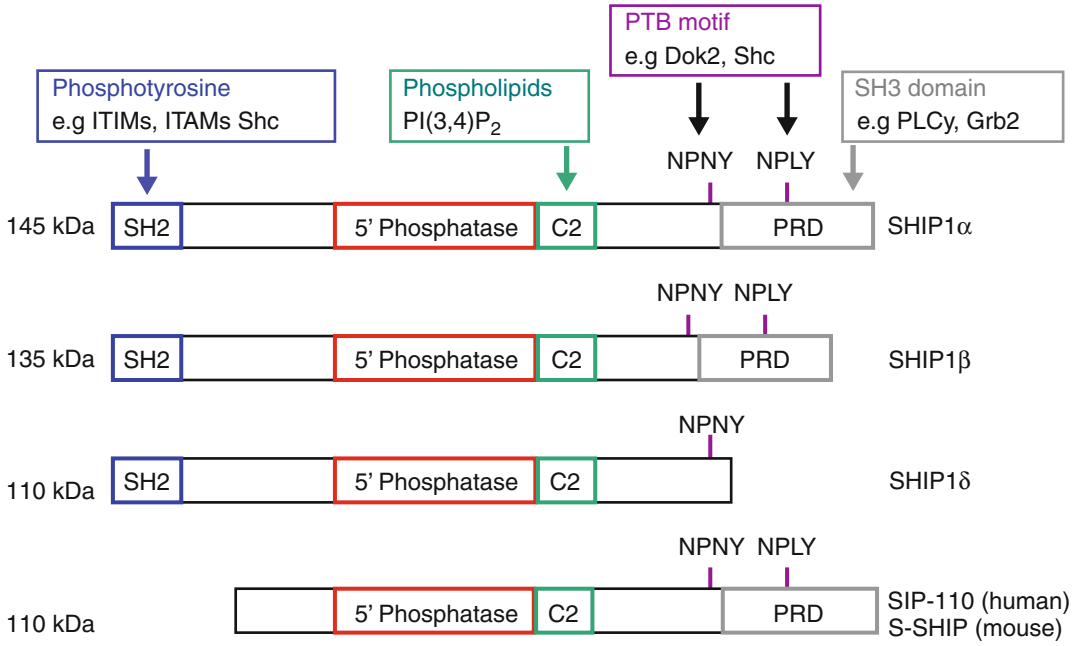
SH2 domain-containing inositol phosphatase-1 (SHIP) is a lipid phosphatase enzyme which regulates phosphoinositide 3-kinase (PI3K) signaling primarily through the degradation of the PI3K product PI(3,4,5)P_3. SHIP is expressed ubiquitously in differentiated cells of the hematopoietic system, in endothelial cells, hemopoietic stem cells (HSC), and embryonic stem (ES) cells. SHIP controls a plethora of immune cell functions and has been the subject of intense research for the past two decades. First identified in 1994, SHIP is a 145 kDa protein which becomes tyrosine phosphorylated after engagement of cell surface receptors on hematopoietic cells (Lioubin et al. 1994; Liu et al. 1994). In the 1990s, the creation of SHIP$^{-/-}$ mice allowed large advances to be made in the understanding of the important role this lipid phosphatase plays in the immune system (Helgason et al. 1998). More detailed analysis followed through the use of cell-restricted deletions of SHIP in myeloid and lymphoid compartments (Leung et al. 2009), while current research is probing further into the role of SHIP in the immune system through the utilization of siRNA and small molecule pharmacological strategies.

Structural Features of SHIP

SHIP protein possesses numerous structural domains as well as a single catalytic domain (Fig. 1). The catalytic domain is responsible for the hydrolysis of the 5-phosphate group on the PI3K product PI(3,4,5)P_3 to form PI(3,4)P_2. Under basal conditions, SHIP is located in the cell cytosol and upon receptor ligation is recruited to the surface membrane, bringing SHIP within close proximity to its lipid substrate. Numerous structural domains are required for SHIP to successfully relocalize to the surface membrane. The SH2 domain within SHIP interacts with proteins via the consensus amino acid sequence pY[Y/S][L/Y/M][L/M/I/V]. Through this SH2 domain, SHIP binds to tyrosine phosphorylated proteins such as Shc, Doks, Gabs, CD150, platelet-endothelial cell adhesion molecule (PECAM), Cas, c-Cbl, certain immunoreceptor tyrosine-based inhibitory motifs (ITIMs), and some immunoreceptor tyrosine-based activation motifs (ITAMs). Proline-rich regions within the C-terminal enable SHIP to bind proteins that contain a SH3 domain, for example, phospholipase-Cγ and Grb2. The phosphorylation of tyrosine residues within the NPXY motifs at the C-terminal tail of SHIP provides sites of interaction for various proteins which express phosphotyrosine-binding (PTB) such as Shc, Dok1, and Dok2. The various structural domains not only serve to bring SHIP in close proximity to its substrate at the surface membrane but also to allow SHIP to perform a scaffolding role, recruiting other proteins to the surface membrane independent of its catalytic activity. SHIP can also negatively regulate PI3K signaling independently of catalytic activity. For example, binding of SHIP to ITAM-containing adaptor proteins via the SH2 domain can prevent PI3K recruitment via the p85 regulatory subunit (Peng et al. 2010).

Variants Within the SHIP Family of Proteins

The *INPP5D* gene located on chromosome 2 (2q37.1) encodes the 145 kDa SHIP protein with multiple forms of SHIP occurring through posttranslational modification, degradation, or alternative mRNA splicing. This produces SHIP proteins of 145 kDa (SHIPα), 135 kDa (SHIPβ), and 110 kDa (SHIPδ) in size. In addition, other 130, 125, and 110 kDa forms of SHIP have been reported (Hamilton et al. 2011; Kerr 2011). Truncated SHIP proteins exhibit differential protein-binding properties owing to the lack of altered expression of certain protein-binding domains (Fig. 1). For example, s-SHIP and its human homologue SIP-110 are truncated at the N-terminus and lack the SH2 domain, but retain the catalytic, C2, and proline-rich domains.



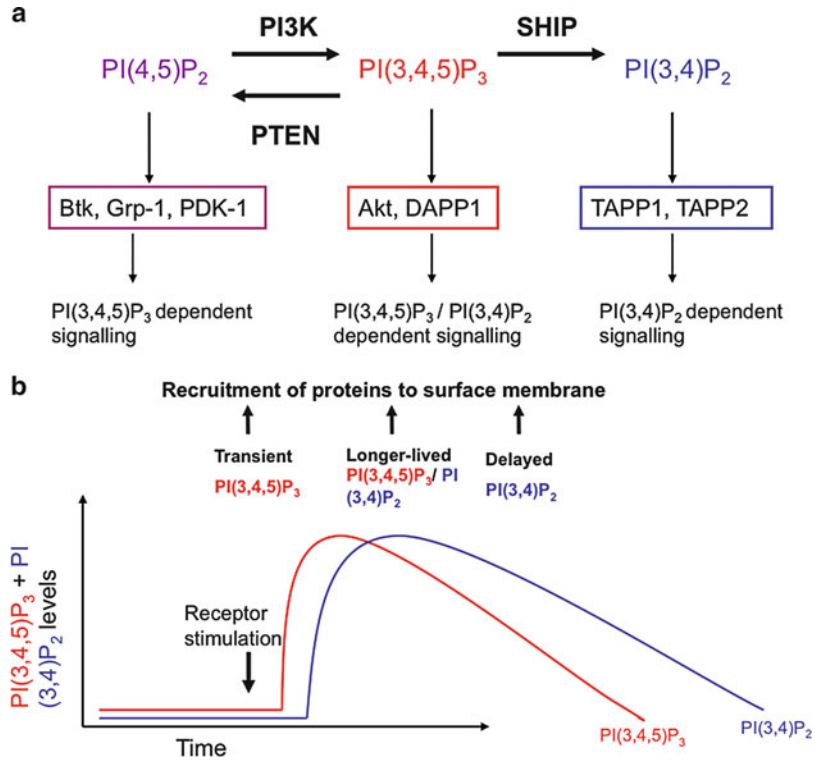
SH2 Domain-containing Inositol Phosphatase-1 (SHIP), Fig. 1 Schematic representation of the SHIP protein isoforms. The protein interaction motifs are indicated, along with their binding partners. The SH2 domain allows SHIP to bind proteins (such as those indicated) which express the sequence pY[Y/S][L/Y/M][L/M/I/V]. The 5′ phosphatase domain catalyzes the conversion of PI (3,4,5)P_3 to PI(3,4)P_2. The C2 domain binds the SHIP product PI(3,4)P_2 which acts to increase the catalytic activity of SHIP. The proline-rich domain (PR) allows SHIP to interact with SH3 domain-containing proteins. The NPXY motifs when phosphorylated provide binding sites for proteins which express phosphotyrosine-binding domains

This limits the repertoire of binding proteins available for interaction, and hence, these forms cannot interact with Shc, yet can still interact with Grb-2. Moreover, s-SHIP is mostly localized at the plasma membrane rather than the cytoplasm (Hamilton et al. 2011; Kerr 2011). Although originally thought to be restricted to embryonic stem cells, s-SHIP expression has been reported in adult hematopoietic cells and synergizes with SHIP to regulate the activation of macrophages (Nguyen et al. 2011).

SHIP-2 is a 142 kDa protein encoded by a separate gene, yet still retains high homology with SHIP. Divergence between SHIP and SHIP-2 occurs within the proline-rich domains and in the ability of SHIP-2 but not SHIP to hydrolyze PI(4,5)P_2 in vitro. SHIP-2 expression is not restricted to hematopoietic cell lineages and can be detected in heart, skeletal muscle, and brain tissues. SHIP-2 appears to have a major role in the negative regulation of insulin signaling in nonimmune cells (Ooms et al. 2009).

SHIP Regulates PI3K Signaling

SHIP degrades the PI3K product PI(3,4,5)P_3 by removing the 5′-phosphate group to yield PI(3,4)P_2. This has lead to the classical view of SHIP acting as a negative regulator of the PI3K/Akt signaling pathway. However, SHIP may also act as a type of molecular switch, able to divert PI3K signaling away from one set of effector proteins toward a second distinct set of effector proteins. Pleckstrin homology (PH) domains encoded in many proteins (e.g., Grp-1) bind exclusively to PI(3,4,5)P_3, whereas others such as that found in dual adaptor of phosphotyrosine and



SH2 Domain-containing Inositol Phosphatase-1 (SHIP), Fig. 2 SHIP acts as a molecular "switch." SHIP catalyzes the conversion of the PI3K lipid product $PI(3,4,5)P_3$ to $PI(3,4)P_2$. Effector proteins which express PH domains are recruited and activated by these lipid second messengers at the cell surface membrane. PH domains of proteins are able to discriminate between $PI(3,4,5)P_3$ and $PI(3,4)P_2$. Examples of proteins which bind only $PI(3,4,5)P_3$, both $PI(3,4,5)P_3$ and $PI(3,4)P_2$, or only $PI(3,4)P_2$ are shown (**a**). This diversity allows SHIP to both negatively regulate PI3K signaling and also to "switch" signal transduction pathways away from $PI(3,4,5)P_3$-dependent effectors toward $PI(3,4)P_2$-dependent effectors, in turn influencing kinetics and duration of recruitment of 3′-phosphoinositide lipid-binding proteins at the plasma membrane (depicted in (**b**))

3-phosphoinositides −1 (DAPP-1) can interact with both $PI(3,4,5)P_3$ and $PI(3,4)P_2$ (Lemmon and Ferguson 2000). In addition, the tandem PH domain-containing protein TAPP-1 encodes PH domains that show exclusive selectivity toward $PI(3,4)P_2$ (Harris et al. 2008). The ability of PH domain-containing proteins to distinguish between different 3′-phosphoinositide lipids suggests that SHIP can redirect PI3K-dependent signaling toward a set of distinct effectors that are temporally and functionally separate from PI $(3,4,5)P_3$-dependent events. Thus, SHIP may function to fine-tune phosphoinositide signaling, rather than terminate it (Fig. 2). In this regard, SHIP promotes recruitment of the GTPase Irgm1 to sites of phagocytosis in macrophages via generation of $PI(3,4)P_2$, a critical step in maturation of the phagosome and engulfment of bacteria. $PI(3,4,5)P_3$ and $PI(3,4)P_2$ appear sequentially following agonist stimulation in many cell types including T lymphocytes but show temporal overlap. Some cell types, notably B lymphocytes and platelets, exhibit sustained PI $(3,4)P_2$ production, lasting for up to 45–60 min poststimulation (Harris et al. 2008).

Role of SHIP in Stem Cell Biology and Transplantation

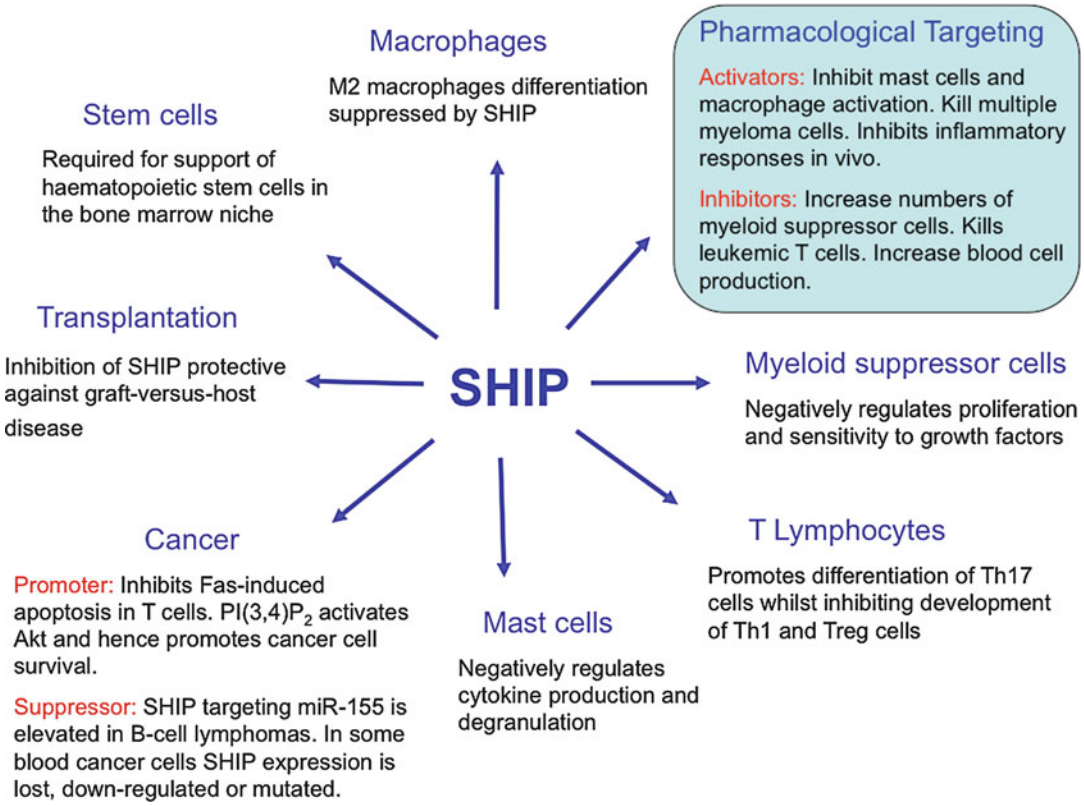
Both SHIP and s-SHIP have been implicated in the biology of pluripotent and adult stem cells.

More recently, it has been shown to play a key role in the function of the bone marrow microenvironment (Kerr 2008). HSC proliferation and numbers are increased in SHIP$^{-/-}$ mice. However, despite expansion of the compartment, SHIP-deficient HSCs exhibit reduced capacity for long-term repopulation and home inefficiently to bone marrow. The role of SHIP in the biology of both HSC and the hematopoietic stem cell niche suggests that it may be a useful target for treatment of bone marrow failure syndromes caused by viruses, radiation, chemotherapy, or malignancy. A common complication arising after bone marrow transplantation is graft-versus-host disease (GVHD) which involves priming of allogeneic T cells. Remarkably, SHIP-deficient mice express more myeloid-derived suppressor cells (MDSCs) than their WT counterparts. MDSCs function to repress allogeneic T cells. Hence, SHIP-deficient mice accept allogeneic bone marrow grafts with a reduced incidence of GVHD (Ghansah et al. 2004; Kerr 2008).

Role of SHIP in the Immune System

SHIP was originally recognized as an important component of the inhibitory signaling pathway triggered by the IgG receptor FcγRIIB in mast cells and B cells (Ono et al. 1996). Once recruited to the plasma membrane by signaling complexes, its catalytic activity depletes PI(3,4,5)P_3 and prevents membrane localization of some PH domain-containing effectors, leading to inhibition of extracellular calcium influx and ultimately reducing transcription activation and cytokine release. SHIP has subsequently also been implicated in signaling pathways triggered by cytokine, chemokine, antigen, and IgG engagement in a variety of immune cells (Harris et al. 2008). SHIP is now known to play a key role in regulating the receptor repertoire and cytolytic function of natural killer (NK) cells, B lymphocyte development and antibody production, the myeloid cell response to bacterial mitogens, development of marginal zone macrophages, lymph node recruitment of dendritic cells, and mast cell degranulation (Fig. 3). The negative regulatory role for SHIP in the immune system is highlighted by the phenotype of SHIP null mice, which develop progressive myeloid hyperplasia and myeloid infiltration in the lungs that leads to respiratory failure and to a dramatic decrease of life span. The myeloid hyperproliferation is caused by the combination of two factors. First, the myeloid cells and their precursors are more sensitive to growth factors, and second, these cells show a decreased sensitivity to proapoptotic stimuli (Helgason et al. 1998). Additionally, SHIP plays an important regulatory role in establishing endotoxin tolerance in macrophages as well as regulating leucocyte polarization during migratory responses to chemoattractants (Hamilton et al. 2011; Harris et al. 2008; Kerr 2011).

SHIP plays a critical role in homeostasis of myeloid and lymphoid effector and regulatory cells. As mentioned above, SHIP-deficient mice exhibit more myeloid-derived suppresser cells (MDSCs) than their wild type counterparts. SHIP also plays a role in regulating the balance of M1 macrophages (implicated in the first inflammatory response) and M2 macrophages (implicated in inflammatory response termination, tissue repair, regeneration, and remodeling). Hence, SHIP deficiency leads to increased macrophage skewing toward M2 macrophages, indicating that PI(3,4,5)P_3 drives macrophage progenitors toward an M2 phenotype which is suppressed by SHIP (Hamilton et al. 2011; Harris et al. 2008; Kerr 2011). SHIP has a key role in regulating CD4$^+$ T cell differentiation via its capacity to promote Th17 and limit regulatory T cell (Treg) development. In vitro and in vivo analyses revealed that in the absence of SHIP, T cells have an enhanced capacity to develop into Tregs with a parallel decrease in Th17 cell development (Hamilton et al. 2011; Harris et al. 2008; Kerr 2011). Curiously, mice with a T cell-specific deletion of SHIP do not skew efficiently to a Th2 phenotype as a result of its inhibitory effect on T-bet expression and consequently display Th1-dominant immune responses in vitro and in vivo (Leung et al. 2009). This is in contrast to evidence from germ line SHIP$^{-/-}$ mice, which



SH2 Domain-containing Inositol Phosphatase-1 (SHIP), Fig. 3 SHIP regulates immune cell functions and tumor development and growth. SHIP plays a key role in the generation of myeloid and lymphocyte subsets, thus maintaining a balance between inflammatory and regulatory cells. Modulation of SHIP offers potential for therapeutic intervention in cancer, transplantation, and a range of inflammatory and autoimmune diseases

indicates that SHIP can also repress Th2 skewing by inhibiting IL-4 production from basophils (Hamilton et al. 2011).

SHIP has been targeted by several opportunistic pathogens in order to evade immune detection. Thus, lymphocytes are particularly sensitive to the cytolethal distending toxin subunit B (CdtB), an immunotoxin produced by *Actinobacillus actinomycetemcomitans*, that can hydrolyze $PI(3,4,5)P_3$ to $PI(3,4)P_2$. Exposure to CdtB leads to cell cycle arrest and death by apoptosis. The lipid phosphatase activity of CdtB may therefore result in reduced immune function, facilitating chronic infection with *Actinobacillus* and other enteropathogens that express Cdt proteins (Shenker et al. 2007). The measles virus induces expression of SIP-110 which depletes the cellular $PI(3,4,5)P_3$ pools, probably leading to increased activation thresholds for T cell activation (Avota et al. 2006).

Role of SHIP in Cancer

PI3K signaling is activated in human cancers via several different mechanisms including activating mutations in the catalytic subunit as well as downregulation of expression of negative regulators such as the 3′ lipid phosphatase PTEN, a well-known tumor suppressor gene (Manning and Cantley 2007). Similarly, SHIP is often lost, downregulated, or mutated in many cancer cells including acute myeloid leukemia (AML) and T acute lymphoblastic leukemia (T-ALL)

(Hamilton et al. 2011). SHIP is also targeted by microRNAs, in particular miR-155. Elevated levels of miR-155 and consequent diminished SHIP expression have been linked to B cell lymphomas (Costinean et al. 2009). In addition, oncogenic proteins such as BCR/Abl and Tax (implicated in chronic myelogenous leukemia and adult T cell leukemia/lymphoma, respectively) can induce SHIP downregulation by a variety of mechanisms (Kerr 2011). Another way in which SHIP can influence tumor growth relates to its role in restricting development of MDSCs and Tregs. Since SHIP deficiency leads to an expansion of MDSCs and Tregs, this could lead to the suppression of antitumor effects mounted by T cell-mediated immune responses. Conversely, there is evidence that SHIP can actually support cancer cell survival. In this regard, SHIP inhibits CD95/APO-1/Fas-induced apoptosis in T cells by promoting CD95 glycosylation independently of its phosphatase activity (Charlier et al. 2010). In addition, pharmacological inhibition of SHIP induces apoptosis of multiple myeloma cells (Brooks et al. 2010). This effect likely arises as a result of the production of $PI(3,4)P_2$ which is known to facilitate Akt activation and, hence, survival and tumorigenesis (Manning and Cantley 2007).

Targeting SHIP with Small Molecules

The role of SHIP in regulating the development and function of various hematopoietic cells and evidence linking SHIP to cancer and other diseases has led to the search for small molecules that are able to modulate activity and which may be useful as drugs. Several compounds that bind to the C2 domain and lead to allosteric activation of SHIP have now been reported and have been shown to exert an anti-inflammatory effect in vitro and in vivo (Harris et al. 2008). Moreover, these molecules have been successfully used to kill multiple myeloma cells in vitro indicating that SHIP agonists could be effective anticancer agents. Small molecule inhibitors of SHIP have also been reported which, consistent with observations from SHIP deleted mice, led to increased MDSCs and protected against GVHD. SHIP inhibitors increased levels of granulocytes, red blood cells, neutrophils, and platelets (Harris et al. 2008) in mice and could therefore have application to improve blood cell number in patients with myelodysplastic syndrome or myelosuppressive infection. A SHIP inhibitor also triggered the apoptosis of human acute myeloid leukemia cell lines, consistent with SHIP being antiapoptotic under some circumstances (Brooks et al. 2010)

Conclusion

SHIP is largely confined to hematopoietic cells and hydrolyzes the PI3K-generated second messenger $PI(3,4,5)P_3$, to $PI(3,4)P_2$. As a consequence, SHIP is able to modulate PI3K-/Akt-mediated signaling and hence the proliferation, differentiation, survival, activation, and migration of hematopoeitic cells. SHIP possesses a centrally located catalytic domain responsible for the hydrolysis of the 5′-phosphate of the membrane phosphoinositide lipid $PI(3,4,5)P_3$. Moreover, the presence of multiple structural domains that facilitate protein-protein interactions and cellular relocalization upon receptor stimulation allows SHIP to fulfill a scaffolding role independently of its catalytic function. The ability of PH domain-containing proteins to distinguish between different 3′-phosphoinositide lipids allows SHIP to act as a switch to redirect PI3K signaling toward $PI(3,4)P_2$-dependent effectors that are distinct from $PI(3,4,5)P_3$-dependent events. Thus, SHIP may function to fine-tune phosphoinositide signaling, rather than terminate it. SHIP can regulate signaling pathways elicited by engagement of appropriate receptors with cytokines, chemokines, antigens, and IgG in both lymphoid and myeloid cells. It plays a key role in the generation of lymphocyte and myeloid subsets and maintaining a balance between inflammatory and regulatory cells. Additionally, SHIP plays an important regulatory role in establishing endotoxin tolerance in macrophages, as well as regulating leukocyte polarization during migratory responses to

chemoattractants. The expression of SHIP is often lost, downregulated, or mutated in many cancer cells and is often targeted by pathogens to avoid detection and destruction by the immune system. Hence, modulation of SHIP offers potential for therapeutic intervention in an inflammatory/autoimmune and infectious disease as well as in cancer and transplantation settings.

Synonyms

Autoimmune epithelitis; Gougerot's syndrome; Sicca syndrome

Definition

Sjögren's syndrome (SS) is a chronic autoimmune disease characterized by lymphocytic infiltration of the exocrine glands (mainly the lacrimal and salivary glands), leading to dry eyes and dry mouth (also known as sicca symptoms), as a result of impaired secretions. The disease can also affect virtually all exocrine glands of the body, such as nose, throat, bronchi, trachea, skin, and vagina. Extraglandular manifestations and non-Hodgkin lymphoma may occur in about one third and in 5–8 % of SS patients respectively.

SS can occur alone (primary SS) or with other autoimmune diseases, such as rheumatoid arthritis, systemic lupus erythematosus, systemic or limited sclerosis, and autoimmune thyroid disease. The term "SS associated with other disease" has been recently proposed to replace the term "secondary SS" which traditionally was implemented to describe sicca features following the diagnosis of other connective tissue diseases such as rheumatoid arthritis.

Epidemiology

Sjögren's syndrome has a prevalence of 0.5–1 % of the general population and affects predominantly middle-aged females (women to men ratio of 9–1).

Diagnosis

Subjective Evaluation

The diagnosis of SS is based on a combination of findings from a detailed medical and family history, alcohol and smoking habits, intake of medications and other substances, physical examination findings, and laboratory test results; occasionally, minor salivary gland biopsies are available to support the diagnosis. Specific questionnaires addressing the presence of symptoms of oral and ocular dryness can also be helpful (Mavragani and Moutsopoulos 2009).

Objective Tests for Oral and Ocular Dryness

Ocular component

- Schirmer's test: This test evaluates the function of the lacrimal glands by measuring the amount of tears produced. A thin filter paper strip is placed on the back of the lower lid and measures the wetting of the film after 5 min. In patients with SS, wetting of the filter strip does not exceed 5 mm in 5 min.
- Rose Bengal or Lisamine Green staining: These tests reveal the presence of epithelial damage as the result of tear deprivation (keratoconjunctivitis sicca). A drop of dye solution is placed in the lower conjunctiva; the pigmented lesions detected by slit lamp exam reflect the affected areas of the conjunctiva and cornea.
- Break-up time (BUT): This is a nonspecific test assessing the quality of the tears. Under physiological conditions, the tear film breaks at least after 10 s. In SS, this test is usually reduced to less than 10 s, an indication of tear instability.

Oral component

- Sialometry: Saliva secretion is measured in a graded tube; it is considered abnormal for volumes less than 1.5 mL/15 min.
- Salivary gland scintigraphy: Reduced technetium 99 m pertechnetate uptake reflects salivary gland dysfunction. Its use is limited in clinical practice, given the high cost and the nonspecific results.
- Parotid sialography: In patients with SS, this test discloses alteration of the normal

structural pattern of parotid ductules. It is painful, poorly specific, and therefore, it is rarely used.

- Ultrasonography/MRI sialography/MRI: These are promising imaging techniques which need further validation (Tzioufas and Moutsopoulos 2008).
- Labial salivary gland biopsy: This is a relatively simple diagnostic procedure aimed at removal of minor salivary glands. Lymphocytic infiltrates around salivary gland epithelium are the hallmark of SS. A focus score ≥ 1 (defined as the presence of at least 50 lymphocytes/4 mm^2) is included in the classification criteria for the disease.

Serological Evaluation

Serological testing for the presence of autoantibodies [rheumatoid factor (~60 %), ANA (~90 %), anti-Ro/SSA (~60 %) and/or anti-La/SSB (~50 %)], hypergammaglobulinemia, chronic viral infections (HCV, HIV, HTLV-1), and thyroid function provides helpful insights for the disease diagnosis. The role of antibodies to muscarinic receptors in the pathogenesis of sicca features through mechanisms of autonomic dysfunction is emerging.

Classification Criteria

The most widely accepted criteria for the classification of SS are the "European American consensus group criteria," which require symptoms and signs of mucosal dryness along with the presence of either a focus score of 1 or more in minor salivary glands or the presence of anti-Ro/SSA and/or anti-La/SSB autoantibodies (Table 1) (Peri et al. 2012).

Sjögren's Syndrome, Table 1 European American Consensus Group criteria

1. Ocular symptoms (at least one present)
Persistent, troublesome dry eyes every day for longer than 3 months
Recurrent sensation of sand or gravel in the eyes
Use of a tear substitute more than three times a day
2. Oral symptoms (at least one present)
Feeling of dry mouth every day for at least 3 months
Recurrent feeling of swollen salivary glands as an adult
Need to drink liquids to aid in swallowing dry food
3. Objective evidence of dry eyes (at least one present) (see how at pages 7 and 8)
Schirmer's test $\leq$5 mm/5 min
Van Bijsterveld score $\geq$4 (after lissamin test)
4. Objective evidence of salivary-gland involvement (at least one present)
Salivary-gland scintigraphy
Parotid sialography
Unstimulated salivary flow ($\leq$1.5 mL per 15 min, $\leq$0.1 mL/min)
5. Histological features
Positive minor salivary-gland biopsy sample (focus score $\geq$1 : This refers to a cluster of 50 or more lymphocytes per lobule when at least four lobules are assessed)
6. Autoantibodies
Presence of antibodies to Ro/SSA or to La/SS-B
Classification of primary Sjögren's syndrome requires four of six criteria, including a positive minor salivary-gland biopsy sample or antibody to Ro/SSA and/or to La/SSB, or three of the four objective criteria (criteria 3–6)
Classification of secondary Sjögren's syndrome requires an established connective-tissue disease and one sicca symptom (criteria 1 or 2) plus any 3 of the four objective criteria (Items 3, 4, 5)
Exclusions include previous radiotherapy to the head and neck, lymphoma, sarcoidosis, graft-versus-host disease, and infection with hepatitis C virus, or HIV, use of anticholinergic drugs

Differential Diagnosis

Diseases and conditions mimicking SS include, among others, medications that can cause sicca symptoms (e.g., antihistamines, nasal decongestants, diuretics, antidiarrhoeals, antipsychotics, sedatives, antidepressants), sarcoidosis, infections (HCV, HIV), hyperlipoproteinemias (types II, IV, and V), diabetes mellitus, irradiation and the IgG4-related sialadenitis (formerly known as Mikulicz disease or as Kuttner's tumor) (Ramos-Casals et al. 2007).

Clinical Manifestations

The clinical features of SS are divided into those related to exocrine dysfunction (glandular) and to

those affecting other organs beyond exocrine glands (extraglandular or systemic). The latter can be further divided into those characterized by periepithelial infiltrates in parenchymal organs (kidney, lung, liver) and to those derived by immunocomplexes deposition as a result of B cell hyperactivity (glomerulonephritis, purpura, peripheral neuropathy) (Mavragani and Moutsopoulos 2010; Skopouli et al. 2000).

Glandular Features

- Dry eyes: Symptoms include burning, itching, or sand feeling in the eyes, which may be red and irritated. The vision may be blurry.
- Dry mouth: Difficulty in chewing, swallowing and speaking, adherence of food to the buccal surfaces, and abnormalities of taste and smell are common manifestations. Moreover, lack of saliva protection increases the chances of fungal stomatitis and dental caries. The tongue appears dry and fissured.
- Salivary gland swelling: This is a frequent SS-related symptom, associated with increased risk for the development of lymphoma. Differential diagnosis includes superimposed infection, metabolic derangement, infiltrative disorders, and IgG4-related sialadenitis.
- Dry cough/xerotrachea: These are mainly related to the desiccation of tracheobronchial tree. Pulmonary function tests usually reveal a small airway obstructive pattern which is thought to result from peribronchial and/or peribronchiolar lymphocytic infiltrates. A "dirty lung" appearance on a chest-X-ray and peribronchial thickening on high-resolution computed tomography imaging are the main imaging findings observed.
- Vaginal dryness
- Dry skin

Extraglandular Features

Musculoskeletal

Arthralgias, non-erosive arthritis, and myalgias are common in SS. Fibromyalgia and chronic fatigue are also common, affecting the quality of life of these patients.

Raynaud's Phenomenon

Raynaud's phenomenon, which may occur prior to the appearance of sicca symptoms, affects about one third of SS patients.

Respiratory Tract Involvement

The majority of pulmonary symptoms are related to glandular involvement of the trachea and bronchial glands. Less frequently interstitial lung disease is diagnosed.

Gastrointestinal and Hepatobiliary Manifestations

Dysphagia related to esophageal dysmotility and reduced saliva is observed in SS patients. Hoarseness as a result of gastroesophageal and laryngopharyngeal reflux is also observed. Liver involvement mainly in the form of primary biliary cirrhosis (PBC) has been described in around 5–10 % of SS patients often associated with the presence of serum anti-mitochondrial (AMA) antibodies.

Renal Involvement

Two types of renal involvement have been described and include tubulointerstitial nephritis and glomerulonephritis. The former is more common and mild, expressed as hypokalemia, low urine specific gravity (hyposthenuria), and alkaline urine pH. Glomerulonephritis is rather rare, usually occurring in association with systemic vasculitis, hypocomplementemia, and cryoglobulinemia; these features increase the risk for the development of lymphoma. IgM and complement are detected in renal biopsy by immunofluorescence.

Vasculitis

Vasculitis affecting small vessels of the skin occurs in about 15 % of SS patients, usually many years after the diagnosis of SS. Palpable purpura and more rarely urticarial lesions are the most common clinical manifestations, often in association with cryoglobulins, high titers of rheumatoid factor, antinuclear antibodies (ANA), hypocomplementemia, and hypergammaglobulinemia. Less frequently, peripheral nerves, muscles, and kidneys are affected. Vasculitic lesions in the context of SS are

associated with increased risk for the development of lymphoma and increased mortality.

Neuropsychiatric Involvement

The prevalence of peripheral neuropathy in SS displays a wide variability between studies; the main subtypes observed are purely sensory (stocking-glove distribution), small fiber neuropathy (SFN), expressed as painful and burning paresthesias, and sensorimotor neuropathy (Pavlakis et al. 2012).

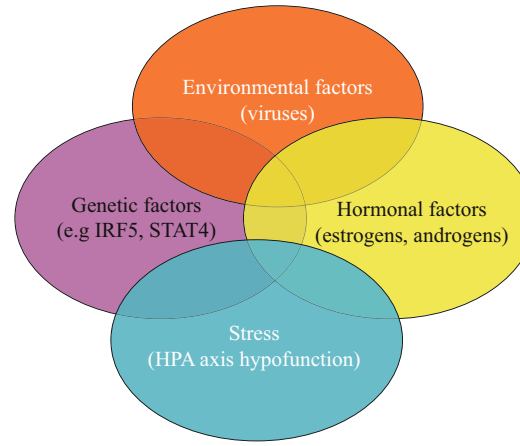
Central nervous system involvement in primary SS remains controversial. While earlier studies reported high prevalence of CNS pathology in SS (including demyelinating lesions that may mimic multiple sclerosis), subsequent reports failed to confirm these findings. Finally, compared to healthy individuals, SS patients reportedly display psychopathological abnormalities and distinct personality traits such as neuroticism, psychoticism, and obsessiveness (Mavragani and Moutsopoulos 2010).

Lymphoma

Non-Hodgkin B cell lymphoma occurs in approximately 5–8 % of patients with SS, conferring increased mortality. Mucosa-associated lymphoid tissue (MALT) type is the most common type; however, follicular lymphoma, lymphoplasmacytoid, and diffuse large B cell lymphoma (DLBCL) have also been described. Adverse prognostic factors associated with the development of lymphoma include lymphopenia, low C4 serum levels, cryoglobulinemia, peripheral neuropathy, glomerulonephritis, vasculitis, salivary gland enlargement, and the presence of germinal centers at salivary gland biopsy. Lymphoma complicating SS most commonly involve the salivary glands. Other organs, however, such as stomach, lung, nasopharynx, and thyroid, can also be involved. In high-risk patients, close follow-up for the development of lymphoma is appropriate (Voulgarelis et al. 2012; Ioannidis et al. 2002).

Etiopathogenesis

As proposed for a number of other autoimmune diseases, SS probably results from a complex interplay between genetic, environmental, hormonal, and stress factors, leading to aberrant epithelial cell activation (Fig. 1).



Sjögren's Syndrome, Fig. 1 The underlying mechanism of Sjogren's syndrome pathogenesis is a complex interplay between genetic, hormonal, environmental, and psychopathological factors. *HPA* hypothalamic-pituitary axis

Genetics

Genetic predisposition of SS is supported by the observed familial clustering and the increased frequency of certain alleles implicated in innate and adaptive responses inside and outside the HLA locus. The presence of polymorphisms in the MHC II, the interferon regulating factor-5 (IRF5), and signal transducer and activator of transcription 4 (STAT4) genes have been associated with disease susceptibility (Ice et al. 2012).

Stress

The occurrence of stressful events prior to disease onset and defective coping strategies in conjunction with the presence of a hypoactive hypothalamic-pituitary-adrenal axis imply stress as a potential trigger in disease pathogenesis.

Hormonal Factors

Disease onset around menopause and the female predominance support the contributory role of hormones in disease pathogenesis. SS patients are characterized by low androgen and estrogen levels which have been previously shown to

protect salivary epithelium apoptosis; development of SS-like disease in mice lacking estrogens is also supportive (Konttinen et al. 2012).

Viruses

Activation of the type I interferon pathway in SS, as confirmed by gene expression, serological, and immunohistochemical studies, strongly suggests a role for viral infection in disease pathogenesis. Thus far, several viruses and viral particles have been implicated including Coxsackie virus, EBV, HTLV-1, HCV, CMV, HHV-6, and HHV-8, among others (Sipsas et al. 2011).

Pathophysiology

According to the currently proposed pathophysiological scenario for SS, epitheliotropic viruses or endogenous nucleic acids might serve as initial triggers of epithelial activation, a central event in disease pathogenesis (autoimmune epithelitis). The latter is evidenced by increased expression of several immunomodulatory molecules implicated in:

- Lymphocyte recruitment/homing/expansion/differentiation (proinflammatory and immunoregulatory cytokines, lymphoid chemokines, BAFF, adhesion molecules)
- Apoptosis (FaS, FaSL, Perforin, granzymes)
- Ag-presentation (MHC molecules, B7 costimulatory molecule, translocation of nuclear autoantigens)
- Sensing innate stimuli (TLRs, CD91)

As a result of increased apoptosis, exposure of autoantigens, such as Ro/SSA and La/SSB, and subsequent production of disease-specific autoantibodies with immunocomplexes formation can lead to robust type I interferon (IFN) production by plasmacytoid dendritic cells (PDCs), the "professional IFNα producers" in genetically susceptible individuals. Type I IFN along with low estrogen/androgen status might further activate epithelial cells, leading to BAFF overexpression and autoantibody production. The activated epithelial cell acts as an antigen-presenting cell and through upregulation of chemotactic molecules may lead to further recruitment of inflammatory cells, activation of T and B cells, and autoantibody production. Tissue damage, occasionally associated with B cell monoclonal expansion, may follow (Jonsson et al. 2011; Manoussakis and Kapsogeorgou 2010; Mariette and Gottenberg 2010; Nikolov and Illei 2009; Tzioufas et al. 2012; Vakaloglou and Mavragani 2011) (Fig. 2).

Therapy

Treatment of SS is mainly symptomatic, aimed at relief of mucosal dryness. Avoiding dry environments and dehydration along with artificial tears, lubricative ointments, ocular cyclosporine drops, and occlusion of the punctae lacrimales are the main modalities implemented in the management of keratoconjunctivitis sicca. Muscarinic agonists, including pilocarpine and cevimeline hydrochloride, have been proved efficacious, increasing saliva and tear secretion.

Immunomodulatory agents are generally reserved for the treatment of extraglandular SS manifestations. Hydroxychloroquine may be effective for arthralgias, arthritis, and myalgias, while corticosteroids, methotrexate, azathioprine, and cyclophosphamide have been tried for persistent arthritis, interstitial lung disease, peripheral nerve involvement, severe vasculitis, and renal involvement. Cytotoxic drugs, however, should be administered with extreme caution since they may increase the risk of lymphoma, particularly in the high-risk groups.

Given the contributory role of B cells in disease pathogenesis, B cell depletion strategies provide a rational therapeutic approach. Anti-CD20 administration seems promising in the management of several extraglandular disease manifestations, including lymphoma. Such agents may also reduce fatigue and mucosal dryness in the presence of residual glandular function.

Studies suggest that anti-TNF agents (e.g., infliximab and etanercept) are not effective in SS; augmentation of the already activated type I interferon-BAFF pathway is a plausible explanation (Ramos-Casals et al. 2012; Ramos-Casals et al. 2010).

Definition

The autoimmune disease lupus erythematosus (LE) shows many different clinical manifestations reaching from primarily cutaneous lesions (cutaneous lupus erythematosus, CLE) to severe systemic organ manifestations (systemic lupus erythematosus, SLE). Skin manifestations appear in 73–85 % of patients with SLE and may occur at any stage of the disease; conversely, only a small percentage of patients with CLE subsequently develop a systemic manifestation of the disease.

Introduction

In 1982, the American College of Rheumatology (ACR) introduced a set of criteria for the classification of SLE that provided some degree of uniformity in classifying the patient populations of clinical studies (Tan et al. 1982). Although 4 of the 11 ACR criteria are mucocutaneous manifestations (malar rash, discoid lesions, photosensitivity, and oral ulcers), the clinical presentation of skin involvement in SLE presents with a much broader spectrum. Importantly, photosensitivity is not specific for SLE, and it is observed in other conditions, such as polymorphous light eruption (PLE) (Albrecht et al. 2004). In 2012, the Systemic Lupus Collaborating Clinics (SLICC) revised and validated the ACR criteria in order to improve clinical relevance and incorporate new knowledge in SLE immunology (Petri et al. 2012). Moreover, the Cutaneous Lupus Erythematosus Disease Area and Severity Index (CLASI) was revised in 2010, taking into account both anatomical regions (e.g., face, chest, arms) and morphological aspects (e.g., erythema, edema/infiltration, scarring/atrophy) to evaluate "activity" and "damage" of skin manifestations in all subtypes of CLE (Kuhn et al. 2010b). Although several agents are approved for the treatment of SLE, including the novel monoclonal antibody belimumab (Manzi et al. 2012), a B lymphocyte stimulator-specific inhibitor, no drugs have been licensed specifically for the treatment of skin manifestations of the disease. Thus, topical and systemic agents in CLE are mostly used "off-label." In this entry, recent information on pathogenesis, clinical manifestations, and treatment of CLE are summarized.

Pathogenesis

Cutaneous manifestations of autoimmune diseases may be caused by autoantibodies and immune complexes, independent of the question

Comment: As the number of references is limited in the "Encyclopedia of Medical Immunology," mainly review articles are cited. If the original articles are of interest, please consult the original articles referred to in the review articles.

of whether skin lesions are the primary sign of the disease, as in CLE, or part of a disease spectrum, as in SLE (Liu and Davidson 2012). In fact, immune complex deposition and complement activation can be demonstrated in tissue samples of both CLE and SLE patients (Kuhn et al. 2010a). As skin lesions mainly occur in sun-exposed areas, such as the face, upper back, V area of the neck, and extensor aspects of the arms, it is commonly accepted that sun exposure can induce and exacerbate cutaneous manifestations in patients with all subtypes of CLE and SLE, which supports the role of ultraviolet (UV) light in the pathogenesis of the disease (Kuhn et al. 2010d). The mechanisms by which UV irradiation activates the autoimmune response are not completely understood. However, recent studies assessing the molecular mechanisms, which underlie UV-induced apoptosis, contribute to a better understanding of the disease pathogenesis (Lehmann and Homey 2009). In primary and UV-induced skin lesions of patients with CLE, compared with healthy controls, a significant increase of apoptotic keratinocytes has been found by immunohistochemistry (Baima and Sticherling 2001; Kuhn et al. 2010a). In the majority of patients with CLE, the number of apoptotic nuclei in the epidermis already increased significantly between day 1 and day 3 after a single UV exposure (Kuhn et al. 2006). These data suggest that accumulation of apoptotic cells or a deficiency in clearance might play an important role in the development of skin lesions. It has further been demonstrated that the cytoplasmatic molecule, annexin 1, which is externalized during apoptosis to the outer leaflet of the plasma membrane, leads to the suppression of dendritic cells (Weyd et al. 2013; Arur et al. 2003). A recent study showed that the percentage of anti-annexin 1 antibodies was significantly higher in the sera of patients with CLE compared to healthy controls (Kretz et al. 2010); however, the functional role of anti-annexin 1 antibodies in this disease is not known. The results of this study may suggest that blocking anti-annexin 1 antibodies might interfere with the generation of tolerance and support the development of autoimmunity.

Clinical Manifestations

The clinical expression of the skin lesions in SLE shows a great variety and has led to the practice of identifying different subtypes of the disease. However, the development of a unified classification of skin manifestations has proven difficult. The classification system developed by Gilliam in 1977 divided cutaneous lesions into LE-specific and LE-nonspecific manifestations by histological analysis of skin biopsy specimens (Gilliam 1977). Skin lesions such as urticarial vasculitis and livedo reticularis are some of the most common LE-nonspecific cutaneous lesions and are primarily associated with active SLE, reflecting potentially serious complications (Costner et al. 2003). In contrast, the LE-specific cutaneous findings encompass the various subtypes of CLE, which were subdivided into three different categories defined by constellations of clinical features, histological changes, serological abnormalities, and average duration of skin lesions: acute cutaneous LE (ACLE), subacute CLE (SCLE), and chronic cutaneous LE (CCLE), including discoid LE (DLE), chilblain LE (CHLE), and LE panniculitis (LEP). After the initial description of Gilliam's nomenclature more than three decades ago, this classification system has been modified in 2004 (Kuhn and Ruzicka 2004). An additional subtype with characteristic clinical, histological, and photobiological features, termed LE tumidus (LET), was first described in 1909 and has only recently been defined as a separate entity of CLE (Table 1).

Acute Cutaneous Lupus Erythematosus (ACLE)

ACLE may occur as a localized, occasionally transient form or as a generalized widespread form of the disease (Costner et al. 2003). The more common localized form is characterized by the classical "butterfly rash" which is often misdiagnosed as sunburn. It is defined as a sharply bordered erythema with symmetrical distribution in the central part of the face, typically sparing the nasolabial folds. The less common generalized form of ACLE (5–10 %) is often associated with the occurrence of

systemic manifestations. Symmetrically distributed maculopapular, erythematous to violaceous, and sometimes pruritic lesions may involve the trunk, in particular the UV-exposed areas, but may also be localized on the hands or feet, while knuckles are typically spared. Telangiectases and periungual erythema can occur at the nail fold and are often associated with a red lunula. Usually, the generalized form of ACLE presents with increased disease activity of SLE, which may be accompanied by mucosal changes affecting the mouth (hard palate, buccal mucosa, gingiva, uvula), nose, pharynx, and vagina. In most of the cases, ACLE does not lead to depigmentation and is a non-scarring subtype, but diffuse thinning of the hair ("lupus hair") can occur along the hairline (Kuhn et al. 2007). The highly acute form of generalized ACLE characterized by toxic epidermal necrolysis (TEN)-like lesions is rarely seen in SLE patients.

Subacute Cutaneous Lupus Erythematosus (SCLE)

SCLE presents as erythematous macules or papules that expand and merge into hyperkeratotic papulosquamous or annular, sometimes polycyclic plaques with a garland-like appearance (Fig. 1). Two forms of this subtype can be distinguished: a papulosquamous variant consisting of psoriasis-like or eczema-like lesions and an annular variant consisting of slightly raised erythema with central clearing (Sontheimer 2005). Both forms may be found in the same patient. Typically, SCLE lesions are located on sun-exposed skin including the lateral aspects of the face, the V area of the neck (often with sparing of area under the chin), the upper ventral and dorsal part of the trunk, and the dorsolateral aspects of the arms. Skin lesions of SCLE can heal with vitiligo-like depigmentation, as a diagnostic "clue" of the disease (Kuhn et al. 2007). Similar to ACLE, a TEN-like picture can develop in some patients, especially after UV exposure. SCLE shows recurrent episodes in the majority of patients, and in 10–15 % it develops into a moderate form of SLE. In contrast to other subtypes of CLE, SCLE is often induced by drugs, for example, including hydrochlorothiazide, ACE inhibitors, and terbinafine. In drug-induced SCLE, skin lesions can be more widespread with extension to the lower extremities.

Chronic Cutaneous Lupus Erythematosus (CCLE)

CCLE includes three different forms of the disease: discoid LE (DLE), LE profundus/panniculitis (LEP), and chilblain LE (CHLE).

Discoid Lupus Erythematosus (DLE)

DLE is the most common form of CCLE and consists of sharply bordered, coin-shaped ("discoid") erythematous plaques, on which adherent scales are present (Fig. 2). Removal of the scale shows follicle-sized keratotic spikes, the "carpet tack sign" (Kuhn et al. 2007). This form of CCLE can lead to atrophy and scarring with central depigmentation and peripheral hyperpigmentation. Periorally, characteristic pitting scars can develop. As hair follicles are irreversibly damaged, areas such as the scalp, eyebrows, and hairy regions of the face develop scarring alopecia. The localized form of DLE occurs in 80 % and has a predilection for the face and scalp, especially the cheeks, forehead, ears, nose, and upper lip (Costner et al. 2003). The disseminated form of DLE, involving mostly the

Skin in Systemic Lupus Erythematosus, Fig. 2 Discoid lupus erythematosus (*DLE*). Coin-shaped plaques with peripheral erythematous, hyperkeratotic border, and central atrophic scarring on the left cheek

upper part of the trunk and the extensor surfaces of the extremities, is less common. Exposure to the sun or irritating stimuli (Koebner phenomenon) can provoke or exacerbate the disease (Ueki 2005).

Lupus Erythematosus Profundus/Panniculitis (LEP)

LEP is clinically characterized by painful subcutaneous nodules and plaques, which may later adhere to the overlying skin. At a later stage of the disease, the lesions can develop into asymptomatic lipatrophy (Fig. 3). Skin lesions of LEP are typically located in the gluteal region and on the thighs as well as on the upper extremities. The face, scalp, and chest may also be affected; the salivary glands are rarely involved. Periorbital edema may be an initial presenting symptom prior to the development of typical skin changes (Kuhn et al. 2007). In the course of disease, the nodules can develop ulcerations and deeply indented scars, which can be a major cosmetic concern to patients. In older lesions, calcification may occur. LEP can be induced by

Skin in Systemic Lupus Erythematosus, Fig. 3 Chilblain lupus erythematosus (*CHLE*). Erythematous plaques with livid infiltration or scaling on the fingers III–V of the left hand

Skin in Systemic Lupus Erythematosus, Fig. 4 Lupus erythematosus panniculitis (*LEP*). Lipoatrophy on the right upper arm

irritative stimuli and is associated with DLE lesions in about 70 % of patients (Costner et al. 2003). The association with SLE is common and four or more of the ACR criteria are formally met in 35–50 % patients with LEP.

Chilblain Lupus Erythematosus (CHLE)

CHLE typically presents with tender, bluish plaques and nodules in cold-exposed areas (Fig. 4) (Kuhn et al. 2007). Edematous plaques and nodules may have central erosions or ulcerations, which affect the acral surfaces, especially the fingers, toes, heels, nose, and ears. In particular, CHLE appears during cold and damp times of the year or after a critical drop in temperature. Therefore, this subtype is clinically and histologically often difficult to distinguish from pernio ("chilblains"). The recent description of the genetic basis of a rare familial form of chilblain lupus has provided novel insights into the molecular pathogenesis and on understanding of the disease (Lee-Kirsch et al. 2006).

Skin in Systemic Lupus Erythematosus, Fig. 5 Lupus erythematosus tumidus (*LET*). Erythematous, edematous, urticaria-like plaques without epidermal involvement on the left facial area

Intermittent Cutaneous Lupus Erythematosus (ICLE)

Lupus Erythematosus Tumidus (LET)

On the basis of new clinical and scientific findings which identified specific clinical, histological, and photobiological criteria, LET was distinguished from CCLE in 2004 (Kuhn and Ruzicka 2004). Due to its benign, intermittent course, this subtype was included in the classification of CCLE as a separate entity, named ICLE. Clinically, LET is characterized by sharply bordered, "succulent," urticaria-like, erythematous papules and plaques with a smooth surface and without epidermal involvement (Kuhn et al. 2000) (Fig. 5). Skin lesions of this subtype are typically found on UV-exposed areas (face, upper back, chest, extensor surfaces of the upper arms) and may be annular, centrifugal, or crescent shaped and can, in rare cases, spread along the Blaschko's lines (Hinz et al. 2012). LET lesions may persist for months or resolve spontaneously without residual defects, such as scarring or dyspigmentation. Photosensitivity is a characteristic sign of this subtype, and skin lesions can be induced by UV light in more than 70 % of patients (Kuhn et al. 2001). Up to date, only isolated cases of LET associated with SLE have been reported. Therefore, LET has a good prognosis with a variable course of the disease in the majority of patients (Schmitt et al. 2010).

Bullous Lupus Erythematosus (BLE)

BLE is a rare subepidermal bullous disorder which is usually associated with acute and severe forms of SLE (Vassileva 2004). The skin lesions may present as solitary small vesicles or groups of vesicles or as large tense blisters on erythematous or normal skin. During the course of the disease, hyperpigmentation, milia, and scarring may occur. Clinically, BLE should be distinguished from bullous lesions arising from preexisting skin lesions in ACLE or at the margins of SCLE lesions. In addition, vesiculobullous skin changes have also been described as "TEN-like" ACLE and "TEN-like" SCLE, which are clinically similar to classic TEN. However, these diseases are usually not drug-induced but may rather be triggered, for example, by UV exposure. In a recent retrospective analysis from the international literature, it was highlighted that CLE with erythema multiforme (EM)- like or TEN-like lesions might be variants of already known CLE subpatterns (Torchia et al. 2012). The name "acute syndrome of apoptotic pan-epidermolysis (ASAP)" has also been suggested to define

a life-threatening acute cleavage of the epidermis resulting from hyperacute apoptotic injury of the epidermis (Ting et al. 2004).

Treatment of CLE

Prevention and Sunscreens

In all patients with SLE and CLE, it is necessary to provide instructions concerning methods of protection from sunlight and artificial sources of UV radiation and avoidance of potentially photosensitizing drugs (Kuhn et al. 2010d). As clinical evidence has proven a clear relationship between sun exposure and skin manifestations of SLE and CLE, experimental photoprovocation with different wavelengths has confirmed that cutaneous lesions can be induced by UV exposure (Kuhn et al. 2001). Therefore, patients should be advised that sunbathing and visiting tanning salons can induce the disease and exacerbate preexisting skin lesions. In SLE patients, even induction of systemic organ involvement, such as lupus nephritis, has been reported as a result of sun exposure (Kuhn et al. 2010d). It is recommended that UV irradiation on midday during summer should be avoided, as should traveling to sunny regions, and outdoor jobs with intensive sun exposure (e.g., roofer or gardener) should not be recommended to CLE patients. In addition, it needs to be considered that window glass is UVA permeable; therefore, sun exposure can induce skin lesions during a long car drive, depending on the tinge/coating of the glass and the duration of irradiation (Hampton et al. 2004). Consistent UV protection may also involve photoresistant clothing and thorough application of lightshielding substances with highly potent chemical (organic) and/or physical (inorganic) UVA- and UVB-protective filters (Hexsel et al. 2008). These substances should be used in sufficient amounts (approximately 2 mg/cm^2) and should contain a high sun protection factor (SPF 50). To avoid induction and exacerbation of cutaneous manifestations, sunscreens should be applied at least 20–30 min before sun exposure. In a recent randomized, double-blind, vehicle-controlled study, it was demonstrated that a broad-spectrum liposomal sunscreen with a very high sun protection factor can prevent damage induced by UV irradiation in photosensitive patients with CLE under standardized conditions (Kuhn et al. 2011a). Moreover, consistent sunscreen protection in patients with SLE is associated with significant better clinical outcomes, such as less frequent renal involvement and a decreased need for immunosuppressive treatment (Vila et al. 1999).

Topical Treatment

Topical Corticosteroids

Topical corticosteroids are the first-line treatment for skin manifestations in CLE and SLE. One randomized, controlled, 12-week crossover study exists according to the Cochrane Database of Systematic Reviews, which compares 0.05 % fluocinonide (a potent corticosteroid cream) with 1 % hydrocortisone (a low-potency corticosteroid cream) in 78 patients with DLE (Roenigk et al. 1980; Jessop et al. 2009). This trial demonstrated that high-potency corticosteroid cream is more effective than low-potency corticosteroid cream; the choice of the corticosteroid class depends on the location and the activity of the skin lesion (Kuhn et al. 2010c). Corticosteroid solution, lotion, or foam can be used in hairy areas, such as the scalp. Occlusive techniques (e.g., plastic food wrap, adhesive gas-permeable surgical dressings) and salicylic acid increase penetration and efficacy of topical corticosteroids. In skin lesions of localized DLE, intralesional injection of corticosteroids (triamcinolone acetonide 5–10 mg/ml) can be applied with high efficacy; however, there is a risk of subcutaneous atrophy (Kuhn et al. 2011c). Due to the well-known side effects, such as atrophy, telangiectasia, and steroid-induced rosacea-like dermatitis, treatment with topical corticosteroids should be time limited and intermittent.

Calcineurin Inhibitors

Calcineurin inhibitors, such as tacrolimus ointment and pimecrolimus cream, have shown efficacy in treating skin lesions of SLE and CLE

(Kuhn et al. 2010c). In a randomized, double-blind, bilateral comparison study, 0.1 % tacrolimus ointment showed a similar efficacy as 0.05 % clobetasol propionate in 18 patients with CLE lesions on the face (Tzung et al. 2007). Once weekly, microdermabrasion was added to potentiate the delivery of tacrolimus. In contrast to clobetasol propionate, tacrolimus ointment showed no side effects, such as telangiectasia. A further retrospective study compared the efficacy of a specially formulated preparation of tacrolimus 0.3 % in clobetasol propionate 0.05 % ointment in 13 therapy-resistant CLE patients with the application of only 0.1 % tacrolimus ointment in five patients (Madan et al. 2010). The combined preparation was more effective than the monotherapy with 0.1 % tacrolimus ointment. In a recent multicenter, randomized, double-blind, vehicle-controlled trial, 0.1 % tacrolimus ointment was applied in 30 patients with different CLE subtypes and resulted in a significantly higher response rate than the vehicle (Kuhn et al. 2011b). Patients with ACLE, SCLE, and LET showed significant improvement of edematous lesions on all time points comparing 0.1 % tacrolimus ointment with the vehicle, whereas DLE showed the lowest improvement as described in previous case reports.

In an open-label and uncontrolled study, 1 % pimecrolimus cream was applied in 11 patients with different subtypes of CLE twice daily for 3 weeks (overnight occlusion with hydrocolloid dressings), and improvement was observed in all patients (Kreuter et al. 2004). Similar results were seen in 10 patients with DLE treated with 1 % pimecrolimus cream twice daily for 8 weeks (Tlacuilo-Parra et al. 2005). In a recent randomized double-blind pilot study, significant improvement was obtained by 1 % pimecrolimus cream and topical 0.1 % betamethasone 17-valerate cream in 10 patients with moderate to severe facial DLE groups (Barikbin et al. 2009). A decrease of 86 % and 73 % in clinical disease severity score was seen with 1 % pimecrolimus and 0.1 % betamethasone cream, respectively. To date, tacrolimus ointment and pimecrolimus cream are only approved for the use in atopic dermatitis in children and adults. Despite their off-label use, calcineurin inhibitors are recommended for topical application in SLE and CLE, particularly in atrophy-prone areas such as the face.

R-Salbutamol

In 37 patients with DLE, a multicenter, double-blind, randomized, placebo-controlled phase II trial was performed using R-salbutamol for 8 weeks twice daily (Jemec et al. 2009). Scaling/hypertrophy, pain, itching, and allover patient assessment were significantly more efficient in the R-salbutamol-treated group compared with the placebo-treated group. However, phase III trials still need to be performed to approve the efficacy of R-salbutamol in SLE and CLE.

Other Topical Therapies

Topical retinoids, such as tazarotene and tretinoin, have only been applied in single case reports of therapy-refractory hypertrophic CLE or in disseminated DLE (Seiger et al. 1991; Edwards and Burke 1999). In addition, the topical agent 5 % imiquimod cream was applied in one patient with DLE once daily in two cycles over 3 weeks, and imiquimod showed a marked improvement in treating erythema and follicular scaling of the scalp in a patient with DLE (Gerdsen et al. 2002). However, there may be a theoretical risk in some patients of exacerbating cutaneous and systemic diseases, as imiquimod is a toll-like receptor agonist. Physical therapies, such as laser or cryotherapy and dermabrasion, are reported to be successful in single case reports but should only be used in persistent DLE lesions, after risk-benefit analysis and evaluation of other therapeutic options due to the possible induction of Koebner phenomenon (Kuhn et al. 2011c).

Systemic Treatment

Antimalarials

Antimalarials, such as hydroxychloroquine (HCQ), chloroquine (CQ), and mepacrine (synonym: quinacrine), are the first-line therapy for all skin manifestations in SLE and CLE (Kuhn et al. 2010c). However, only one randomized,

placebo-controlled study comparing acitretin with hydroxychloroquine was performed in 1992 (Ruzicka et al. 1992). About 50 % of patients improved when treated with HCQ, and 46 % showed improvement after being treated with acitretin, but more side effects were seen in the acitretin group. HCQ has been suggested to be more compatible than CQ but less effective. This might be due to the fact that especially in earlier case series, CQ was used in higher doses than HCQ; comparative studies are missing. The maximal oral daily doses of HCQ are 6–6.5 mg/kg ideal body weight and 3.5–4 mg/kg ideal body weight for CQ; higher dosages should only be given for a short period of time (Ochsendorf 2010). Oral doses of 100 mg/day mepacrine (one tablet) should not be exceeded. After achieving a good response (within 3–6 months), the dose of mepacrine should be tapered until maintenance doses of one to three tablets a week. In case of adverse reactions, the daily dose may be reduced to 25–50 mg.

Irreversible retinal changes are the most feared side effect of HCQ and CQ treatment. The incidence of retinopathy is related to the maximal daily dosage, which should comply with the ideal body weight of adults and children to avoid this effect (Kuhn et al. 2011c). Due to the toxicity and side effects, it is important to evaluate the visual findings before or during treatment initiation. Acute overdosing happens accidentally, mainly in children, or during an attempted suicide. Therefore, patients have to be informed about the importance of a safe storage of these drugs in order to protect their children. Several studies confirm that smoking interferes with the efficacy of antimalarials (Kreuter et al. 2009), and some mechanisms by which smoking may alter the antimalarial metabolism have been proposed. For example, it has been suggested that nicotine inhibits CQ uptake in cultured cells and blocks the accumulation of antimalarials within lysosomes (Polet 1985). Recent studies investigating the relationship between smoking and the efficacy of antimalarials in CLE patients, however, indicate that cigarette smoking does not have any significant influence on the response to HCQ and CQ (Wahie et al. 2011). Therefore, prospective studies are required to determine whether antimalarials are more likely to benefit current nonsmokers (Dutz and Werth 2011).

Systemic Corticosteroids

Systemic corticosteroids may be indicated for cutaneous manifestations in SLE and CLE despite the well-known side effects such as hyperglycemia and osteoporosis. The application should, however, be limited to patients with highly acute and severe skin lesions or may be given due to the delayed onset of action of antimalarials (Kuhn et al. 2011c). The usual dose of systemic corticosteroids is 0.5–1 mg/kg bodyweight/day over 2–4 weeks followed by tapering of the dose or as a 3-day intravenous (IV) pulse therapy as described in SCLE (Goldberg and Lidsky 1984). In this study, it has been demonstrated that refractory disease improved within 1–2 weeks after IV pulse therapy with 1 g of methylprednisolone on three successive days. Although DLE responds to high doses (>1 mg/kg bodyweight), systemic corticosteroids are usually not indicated in this subtype due to rapid rebound above the Cushing threshold dose.

Methotrexate (MTX)

MTX has been successfully used for the treatment of therapy-refractory CLE (Kuhn et al. 2011d). In SCLE and DLE, it is recommended to apply MTX in a dose of 7.5–25 mg via subcutaneous (sc) injection; to prevent gastrointestinal side effects, folic acid supplementation may additionally be given once 24 h after MTX injection excluding the day of MTX application and the day thereafter (Kuhn et al. 2010c). In a retrospective analysis from 1998, 12 patients with different subtypes of CLE were treated with MTX in a low dose of weekly 10–25 mg (orally or IV) (Boehm et al. 1998). The beneficial effect of MTX for skin lesions was confirmed in a study including 43 patients with different subtypes of recalcitrant CLE (Wenzel et al. 2005). In 98 % of patients, the skin lesions improved with low-dose MTX, administered either orally or IV; a better improvement was observed in patients with SCLE and localized DLE than in disseminated DLE.

In a follow-up study, MTX IV administration was changed to sc application in 15 of the 43 CLE patients with good tolerance and acceptance due to easier and self-administered injection; the efficacy was comparable (Huber et al. 2006).

Retinoids

Retinoids, such as acitretin and isotretinoin, are listed as second-line substances for CLE in the American Academy of Dermatology guidelines due to their relatively innocuous side-effect profile (Drake et al. 1996). These agents have been effectively applied in cases of DLE and SCLE (Bacman et al. 2004). The recommended dose for acitretin and isotretinoin is 0.2–1.0 mg/kg body weight per day. Both retinoids are teratogenic; therefore, effective contraception is essential during and after treatment (isotretinoin, 1 month; acitretin, 2 years). Isotretinoin is preferable in female patients of childbearing potential due to the shorter half-life. Recently, a case report on three patients with different subtypes of CLE who received alitretinoin showed a high efficacy in the treatment of CLE skin lesions (Kuhn et al. 2012). Thus, this agent may be an effective alternative in the treatment of CLE. Most common side effects of retinoids include dryness of skin and mucous membranes (xerophthalmia, xerostomia), less common are gastrointestinal disturbances and skeletal toxicity, as well as muscle pain and arthralgia (Bacman et al. 2004). Treatment with retinoids may cause hyperlipidemia and alter liver function tests, but severe hepatotoxic reactions are only seen in single cases. During treatment with acitretin, reversible hair loss has been reported in up to 50 % of patients.

Dapsone

Dapsone has been demonstrated to be effective in SCLE, LEP, urticarial vasculitis, oral ulcerations, and bullous eruptions complicating SLE (Bacman et al. 2004; Ludgate and Greig 2008). Therapeutic dosages of dapsone range from 25 to 150 (maximum 200) mg/day; it is recommended to start with a low dose and to increase the dose gradually. The lowest effective dose should be applied to minimize possible side effects, such as hemolysis and methemoglobinemia. Prior to treatment, exclusion of glucose-6-phosphate dehydrogenase deficiency is necessary as regular monitoring of blood cells and liver enzymes during treatment with dapsone. Several studies report the efficacy of dapsone in patients with DLE, and single case reports of successful treatment of SCLE with dapsone have also been described in the literature (Kuhn et al. 2011d). In LEP, successful treatment with dapsone was reported in 12 patients published by a Japanese group (Ujiie et al. 2006).

Mycophenolate Mofetil (MMF) and Mycophenolate Sodium (EC-MPS)

Another immunosuppressive drug is MMF, which has been proved to be effective in single case reports of SCLE, DLE, and CHLE. MMF should be administered in doses between 1 and 3 g per day, and the highest efficacy is achieved with 2–3 g per day, but it can take 1–2 months for clinical effects to become visible. In general, MMF is well tolerated by the most patients (Kuhn et al. 2011d). In 2002, four therapy-resistant patients with various skin manifestations of CLE and smoldering systemic involvement resulted in a complete remission within 3 months after starting MMF (Hanjani and Nousari 2002). However, this result could not be confirmed by Pisoni et al. (2005) in five of seven SLE patients with various LE-specific and nonspecific skin manifestations. In a recent nonrandomized, open-pilot study, the enteric-coated form of MMF (EC-MPS) was applied in 10 patients with active SCLE resistant to at least one standard therapy (Kreuter et al. 2007). The treatment resulted in significant improvement of the cutaneous manifestations, while no serious side effects were reported. However, controlled trials with a larger number of patients are required to further assess efficacy and safety of MMF or EC-MPS in SLE and CLE.

Thalidomide and Lenalidomide

In a high number of patients with DLE, thalidomide has been proven to be effective due to the agent's immunomodulatory and anti-inflammatory features. These studies also

demonstrated the high relapse rate and, most importantly, the high risk of potential irreversible polyneuropathy (Kuhn et al. 2011d). Therefore, thalidomide should only be used to treat severe refractory DLE; however, there is a high incidence of neurotoxicity even at low doses (Cuadrado et al. 2005). Thalidomide should only be applied in appropriately selected patients after intensive consideration of the risk-benefit ratio. Moreover, due to its teratogenic effect, this agent should only be prescribed to women of childbearing potential with severe and refractory DLE and if highly effective contraceptive measures are applied (Kuhn et al. 2010c).

Lenalidomide is a structural derivative of thalidomide introduced in 2004. In one recent open-label study, 5 mg of oral lenalidomide daily during the first 6 weeks of treatment led to clinical improvement in 4 of 5 patients with CLE (Braunstein et al. 2011). However, one of the patients subsequently developed symptoms of SLE. The same strict safety measures used for thalidomide have to be applied for lenalidomide, but the risk of neurotoxicity seems to be lower for lenalidomide.

Belimumab

Belimumab belongs to a new class of immunomodulators with a novel mechanism of action, which was approved 2011 for SLE based on two phase III studies (Furie et al. 2011; Navarra et al. 2011). In doses of 1 and 10 mg/kg, belimumab was applied in 1,684 autoantibody-positive patients. Disease activity significantly improved in mucocutaneous organ manifestations as analyzed by the Safety of Estrogens in Lupus National Assessment-Systemic Lupus Erythematosus Disease Activity Index (SELENA-SLEDAI) and the British Isles Lupus Assessment Group score (BILAG) organ domain scores (Manzi et al. 2012). However, a validated skin activity and damage score such as the RCLASI was not applied to assess improvement of skin manifestations in SLE. Therefore, future prospective studies using a validated skin score, such as the RCLASI, are necessary to evaluate the effect of belimumab on mucocutaneous lesions.

Conclusion

SLE patients show a wide variety of skin manifestations and should be recommended to follow instructions regarding methods of protection from sunlight and artificial sources of UV radiation including application of broad-spectrum sunscreens with physical and chemical filters as well as wearing hats and tightly woven clothing. Topical corticosteroids have been proven to be a highly effective treatment for skin lesions in all disease subtypes; a short and intermittent treatment is preferable due to the well-known side effects. Topical calcineurin inhibitors are particularly useful for facial lesions, but the efficacy of these agents still needs to be evaluated in randomized controlled phase III trials. The indication for systemic therapy in CLE is given when skin lesions are widespread, disfiguring, scarring, or refractory to topical agents. Although antimalarials have been available for more than 50 years, these agents still represent the first-line systemic treatment in all CLE subtypes. Second-line treatment includes retinoids, dapsone, MTX, and MMF (EC-MPS). Belimumab has recently demonstrated significant improvement in mucocutaneous manifestations, but further prospective studies using a validated skin score are necessary to assess its efficacy in skin lesions of SLE.

Acknowledgments We thank P. Wissel, J. Bückmann, and Professor T. A. Luger, Department of Dermatology, University Muenster, Germany, for providing the clinical pictures.

Small Molecules Targeted For the Treatment of Rheumatoid Arthritis

Laura Geraldino-Pardilla and Jon T. Giles
Division of Rheumatology, Department of Medicine, Columbia University, College of Physicians and Surgeons, New York, NY, USA

Synonyms

Chemokine receptor inhibitors; JAK-3 inhibitor; Kinase inhibitors; Syk inhibitor

Introduction

Despite the remarkable therapeutic advancements in rheumatoid arthritis (RA) of the past decades, still only a subset of patients responds to available treatments and few go into sustained remission (Breedveld et al. 2006). Hence, the search for drugs with novel mechanisms of action and/or more convenient forms of administration vigorously endures.

Definition

The term *small molecule in RA* designates cellular elements that are involved in the signal transduction, activation, and/or overall function of the immune cells implicated in the pathogenesis of RA. In the pursuit for innovative therapeutic agents for RA, a rising interest has focused in the development of oral inhibitors of these small molecules.

Protein Kinases

Kinases are enzymes that modify proteins by phosphorylation. Through this transfer of phosphate groups, they regulate the majority of intracellular biochemical pathways and signal transduction.

Janus Kinase 3 Inhibition

The Janus kinase (JAK) family of tyrosine kinases includes JAK1, JAK2, JAK3, and TYK2. These proteins are involved in the growth, survival, development, and differentiation of a variety of cells, being critically important for immune and hematopoietic cells in particular. JAK1 and JAK2 are ubiquitously expressed; however, JAK3 is predominant in T-cells, NK cells, and monocytes, and uniquely binds the γ-chain that serves as the common receptor for the cytokine subfamily of IL-2, IL-4, IL-7, IL-9, IL-15, and IL-21 (O'Shea et al. 2004). JAK3 inhibition therefore blocks early cytokine signaling and the resultant STAT activation, abrogating cytokine-dependent gene regulation and subsequent lymphocyte activation (O'Shea et al. 2004). While most immunosuppressive drugs target widely expressed molecules resulting in systemic adverse reactions, the selectivity of JAK3 inhibitors makes them a very attractive therapeutic target.

CP-690,550 (tofacitinib) is a potent oral JAK 3 inhibitor currently completing phase III trials for the treatment of RA and showing promise toward FDA approval in the near future. In a phase IIA trial, 264 patients with active RA with an inadequate response or toxicity to methotrexate (MTX) or tumor necrosis factor (TNF)-inhibitor therapy were randomized to receive placebo vs. CP-690,550 at 5, 15, or 30 mg twice daily for 6 weeks with an additional 6 weeks of follow-up. At week 6, the ACR20 response rates were 70.5 %, 81.2 %, and 76.8 % in the 5, 15, and 30 mg groups, respectively, compared with 29.2 %

in the placebo group ($P < 0.001$). Improvements in disease activity in CP-690,550-treated patients compared with placebo were seen in all treatment groups as early as week 1. ACR50 and ACR70 response rates significantly improved in all treatment groups by week 4 (Kremer et al. 2009). These response rates have been reproduced in phase 2b dose-ranging studies in RA patients on background MTX with outcome assessments at 12 and 24 weeks (Tanaka et al. 2009; Kremer et al. 2012), as well as in a 6 month phase 2b dose-ranging monotherapy trial (Fleischmann et al. 2012). Data, presented in abstract form, from the phase 3 trials are consistent with the phase 2 responses, but the complete final results have yet to be published. The overall frequency of adverse events (AEs) was higher in tofacitinib-treated patients in all the clinical trials compared to placebo (Kremer et al. 2009, 2012; Tanaka et al. 2009; Fleischmann et al. 2012). These included infections (mainly upper respiratory infections, urinary tract infections, and influenza), gastrointestinal disorders (abdominal pain, diarrhea, and nausea), headache, and cytopenias (leukopenia and anemia). Infections were the main serious AEs (SAEs) seen in the CP-690,550-treated arms (Kremer et al. 2009, 2012; Tanaka et al. 2009; Fleischmann et al. 2012).

Spleen Tyrosine Kinase Inhibition

Spleen Tyrosine Kinase (syk) is an intracellular tyrosine kinase isolated in 1991 from a porcine cDNA library (Taniguchi et al. 1991). It is predominantly expressed in hematopoietic cells where it binds phosphorylated tyrosine-based activation motifs (ITAMS) and mediates B-cell receptor (BCR) signaling in B cells; FcγR signaling in mast cells, macrophages, neutrophils, and basophils; and natural killer receptor's activation (Pamuk and Tsokos 2010). It promotes B- and T-cell development and activation, mast cell degranulation, osteoclast function, neutrophil and macrophage phagocytosis, and platelet activation (Pamuk and Tsokos 2010). In addition, syk activity is upregulated in the RA synovium, where it mediates IL-6 and MMP-3 production and TNFα-induced IL-32, highly expressed in rheumatoid synovial fibroblasts (Lindstrom and Robinson 2010; Mun et al. 2009).

Syk inhibition with R406 and its prodrug R788 is being studied in the treatment of RA. In the collagen-induced arthritis animal model, R788/R406 showed significant improvement in arthritis and suppression of bone erosions, pannus formation, and synovitis (Pine et al. 2007). Following the promising preclinical data, 50, 100, and 150 mg twice daily oral doses of R788 (fostamatinib) vs. placebo were tested over 12 weeks in a randomized clinical trial among 189 patients with active RA refractory to MTX therapy (Weinblatt et al. 2008). An ACR20 response at week 12 was achieved in 65 % and 72 % of the 100 and 150 mg groups, respectively, vs. 38 % in the placebo group ($P < 0.001$). ACR50 and ACR70 responses, and DAS28 remission, were significantly different in the 100 and 150 mg groups when compared to placebo, with clinical response seen as early as week 1. Subsequently, 457 patients with active RA despite MTX were randomized to oral R788 100 mg twice daily vs. 150 mg daily vs. placebo for 6 months (Weinblatt et al. 2010). An ACR 20 response was seen in 67 % and 57 % of patients in the 100 and 150 mg groups, respectively, vs. 35 % in the placebo group ($P < 0.001$). ACR50 and ACR70 responses as well as the DAS remission rate were statistically significantly higher in the 100 mg group, and the ACR50 and DAS remission responses were statistically significantly higher in the 150 mg group. Finally, the ACR20 response at 3 months following syk inhibition was tested in 219 RA patients who had failed biologic agents and they were randomized to treatment with oral R788 100 mg twice daily vs. placebo (Genovese et al. 2011a). With an ACR20 response in the R788 group of 38 % vs. 37 % in the placebo arm, this trial showed no difference in the ACR20, ACR50, or ACR70 responses between the R788-treated patients when compared to placebo. The reason for a lack of demonstrable efficacy in patients with inadequate response to prior biologics is unclear.

The most common adverse events seen in the syk-inhibitor arms were a dose-dependent increase in gastrointestinal side effects and

neutropenia. SAEs included infections, dehydration secondary to diarrhea, bladder cancer, and gastritis (Weinblatt et al. 2008, 2010; Genovese et al. 2011a). Moreover, an open-label extension documented three deaths due to septicemia, sudden death, and cerebral hemorrhage; one case of B-cell lymphoma, one cervical carcinoma, and one myocardial infarction were also reported (Weinblatt et al. 2010).

P38 Mitogen-Activated Protein Kinase (MAPK) Inhibition

Mitogen-activated protein kinases (MAPK) are intracellular enzymes that regulate the production of cytokines and metalloproteinases involved in the inflammatory response and tissue injury in RA. Three major groups of MAPKs have been described: MAPKs-extracellular signal-regulated kinase (ERK), c-JUN N-terminal kinase (JNK), and p38 MAPK (Cobb and Goldsmith 1995). Of these, the p38α MAPK isoform has been of particular interest in RA targeted therapy, given its implication in joint destruction in RA (Mbalaviele et al. 2006).

Following promising preclinical results in RA animal models, several clinical trials have evaluated the efficacy of oral p38 MAPK inhibitors (SCIO-460, Pamapinod, VX-702, BMS-582949) (Genovese et al. 2011b; Cohen et al. 2009; Damjanov et al. 2009; Alten et al. 2010 Feb), but to date none have proven to be clinically efficacious. The reason for this is unclear, but further upstream blockade of this pathway has been suggested as likely to be more beneficial.

Other Tyrosine Kinase Inhibitors

Preclinical studies in mouse models of inflammatory arthritis have evaluated other tyrosine kinase inhibitors considered to be of promising potential for the treatment of RA. In this pursuit, imatinib and nilotinib, known selective inhibitors of a set of protein tyrosine kinases including: abelson kinase (Abl), breakpoint cluster region-abelson kinase (Bcr-Abl), stem cell factor receptor (KIT), platelet-derived growth factor receptor (PDGFR), discoidin domain receptor (DDR), and colony stimulating factor-1 receptor (CSF-1R), have been studied and shown to suppress as well as significantly inhibit the progression of arthritis in animal models (Akashi et al. 2011). Efficacy in humans with RA has not yet been tested, and the available evidence is limited to case reports at the time.

Another kinase of interest is Bruton's tyrosine kinase (BTK). It belongs to the Tec kinase family and is critical for B-cell proliferation, differentiation, and signaling. Defects in the BTK gene lead to X-linked agammaglobulinemia and, based on the success of anti-B-cell therapy in RA, BTK inhibitors are being studied in RA (Kim et al. 2011). Both genetic mutation and pharmacological inhibition of BTK have shown to prevent the development of RA-like inflammatory arthritis in animal models, but, to date, no clinical trials have been reported (Xu et al. 2012).

CCR1, CCR2, and CCR5

Chemokines are a family of small proteins that regulate leukocyte recruitment and activation; consequently, they play a major role in the accumulation of these cells at sites of inflammation, such as the RA synovium. The chemokine family is divided into 4 subgroups: C, CC, CXC, and CXXXC (Galligan et al. 2004). Several of these cytokines have been described at high concentrations in RA synovial tissue and fluid where they can interact with receptors on monocytes (Lebre et al. 2011). Of these receptors, CCR1 (main ligands: CCL3/MIP-1α, CCL5/RANTES, CCL7/MCP-3, CCL8/MCP-2), CCR2 (main ligands: CCL2/MCP-1), and CCR5 (main ligands: CCL3/MIP-1α, CCL5/RANTES, CCL7/MCP-3) have been the main focus of chemokine-targeted therapy in RA, aiming to reduce cell migration and resulting synovial inflammation.

Despite promising results in animal models of RA-like inflammatory arthritis, human trials have been unsuccessful for CCR2 and CCR5 blockade (Vergunst et al. 2008; Gerlag et al. 2010; van Kuijk et al. 2010). For CCR1, after a promising trend to improvement in an early proof-of-concept clinical trial (Haringman et al. 2003), several antagonists were developed

(BX471, CP-481,715, MLN3897) (Meyer and St. Clair 2008) and tested in clinical trials; however, these failed to demonstrate a difference in efficacy in the oral CCR1 antagonist plus MTX arm when compared to the methotrexate plus placebo group (Vergunst et al. 2009; Gladue et al. 2010).

Conclusion

As the knowledge of the pathogenesis of RA increases, more therapeutic modalities targeting specific pathways will be pursued. However, balancing the benefits with the potential toxicities of the drugs in question remains the main challenge to overcome. Of all the small molecule inhibitors, JAK 3 inhibition by CP-690,550 appears the most promising at this time and FDA approval seems likely; however, longer-term follow-up is needed to more precisely delineate its safety profile and sustainability of response. Syk inhibition is a novel potential therapy for RA that has promise in patients who have failed MTX, but has not thus far in those who have failed biologic therapies. Moreover, considerable toxicity noted in the phase 2 trials needs to be further balanced with the potential benefits in subsequent long-term studies. MAPK and CCR inhibitors have not proved promising for the treatment of RA, while other kinases such as BTK, imatinib, and nilotinib remain in preclinical phases of investigation for the treatment of RA.

Even with robust efficacy studies and FDA approval of one or more oral small molecule agents, it will remain to be determined where in the RA treatment algorithm, these drugs will best be utilized. Undoubtedly, at first, use will be restricted to 3rd and 4th line status, after failure of agents with a more established efficacy and safety profile. However, upon proof of safety, efficacy, and cost-effectiveness superiority from head-to-head studies in the appropriate clinical context, it is possible that these agents could supplant more established agents and alter the timing and order of the current RA treatment paradigm.

Definition

Minimal change disease and focal segmental glomerulosclerosis represent two causes of primary glomerular disease. Minimal change disease is typified by heavy proteinuria, normal renal function, and steroid responsiveness. Focal segmental glomerulosclerosis is also characterized by proteinuria but contrasts with minimal change disease in its tendency to progress to kidney failure and exhibit resistance to steroid therapy. This section will compare and contrast the two diseases.

Introduction

Minimal change disease (MCD) and idiopathic focal and segmental glomerulosclerosis (FSGS) represent two common glomerulopathies manifesting clinically with nephrotic range proteinuria. The podocyte may represent a key cell in the development of each disease. MCD and FSGS may result from genetic anomalies, circulating plasma factors altering glomerular permeability, and/or immune dysfunction with production of a permeability factor that affects podocyte function. Most patients with MCD are steroid responsive, and the majority of patients with idiopathic FSGS are steroid resistant. Treatment focuses on remission of proteinuria and preservation of renal function, utilizing both hemodynamic and immunosuppressive therapies. Immunosuppressive treatment regimens for both diseases generally include the use of corticosteroids. Relapsing or steroid-resistant patients may require the use of a second, often cytotoxic agent. Future studies may help define the pathophysiologic relationship between MCD and idiopathic FSGS and give clues to improved approaches to therapy.

The basic functional unit of the kidney is the nephron, composed of the glomerulus (the primary filtering apparatus) and an associated tubule (concentrates and refines the urine). The glomerulus is a network of capillary loops suspended in Bowman's space and covered with epithelial cells or podocytes. The podocyte is a specialized epithelial cell encasing the capillary loop and plays a central role in the protein filtration barrier function of the nephron.

The normal glomerular filtration barrier consists of fenestrated endothelial cells, the glomerular basement membrane (GBM), and the podocyte – which normally exhibits interdigitating foot processes connected by slit diaphragms. The slit diaphragms are major barriers to protein filtration, which is based upon both molecular size and electric charge.

Minimal change disease (MCD) and idiopathic focal and segmental glomerulosclerosis (FSGS) represent two common glomerulopathies associated with podocyte dysfunction. Both diseases are examples of a podocytopathy and manifest clinically with nephrotic range proteinuria (>3 g/day). The podocyte may represent the key cell in the development of nephrotic syndrome, with the extent of disease determined by both the extent of podocyte damage and the number of podocytes per glomerulus. In this regard, damaged podocytes with normal numbers are associated with MCD, whereas podocytopenia is linked to the development of FSGS. A reduction in podocyte number may result in a loss of structural integrity of the glomerulus favoring "outward

bulging" (Jefferson and Shankland 2006) of the GBM, facilitating abutment on and fusion to Bowman's capsule, and the potential to develop synechiae, an early lesion of FSGS (Jefferson and Shankland 2006).

Podocyte damage in MCD is dominated by foot process effacement with an otherwise normal histologic appearance of the glomerulus (Mason and Hoyer 2010). Less commonly mild mesangial hypercellularity or positive immunofluorescence staining for IgM may be present. It is unclear if these findings are a variation of MCD or represent early changes of FSGS (Mason and Hoyer 2010).

MCD and idiopathic FSGS may share some clinical and pathologic features, but the diseases also differ in many aspects. The purpose of this review is to examine areas of clinical and physiologic overlap and independence between the two conditions and illustrate the features encountered in each disease.

Clinical Epidemiology

MCD is the most common cause of the nephrotic syndrome in children, accounting for 90 % cases in those <10 years of age, and about 50 % of cases in older children. In adults, MCD accounts for 10–15 % of primary nephrotic syndrome (Mason and Hoyer 2010). There is some geographic variation, with the incidence in the United States at 27 per million as compared to 1 per million in the United Kingdom (Mason and Hoyer 2010). MCD is more common in Native Americans and South Asians, and rare in African Americans (Mason and Hoyer 2010). The disease may be idiopathic or associated with atopy, lymphoid disorders, or drug therapies (Mason and Hoyer 2010). Clinically, MCD may present with the sudden onset of edema, selective proteinuria, and is very responsive to corticosteroid therapy (Chugh et al. 2012).

FSGS is less common than MCD in the pediatric population, causing about 20–40 % of cases of idiopathic nephrotic syndrome (Eddy and Symons 2003). In contrast, FSGS is the second most common cause of primary kidney disease in adults and accounts for ~40 % of cases of nephrotic syndrome. FSGS has an estimated prevalence of 7 per million (Gbadegesin et al. 2011; Kitiyakara et al. 2004). FSGS is more common in males, and the overall incidence is much higher in African Americans than Caucasians (Kitiyakara et al. 2004). Clinically, FSGS is the most common primary glomerular disorder that leads to ESRD. FSGS may be idiopathic or secondary to other diseases, including HIV nephropathy (HIVAN), obesity, heroin injection, chronic glomerulonephritis, reflux nephropathy, or other forms of renal ablation (Eddy and Symons 2003; Gbadegesin et al. 2011). Familial forms of FSGS are also recognized (Gbadegesin et al. 2011). Idiopathic forms of FSGS and MCD may be the result of circulating permeability factors that may damage the glomerular filtration barrier (McCarthy et al. 2010). Clinically, idiopathic FSGS presents with nonselective proteinuria and often manifests as steroid-resistant nephrotic syndrome with rapid progression to end-stage renal disease (Gbadegesin et al. 2011).

Histopathology

Minimal change disease. On renal biopsy, MCD is characterized by normal-appearing glomeruli by light microscopy. The GBM and glomerular cellularity are normal. In biopsies exhibiting prominent mesangial proliferation, a diagnosis of diffuse mesangial hypercellularity (DMH) may be considered. This is a variant seen more commonly in young children and demonstrating higher rates of steroid resistance. However, remission rates at 1 year are similar to more typical forms of MCD. In adults with hypertension and vascular disease, MCD may coexist with acute tubular injury and thus present with nephrotic syndrome and an impairment of glomerular filtration (manifesting as acute kidney injury with an elevation in serum creatinine level). Immunofluorescence staining is usually negative. Positive staining for IgM or C1q suggests, respectively, the presence of IgM or C1q nephropathy, both often considered variants of MCD. By electron microscopy, the ultrastructural changes are dominated by podocyte foot process

effacement of >75 % of the total examined surface area. Immune deposits are absent.

FSGS (adapted from (Appel and D'Agati 2010; D'Agati et al. 2004)). Histologically, primary and secondary forms of FSGS are characterized by heterogenous morphologies resulting in the need for a subclassification system (D'Agati et al. 2004). In this approach, five histologic variants can be identified: (1) FSGS, not otherwise specified (NOS); (2) FSGS, perihilar variant; (3) FSGS, cellular variant; (4) FSGS, collapsing variant; and (5) FSGS, tip variant.

FSGS NOS is the generic form of FSGS and excludes the other classifications. Pathologically, it is characterized by accumulation of extracellular matrix forming segmental solidifications in any portion of the tuft with glomerular capillary occlusion. Hyalinosis, foam cells, GBM wrinkling, synechiae, and swollen epithelial cells may be present. Unaffected lobules are normal except for podocyte swelling. By immunofluorescence, staining IgM, C3, and occasionally, C1q may be demonstrated. Electron microscopy lacks immune deposits but shows foot process effacement.

The perihilar variant demonstrates perihilar hyalinosis and is common in secondary forms of FSGS associated with adaptive responses. FSGS cellular variant is associated with endocapillary hypercellularity with segmental capillary occlusion from endocapillary hypercellularity. The collapsing variant of FSGS demonstrates at least one glomerulus with global collapse, hypertrophy and hyperplasia of visceral epithelial cells, and extensive tubulointerstitial disease. The collapsing variant is typically associated with HIVAN. The tip variant of FSGS is associated with at least one segmental lesion involving the outer 25 % of the tuft adjacent to the origin of the proximal tubule. This lesion may be diagnosed only in the absence of perihilar or collapsing sclerosis.

Pathogenesis of the Nephrotic Syndrome in MCD and FSGS

Nephrotic syndrome in MCD and FSGS may result from genetic anomalies, circulating plasma factors altering permeability, and/or lymphoid dysfunction with production of a permeability factor that affects podocyte function.

Genetic Diseases. Genetic mutations of the slit diaphragm proteins nephrin or podocin may result in two different forms of FSGS. In this regard, congenital nephrotic syndrome of the Finnish type is the result of mutations in nephrin, whereas defects in podocin, which links the slit diaphragm to the cell cytoskeleton, are associated with familial FSGS (Jefferson and Shankland 2006). Other inherited disorders of the slit diaphragm protein complex include CD-2-associated protein (CD2AP), α-actinin-4, and the transient receptor potential cation channel type 6 (TRPC6) (Jefferson and Shankland 2006).

CD2AP interacts with the T lymphocyte adhesion protein CD2. In the slit diaphragm, CD2AP interfaces with podocin and nephrin to form a protein signaling complex with phosphoinositide 3-OH kinase (Gbadegesin et al. 2011). Clinically, mutations of CD2AP in humans leads to the development of FSGS (Gbadegesin et al. 2011). Alpha-actinin-4 is an actin protein expressed in the podocyte foot process. Mutations of α-actinin-4 are gain of function, appear to interfere with actin filament assembly and disassembly, and are associated with autosomal dominant FSGS (Gbadegesin et al. 2011). TRPC6 is a cation channel associated with mechanosensation and cell growth. Mutations of TRPC6 have been associated with familial FSGS in both children and adults (Gbadegesin et al. 2011).

Genome-wide association studies have suggested that *MYH9* and *APOL1* may be associated with FSGS, HIVAN, and non-diabetic end-stage renal disease in African Americans (Quaggin and George 2011). *APOL1* has emerged as the more likely candidate gene (Quaggin and George 2011) and encodes apolipoprotein L1. *APOL1* and its renal disease risk alleles appear to confer a trait protective against *T. brucei*, the cause of sleeping sickness in sub-Saharan Africa (Genovese et al. 2010). This association may explain the high carrier frequency of *APOL1* in African Americans with renal disease (Genovese et al. 2010). *APOL1* is expressed in podocytes and proximal tubular cells, and its expression was reduced in kidney

biopsies from patients with FSGS and HIVAN. The mechanisms whereby *APOL1* variants may predispose to FSGS remain to be determined.

Other genetic syndromes associated with FSGS include mutations to genes encoding phospholipase C ε (*PLCE1*), Wilms' tumor suppressor protein (*WT1*), LIM/Homeobox (*LXMZB1*), mitochondrial sequences ($tRNA^{Leu}$), coenzyme Q2 homolog prenyltransferase (*COQ2*), and integrin β4 (*ITGB4*). Many of these conditions are also associated with extensive extrarenal manifestations (Woroniecki and Kopp 2007). Several animal models as well as additional monomeric causes of FSGS have been reported (D'Agati 2012) but are beyond the scope of this review.

Circulating Permeability Factors. Circulating permeability factors have been described in association with idiopathic FSGS and include the soluble urokinase receptor suPAR (Wei et al. 2011) and cardiotrophin-like cytokine-1 (CLC-1) (McCarthy et al. 2010).

Circulating suPAR activates the β_3 integrin on the podocyte foot process which can initiate effacement and proteinuria (Wei et al. 2011). Elevated serum levels of suPAR were identified in two-thirds of idiopathic FSGS patients, but not in MCD or other glomerular diseases (Wei et al. 2011). Increases in suPAR before kidney transplantation were also associated with recurrent FSGS following transplant (Wei et al. 2011). The release of suPAR from activated leukocytes (Pliyev 2009) and from the synovial fluid of rheumatoid arthritis patients (Pliyev and Menshikov 2010) may suggest a role for suPAR in linking the immune system to the pathogenesis of FSGS.

CLC-1 is a small protein isolated from the serum or plasma of patients with recurrent FSGS following kidney transplantation (McCarthy et al. 2010). CLC-1 mimics the effect of plasma from FSGS patients in an in vitro assay of glomerular permeability, decreases glomerular nephrin expression, and is present in elevated levels in patients with recurrent FSGS (McCarthy et al. 2010).

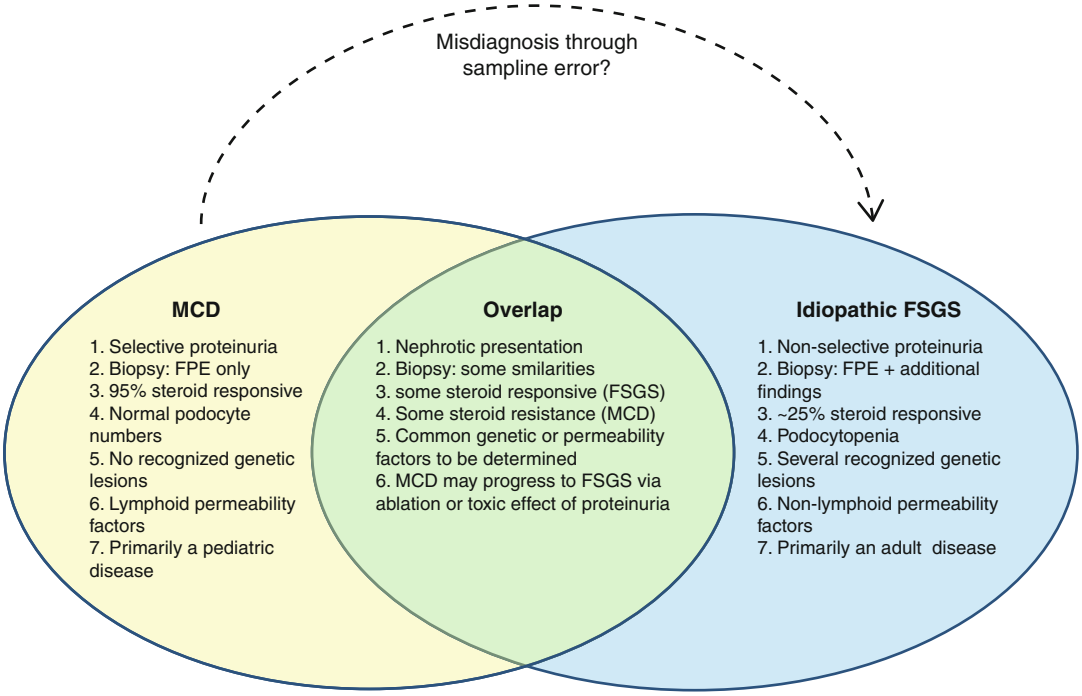
Immune Dysfunction and Circulating Permeability Factors. Nephrotic syndrome has been associated with several primary immunologic disorders, including lymphoma, leukemia, and thymoma (Eddy and Symons 2003; Ishimoto et al. 2011). Variable changes in IL-2, IL-4, and interferon have been reported from subjects with MCD, but findings have been inconsistent (Ishimoto et al. 2011). IL-8 and IL-13 have also been studied as putative mediators of proteinuria in MCD, but the results are inconclusive (Ishimoto et al. 2011).

In 2004, Reiser reported a role for podocyte CD80 as a potential mechanism for proteinuria (Reiser et al. 2004). CD80 is expressed on podocytes, as well as antigen-presenting cells, natural killer cells, and B cells. Expression of CD80 on podocytes results in shape change and proteinuria (Reiser et al. 2004). Urinary CD80 levels are increased in MCD with increased expression on podocytes but not in FSGS (Ishimoto et al. 2011).

The stimuli to increase CD80 podocytes include IL-13 and/or Toll-like receptors (triggered by infection) (Ishimoto et al. 2011). Downregulation of CD80 occurs with CTLA-4, which is secreted and expressed by regulatory T cells (Treg). In this regard, Treg have been shown to be abnormal in MCD. The notion that MCD may represent an imbalance between CD80 induction and CTLA-4 downregulation has been proposed (Shimada et al. 2011). Taken together, these data provide compelling evidence for a pathophysiologic role for CD80 in the development of MCD and suggest it may be a useful biomarker for distinguishing between MCD and FSGS.

Treatment

The goal of treatment for both MCD and FSGS is remission of proteinuria and preservation of renal function. Clinical remission of proteinuria is defined as <1 g/day and is associated with a decreased rate of loss of renal function. Hemodynamic and immunosuppressive therapies alone or in combination may be used to eradicate proteinuria.



Spectrum of Minimal Change Disease to Focal Segmental Glomerulosclerosis, Fig. 1 Comparison of some features of minimal change disease (MCD) to idiopathic focal and segmental glomerulosclerosis (FSGS). The unique characteristics of each disease, and areas of potential overlap are indicated. Areas of overlap support the contention that the two diseases may represent two different spectra of the same disease. *FPE* foot process effacement

Hemodynamic approaches to the management of all forms of glomerular proteinuria include blood pressure control (<130 mmHg systolic), inhibition of the renin-angiotensin-aldosterone system, and/or modification of dietary protein intake to ~0.8 g/kg/day.

Specific immunosuppressive therapies for MCD and FSGS generally include the use of corticosteroids. Children with MCD are typically treated with and have a response rate greater than 95 % (Eddy and Symons 2003). Rates of relapse approach 60 % but may be decreased with longer courses of steroid therapy (Ehrich and Brodehl 1993). Relapses in steroid-dependent cases may require cytotoxic or other therapies to maintain remission. In this regard, 8-week courses of cyclophosphamide or chlorambucil reduced the relapse rate at 12 months compared to prednisone alone, but at 2 years, there was no difference in the relapse rate between the two regimens (Hodson et al. 2008). Prolonged courses of cyclosporine and levamisole may also be useful (Hodson et al. 2008).

The majority of patients with idiopathic FSGS (75–80 %) are steroid resistant and thus do not respond to an 8-week course of high-dose corticosteroids (Eddy and Symons 2003). The patients frequently require consideration of second-line therapy (Eddy and Symons 2003). Cyclosporine significantly increased remission rates in both children and adults (Cattran et al. 2007), but relapses are common after stopping the drug. This must be balanced against the risk of nephrotoxicity (Gbadegesin et al. 2011). A recent NIH trial compared dexamethasone plus mycophenolate mofetil to cyclosporine and found no differences in proteinuria remission rates (Gipson et al. 2011).

Rituximab has also been studied as a second-line approach to the treatment of steroid-resistant

FSGS, but the results did not support its use in the treatment of this disease (Nachman and Glassock 2010). However, in kidney transplant patients at risk for recurrent idiopathic FSGS, rituximab therapy at the time of transplant was associated with a lower incidence of proteinuria and stable renal function following the transplant (Fornoni et al. 2011). In addition, the authors showed that rituximab influences podocyte function by modulating the expression of sphingomyelin phosphodiesterase acid-like 3b (SMPDL-3b). Patients with recurrent FSGS showed a reduction in the number of SMPDL-3b positive podocytes. In cultured podocytes, rituximab partially prevented downregulation of SMPDL-3b, cytoskeleton disruption, and podocyte apoptosis that occurred after exposure to serum from patients with recurrent FSGS (Fornoni et al. 2011). These data provide evidence for a direct effect of rituximab on podocyte function, presumably independent of its immunomodulatory effects, and suggest that the full therapeutic potential of the drug remains to be defined.

FSGS as a Continuum of MCD

MCD and idiopathic FSGS represent podocytopathies and have several features in common; however, the two conditions differ in several important ways (Fig. 1). Clinically, MCD "progression" to FSGS or misdiagnosis of MCD for FSGS due to sampling error is likely in some cases (Appel and D'Agati 2010). However, it is clear from the above discussions that MCD and FSGS may result from several independent stimuli, supporting the contention that many cases of FSGS evolve independently of MCD. Ongoing work in the area may serve to resolve this conundrum.

Definition

The term *ankylosing spondylitis* is derived from the Greek roots *ankylos*, or "bent," and *spondylos*, or "vertebral disc."

Introduction

Spondyloarthritis (SpA) constitutes a relatively common group of arthritides that affect up to 2 % of white individuals and have in common the carriage of the histocompatibility leukocyte antigen (HLA) gene B27. The prototypic form of disease is ankylosing spondylitis (AS), and an overview of the history of AS can be found at www.history-of-ankylosingspondylitis.org. The disease occurs worldwide, but there is marked geographic variation in both the prevalence and phenotypic manifestations. Pathologic hallmarks include inflammation within the sacroiliac joints (sacroiliitis), at specific spinal locations such as vertebral corners and endplates, at the attachment of ligaments and tendons to bone (enthesitis), and at specific extra-articular locations such as the anterior uvea and ascending aorta. Concomitant lesions that may precede the development of musculoskeletal manifestations include

inflammatory bowel disease and psoriasis. A distinguishing feature among other forms of arthritis is the propensity to develop ankylosis, particularly in the sacroiliac joints, intervertebral discs, and facet joints. There is a predilection for males, and disease onset is typically in the third and fourth decades of life although it may present in juveniles, either with asymmetric involvement of large joints in the lower limbs or a syndrome of enthesopathy and involvement of the tarsal joints. Genetic studies have demonstrated additional genes beyond B27 that modify susceptibility to disease. Radiographic sacroiliitis is considered a hallmark in AS and is found in more than 90 % of patients, but in early disease, magnetic resonance imaging (MRI) is more sensitive and shows inflammation in the sacroiliac joints. Management of the disease is still focused on physiotherapeutic modalities to maintain spinal mobility, but new anti-inflammatory agents have been developed that target key inflammatory mediators.

Spondyloarthritis: Ankylosing Spondylitis, Table 1 Modified New York criteria for Ankylosing Spondylitis

Criteria
1. Low back pain of at least 3 months' duration improved by exercise and not relieved by rest
2. Limitation of lumbar spine in sagittal and frontal planes
3. Chest expansion decreased relative to normal values for age and sex
4. Bilateral sacroiliitis grade 2–4
5. Unilateral sacroiliitis grade 3 or 4
Definite ankylosing spondylitis
Unilateral grade 3 or 4, or bilateral grade 2–4 sacroiliitis and any clinical criterion

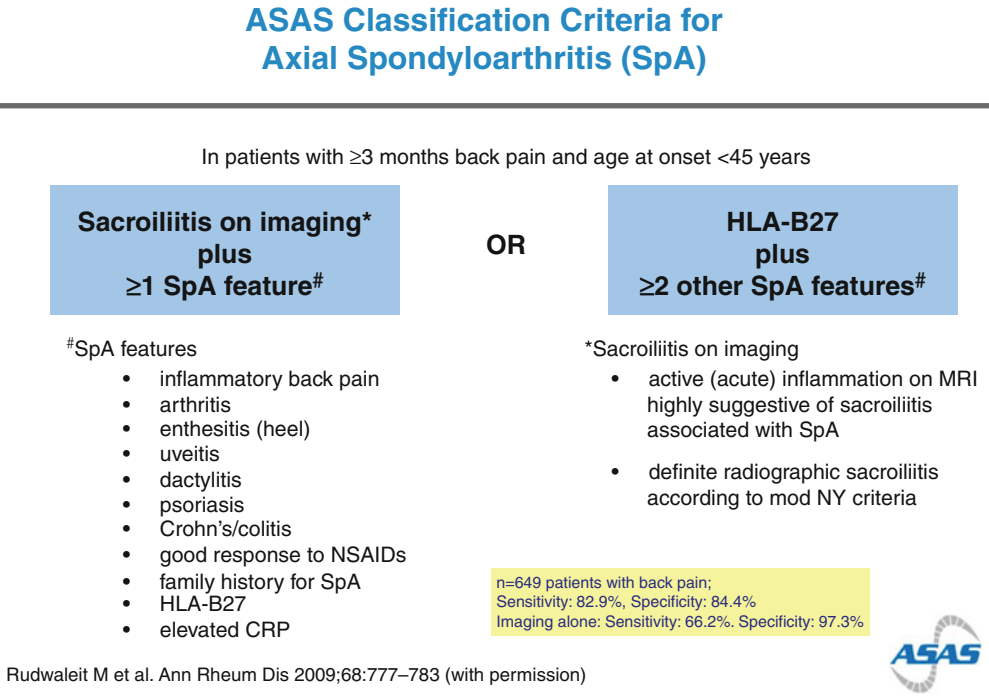
Classification

Radiographic sacroiliitis is considered the primary feature of disease required for establishing a diagnosis and, together with clinical criteria such as the presence of inflammatory back pain and limitation of spinal mobility, is a component of the modified New York criteria. Until recently, these were the primary criteria used to classify AS (Table 1) (van der Linden et al. 1984). Because sacroiliitis may require several years of follow-up before becoming evident on radiography, reliance on these criteria may result in diagnostic delay. It has been shown that sacroiliitis may be evident on MRI prior to the development of radiographic changes, and these patients have been defined as having non-radiographic axial spondyloarthritis (nr-axSpA). In order to combine all patients under the name of a single disease entity, there is now international consensus that the term *axial spondyloarthritis* should be used as the preferred terminology for patients with predominantly spinal disease, and this would include patients with both non-radiographic AS and classical AS according to the modified New York criteria. The Assessments in Ankylosing Spondylitis International Society (ASAS) classification criteria state that a patient can be classified as having axial SpA if there is chronic back pain and age at onset before age 45 together with sacroiliitis on imaging (radiographs or MRI) plus at least one further clinical feature of SpA. In the absence of sacroiliitis on imaging, the diagnosis can be established if the *HLA-B27* is positive and at least two further spondyloarthritis features are present (Table 2) (Rudwaleit et al. 2009). Patients may also present with predominantly peripheral inflammation, and the term for classifying these patients is *peripheral spondyloarthritis*. The ASAS classification criteria state that a patient can be classified as having peripheral SpA in the presence of arthritis and/or enthesitis and/or dactylitis plus (A) one or more of the following parameters, that is, psoriasis, inflammatory bowel disease, preceding infection, HLA-B27, acute anterior uveitis, and sacroiliitis on imaging, or (B) two or more other parameters, that is, arthritis, enthesitis, dactylitis, inflammatory back pain in the past, and family history of SpA (Table 3) (Rudwaleit et al. 2011).

Epidemiology

The prevalence of AS closely parallels the frequency of *HLA-B27*. The estimated prevalence

Spondyloarthritis: Ankylosing Spondylitis, Table 2 ASAS classification criteria for axial spondyloarthritis (SpA)



rate of AS as defined by the modified New York criteria ranges from 68 to 197 per 100,000 but has been estimated at 0.9–1.4 % of the US population and 2.7 million affected persons based on other disease classification criteria and the US National Health and Nutrition Examination Survey (Reveille et al. 2012). AS develops in about 2–5 % of *HLA-B27*-positive adults, and the disease is much more common among *HLA-B27*-positive first-degree relatives of *HLA-B27*-positive AS patients so that 10–30 % of them have signs or symptoms of AS. There are race-related differences in prevalence which may reflect differences in the frequency of *HLA-B27*. For example, AS and *HLA-B27* are nearly absent in African blacks and Japanese.

Pathology

Joint disease in AS most commonly presents as inflammation of the sacroiliac joints. Detailed histopathological studies in early disease are limited but describe granulation tissue beneath the bony endplate eroding through the bone and overlying cartilage into the joint cavity; synovial hypertrophy; infiltration of the subsynovium by macrophages, lymphocytes, and plasma cells; and extension of granulation tissue over the cartilage surface. More advanced disease is highlighted by the presence of many osteoclasts, erosion of bone, obliteration of the synovial joint space by cartilage fusion, and the development of sclerosis in para-articular bone. These lesions account for the classical appearance of joint widening and juxta-articular bone sclerosis observed on radiographic images (Fig. 1). Active degradation of calcified cartilage by chondroclasts and synthesis of endochondral bone by osteoblasts eventually lead to complete replacement of articular cartilage by mature trabecular bone and complete ankylosis of the joint. Immunohistology together with in situ hybridization for mRNA of needle biopsies conducted

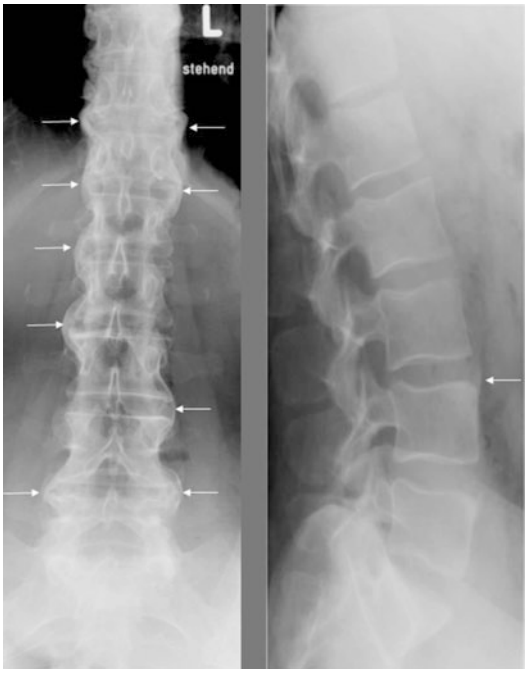
with the guidance of computed tomography has demonstrated dense cellular infiltrates of T lymphocytes and macrophages expressing tumor necrosis factor alpha (TNF-α) (Braun et al. 1995).

In the majority of patients, there is progression of disease to involve the spine with a predilection for involvement of the apophyseal joints, the intervertebral discs, the costovertebral and costotransverse joints, and the extra-articular spinal ligaments. Early inflammation of the apophyseal joints is located at the bony attachment of the joint capsule and is accompanied by a proliferative synovitis with an increase in the number of fibroblasts, small vessels, lymphocytes, plasma cells, and macrophages. This granulation tissue leads to destruction of the capsular insertion and adjacent bone. Ultimately the joint undergoes central cartilage fusion and peripheral ossification leading to ankylosis. Immunohistological analysis of apophyseal joints has shown subchondral lymphocyte infiltrates with CD4+ and CD8+ T cells together with hypervascularization and foci of CD68+ osteoclastic cells.

Spondyloarthritis: Ankylosing Spondylitis, Fig. 1 Pelvic radiograph illustration erosion, pseudo-widening of joints space, and subchondral sclerosis typical of sacroiliitis

At intervertebral disc locations, granulation tissue appears at the attachment of the annulus fibrosus to bone anywhere on the circumference of the vertebra. Cellular infiltration is composed of lymphocytes, plasma cells, and macrophages



Spondyloarthritis: Ankylosing Spondylitis, Fig. 2 New bone formation bridging intervertebral disc space on anteroposterior lumbar radiograph (**a**) and along outer fibers of annulus fibrosus visible as syndesmophyte on lateral lumbar radiograph (**b**)

which results in destruction of the vertebral rim followed by bone proliferation in the adjacent trabecular bone which grows in the direction of the annulus fibrosus, perpendicular to the vertebral axis. As the destruction of the annulus proceeds, ossification extends across the vertical length of the disc and becomes visible on X-ray as a syndesmophyte leading to complete bony ankylosis of adjacent vertebrae as the syndesmophytes encroaching from each vertebra eventually fuse (Fig. 2). This process extends along the length of the vertebral column leading to the appearance of a "bamboo spine." Involvement of the thoracic spine often leads to the development of kyphosis. Vertebral osteoporosis is common and is related to disease activity. It reflects the release of proinflammatory cytokines that promote osteoclastic activity and bone resorption and is associated with an increased risk of vertebral fracture despite the concomitant presence of ankylosis.

Extraspinal lesions can be broadly classified into lesions affecting peripheral entheses, lesions affecting synovial joints such as the hips and knees, and lesions affecting synchondrotic joints such as the manubriosternal joint and symphysis pubis. Entheses affected in AS tend to be those that are rich in fibrocartilage although inflammation within the soft tissue tends to be rather sparse and confined to chronic inflammatory cells such as lymphocytes, macrophages, and plasma cells. Inflammation is prominent within the adjacent bone marrow at the insertion of the ligament, tendon, or joint capsule. Immunohistology shows increased cellular infiltration in the bone marrow with CD8+ T cells and osteoclasts. Synovial joints are affected in about a third of patients with AS, particularly the hips, shoulders, and knees. Immunohistology shows osteoclastic vasoproliferative lesions, while at later stages, there are fibrosis, chondroid metaplasia, and ossification across the joint space and in the joint capsule.

The occurrence of inflammatory lesions in the anterior uvea, aorta, and lungs is well established in AS. Involvement of the aorta is characterized by distinctive fibrous scarring limited to the aortic wall behind and immediately above the sinuses of Valsalva together with dense adventitial scarring extending below the base of the aortic valve to form a characteristic subvalvular ridge. This fibrous tissue may extend into the base of the anterior mitral valve leaflet and may lead to mitral regurgitation. Further extension of this fibrous tissue may also involve the intraventricular septum leading to conduction disturbances. Microscopically there is granulation tissue with accumulation of lymphocytes and plasma cells around small blood vessels in the adventitia followed by fibrosis. Involvement of the anterior uvea is characterized by acute infiltration with inflammatory cells in the iris and ciliary body with accumulation in the aqueous humor. Involvement of the lungs is characterized by apical interalveolar fibrosis or chronic fibrosing pneumonia with lymphocytic infiltration, dilated bronchi, and bullae. A more advanced finding is dense fibrosis, bronchiectasis, and the formation of cavities.

Pathogenesis

The primary role of genetic factors has been known since the first report of an association between AS and the *HLA-B27* gene. More recent data points to an important role for additional genetics factors associated with inflammatory bowel disease and psoriasis and the role of innate immunity.

Genetic Factors

1. *HLA-B27*. Familial aggregation of AS has been recognized for many years, and twin studies have described disease concordance of 75 % in identical twins as compared to 13 % in nonidentical twins.. The risk for AS in *HLA-B27*-positive individuals is in the order of 2–5 %, and 90–95 % of Caucasians with AS are *HLA-B27* positive, but it has been estimated that only about 20 % of the entire genetic risk is due to *HLA-B27*. Only 60–80 % of those individuals with concomitant psoriasis or inflammatory bowel disease carry *HLA-B27*. Of the 50 or so known subtypes of HLA-B27, definite associations have been established with *B*2705* and *B*2702*, the most common subtypes in Caucasians, and *B*2704*, the predominant subtype in Asia among the Chinese and Japanese. Subtypes *B*2706*, the commonest subtype in other Asians, and *B*2709*, primarily observed among Sardinians, do not seem to be associated with AS.

   The main function of HLA class I molecules such as HLA-B27 is to present peptides to cytotoxic T cells. Determination of the crystal structure of *B*2705* as well as characterization of its peptide-binding properties has shown that it has a peptide-binding groove that is conserved between the various *HLA-B27* subtypes but differs from most other *HLA B* molecules. In addition, most naturally bound peptides eluted from *HLA-B27* share an arginine at position 2 that interacts with a glutamine residue in the peptide-binding groove. These observations suggest that the peptide-binding groove of HLA-B27 may convey specificity for the binding of a putative arthritogenic peptide(s) that may elicit T-cell autoreactivity. This forms the basis for one of the main hypotheses addressing the pathophysiological role of *HLA-B27*: cytotoxic T-cell autoreactivity is induced in the course of T-cell-mediated defense to certain bacteria following presentation by *HLA-B27* of an arthritogenic self-peptide(s), perhaps derived from joint and/or entheseal cartilage, in a process that could involve cross-reactivity with bacteria-derived peptides. This is an attractive hypothesis because it conforms to observations demonstrating differing *HLA-B27* subtype associations with disease that could reflect differences in peptide-binding specificities. However, efforts to identify a disease-associated *HLA-B27*-restricted CD8 T-cell response have met with only occasional success, and as yet there have been no examples of cross-reactive CD8 T-cell responses to exogenous antigens demonstrating molecular mimicry with joint antigens. This hypothesis is not consistent with the observation that *HLA-B27* transgenic rats develop severe disease resembling AS even in the absence of CD8+ T cells (Hammer et al. 1990; Taurog et al. 2009).

   A second hypothesis has proposed that peptides derived from the *HLA-B27* molecule itself may be "arthritogenic" when presented to cytotoxic T cells or on class II molecules to $CD4^+$ T cells. A third hypothesis proposes that the *HLA-B27* molecule has additional specific biological properties unrelated to antigen presentation such as an increased propensity to misfold and to form dimers which in turn leads to inflammation on exposure to pathophysiological stimuli. *HLA-B27* may form dimers and multimers through the formation of disulfide links after oxidation of the cysteine residue at position 69, and this has been reported in AS. Binding of these homodimers to macrophages may lead to induction of proinflammatory cytokines such as tumor necrosis factor alpha (TNFα), and they can also trigger direct activation of natural killer (NK) cells through recognition via killer cell immunoglobulin-like

receptors (KIR). Normal folding of the *HLA-B27* molecule is dependent on its association with β_2-microglobulin and peptide. Mutational and peptide-binding analyses of the *HLA-B27* peptide-binding pocket suggest that the propensity of *HLA-B27* to misfold is dependent on its unique structural properties. The assembly of *HLA-B27* into peptide complexes in human *HLA-B27* transgenic rats is indeed slow, leading to misfolding and binding to the binding immunoglobulin protein (BiP) chaperone in the endoplasmic reticulum. BiP is normally bound to certain effector molecules such as activating transcription factor 6 (ATF6), serine/threonine-protein kinase/endoribonuclease (IRE1), and protein kinase RNA-like endoplasmic reticulum kinase (PERK) that trigger stress responses within the cell. Dissociation of BiP from these effector molecules leads to activation of a variety of genes such as nuclear factor kappa-light-chain-enhancer of activated B cells (NFκB) that in turn activate various proinflammatory cytokines (e.g., interleukin-1 and TNF-α). Increased expression of BiP has been reported in synovial fluid cells from patients with AS.

2. *Non-B27* HLA Genes. Population studies and examination of multiplex families have implicated *HLA B60* in risk for disease in *HLA-B27*-positive white individuals, though this is not evident in non-Caucasians. An increased risk associated with *HLA B39* has been observed in the Japanese where the prevalence of *HLA-B27* is low. *HLA B39* shares the same amino acid residues that make up the B pocket in *HLA-B27* and is capable of binding the same peptides.
3. *Non-HLA Genes*. The increased disease concordance of 75 % in identical twins versus 27 % in *HLA-B27* concordant dizygotic twins as well as the increased risk for disease in *HLA-B27*-positive first-degree relatives of AS patients (10–20 %) versus *HLA-B27*-positive individuals in the general population (2–5 %) clearly points to an important contribution from non-HLA genes. Case–control studies have described an association with polymorphism in the cytochrome P450 CYP2D6 gene located on the long arm of chromosome 22. This gene is involved in the metabolism of a variety of drugs and chemicals though the mechanism underlying this association is not understood. Recent genome-wide association studies of AS have identified several novel AS-associated polymorphisms in non-HLA genes (Burton et al. 2007; Reveille et al. 2010). A consistent association has been described with polymorphism in the endoplasmic reticulum aminopeptidase-1 gene (ERAP-1), which encodes an enzyme involved in the trimming of peptides for loading onto MHC molecules. This gene also interacts with *HLA-B27* in predisposing to AS, and polymorphism in this gene is also associated with susceptibility to psoriasis. Disease association has also been described with polymorphisms in the interleukin-23 receptor (IL23R) gene, a locus also associated with susceptibility to Crohn's disease. IL23 is a major regulator of interleukin-17 (IL17) which is expressed in myeloid cells in the spine of patients with AS. In addition, genome-wide association studies have implicated several additional genes with potential roles in inflammation such as the tumor necrosis factor (TNF) receptor 1 (TNFR1), the signaling molecule TNFR1-associated death domain protein (TRADD), the TNF superfamily cytokine TNFSF15, IL-1A and the IL-1 receptor 2 (IL-1R2), the vascular morphogenesis protein gene anthrax toxin receptor 2 (ANTXR2), and the innate immune receptor caspase recruitment domain family member 9 (CARD9). In particular, the associations with genes involved in TNF signaling point to the importance of this cytokine. A TNF-overexpressing mouse model also develops sacroiliitis.

Bacteria and Intestinal Inflammation

Neither *HLA-B27* transgenic rats nor *HLA-B27* transgenic mice develop either intestinal inflammation or peripheral arthritis if maintained in a germ-free environment. Endoscopic studies in patients with AS have demonstrated the presence

of intestinal inflammation in up to 60 % of patients, particularly those with active peripheral joint disease. Prospective assessment of patients who initially present with peripheral joint disease has shown that intestinal inflammation increases the likelihood of progression to axial disease. Altered small intestinal permeability has been described in AS patients and asymptomatic first-degree relatives as well as increased numbers of B cells expressing CD45Ro+, a marker for memory cells, consistent with exposure to luminally derived antigens. Furthermore, identical T-cell expansions in the colonic mucosa and synovium have been reported in AS associated with colitis. Antigen-presenting cells in both intestinal mucosa and synovium express the CD163 scavenger receptor and possess the capacity to secrete TNF-α and IL1 in response to bacterial lipopolysaccharide. Furthermore, this subset of macrophages is increased in AS compared to RA synovium, and levels of CD163 in synovial fluid correlate with disease activity. An abnormal reactivity of innate immune cells such as macrophages, neutrophils, and mast cells has also been proposed on the basis of genetic associations with CARD9 and the IL-1 pathway, and histological studies demonstrating increased infiltration with innate immune cells, but not T, B, or dendritic cells in the peripheral joint and gut of patients with AS. In particular, increased IL17 expression has been noted in cells of the myeloid lineage rather than T cells.

The Link Between Inflammation and Ankylosis

Demonstration of an association between inflammation and spinal ankylosis has been challenging but is of crucial importance because of its implications for treatment. Until the advent of MRI, prospective study was not possible due to inaccessibility of tissue. Recent studies using MRI have described an association between the presence of inflammation at vertebral corners and the subsequent development of syndesmophytes at the corresponding vertebral corners on radiography (Maksymowych et al. 2009). Although reports have also highlighted the development of new syndesmophytes where the baseline MRI shows no inflammation, MRI has limited sensitivity for detection of spinal inflammation that is clearly evident on histopathology. It may be possible that very early inflammatory lesions resolve completely without sequelae if anti-inflammatory therapy with TNF blockers is introduced early at a time when bone formation pathways have not been triggered. Osteoproliferation is dependent on endochondral bone formation which is regulated by several molecular pathways including bone morphogenetic protein (BMP) and wingless protein (Wnt). Dickkopf-1 is a major regulator of Wnt signaling, and its function appears to be impaired in AS.

Clinical Manifestations

The most common presenting feature is lower back pain associated with morning stiffness that is alleviated by activity and exacerbated by rest. The back pain may be particularly prominent at night resulting in nocturnal awakening in the second half of the night. Spinal involvement often ascends the spine but may also skip regions so that occasionally there is severe neck involvement with minimal thoracic disease. On examination there may be limitation of motion of the lumbar spine as elicited by forward flexion, hyperextension, or lateral flexion. Early loss of the normal lumbar lordosis is often the first sign and is easily assessed on inspection. A major complaint is the limitation of ability to drive because of impairment in cervical rotation. Patients may experience chest pain accentuated by coughing or sneezing due to involvement of the costovertebral and costotransverse joints. Mild to moderate reduction of chest expansion is often detectable. Enthesitis may present as pain and swelling around the heel, around the insertion of ligaments and tendons in the patella, at the greater trochanter, and at the insertion of the supraspinatus into the greater tuberosity of the humerus. Shoulder and hip pain is evident in about 20 % of patients.

Extraspinal features include acute anterior uveitis in about 25–30 % of patients. The onset

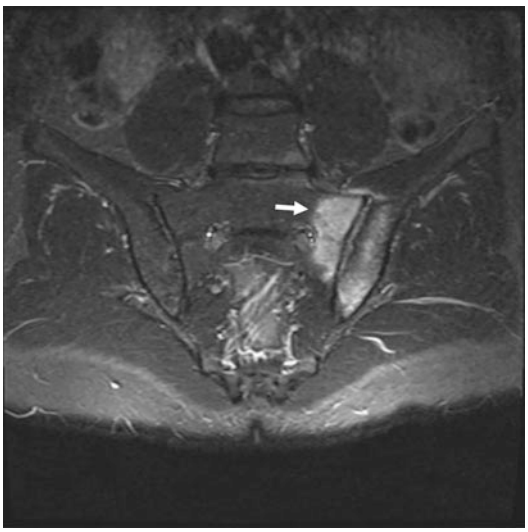
of eye inflammation is usually acute and typically unilateral, but the attacks may alternate. The eye is red and painful, with visual impairment. Photophobia and increased lacrimation may be present. Most attacks subside in 4–8 weeks without sequelae if early treatment is provided. Cardiac involvement includes ascending aortitis, aortic valve incompetence, conduction abnormalities, cardiomegaly, and pericarditis. Cardiac conduction disturbances are seen with increasing frequency with the passage of time. There is an increased incidence of cardiovascular events in patients with AS (Szabo et al. 2011). Lung involvement is characterized by slowly progressive fibrosis of the upper lobes of the lungs and is associated with cough, dyspnea, and hemoptysis.

Neurologic complications of AS can be caused by fracture, instability, compression, or inflammation. Cervical fractures may occur in road traffic accidents. Atlantoaxial joint subluxation, atlantooccipital subluxation, and upward subluxation of the axis may occur in AS as a consequence of instability resulting from the inflammatory process. The cauda equina syndrome is a serious complication of long-standing AS associated with arachnoiditis. The syndrome affects lumbosacral nerve roots giving rise to pain and sensory loss, urinary and fecal incontinence, impotence, saddle anesthesia, and occasionally muscle weakness. Renal manifestations include IgA nephropathy and amyloidosis, especially in very active and long-standing disease. Renal complications such as hypertensive renal disease and renal failure may be associated with long-term use of nonsteroidal anti-inflammatory agents (NSAIDS). The prevalence of symptomatic osteoporotic spinal fractures is increased in AS. Osteoporotic deformities of the thoracic spine contribute significantly to the kyphotic posture.

Diagnosis

In early disease, the presence of back pain with inflammatory features on historical enquiry may be the only helpful diagnostic features. Physical signs are often absent and elevated acute-phase reactants, C-reactive protein, and erythrocyte sedimentation rate are increased in about half of patients. A mild normochromic anemia may be present in 15 % of patients. Elevation of serum alkaline phosphatase (derived primarily from bone) as well as serum IgA may occur.

Physical signs are often absent, while radiography may not reveal evidence of sacroiliitis for several years. The plain anteroposterior view of the pelvis is usually adequate for diagnostic purposes. In young patients with inflammatory chronic back pain, a positive *HLA-B27* test increases the likelihood of having AS, particularly if radiography of the SI joints does not provide conclusive results. MRI shows features of sacroiliitis sooner than radiography and typically shows evidence of bone marrow edema associated with inflammation in the subchondral bone marrow (Fig. 3) (Weber et al. 2011). Consequently, it is now an acceptable imaging criterion for the diagnosis of spondyloarthritis and is especially useful when the history points to inflammatory back pain, the pelvic radiograph is normal or equivocal, and the patient is positive for *HLA-B27*.



Spondyloarthritis: Ankylosing Spondylitis, Fig. 3 Short tau inversion recovery MRI sequence of AS patient demonstrating bone marrow edema in left sacroiliac joint

Prognosis

The course of AS is highly variable, characterized by spontaneous remissions and exacerbations.

Life expectancy is somewhat reduced, particularly after 10 years of disease, with an increased risk of dying due to complications of the disease such as amyloidosis and spinal fractures, as well as cardiovascular, gastrointestinal, and renal disease. Withdrawal from work varies from 10 % after 10 years of disease duration to 30 % after 20 years. Most of the loss of function occurs within the first 10 years and is associated with the presence of peripheral arthritis, spinal radiographic changes, and development of a bamboo spine. Radiographic evidence of spinal involvement, especially the presence of syndesmophytes, is the primary factor that independently predicts further radiographic progression.

Management

Several systematic reviews have recently been published outlining evidence-based approaches to treatment (Zochling et al. 2006; Maksymowych 2006). The treatment objectives are to relieve pain, stiffness, and fatigue, and to maintain good posture and good physical and psychosocial functioning. No drug is currently available that significantly influences the course of spinal disease and retards the process of ossification. Patient education improves self-efficacy and exercise compliance. Patients should avoid vigorous or contact sports if the spine has become fused or osteoporotic because of increased susceptibility to fracture. A program of supervised group physiotherapy is superior to individualized programs in improving thoracolumbar mobility and fitness. Intensive inpatient physiotherapy may also be useful resulting in marked improvement in function and spinal mobility. A Cochrane review concluded that a home exercise program is better than no intervention, supervised group physiotherapy is better than home exercises, and that combined inpatient spa-exercise therapy followed by supervised outpatient weekly group physiotherapy is better than weekly group physiotherapy alone (Dagfinrud et al. 2004).

Many nonsteroidal anti-inflammatory agents (NSAIDs) are effective in patients with AS, and no NSAID has documented superiority in terms of efficacy. Selective cyclooxygenase-2 (COX-2) inhibitors have similar efficacy to conventional NSAIDs. Up to 2 weeks may be required to demonstrate maximal symptomatic benefit from an NSAID. When given for prolonged periods of up to a year, there may be improvement in spinal mobility and acute-phase reactants. There is increasing evidence that continuous use of NSAID may be associated with less spinal fusion, especially in patients with significant inflammatory manifestations of disease.

Disease-modifying agents typically used in rheumatoid arthritis have also been assessed in AS. Most data has focused on the use of sulfasalazine and has demonstrated a beneficial impact of treatment in those patients with peripheral inflammation but not those with axial manifestations (Clegg et al. 1996). A meta-analysis, based on 11 trials, concluded that this agent has a significant impact only on the ESR and the severity of spinal stiffness (Chen and Liu 2006). The primary indication for this agent is a patient who has concomitant peripheral arthritis and has had an inadequate response to NSAIDs and physical modalities. While methotrexate is often used for AS, a meta-analysis concluded that there was no evidence of efficacy and that higher-quality trials and higher dosages of methotrexate were necessary before any definitive conclusions could be drawn (Chen and Liu C 2003). Intra-articular corticosteroids may be helpful when administered into peripheral joints or into the SI joints, if given under fluoroscopic guidance. Systemic steroids are of unproven benefit.

A major advance in the treatment of AS is the development of anti-TNF therapies which block the effect of this cytokine in inflammation. The expression of TNF is increased in SI joint biopsies of AS patients, and overexpression of

TNF leads to sacroiliitis in animal models. Four anti-TNF agents are of proven benefit in AS: infliximab, etanercept, adalimumab, and golimumab (van der Heijde et al. 2005, 2006; Davis et al. 2003; Inman et al. 2008). Infliximab is an IgG1 chimeric monoclonal antibody with the Fab portion derived from the mouse. It is given in a dose of 3–5 mg/kg every 6–8 weeks after initial treatment at 0, 2, and 6 weeks. Etanercept is a recombinant 75-kD TNF receptor IgG1 fusion protein that is self-administered by subcutaneous injection either once (50 mg) or twice (25 mg) weekly. Adalimumab and golimumab are human monoclonal antibodies that are self-administered by subcutaneous injection on alternate weeks (40 mg) or monthly (50 mg), respectively. All of these agents show response rates in 55–60 % of patients for both axial and peripheral inflammation, and responses may be even better in patients with early disease. However, almost all patients relapse when treatment is discontinued. Besides improvement in symptoms and signs of AS, there is improvement in acute-phase reactants, synovial histopathology, and MRI features of inflammation. No evidence indicates that these agents are disease controlling with respect to the prevention of structural damage on plain radiography. Response to treatment appears to be increased in those with short disease duration and high disease activity as indicated by elevated CRP, and worse in those with a long disease duration, impaired function, and no discernible evidence of inflammation on MRI. Even patients with complete spinal ankylosis may benefit from treatment. All these agents are effective for psoriasis, and the monoclonal anti-TNF antibodies, infliximab and adalimumab, also have demonstrated efficacy in both uveitis and colitis. Primary side effects are an increased risk of infection and infusion or injection reactions.

Surgery may be necessary for patients with hip involvement although the results of hip replacement are excellent. Vertebral osteotomy may be required in selected cases to correct marked flexion deformity when forward vision is severely impaired.

Conclusion

Spondyloarthritis is a common disease that manifests early in life and has a strong association with genetic factors such as *HLA-B27*, ERAP-1, and IL23R although their role in the pathogenesis of disease remains unclear. Increasing evidence points to an important role for abnormalities in innate immunity as a driving factor for inflammation. Two major advances have been the introduction of MRI for early diagnosis of sacroiliac joint inflammation and the use of anti-TNF agents for treatment.

Spondyloarthritis: Psoriatic Arthritis

Dafna D. Gladman and Vinod Chandran
Centre for Prognosis Studies in the Rheumatic Diseases University of Toronto Psoriatic Arthritis Clinic, Toronto Western Hospital, Toronto, ON, Canada

Definition

Psoriatic arthritis (PsA) is an inflammatory musculoskeletal disease associated with psoriasis. Although initially described as seronegative for rheumatoid factor, it has become apparent that some patients with PsA do have a positive rheumatoid factor which may be related to age or other reasons. There are specific features of PsA which help distinguish it from other forms of inflammatory arthritis. Because of its association with extra-articular features, peripheral and axial arthritis, radiological sacroiliitis, and HLA*B27, PsA is classified among the seronegative spondyloarthritis (SpA) group of conditions (Wright and Moll 1976 book).

While the first descriptions of PsA were published in the nineteenth century, it was the efforts of Moll and Wright which led to the recognition of PsA as a specific entity. However, while Moll and Wright considered PsA as a benign condition relative to rheumatoid arthritis (RA), over the past several decades, it has become clear that the disease was more frequent and more severe than previously thought, with disease progression, disability, and increased mortality (Gladman 2008).

Pathogenesis

The cause of PsA is unknown. While it occurs primarily among patients with psoriasis, the exact mechanism by which a patient with psoriasis might develop arthritis is unclear. Nonetheless, three factors are considered important: genetic, immunological, and environmental (Haroon and FitzGerald 2012).

Genetic Factors

Both psoriasis and its associated arthritis run in families. Family studies have demonstrated a recurrence risk ratio of 30 for PsA and 4–10 for psoriasis. Several loci have been identified for psoriasis using traditional linkage studies. These include psoriasis susceptibility locus (PSORS) 1 on 6p21.3 [with a number of candidate genes including *HLA-C*06*, *CDSN*, *HCR*, *HERV-K*, *HCG22*, *PSORS1C3*, *POU5F1*, *TCF19*, *CCHCR1*, *LMP*, *SEEK1*, *SPR1*], PSORS2 on 17q [with candidate genes *RUNX1*, *RAPTOR*, *SLC9A3R1*, *NAT9*, *TBCD*, *CARD14*], PSORS3 on 4q [candidate gene *IRF2*], PSORS4 on 1q21.3 [candidate genes Loricrin, Filaggrin, Pglyrp, S100 genes within epidermal differentiation complex], PSORS5 on 3q21 [candidate genes *SLC12A8*, cystatin A, Zn finger protein 148], PSORS6 on 19p [candidate gene *JunB*], PSORS7 on 1p [candidate genes *PTPN22*, *IL23R*], PSORS8 on 16q [candidate genes *CX3CL1*, *CX3R1*, *NOD2/CARD15*], PSORS9 on 4q28–32 [candidate gene *IL15*], and PSORS10 on 18p11 (Chandran 2012). The strongest association is with a locus within the major histocompatibility complex (MHC) on chromosome 6p21 (PSORS1) (Chandran 2012). Fine-mapping studies suggest that HLA-C*0602 is the psoriasis susceptibility gene in this region, although additional susceptibility loci (e.g., MICA) need further evaluation. In PsA there is a stronger association with HLA-B alleles than with HLA-C alleles, while psoriasis (particularly early-onset psoriasis) is associated with HLA-C. The susceptibility locus for PsA may lie more centromeric to that of psoriasis, closer to HLA-B and TNFA.

Several genome-wide association studies (GWAS) in psoriasis have confirmed associations of *HLA*, *IL12B*, *IL23R*, *TNFAIP3*, *TNIP1*, *IL4*, *IL13*, *IL28RA*, *REL*, *IFIH1*, *ERAP1*, *TRAF3IP2*, *NFKBIA*, *TYK2*, *NOS2*, *FBXL19*, *PSMA6-NFKBIA*, *and RNF114* with psoriasis. Several of the GWAS in psoriasis included patients with PsA, thus allowing for comparison between PsA and psoriasis. *HLA-C* and *IL23R* are more strongly associated with psoriasis alone, and *IL12B* with PsA. Several HLA alleles have been found to be associated with PsA. HLA-B*27, HLA-B*08, and HLA-B*38 are significantly more frequent among patients with PsA compared to those with psoriasis alone, while HLA-C*06 is more common among patients with psoriasis alone than those with PsA, although it is increased among PsA patients compared to healthy controls. It has been demonstrated that patients with psoriasis who carry the HLA-C*06 allele develop PsA at a later time in the course of their disease than those who do not carry the allele (Eder et al. 2012).

Thus, a number of susceptibility loci for psoriasis and PsA have been discovered. Although these loci explain only a fraction of the heritability estimates, a model of important pathways in psoriasis pathogenesis is emerging that combines skin barrier function (*LCE3B*, *LCE3C*), TH17 pathway (*IL12B*, *IL23A*, *IL23R*, *TRAF3IP2*, *TYK2*), innate immunity [NFκB and IFN signaling pathway (*TNFAIP3*, *TNIP1*, *NFKBIA*, *REL*, *TYK2*, *IFIH1*, *IL23RA*) and β-defensin], TH2 pathway (*IL4*, *IL13*), and adaptive immunity involving CD8 T cells (ERAP1, ZAP70).

Immunological Factors

The association with class I HLA alleles, the presence of activated state of CD8+ T cells and natural killer (NK) cells in the psoriatic synovium, and the response of the disease to immunomodulatory therapy indicate that the immune system, especially the lymphocytes, plays an important role in PsA pathogenesis. McGonagle and colleagues have proposed that the synovial membrane and entheses form a "synovioentheseal complex." Tissue-specific factors, including microtrauma, lead to regional innate immune activation and persistent

inflammation. The genetic association of PsA with class I HLA alleles, MICA, and KIR genes indicates that PsA is closer to the "autoinflammatory" end rather than the "autoimmune" end of the spectrum of immune-mediated diseases (Benjamin and McGonagle 2009).

There is also evidence that the monocyte-macrophage system plays a major role in the initiation and perpetuation of joint inflammation. Monocytes differentiate into macrophages, osteoclasts, Langerhans cells, or dendritic cells in response to microenvironmental signals. In entheseal tissues, monocytes are the principal cells that infiltrate fibrocartilage. Monocytes are also present in the synovial lining of psoriatic joints, and they infiltrate the subsynovial lining. There is an increased frequency of circulating osteoclast precursors in peripheral blood and synovial tissues of PsA patients. These precursors, derived from circulating CD14+ monocytes, differentiate into osteoclasts after exposure to monocyte colony-stimulating factor (M-CSF) and receptor activator of nuclear factor κB ligand (RANKL) expressed by synovial lining cells in inflamed psoriatic synovium and is responsible for bone erosions (Mensah et al. 2008).

Environmental Factors

Associations of psoriatic arthritis have been reported with a host of environmental exposures, including Rubella vaccination, injury sufficient to require a medical consultation, recurrent oral ulcers, moving between homes, bone fractures requiring hospital admission, lifting heavy loads, infections that require treatment with antibiotics, HIV infection, and corticosteroid use. Smoking is less prevalent in PsA patients compared to patients with psoriasis without PsA. *IL13* gene polymorphisms are associated with PsA, especially in nonsmokers (Eder et al. 2012).

Clinical Features

Psoriatic arthritis is an inflammatory musculoskeletal disease which affects the peripheral joints, axial skeleton, and periarticular structures such as entheses and tendons. Moll and Wright described five "predominant" patterns of PsA, including distal, oligoarticular, polyarticular, arthritis mutilans, and spinal disease. However, because these patterns change over time and do not appear to carry prognostic value, more recently PsA is described as peripheral, axial, or combined (Gladman et al. 2005).

Peripheral Arthritis

The majority of patients with PsA present with peripheral arthritis. Early on, the arthritis is likely to be oligoarticular, with four or less joints involved, and asymmetric. However, with time, more joints are involved such that after several years of disease, the majority of patients have polyarticular disease. All joints in the body may be affected, but the most commonly affected at presentation to clinic are the small joints of the hands and feet, followed by wrists, ankles, knees, shoulders, elbows, hips, and the temporomandibular and sternoclavicular joints. The majority of the patients present with arthritis which is inflammatory in nature, presenting with painful swollen joints, which are worse with inactivity and improve with exercise and associated with morning stiffness in at least 50 % of the patients. However, it should be noted that patients with PsA are not as tender as patients with rheumatoid arthritis, and their arthritis is often missed until they develop obvious deformities. A unique feature of PsA is a purplish discoloration over the affected joint. The peripheral arthritis of PsA may be quite destructive and may result in **arthritis mutilans**, where there is complete lysis of a joint leading to a flail joint. At the same time, the arthritis may lead to ankylosis, leading to fused joints. Both of these features are quite devastating to the patient who may become quite disabled.

Dactylitis

Defined as inflammation of a whole digit, this feature is unique to PsA and affects about 48 % of the patients. It affects fingers and toes occasionally in a symmetric distribution. It results from inflammation in joints, bones, tendons, and soft tissues. Acutely it is associated with pain, swelling, and redness but may become chronic when there is no longer pain but persistent

swelling of the digit. Joints of digits with dactylitis are more likely to develop radiological erosions, suggesting that this feature is prognostically important.

Axial Disease

About 50 % of patients with PsA develop axial involvement manifesting with sacroiliitis as well as syndesmophyte formation. However, only 2–4 % of the patients have isolated axial disease. Axial PsA differs from ankylosing spondylitis in its severity and, like the peripheral arthritis, is less painful. It is associated with HLA-B*27 although to a lesser degree than ankylosing spondylitis. Axial disease is associated with more severe peripheral arthritis as well as arthritis mutilans.

Enthesitis

Inflammation at the insertion of tendons and ligaments into bone is a feature of all types of spondyloarthritis, and in PsA it is clinically detectable in approximately 40 % of patients. The most common sites involved include the Achilles tendon and plantar fascia insertions into the calcaneus. However, other sites may be affected as well.

Extra-Articular Manifestations

Skin: By definition most patients with PsA have psoriasis. It seems that patients with severe psoriasis are more likely to develop PsA, although a direct relationship between skin and joint disease has not been demonstrated. Most patients have psoriasis vulgaris or chronic plaque psoriasis, and a minority may have pustular or guttate psoriasis.

Nail disease: Nail lesions are the only clinical manifestation which identifies patients with psoriasis more likely to develop PsA. They occur in more than 85 % of patients with PsA compared to 40–50 % of patients with cutaneous psoriasis alone. Pits and onycholysis are the major features of nail disease in PsA.

Mucous membrane lesions occurring in patients with PsA tend to be painless. However, it should also be noted that mucous membrane lesions may complicate methotrexate therapy, although these tend to be painful. Urethritis occurs in about 7 % of patients with PsA. Inflammatory bowel disease may occur in a proportion of patients with PsA, usually Crohn's disease. Aortic root dilation, which is much less common in PsA than in ankylosing spondylitis, presents with aortic regurgitation and has a characteristic tambour quality of the second heart sound.

Diagnosis

The diagnosis of PsA is based on clinical features and is usually made at the bedside. The type and distribution of joint involvement is helpful, the presence of the purplish discoloration is suggestive, and the combination of peripheral and axial disease is supportive of the diagnosis of PsA. Confirmation may be obtained through laboratory tests demonstrating a negative rheumatoid factor and radiographs showing fluffy periostitis, the presence of the classic pencil-in-cup change as well as ankylosis. A number of classification criteria have been proposed, but the CASPAR criteria are the most widely accepted and used (Table 1).

Since it has become clear that early diagnosis is helpful to provide proper care for patients with PsA and since patients usually present with skin disease prior to the onset of joint disease, it is important for dermatologists to identify patients with psoriasis who are developing PsA. A number of screening tools have been developed and should provide help in identifying patients that should be reviewed by rheumatologists (Dominguez et al. 2010).

Course and Prognosis

Although Moll and Wright described arthritis mutilans as a severe destructive form of the disease, they identified it in only 5 % of their cases. They and others have considered PsA as a mild disease compared to rheumatoid arthritis. However, studies over the past three decades have demonstrated that PsA can be a progressively destructive form of arthritis,

Spondyloarthritis: Psoriatic Arthritis, Table 1 CASPAR criteria for the classification of psoriatic arthritis

Primary requirement: inflammatory musculoskeletal disease (joint, spine, or entheseal) with three or more of the following:		
1. Evidence of psoriasis (one of a, b, c)	(a) Current psoriasis[a]	Psoriatic skin or scalp disease present today as judged by a dermatologist or rheumatologist
	(b) A history of psoriasis	A history of psoriasis that may be obtained from patient, family doctor, dermatologist, or rheumatologist
	(c) Family history of psoriasis	A history of psoriasis in a first- or second-degree relative according to patient report
2. Psoriatic nail dystrophy		Typical psoriatic nail dystrophy including onycholysis, pitting, and hyperkeratosis observed on current physical examination
3. A negative test for rheumatoid factor		By any method except latex but preferably by ELISA or nephelometry, according to the local laboratory reference range
4. Dactylitis either a or b		Swelling of an entire digit
		Recorded by a rheumatologist
5. Radiological evidence of juxta-articular new bone formation		Ill-defined ossification near joint margins (but excluding osteophyte formation) on plain x-rays of hand or foot

Taylor et al. 2006
[a]Current psoriasis scores 2, others 1

associated with marked limitation of activities of daily living, reduced quality of life, and fatigue. Moreover, there is an increased mortality risk. Both progression of joint damage and mortality are predicted by the degree of inflammatory joint disease (Bond et al. 2007; Cresswell et al. 2011). It has also been demonstrated that patients seen within 2 years of diagnosis fare better than those who present later in the course of their disease (Gladman et al. 2011). Thus, patients with PsA should be diagnosed and treated early in order to prevent these untoward outcomes.

Treatment

Treatment of PsA includes treatment of skin and joint manifestations. Ideally, approaches which address both aspects of the disease should be used. There are patients with PsA whose major issue is the joint disease and in whom the skin disease is minimal. If the joint disease is mild, nonsteroidal anti-inflammatory medications may be sufficient. However, if the arthritis persists, then disease-modifying antirheumatic drugs (DMARDs) should be used. Unfortunately there is limited evidence for efficacy for most DMARDs. Methotrexate has been the most commonly used DMARD in PsA, and it is helpful for psoriatic skin lesions. However, clinical trials have not demonstrated efficacy for joint disease. Nonetheless, most therapeutic guidelines for the treatment of PsA recommend using methotrexate as the first-line DMARD (Ash et al. 2012).

Leflunomide has also been used with some success. Neither drug has demonstrated an effect on progression of radiographic damage. Other DMARDs used in PsA include sulfasalazine, which has been shown to have a marginal therapeutic advantage over placebo, and cyclosporine, which works for the clinical signs and symptoms but is more toxic than other drugs.

Based on the pathogenesis of the disease, anti-TNF agents have been used since 2000 with remarkable results. These medications are effective for the signs and symptoms of the disease as well as for prevention of progression of joint damage. There is some evidence that damage may be reversed with the use of these drugs. Thus, the management of PsA has been facilitated in the past decade. Nonetheless, not all patients respond to the treatment currently available and additional medications are required. Other biologic therapies including IL-12/23 inhibitors, IL-17 inhibitors, and IL-6 inhibitors are being investigated and are promising.

The Group for Research and Assessment of Psoriasis and Psoriatic Arthritis provided

international recommendations for the management of PsA. These recommendations reflect the five domains of PsA including peripheral joints, axial disease, skin and nail disease, dactylitis, and enthesitis. The choice of therapy would be dictated by the domain which is most severe in each patient (Ritchlin et al. 2009).

Spondyloarthritis: Reactive Arthritis

John D. Carter[1] and Alan P. Hudson[2]
[1]Internal Medicine, University of South Florida, Tampa, FL, USA
[2]Wayne State University, Detroit, MI, USA

Synonyms

Arthritis urethritica; Fiessinger-Leroy syndrome; Polyarteritis enterica; Reactive arthritis; Reiter syndrome; Sexually acquired reactive arthritis (SARA)

Definition

Reactive arthritis (ReA) is an inflammatory arthritis that occurs within 1–6 weeks after the patient is exposed to one of the triggering bacterial organisms. ReA belongs to the group of arthritides known as the spondyloarthropathies. Two main types of ReA have been described, post-venereal and post-dysentery (or post-enteric) ReA.

Historical Background

Reactive arthritis (ReA) is an inflammatory joint disease that belongs to the group of arthritides

known as the spondyloarthropathies. These are a group of arthritides that share clinical, radiographic, and laboratory features. The history of ReA is confusing because multiple terms and eponyms have been used in the literature throughout the years to describe this condition. The most commonly used historical term to describe this condition was Reiter syndrome, but Fiessinger-Leroy syndrome, sexually acquired reactive arthritis (SARA), arthritis urethritica, and polyarteritis enterica also have been utilized to describe this same condition.

The eponym Reiter syndrome is a term that should no longer be utilized for several reasons. First, a general push in the medical literature exists to avoid the use of eponyms. Second, this eponym is used to denote the clinical triad of conjunctivitis, urethritis, and arthritis; this triad is far too restrictive to describe ReA, and it is even possible for ReA to present with the complete absence of these three "classic" symptoms. Thus, a more descriptive term is preferred. Third, contrary to common belief, Hans Conrad Reiter was not the first to describe the condition; there are many well-documented cases of ReA in the medical literature long before Reiter's description (Carter and Hudson 2009). Finally, there is a moral issue with the use of the eponym because during World War II, Hans Reiter performed unauthorized medical experiments on concentration camp victims. After World War II, Reiter was charged with "overtly criminal" acts that included involuntary sterilization, involuntary vaccination with typhus, and euthanasia (Keynan and Rimar 2008). For these reasons, the term ReA is the current and most appropriate term for this disease process.

Spondyloarthritis: Reactive Arthritis, Table 1 Triggering microbes of reactive arthritis (Reprinted from Carter (2006) with permission from Elsevier)

Definite causes
Post-venereal:
Chlamydia trachomatis
Post-enteric:
Salmonella (S. enteritidis, S. typhimurium, S. bovismorbificans, S. blockley)
Shigella (S. flexneri, S. dysenteriae, S. sonnei, S. boydii)
Campylobacter (C. jejuni, C. coli)
Yersinia (Y. enterocolitica, Y. pseudotuberculosis)
Probable causes
Chlamydophila (Chlamydia) pneumoniae
Ureaplasma urealyticum
Bacille Calmette-Guerin (intravesicular)
Possible causes
Bacillus cereus
Brucella abortus
Clostridium difficile
Escherichia coli
Helicobacter pylori
Hafnia alvei
Lactobacillus
Neisseria meningitidis serogroup B
Pseudomona
Intestinal parasites (*Strongyloides stercoralis, Taenia saginata, Giardia lamblia, Ascaris lumbricoides, Filariasis*, and *Cryptosporidium)*
Other types of inflammatory arthritis in which bacteria may play a causative role
Borrelia burgdorferi (Lyme disease)
Propionibacterium acnes (SAPHO)
Streptococcus sp (post-streptococcal reactive arthritis)
Trophyrema whippelii (Whipple's disease)

Disease Description

ReA is an inflammatory arthritis that occurs within 1–6 weeks after the patient is exposed to one of the triggering bacterial organisms. Two main types of ReA have been described, post-venereal and post-dysentery (or post-enteric) ReA. Although many triggering organisms have been implicated for both variants (Table 1), definitive triggers of post-dysentery ReA include *Salmonella, Shigella, Campylobacter*, and *Yersinia*, while *Chlamydia trachomatis* is a definitive trigger of the post-venereal variant. Other possible etiologic triggers include *Chlamydia pneumoniae*, *Ureaplasma urealyticum*, *H. pylori*, and various intestinal parasites. Reports of ReA secondary to *E. coli* (Townes et al. 2008), *C. difficile* (Birnbaum et al. 2008), and intravesicular Bacillus Calmette-Guerin (BCG) (Tinazzi et al. 2006) have garnered recent recognition.

Because certain bacteria are known to be etiologic of this condition, ReA represents the classic interplay between host and environment. Many studies have been performed in hopes of unraveling the pathogenesis of this condition. In general, these organisms are acquired through the gastrointestinal or genitourinary tract. Remarkably, many different studies performed in several different laboratories have demonstrated that these bacteria traffic from the initial site of infection to the synovial tissue (Gerard et al. 1998). These synovial-based bacteria are not detectable by routine culture, so it was previously felt that ReA was a sterile arthritis resulting from a bacterial trigger. However, the routine documentation of these organisms in synovial samples by polymerase chain reaction has called into question this disease description. It is generally accepted that these bacteria travel through the peripheral blood in macrophages and monocytes until they ultimately reside in the synovial tissue and/or fluid. Even more intriguing, synovial samples from patients with *Chlamydia*-induced ReA have demonstrated these synovial-based chlamydiae to be viable (Gerard et al. 1998). They exist in an aberrant, persistent form, but these chlamydiae are intact and metabolically active. Similar studies have been performed on patients with the post-dysentery variant of ReA; with one exception (Gaston et al. 1999), these data demonstrate that these causative organisms also traffic to the synovial compartment, but only bacterial fragments have been demonstrated (Nikkari et al. 1999). The synovial-based post-dysentery organisms are no longer viable.

While the true significance of viable versus nonviable synovial-based organisms is not yet fully defined, these findings could have important treatment implications, specifically regarding the use of antibiotics (discussed in the Treatment section). The mystique that surrounds this pathophysiology is further heightened by fact that the phenotypic disease characteristics of post-dysentery and post-venereal ReA are generally congruent. These same bacteria have rarely been demonstrated in synovial samples of patients with osteoarthritis and even normal controls (Schumacher et al. 1999). However, data demonstrate that these etiologic synovial-based bacteria are significantly more prevalent in patients with ReA compared to osteoarthritis (Carter et al. 2009).

Epidemiology

The lack of a standard disease definition, well-validated diagnostic criteria, and the uses of multiple terms and eponyms to describe this condition makes epidemiologic studies problematic. Because only a minority of patients exposed to the causative organisms will develop ReA, the epidemiology of ReA includes not only the incidence and prevalence of the disease but also the attack rate (i.e., the percentage of individuals who develop the condition after acquiring one of the etiologic infections). The incidence, prevalence, and attack rate of ReA vary widely among different studies. The variability of the genetic background of the population studied, differences in local environmental factors, and differing arthritogenic propensity of the several etiologic organisms offer some explanation for the variability of the epidemiologic data in the literature. Interestingly, the arthritogenic propensity of these organisms appears to vary even between different species within the same genus. For example, recent data suggest that within the *Chamydia* genus, the ocular serovars, not the genital species, appear to be particularly arthritogenic; they may be uniquely arthritogenic within the genus (Gerard et al. 2010). Other observational data demonstrate similar findings with the post-dysentery organisms. For example, in 2008 there was a large outbreak of *Salmonella saint-paul* in the USA and Canada without any known subsequent reported cases of ReA. Yet other species of *Salmonella* (e.g., *S. typhimurium*, *S. enteritidis*) are well-known causes of ReA.

The post-dysentery form of ReA affects males and females with the same frequency, whereas the post-venereal form occurs more commonly in males. It has been stated that the male to female ratio of post-venereal ReA is 9:1; it is difficult to know the true ratio because women often present

with more subtle clinical symptoms, and the triggering *Chlamydia trachomatis* infection is more likely to be asymptomatic in women than men. Adults are more likely to develop ReA than children. The attack rate of post-dysentery ReA generally ranges from 1.5 % (Eastmond et al. 1983) to about 30 % (Dworkin et al. 2001) depending on the study and causative organism; however, one recent study of self-reported cases suggested as many as 63 % of patients experienced symptoms consistent with ReA after an acute *Salmonella* infection (Rohekar et al. 2008). ReA is thought to occur in about 5 % of individuals who develop an acute *Chlamydia trachomatis* infection (Rich et al. 1996).

It is also possible – perhaps even likely – that ReA is underdiagnosed. A review of the prevalence of the triggering organisms and expected attack rates suggest that the incidence of ReA exceeds that of rheumatoid arthritis (Carter and Hudson 2009). A final complicating factor involving the epidemiology of ReA is that the condition spontaneously remits as up to 70 % of cases.

Clinical, Radiographic, and Laboratory Features

As stated, ReA is a type of spondyloarthritis. The spondyloarthritidopathies include ankylosing spondylitis, inflammatory bowel disease-related arthritis, psoriatic arthritis, ReA, and undifferentiated spondyloarthritis. The acute and chronic symptoms (see Table 2) can include articular, tendon, mucosal, cutaneous, ocular, and occasionally cardiac manifestations or systemic features (fever, malaise, weight loss); the latter are usually confined to the acute stage. Symptoms typically start within 1–6 weeks of the initial infection.

The inflammatory arthritis of ReA can be an axial or peripheral arthritis, or combinations of both. The axial inflammatory arthritis typically involves the sacroiliac joints and lumbar spine and can spread caudally over time. The peripheral arthritis has a predilection for the large joints of the lower extremities. More data are needed to better define the percentage of patients who present with axial symptoms, peripheral symptoms, or both.

Over time, this inflammatory arthritis can lead to radiographic damage. The radiographic features of ReA include sacroiliitis, periostitis and periosteal new bone formation, non-marginal syndesmophytes, joint erosions, and joint space narrowing. Sacroiliac involvement tends to be asymmetric and typical spinal features include non-marginal syndesmophytes. The peripheral arthritis can also lead to permanent radiographic damage. In general, the radiographic features of ReA mimic those of psoriatic arthritis. Growing evidence demonstrate that MRI is quite useful at detecting the acute inflammatory changes of sacroiliitis (i.e., pre-radiographic sacroiliitis).

Common extrarticular features include enthesitis, cutaneous/mucosal, and ocular manifestations. Enthesitis is inflammation at the transitional zone where collagenous structures such as tendons and ligaments insert into bone. These sites are unique in that the tendons insert directly into trabecular bone. This is a hallmark feature of any of the spondyloarthropathies, including ReA. Common types of enthesitis in ReA are Achilles tendonitis and plantar fasciitis, but inflammation can occur at any enthesis. Typical cutaneous features include a pustular and/or psoriasiform rash of the palms, soles, or penis; shallow oral ulcers are also commonly seen. Ocular involvement includes both conjunctivitis and/or anterior uveitis (iritis).

Regarding laboratory features, it is important to remember that ReA can follow at least two disease courses. The first is an acute syndrome occurring shortly after the triggering infection followed by gradual resolution of the symptoms, the second begins in a similar fashion yet can progress to chronic disease. During the acute stage, individuals will often have elevated acute phase reactants such as an elevated erythrocyte sedimentation rate (ESR) or C-reactive protein. Conversely, patients with chronic ReA typically display normal inflammatory markers. Patients in the acute phase might also display other indicators of inflammatory response including leukocytosis and/or thrombocytosis.

Spondyloarthritis: Reactive Arthritis, Table 2 Clinical manifestations of reactive arthritis (Reprinted from Carter (2006) with permission from Elsevier)

Acute symptoms		
Articular		
Most commonly present with oligoarthritis, but can also present with polyarthritis or monoarthritis		
Axial:	*Frequently involved:*	
	Sacroiliac joints	
	Lumbar spine	
	Occasionally involved:	
	Thoracic spine (usually seen in chronic ReA)	
	Cervical spine (usually seen in chronic ReA)	
	Cartilagenous joints (symphysis pubis; sternoclavicular and costosternal joints)	
Peripheral:	*Frequently involved:*	
	Large joints of the lower extremities (especially knees)	
	Dactylitis (sausage digit): Very specific for a spondyloarthropathy	
Enthesitis		
Hallmark feature		
Inflammation at the transitional zone where collagenous structures such as tendons and ligaments insert into bone		
Common sites: Plantar fasciitis, Achilles tendonitis; but any enthesis can be involved		
Mucosal		
Oral ulcers (generally painless)		
Sterile dysuria (occurs with both post-venereal and post-dysentery forms)		
Cutaneous		
Keratoderma blenorrhagicum:	Pustular or plaque-like rash on the soles and/or palms	
	Grossly and histologically indistinguishable from pustular psoriasis	
	Can also involve nails (onycholysis, subungual keratosis, nail pits), scalp, extremities	
Circinate Balanitis:	Erythema or plaque-like lesions on the shaft and/or glans of penis	
Ocular		
Conjunctivitis:	Typically during acute stages only	
Anterior Uveitis (iritis):	Often recurrent	
Rarely described:	Scleritis, pars planitis, iridocyclitis, and others	
Cardiac		
Pericarditis (uncommon)		
Chronic symptoms (>6 months)		
Articular		
Axial:	Sacroiliac joints	
	Lumbar spine	
	Thoracic spine	
	Cervical spine	
	Cartilagenous joints (symphysis pubis; sternoclavicular joints)	
Peripheral:	Large joints of the lower extremities (especially knees)	
Dactylitis (sausage digit):	Very specific for a spondyloarthropathy	
Enthesitis		
Chronic inflammation can cause collagen fibers to undergo metaplasia forming fibrous bone		
Chronic enthesitis leads to radiographic findings:		
Plantar/Achilles spurs		
Periostitis		
Non-marginal syndesmophytes		
Syndesmoses of the sacroiliac joints		

(*continued*)

Spondyloarthritis: Reactive Arthritis, Table 2 (continued)

Mucosal	
Sterile dysuria	
Cutaneous	
Keratoderma blennorrhagicum	
Circinate Balanitis	
Ocular	
Anterior Uveitis (iritis):	Often recurrent
Rarely described:	Scleritis, pars planitis, iridocyclitis, and others
Cardiac	
Aortic regurgitation	
Valvular pathologies	

HLA-B27 is felt to increase susceptibility to ReA, but the data suggest there may be too much emphasis on this HLA haplotype. The majority of the data suggest an HLA-B27 prevalence of 30–50 % in patients who develop ReA (Carter and Hudson 2009). Recent reports indicate that HLA-B27 plays little role in determining post-enteric ReA susceptibility (Carter and Hudson 2009); the same is likely to be true for post-chlamydial ReA. Rather than truly increasing disease susceptibility, HLA-B27 positive patients may have more severe symptoms thereby making the condition more clinically apparent (Schiellerup et al. 2008).

Treatment

Although there are no well-designed prospective trials assessing the efficacy of NSAIDs in the treatment of ReA, these remain the mainstay of therapy for the inflammatory arthritis of this condition. For more severe cases, corticosteroids can be utilized; data suggest these are more effective for the peripheral arthritis and less so for the axial symptoms (Flores et al. 2003). Topical corticosteroids are also quite useful for treating the ocular and/or cutaneous manifestations of ReA.

Disease modifying antirheumatic drugs (DMARDs) have been utilized in the treatment of ReA; these medications probably have a better role for treating those with chronic disease. The best studied DMARD in the setting of ReA is sulfasalazine. In a large Veterans Administration study, sulfasalazine demonstrated an overall trend of efficacy, but not statistically significant improvement compared to placebo (Clegg et al. 1996). Methotrexate, azathioprine, and cyclosporine have been advocated as potential treatments for ReA but never formally evaluated in a prospective trial.

The tumor necrosis factor (TNF)-alpha antagonists have demonstrated great success in the treatment of other types of spondyloarthritis, but there are no randomized trials in ReA to assess the efficacy of these biological therapies. Several case reports, a small open-label study, and a retrospective analysis of ten patients suggest clinical benefit with these drugs in the treatment of ReA (Meyer et al. 2011). However, there are theoretical concerns regarding TNF-alpha antagonism in ReA. Chlamydiae are the most common trigger of ReA and in vitro data suggest that growth and infectivity of *Chlamydia trachomatis* are inversely associated with TNF-alpha levels (Ishihara et al. 2005). The general lack of viability of the post-enteric organisms in the setting of ReA suggests that anti-TNF therapy might be more appropriate in these patients.

The fact that ReA is triggered by bacteria and because long-term viability of the organism in the synovium has been demonstrated (at least in the case of *Chlamydia*-induced ReA) suggest a potential role for antibiotics. One of the earliest trials assessing the role of antibiotics in ReA analyzed 3 months of treatment with lymecycline in patients with acute ReA (Lauhio et al. 1991). This study demonstrated no benefit

to patients with post-dysentery ReA, whereas there was improvement in patients with *Chlamydia*-induced ReA. The initial optimism generated by this study was dampened by several follow-up studies suggesting that antibiotics were not effective for ReA. However, these follow-up studies did not separate post-venereal and post-dysentery patients and they included patients with chronic disease. More recent data suggest that 6-months of antibiotics are efficacious if utilized specifically in those ReA patients whose disease was triggered by chlamydiae and if a combination of two antibiotics are used (Carter et al. 2010).

Conclusion

Although the notion of viruses and/or bacteria being etiologic to chronic human disease has been proposed for many years, ReA is one of a few human diseases with a definitive bacterial trigger. This insight into disease initiation has led to significant advances in understanding of the pathophysiology of this condition. However, the more we discover about this classic interplay between host and environment, the more questions arise. Interestingly, the post-venereal and post-dysentery variants are clinically congruent but have surprising differences in their pathophysiology. These same differences could have important treatment implications.

Subepidermal Blistering Diseases: Bullous Pemphigoid

Bryan D. Sofen and Nicholas A. Soter
The Ronald O. Perelman Department of Dermatology, New York University School of Medicine, New York, NY, USA

Synonyms

Benign pemphigus; Old-age pemphigus; Parapemphigus; Pemphigoid; Senile dermatitis herpetiformis

Definition

Bullous pemphigoid (BP), which is often referred to as "pemphigoid," is the most common autoimmune blistering disease of the elderly. Usually a chronic disease, it is characterized by spontaneous exacerbations and potentially appreciable morbidity.

Clinical

Bullous pemphigoid typically presents with a generalized, intensely pruritic eruption. Early erythematous lesions may be eczematous or urticarial and evolve into tense blisters and erosions, rarely with mucous membrane involvement. A broad spectrum of clinical presentation exists, and that polymorphic nature leads to frequent misdiagnoses during the early stages when overt bullae are absent. Lesions may be localized, and there may be appreciable morbidity.

Bullous pemphigoid has become the paradigm for autoimmune disease understanding, with the target antigens being well characterized and their genes cloned.

Pemphigoid gestationis is an intensely pruritic bullous eruption that is associated with pregnancy. Autoantibodies most often target BP180. A transient eruption in newborns may be observed after transplacental transfer of IgG autoantibodies from affected mothers.

Numerous medications and physical vehicles such as wounds, trauma, and UV light have been reported in association with the drug-induced form of bullous pemphigoid, but there are no well-defined causal agents. Bullous pemphigoid has been associated with other inflammatory skin conditions such as psoriasis (▶ PSORIASIS-PATHOGENESIS) and lichen planus as well as with systemic disorders such as diabetes mellitus, rheumatoid arthritis (RA-PATHOGENESIS), and ulcerative colitis (IBD), and neurological diseases such as multiple sclerosis and Parkinson's disease (Ahmed et al. 1982).

On histopathologic examination, these blisters are subepidermal with viable epidermis forming the roof. A sparse or dense infiltrate of

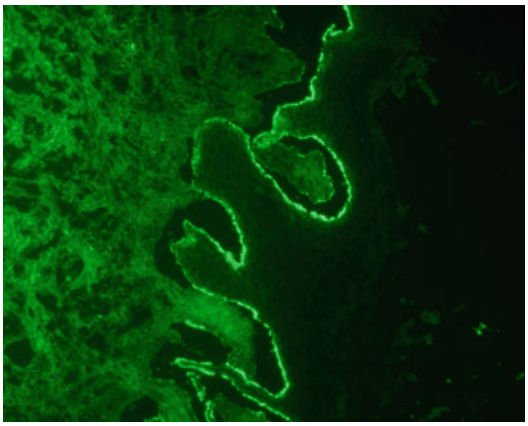
neutrophils, eosinophils, and other inflammatory cells is observed particularly in the upper dermis.

Pathophysiology

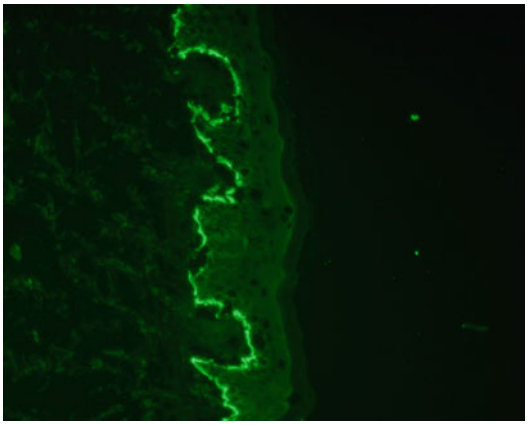
Circulating and tissue-bound pathogenic antibodies (chiefly IgG1 and IgG4 but also IgA) target the 180 kDa bullous pemphigoid antigen (BP180, BPAG-2, type XVII collagen, or LAD1) and the 230 kDa bullous pemphigoid antigen (BP230 or BPAG-1), which are both components of basement membrane zone hemidesmosomes. Hemidesmosomes are junctional complexes that function in dermal-epidermal adhesion. BP230, which is an intracellular cytoplasmic plakin that is localized to the dense plaque, is targeted most commonly at the carboxy-terminal end that mediates the interaction of the hemidesmosome with cellular keratin intermediate filaments (Ishiko et al. 1993; Miller et al. 1993; Skaria et al. 2000). For the transmembrane BP180 molecule, the extracellular NC16A domain is the primary immunodominant epitope. The carboxy-terminal, the intracellular region, and the 97 kDa collagenous ectodomain (LABD97), which is shed normally under physiologic conditions, also serve as targets in some patients (Di Zenzo et al. 2004; Hofmann et al. 2002; Zillikens et al. 1997).

Pathogenesis involves both a humoral and cell-mediated response. Autoantibodies are deposited along the basement membrane zone, with binding C3 along the dermal-epidermal junction. Complement is essential for blister formation in bullous pemphigoid (Schmidt-Ullrich et al. 1975; Anhalt et al. 1981). The activated complement sets off an inflammatory cascade that attracts T cells (both Th1 and Th2), macrophages, mast cells, neutrophils, eosinophils, and other inflammatory mediators such as γ-interferon (γ-IFN), interleukin (IL)-4, IL-5, IL-6, IL-8, and IL-13 (Chen et al. 2002; Liu et al. 1997; Schmidt et al. 2000). Released lysosomal enzymes and proteases, such as matrix metalloproteinase-9 and neutrophil elastase, cleave BP180 and other extracellular matrix proteins and disrupt the hemidesmosome and forming blisters (Verraes et al. 2001; Shimanovich et al. 2004). B cells are further stimulated to produce pathogenic antibodies by autoreactive T cells. Complement, macrophages, T cells, and neutrophils have all been independently shown to be necessary to the process, but the specific sequence and pathways are not fully understood (Chen et al. 2002; Liu et al. 1995, 1997).

Direct IF, which is performed perilesionally as immunoreactants are often lost on the blister roof, shows IgG (Fig. 1) and C3 (or C3 alone) (Fig. 2)



Subepidermal Blistering Diseases: Bullous Pemphigoid, Fig. 1 IgG along the basement membrane zone at the dermal-epidermal junction in bullous pemphigoid, with clefting and early blister formation visible



Subepidermal Blistering Diseases: Bullous Pemphigoid, Fig. 2 C3 deposited along the basement membrane zone at the dermal-epidermal junction in bullous pemphigoid

along the basement membrane zone. Rarely, IgA and IgM deposition may also be observed. Indirect IF is positive in 75 % of patients, false-positive reactions are rare, and the circulating antibodies are diagnostic.

Systemic Autoimmune Disease and Premature Atherosclerosis

Jason S. Knight[1] and Mariana J. Kaplan[2]
[1]Division of Rheumatology, Department of Internal Medicine, University of Michigan Medical School, Ann Arbor, MI, USA
[2]Systemic Autoimmunity Branch, Intramural Research Program, National Institute of Arthritis and Musculoskeletal and Skin Diseases, National Institutes of Health, Bethesda, MD, USA

Synonyms

Cardiovascular disease (CVD) = atherosclerotic disease; Premature atherosclerosis = accelerated latherosclerosis; Systemic autoimmune disease = rheumatologic disease

Definition

Premature atherosclerosis is the formation of arterial atheromatous plaques at an earlier age than would be expected based on traditional (Framingham) CV risk factors. This is a well-recognized process in systemic autoimmune diseases, most notably rheumatoid arthritis (RA) and systemic lupus erythematosus (SLE).

Atherosclerosis in RA: Epidemiology, Screening, and Treatment

RA, a disease that affects approximately 1 % of the population, is associated with a 50 % enhanced risk for death secondary to CVD compared to healthy controls, with patients who are seropositive for either rheumatoid factor (RF) activity or antibodies against citrullinated peptides at particular risk (reviewed in Kaplan 2010). Patients with prolonged arthritis have more atherosclerosis than patients of the same age with more recent disease onset. In addition, extra-articular manifestations of RA, usually related to uncontrolled inflammation, are associated with increased CV mortality – suggesting that processes intrinsic to RA pathogenesis play an important role in vascular damage and its clinical consequences (see also ▶ Rheumatoid Arthritis, Clinical Features).

While a practical approach to the detection and treatment of traditional CV risk factors in RA has been suggested (reviewed in Kaplan 2010), consensus guidelines have been, until recently, lacking. In 2010, the European League Against Rheumatism (EULAR) issued recommendations for CV risk management in patients with RA and other forms of inflammatory arthritis – proposing a 1.5-fold multiplication factor to standard CV risk score models in patients with (1) RA for at least 10 years, (2) RF and/or anti-cyclic citrullinated peptide (CCP) positivity, or (3) severe extra-articular features. While there is a general consensus regarding aggressive assessment and management of traditional CV risk factors in RA patients, the role of specialized CV diagnostic testing remains unknown.

As discussed above, there are hints that improved control of disease activity and systemic inflammation in RA can help reduce the atherosclerotic burden. While exposure to classic disease-modifying antirheumatic drugs (like methotrexate, leflunomide, and sulfasalazine) is associated with a reduction in CV risk (reviewed in Kaplan 2010), this "win-win" concept is not as straightforward as it might at first appear – as a number of the medications used to treat RA (including corticosteroids, NSAIDs, and TNF-α blockers) may have competing effects on CV risk. This concept is exemplified by corticosteroids, which on the one hand decrease inflammation but on the other hand promote dyslipidemia, hypertension, and insulin resistance. Regarding biologic therapy, studies in non-RA patients have shown that short-term TNF-α antagonism with infliximab does not improve, and may adversely affect, the clinical condition of patients with moderate-to-severe chronic heart failure. While there are no prospective studies to assess the interplay between biologic therapy and atherosclerosis, the balance of the retrospective literature points toward a protective effect – in terms of both endothelial function and plaque formation (reviewed in Kaplan 2010; see also ▶ Rheumatoid Arthritis, Treatment and ▶ Rheumatoid Arthritis, Biologics in its Treatment).

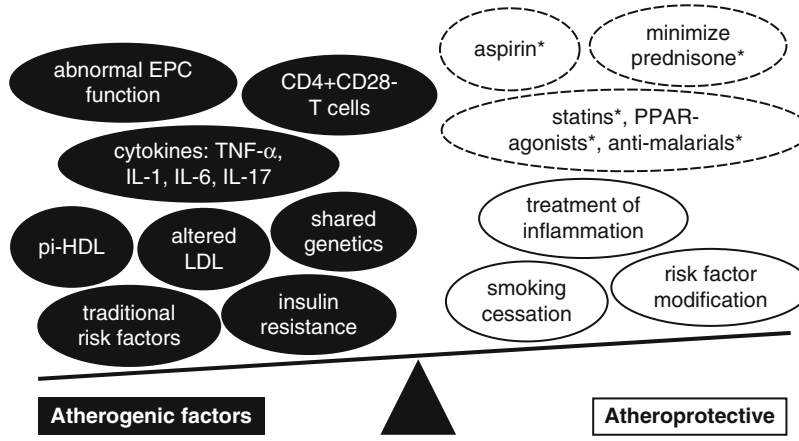
Atherosclerosis in RA: Potential Mechanisms

For many years, striking similarities in the inflammatory and immunologic characteristics of atherosclerosis and RA have been noted. While RA patients do have higher Framingham risk scores than the general population, traditional risk factors are insufficient to entirely explain the increased CV risk in this disease. Many factors have been put forth to explain this enhanced risk (Fig. 1), including metabolic derangements like insulin resistance, family history, altered low-density lipoprotein (LDL) subclass distribution, proinflammatory high-density lipoprotein (HDL), genetic associations, inflammatory cytokines, abnormal lymphocyte populations, and defective endothelial homeostasis (reviewed in Kaplan 2010).

Nevertheless, there is no clear consensus, and the overall story appears to be fairly complex. The most nuanced of the above factors will be discussed below.

Atherosclerosis in RA: Proinflammatory HDL

HDL is considered an atheroprotective factor, facilitating cholesterol efflux from peripheral tissues and protecting endothelial LDL against



Systemic Autoimmune Disease and Premature Atherosclerosis, Fig. 1 Potential atherogenic and atheroprotective factors in RA. On the *left side* of the schematic are factors that are potentially atherogenic in RA. On the *right* are strategies that may be atheroprotective. The items marked with an asterisk (*) are of theoretical benefit, but insufficient data exists to make these standard recommendations. Abbreviations: *pi-HDL* proinflammatory HDL

oxidation. However, HDL undergoes a number of changes in content when exposed to an inflammatory milieu; these include a reduction in apoA1 and paraoxonase (a potent antioxidant) and an increase in serum amyloid A and atherogenic lipids such as nonesterified cholesterol (reviewed in Norata et al. 2011). This is sometimes referred to as proinflammatory HDL as it loses its ability to suppress inflammation at the level of the endothelium. Individuals with both RA and SLE (as discussed below) are more likely to have HDL with a proinflammatory phenotype, which, as expected, correlates with increased levels of oxidized LDL (oxLDL) (McMahon et al. 2006).

Atherosclerosis in RA: Genetic Associations

One of the potential genetic influences linking RA and atherosclerosis involves a polymorphism in the type III promoter of the MHC class II transactivator (MHC2TA). The polymorphism results in differential MHC expression in vitro and has been associated with increased susceptibility to both RA and myocardial infarction (MI). Shared epitope (SE) alleles (from the HLA-DRB1 genotype) have also come under scrutiny with several studies linking the SE, sometimes in combination with other factors, to coronary artery disease; a mechanism by which the SE leads to vascular damage has not been proposed. Single papers have also implicated polymorphisms in IL-6, TNF-α, plasminogen activator inhibitor I, coagulation factor XIII, and TNF receptor type II as risk factors for CVD (or related disease features such as dyslipidemia) in RA patients (reviewed in Kaplan 2010; See also ▶ Rheumatoid Arthritis, Genetics).

Atherosclerosis in RA: Inflammatory Cytokines

Myriad studies have considered the correlation between markers of inflammation – such as erythrocyte sedimentation rate (ESR), C-reactive protein (CRP), hsCRP, TNF-α, IL-1, IL-6, and IL-17 – and atherosclerosis in RA patients (reviewed in Sattar et al. 2003). At this point, the balance of the data points toward a positive correlation between all of the aforementioned biomarkers and CVD in RA. While the mechanism by which the inflammation of RA promotes atherosclerosis is not entirely clear, it presumably parallels emerging data regarding the general role of inflammation in atherosclerosis (reviewed in Hansson and Hermansson 2011; see also ▶ Atherosclerosis and Cytokines).

Atherosclerosis in RA: Abnormal Lymphocyte Populations

In terms of the adaptive immune system, T cells provide the best studied link between RA and atherosclerosis. The most referenced story involves an unusual and expanded population of oligoclonal $CD4^+CD28^-$ T cells present in the blood of patients with RA, as well as patients with unstable angina and no inflammatory arthritis. These cells have enhanced cytolytic and survival potential and can infiltrate unstable plaques. Patients with RA with persistent $CD4^+CD28^-$ T-cell expansion have increased preclinical atherosclerotic changes, including endothelial dysfunction (reviewed in Kaplan 2010). Also warranting further study is the emerging role of T_H17 cells and IL-17 (both critical for RA pathogenesis) in atherosclerosis, as murine studies have heretofore hinted at both atherogenic and atheroprotective phenotypes (see also ▶ Lymphocytes in Atherosclerosis).

Atherosclerosis in RA: Defective Endothelial Homeostasis

A final point involves the disruption of the normal balance between endothelial damage and repair in RA. Endothelial progenitor cells (EPCs) are present in the circulation of patients with CV damage and are released from the bone marrow in increased numbers during acute vascular injury. Indeed, data (independent of RA) has correlated reduced EPC numbers and abnormal EPC function with atherosclerosis and future CV events. It has also been shown that EPC numbers are reduced in the circulation of patients with active RA (reviewed in Kaplan 2010), an effect which may be rescued by anti-inflammatory treatment, such as anti-TNF-α therapy.

Atherosclerosis in Other Inflammatory Arthritides

The majority of the focus has been on two diseases classified as seronegative spondyloarthropathies, namely, ankylosing spondylitis (AS) and psoriatic arthritis (PsA) (see also ▶ Spondyloarthritis: Ankylosing Spondylitis and ▶ Spondyloarthritis: Psoriatic Arthritis). In terms of CV manifestations, the risk of atherosclerosis is usually assumed to be similar to that for RA – which is more amenable to study and formulation of clinical guidelines given large, well-established cohorts.

One potential confounder to the evaluation of CVD in the spondyloarthropathies is that AS, in particular, is commonly associated with aortic root disease – an inflammatory sclerosis involving all three layers of the aortic wall which differs markedly from endothelial-based atherosclerosis. Aortic root disease is frequently associated with aortic regurgitation and may be detected in as many as 61 % of AS patients by echocardiography (reviewed in Vinsonneau et al. 2008). Mitral regurgitation, atrioventricular conduction abnormalities, myocardial inflammation, and pericardial involvement have also been described.

Up to 50 % of deaths in AS patients may be attributable to CVD, although at least some of this burden is borne by non-atherosclerotic disease (reviewed in Peters et al. 2004). In terms of conventional CV risk factors, the most reproduced data involves low circulating levels of HDL in AS patients as compared to controls, which inversely correlate with IL-6 and CRP levels; in contrast, there are no definitive data to implicate other risk factors such as hypertension, smoking, or decreased physical activity. Studies of preclinical vascular function in AS are limited by sample size and are much less definitive than for RA. Nevertheless, individual studies – showing abnormal vascular function which improves with anti-inflammatory treatment (i.e., TNF-α blockers) – are reminiscent of the pattern seen in RA. Overall, expert consensus suggests that AS should be considered on par with RA in terms of accelerated atherosclerosis.

More so than in patients with AS and RA, PsA patients have an increased prevalence of traditional CV risk factors (reviewed in Ramonda et al. 2011). In terms of preclinical disease, a significant increase in carotid intima-media thickness (CIMT) and an impairment of flow-mediated vasodilatation (FMD) have been observed in PsA patients without clinically evident CVD. And, similar to what has been described for

AS and RA, anti-inflammatory treatment improves vascular parameters such as aortic stiffness. Presently, the consensus is that accelerated atherosclerosis is a part of PsA. Whether traditional risk factors play a bigger role in PsA than in the other inflammatory arthritides is possible, although has not been definitively proven.

Atherosclerosis in Psoriasis

This topic is closely related to the above discussion regarding PsA. Even in the absence of inflammatory arthritis, psoriatic skin disease itself is strongly associated with CVD, a link that is partly explained by the prevalence of comorbid diseases including the metabolic syndrome. Because psoriasis is a common disease affecting 1–3 % of the white population, epidemiologic data is relatively robust and supports an increased relative risk for MI in patients with psoriasis compared to controls, even after controlling for traditional risk factors (reviewed in Gelfand et al. 2006). The presumed pathophysiology parallels that for RA and inflammatory arthritis above (see also ▶ Psoriasis).

Atherosclerosis in SLE: Epidemiology and Treatment

SLE, a multisystem autoimmune disease that primarily affects women of childbearing age, is characterized by aberrant autoantibody and immune complex (IC) formation, as well as a markedly heterogeneous clinical phenotype (see also ▶ Systemic Lupus Erythematosus, Clinical Features and Diagnosis). Dating back to the 1970s, a so-called bimodal pattern of mortality was recognized, with early deaths attributable to disease activity and complications of treatment, such as infection, and later deaths largely secondary to CVD. The frequency of premature CVD, especially when considered in young females, is striking and may be as high as 50-fold depending on the study and the specific outcome measure. Further, a significant percentage of patients with SLE have evidence of endothelial dysfunction and subclinical vascular disease (i.e., increased CIMT), while as many as 40 % have evidence of asymptomatic myocardial perfusion abnormalities (reviewed in Kaplan 2009). Traditional risk factors are insufficient to explain the risk of CVD in SLE patients, with both duration of SLE and the amount of lupus-attributable damage predictive of atherosclerosis. While all-cause mortality in SLE has improved significantly with improved immunosuppressive treatment, death secondary to CVD has yet to show a decline.

Presently, there are no consensus guidelines on the management of CVD in SLE, although an assessment of traditional risk factors should begin soon after diagnosis. Despite hints that some SLE medications like antimalarials and mycophenolate mofetil may be vasculoprotective, there is no current indication to employ these agents beyond their typical role in SLE disease management. While the data is probably less clear-cut than in RA, there is certainly a reason to hypothesize (as discussed below) that improved disease control will have an overall atheroprotective effect.

Atherosclerosis in SLE: Potential Mechanisms

The etiology of accelerated atherosclerosis in SLE likely differs from that for RA and other inflammatory arthropathies; in particular, the role of "high-grade" inflammation is less important in lupus, highlighted by the distinct cytokine milieu of SLE in which CRP is classically suppressed during disease flares. A number of unique factors may play a role in the accelerated CVD of SLE – of these, type I interferons (IFNs), like IFN-α, are especially important. Other factors including proinflammatory lipids, potentially pathogenic autoantibodies, and the emerging role of platelets and neutrophils will also be discussed here.

Atherosclerosis in SLE: Defective Endothelial Homeostasis

As endothelial cell (EC) death is likely a critical early event in plaque development, proper repair of damaged endothelium is assumed to be atheroprotective. Because the proliferation of

mature ECs plays a relatively limited role in regeneration, circulating cells, both the aforementioned bone marrow-derived EPCs and so-called myeloid circulating angiogenic cells (CACs), are critically important for endothelial health. Similar to RA (and to other conditions with a high risk of atherosclerosis), patients with SLE have lower numbers of circulating EPCs, with impaired ability to differentiate into mature ECs and to incorporate into vascular structures; this is true even in patients without a history of CV events or traditional CV risk factors.

Atherosclerosis in SLE: Type I Interferons

In recent years, it has been suggested that IFN-α (possibly in concert with other type I IFNs) is a principle player in the abnormal endothelial repair of SLE. Type I IFNs (including 15 subtypes of IFN-α, one IFN-β, one IFN-ω, and, in some species, several subtypes of IFN-τ) are important cytokines in host defense – engaging in a number of important processes including growth and differentiation, induction of other cytokines, and stimulation of different immune effector cells. Recently, IFN-α has received considerable interest as a mediator of SLE pathogenesis, as gene expression studies have repeatedly demonstrated elevated expression of type I IFN-regulated genes in lupus peripheral blood mononuclear cells (PBMCs) and in some SLE animal models (reviewed in Kaplan and Salmon 2011).

Building on data from the cancer literature – where type I IFNs have been shown to have potent antiangiogenic properties – investigators have recently considered the role of IFN-α in SLE vasculopathy (Fig. 2). Indeed, IFN-α induces EPC/CAC apoptosis and skews myeloid CACs toward nonangiogenic phenotypes such as dendritic cells (reviewed in Kaplan and Salmon 2011). Further, neutralization of type I IFN pathways completely restores a normal EPC/CAC phenotype in SLE in vitro. The IFN-α antiangiogenic signature is at least partially attributable to repression of IL-1 pathways via upregulation of IL-1 receptor antagonist (IL-1Ra) and downregulation of the angiogenic molecule vascular endothelial growth factor (VEGF). Indeed, this pattern is appreciated in SLE patients who demonstrate vascular rarefaction, repression of VEGF, and increases in IL-1Ra in both renal blood vessels and serum. Cyclic injury and failed repair could allow initiation and expansion of vascular lesions during disease flares, ultimately predisposing to atheroma formation.

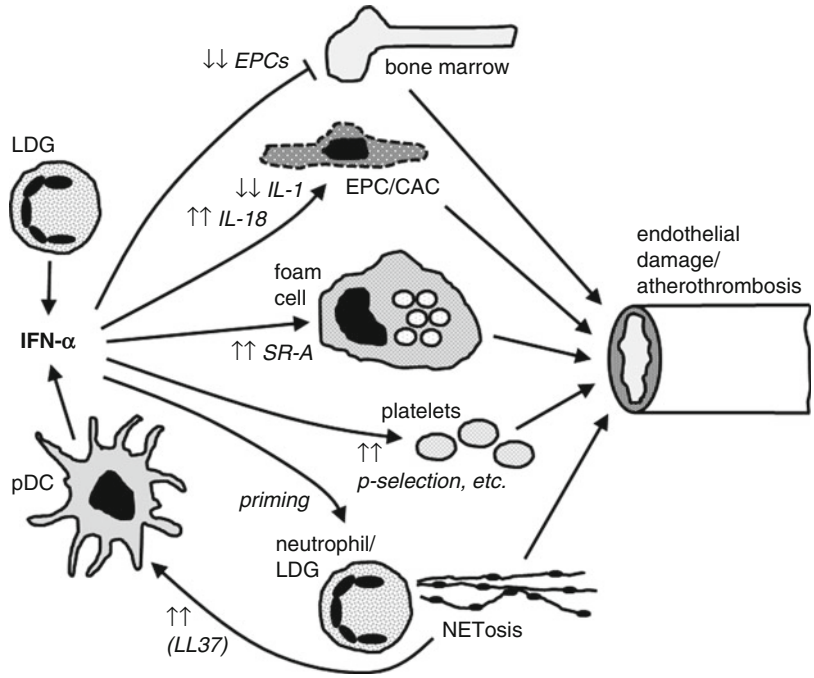
Potentially deleterious links between type I IFNs and the vasculature continue to be described. For example, IFN-α sensitizes the antigen-presenting cells of plaque tissue to bacterial lipopolysaccharide by upregulating TLR4, thereby intensifying TNF-α, IL-12, and matrix metalloproteinase-9 production – all of which have been implicated in plaque destabilization (Niessner et al. 2007). IFN-β treatment accelerates the formation of atherosclerotic lesions in mouse models, while blockade of type I IFN signaling in myeloid cells inhibits lesion development and protects against lesional accumulation of macrophages (Goossens et al. 2010). Further, IFN-α upregulates scavenger receptor A, thereby priming macrophages for oxLDL uptake and foam cell formation (reviewed in Kaplan and Salmon 2011). Finally, the effect of IFN-α on platelets and neutrophils has recently been explored and will be considered in more detail below.

Atherosclerosis in SLE: Proinflammatory HDL

Even more so than patients with RA, patients with SLE have proinflammatory HDL (20 % of patients vs. 45 %) which correlates with increased oxLDL formation, prevalence of carotid plaque, and higher CIMT (McMahon et al. 2006). Proinflammatory HDL has also been appreciated in murine models of SLE where treatment with apoA1 mimetics is currently under investigation (reviewed in Norata et al. 2011).

Atherosclerosis in SLE: Autoantibodies

The role of autoantibodies in the accelerated atherosclerosis of SLE is a complex topic (reviewed in Narshi et al. 2011). Early reports from the 1980s demonstrated IgG-containing ICs within atherosclerotic plaques, although such clear-cut data has not necessarily been reproduced. There are also hints that ICs have biologic activity at the



Systemic Autoimmune Disease and Premature Atherosclerosis, Fig. 2 Potential roles for IFN-α in atherosclerosis. Plasmacytoid dendritic cells (*pDCs*) and low-density granulocytes (*LDGs*) are the primary sources of IFN-α in SLE. IFN-α downregulates EPC/CAC numbers and function, while upregulating foam cell formation, platelet activity, and NET formation (*NETosis*). NETosis, and the antibacterial peptide LL37, can stimulate additional IFN-α production from pDCs. Ultimately, the imbalance between vascular damage and repair leads to a dysfunctional endothelium and potentially atherothrombosis. Other abbreviations: *SR-A* scavenger receptor A

level of the endothelium, although a definitive contribution of ICs to atherosclerosis has yet to be proven.

There has been considerable focus on autoantibodies directed against structural endothelial proteins, so-called anti-EC antibodies, especially in the context of lupus vasculitis. While there are no definitive links to atherosclerosis, anti-EC antibodies may mediate apoptosis through an Fc receptor-independent mechanism, while also inducing a proinflammatory phenotype through NF-κB-dependent pathways.

While there is murine data to support a pathogenic role of IgG anti-oxLDL antibodies, the bulk of the human data (especially for natural IgM antibodies) points toward an atheroprotective effect. Data is further confounded by the fact that oxLDL forms complexes with β_2-glycoprotein 1 (β_2GP1), the key antigen of the antiphospholipid antibody syndrome (APS), making the true target of potentially pathogenic antibodies less clear. Other potentially relevant atherogenic autoantibodies include those directed against HDL, apoA1, HSP 60/65, and unmodified LDL. Finally, an atherogenic role for antiphospholipid antibodies (aPLs) – found in 20–30 % of lupus patients – has been suggested, although epidemiologic data linking aPLs to atherosclerosis in SLE is mixed. These antibodies will be considered in more detail in the section pertaining to primary APS (see also ► Autoantibodies to Endothelial Cells).

Atherosclerosis in SLE: Platelets

Platelets from patients with SLE have an activated phenotype. As mentioned above, an IFN-α signature has recently been described in platelets isolated from SLE patients, correlating with both

platelet activation and a history of CVD (reviewed in Kaplan and Salmon 2011). CD40L expressed on the platelet surface may also modulate plasmacytoid dendritic cell activity and resultant IFN-α production; in this model, platelet depletion reduced SLE activity and disease damage in murine lupus. The mechanism by which platelets contribute to CVD in SLE awaits further study, although it is likely (drawing parallels to the emerging role for platelets in atherosclerosis) that platelets modulate inflammation at the level of the lupus endothelium, with potential implications for the employment of antiplatelet drugs to prevent CVD in SLE (see also ▶ Platelets, Atherosclerosis, and Immunity).

Atherosclerosis in SLE: Neutrophils

Since 2010, a number of groups have recognized, and begun to explore, the role of so-called neutrophil extracellular traps (NETs) in SLE pathogenesis (reviewed in Kaplan 2011). NET formation is a recently recognized form of neutrophil cell death, distinct from apoptosis and necrosis, by which strands of chromatin "beaded" with granule-derived antimicrobial peptides are extruded from the cell. Certainly in sepsis models, and now in one SLE model, NET release damages the endothelium; at this point, the role of NETs in atherosclerosis is unknown (see also ▶ Neutrophils in Endothelial Damage).

Other Diseases

At this point, accelerated atherosclerosis is a well-accepted manifestation of the inflammatory arthritides (RA, AS, and PsA) and SLE. There are hints that patients with other systemic autoimmune diseases (as will be discussed below) may also develop premature atherosclerosis.

Atherosclerosis in Primary Antiphospholipid Antibody Syndrome (APS)

APS is a syndrome which, by definition, requires either vascular thrombosis or pregnancy loss *and* a durably positive lab test for either anticardiolipin antibodies, anti-β_2GP1 antibodies, or a functional lupus anticoagulant (see also ▶ Antiphospholipid Syndrome, Clinical Manifestations). Of these, the majority of basic science work over the past decade has focused on antibodies to β_2GP1, an apolipoprotein which binds to negatively charged lipids (such as phosphatidylserine and oxLDL). Anti-β_2GP1 antibodies produce a procoagulant state, probably by interacting with endothelial and platelet surfaces, while also modulating the coagulation cascade. Both arterial and venous thromboses have been described in APS, and the syndrome is sometimes associated with other systemic autoimmune diseases, classically SLE. When the syndrome is found in isolation, it is referred to as primary APS. In the largest APS cohort published to date, deep venous thrombosis was observed in 32 % of patients, stroke in 13 %, pulmonary embolus in 9 %, and MI in 3 %.

Since arterial thrombosis is a prominent part of the disease process (as well as the diagnostic criteria), an event-based assessment of atherosclerotic disease is not straightforward. Studies have therefore focused on markers of preclinical disease (CIMT/FMD) in an attempt to understand whether the typical endothelial alterations seen in classic early atherosclerosis (as in SLE) are present in primary APS. The results have been mixed and confounded by the inclusion of patients with secondary APS. Nevertheless, a recent consideration of the topic (reviewed in Ames et al. 2009) found that the majority of published studies do show a significant increase in CIMT in primary APS patients as compared to controls. Further, because these patients are typically young, the differences are not explained by traditional risk factors. A definitive statistical consideration of the topic (which also takes into account studies of FMD in APS patients) has not been performed.

Atherosclerosis in Primary Sjogren's Syndrome (SS)

SS is a systemic connective tissue disease resulting in lymphocytic infiltration of exocrine

glands and other tissues (see also ▶ Sjögren's Syndrome). Like APS, a secondary form of SS is well recognized and can be associated with diseases like RA and SLE. There is no comprehensive review of the association between primary SS and atherosclerosis in the literature, with only a few published studies available.

A higher-than-expected prevalence of CIMT has been described, associated with anti-SSA antibodies and leukopenia (Vaudo et al. 2005). Furthermore, endothelium-independent vasodilation is impaired in Sjogren's syndrome – the significance of this finding is not entirely clear, although the authors suggest that it may point toward a smooth muscle-specific defect in patients with primary SS (Gerli et al. 2010). Presently, there is insufficient data to suggest that primary SS is an independent risk factor for atherosclerosis.

Atherosclerosis in Systemic Sclerosis (SSc)

SSc is a chronic disease of unknown etiology, characterized by enhanced fibrosis and microvascular abnormalities (see also ▶ Scleroderma (Systemic Sclerosis): Pathogenesis and Clinical Manifestations). Because SSc is characterized by calcification, vasculopathy, and endothelial wall damage, it has been hypothesized that these patients may be at increased risk for atherosclerosis (Au et al. 2011). Further, over the past four decades, death rates owing to SSc-related complications have gradually decreased, while death rates due to atherosclerotic CVD or cerebrovascular disease have substantially increased; indeed, CV-related deaths are responsible for a 20–30 % mortality rate in SSc patients. Analysis of traditional risk factors has primarily focused on lipid profiles, with studies looking at both proinflammatory HDL and oxLDL; results have not been consistent and have often not reached statistical significance (reviewed in Nussinovitch and Shoenfeld 2011).

It should be noted that other cardiac manifestations of SSc, such as myocardial fibrosis due to ischemia-reperfusion injury, have been noted. Also, while endothelial dysfunction in the capillaries and arterioles is a common and characteristic finding in SSc, there is controversy as to whether this involvement extends to medium and large vessels.

A recent meta-analysis focusing on the preclinical parameters of CIMT and FMD did suggest dysfunction in scleroderma patients (Au et al. 2011). The mean CIMT was associated with SSc disease duration and was comparable to data from patients with RA, diabetes, and familial hypercholesterolemia. Overall, there is no consensus opinion on this topic with recent reviews coming to differing conclusions as to whether there is true accelerated macrovascular disease in SSc, as has been proven for RA and SLE (Au et al. 2011; Nussinovitch and Shoenfeld 2011). Further study is clearly needed.

Atherosclerosis in the Idiopathic Inflammatory Myopathies (IIMs)

IIMs represent a heterogeneous group of systemic autoimmune diseases characterized by chronic muscle weakness and inflammatory cell infiltrates in skeletal muscle; polymyositis and dermatomyositis are the most common IIMs (see also ▶ Myositis: Polymyositis, Dermatomyositis, Inclusion Body Myositis, and Myositis Autoantibodies). Extramuscular manifestations have been described, and CV manifestations include isolated electrocardiographic changes, valve disease, coronary vasculitis, ischemic abnormalities, heart failure, and myocarditis. The literature contains scant references specifically addressing accelerated atherosclerosis in the IIMs (Soltesz et al. 2009), and no clear consensus has been reached.

Atherosclerosis in Systemic Vasculitis

The clinical manifestations of vasculitis are dependent upon both the location and size of the involved vessels, as well as upon the nature of the inflammatory process (see also ▶ Cutaneous Vasculitis). While vasculitis can occur as a secondary condition (e.g., in infection or RA),

primary idiopathic vasculitides are well described and have a chronic disease course that resembles the systemic autoimmune diseases discussed above.

In the so-called "large-vessel" vasculitides, giant cell arteritis (GCA), and Takayasu arteritis (TA), the vasculitic process is confined to the aorta and its major branches. GCA, typically a disease of individuals over 50 years old, has not been associated with accelerated atherosclerosis (reviewed in Tervaert 2009). In contrast, accelerated atherosclerosis has been documented in TA; this is based on both autopsy data and evaluations of preclinical disease. TA patients with plaques tended to be older and have higher levels of total cholesterol.

The medium-vessel vasculitides include Kawasaki disease (KD) and polyarteritis nodosa (PAN). KD typically affects children younger than 5 years of age, with one-third of patients developing CV complications such as coronary artery dilatation and pericarditis. A study in adolescents with a history of KD and coronary lesions did reveal increased CIMT not explained by alterations in lipid profiles; this result was subsequently confirmed by a larger and more recent study from Hong Kong (reviewed in Tervaert 2009); in contrast, studies of brachial artery FMD have not been as consistent in KD. Although PAN can also potentially result in inflammation of the coronary arteries, the issue of accelerated atherosclerosis in PAN has not been evaluated in the literature.

The small-vessel vasculitides include granulomatosis with polyangiitis (Wegener's), microscopic polyangiitis (MPA), Churg-Strauss syndrome (CSS), Henoch-Schonlein purpura, and essential cryoglobulinemia, among others; disease manifestations are diverse but frequently include glomerulonephritis. ANCA-associated vasculitis (which includes Wegener's, MPA, and CSS) is the only group that has been studied from a CVD perspective. Indeed, by long-term follow-up studies, CVD does appear to be a major cause of mortality in these patients with stroke and MI having odds ratios on the order of 3–4 (reviewed in Tervaert 2009). However, noninvasive testing (CIMT and FMD) results have been mixed with no clear consensus emerging.

Conclusions

Premature atherosclerosis is clearly a manifestation of RA and SLE; both disorders have large well-established patient cohorts that have made this recognition possible. For RA (and inflammatory arthritis as a group), "high-grade" inflammation seems to be an important part of the pathogenesis of atherosclerosis, with many interesting parallels drawn between the inflammatory milieu (both local and systemic) of RA and atherosclerosis. For SLE, the situation may be more complex, as type I IFNs clearly contribute to lupus endothelial dysfunction; autoantibodies and proinflammatory lipids may also play a role. Management guidelines for CVD in RA and SLE are just beginning to emerge – at this point, guidelines focus on identification and treatment of traditional risk factors, while optimizing control of disease activity.

The situation is less clear for the other systemic autoimmune diseases. For almost all of these, reports and small series can be found which point toward an increased frequency of either CV events or preclinical disease. However, series that do not show an association also exist, and, in general, definitive meta-analyses have not been performed. At this point, it is probably prudent to consider all of the systemic autoimmune diseases as potentially carrying the risk of accelerated atherosclerosis, with the idea that this will heighten the clinician's attention to treatable traditional risk factors.

Synonyms

Lupus models; Lupus-prone mice

Definition

Certain animals, mostly mice, are prone to developing autoimmune manifestations and organ damage reminiscent of human SLE. Such animals are extensively used to understand mechanisms of disease pathogenesis and conduct preclinical therapeutic trials.

Introduction

SLE animal models have greatly facilitated the study of lupus and helped to develop rational

new treatments. In addition, lupus-prone mice have served as important tools in the study of genes involved in the expression of autoimmunity. Genes that facilitate or inhibit disease have been identified, and these have in turn facilitated the study on immunogenetics and immunopathogenesis of lupus (Tsokos 2011). Etiology of SLE is heterogeneous and complicated, but animal models bring a rational understanding of disease pathogenesis. Mouse models can be grouped into three types: spontaneous, gene manipulation derived, and induced (Kono and Theofilopoulos 2011).

Spontaneous Models

Hybrids with New Zealand White (H-2^z), (NZBxNZW) F1 mice develop systemic autoimmune disease with high titer of anti-DNA antibodies and severe glomerulonephritis (GN) that becomes apparent at 5–6 months of age. The average lifespan of these mice is 8 months for females and 13 months for males (Cohen and Maldonado 2003).

NZM2328 and NZM2410 mice: These strains derive from New Zealand Mixed (NZM) mice generated by (NZBxNZW) F1 and NZW backcross and sib mating. They were found to develop lupus-like disease. Importantly, three lupus susceptibility loci, *Sle1-3*, were identified by lupus linkage analysis of NZM2410 mice. Study of these mice has revealed variations in many genes in these loci to be directly associated with human SLE. *Sle1b* corresponds to polymorphisms in four signaling lymphocytic activation molecule (SLAM) family member genes including Ly108, which is directly implicated in the regulation of B-cell tolerance. Variants of SLAMF3 (Ly9) and SLAMF4 (CD244) have been associated with human SLE and RA.

MRL-Fas$^{lpr/lpr}$ (MRL/lpr) mice: They show accelerated autoimmune disease characterized by severe lymphoadenopathy due to the accumulation of $CD3^+CD4^-CD8^-B220^+$ (double-negative) T cells. Disease onset with severe dermatitis and/or lymphoadenopathy is seen from 10 to 12 weeks and death occurs at around 25 weeks. Disease is severe in female and the average lifespan for female MRL/*lpr* mice ranges from 17 to 35 weeks, depending on the environment. Mice display high concentrations of immunoglobulins including elevated levels of autoantibodies such as ANA, anti-ssDNA, anti-dsDNA, anti-Sm, and rheumatoid factors (Seavey et al. 2011). B cells and T cells from these mice have a defect in apoptosis due to the lack of functional Fas receptor. A mutation of Fas Ligand gene leads to generalized lymphoproliferative disease (gld) similar to that caused by the *lpr* mutation. In humans, defective Fas signaling can lead to the development of autoimmune lymphoproliferative syndrome (ALPS) which shares manifestations with SLE. Expression of the *lpr* mutation in non-autoimmune strains such as C3H/HeJ and C57BL/6 leads to the development of lymphoproliferation and autoantibody production but limited glomerulonephritis in female mice.

BXSB mice develop severe glomerulonephritis and autoantibodies, but the disease is limited to males. The genetic locus responsible for the expression of the disease is located in the Y chromosome and is known as *Yaa* (Y chromosome-accelerated autoimmunity). *Yaa* was first identified from a cross between a C57BL/6 female and an SB/Le male that produced the BXSB hybrid line. BXSB mice develop SLE at much higher incidence and with earlier onset in males compared to females, whereas mice from the reciprocal cross (SB/LE female and B6 male) do not show the same acceleration of disease in males. The disease is heavily dependent on the presence of the H-2^b allele, because its replacement with the H-2^d allele results in prolonged survival. Toll-like receptor-7 (TLR7), a single-stranded RNA-binding innate immune receptor, is a gene responsible for the Y chromosome-linked autoimmune accelerator (Pisitkun et al. 2006).

Mice that develop spontaneous autoimmunity have helped understand the role of hormonal and immunoregulatory influences in autoimmunity, but obvious restraints limit direct transfer of this information to human disease. Human disease develops in individuals with a permissive genetic

background in conjunction with environmental and stress factors, possibly acting over a long period. However, the murine models allow us to analyze disease mechanisms and are very useful to test potential therapies. Moreover, analysis of gene-manipulated mice in these genetic backgrounds enables investigators to identify a number of molecules involved in the development of disease pathogenesis.

Genetically Manipulated Models

Loss of tolerance is a fundamental immunologic abnormality in SLE. Numerous studies in mice with genetic manipulations including gene deletions and transgenes that develop autoantibodies and other features of SLE on non-autoimmune genetic backgrounds have provided great insights into mechanisms that govern tolerance and autoimmunity and suggested novel rational treatments.

Lymphocyte Activation Molecules

PD-1-deficient mice: Programmed death-1 (PD-1) is a member of the CD28 family of receptors and its intracytoplasmic domain defines an immunoreceptor tyrosine-based inhibition motif (ITIM), and when engages with its ligands PD-L1 and PD-L2 delivers a negative signal. Mice lacking the PD-1 gene develop either autoantibody-mediated cardiomyopathy in BALB/c or glomerulonephritis in C57BL/6 background.

Mgat5-deficient mice: Mice with beta-1,6 N-acetylglucosaminyltransferase V (Mgat5) deficiency display decreased glycosylation of T-cell membrane proteins, which prevents galectin binding and thereby disrupts the galectin-glycoprotein lattice, leading to increased clustering of TCR. Increased TCR clustering in these autoimmune mice provides a phenotype comparable with human SLE involving lowered T-cell activation thresholds and increased TCR signaling.

Lyn-deficient mice: A state of B lymphocyte hyperactivity resembling SLE is seen in mice lacking the src-family kinase Lyn. Lyn is an essential inhibitory component on B-cell receptor (BCR) signaling. Negative regulation of the BCR is a complex quantitative trait in which Lyn, the coreceptor CD22, and the tyrosine phosphatase SHP-1 are each limiting elements. Lyn-deficient mice display decreased numbers of mature peripheral B cells, greatly elevated serum IgM and IgA, and production of autoantibodies that cause autoimmune glomerulonephritis reminiscent of SLE. Sustained activation of Lyn in vivo using a targeted gain-of-function mutation ($Lyn^{up/up}$ mice) led to the development of autoantibodies and lethal autoimmune glomerulonephritis.

FcγRIIb-deficient mice: Antigen presented in the context of immune complexes engages not only the BCR but also the FcγRIIb, which results in the phosphorylation of the immunoreceptor tyrosine-based inhibitory motif (ITIM) defined by its intracytoplasmic domain. Recruitment of the phosphatases SHIP (Src homology 2 domain-containing inositol-5-phosphatase) and SHP1 suppresses signaling. FcγRIIb-deficient mice display increased production of autoantibodies, and glomerulonephritis and FcγRIIb deficiency exacerbates autoimmunity in B6/lpr mice.

Ubiquitination-Protein Ligases

Cbl-b-deficient mice: The Cbl-b and Cbl adaptor proteins are E3 ubiquitin ligases that inhibit receptor and non-receptor tyrosine kinases by promoting ubiquitination of signaling molecules. Loss of Cbl-b rescues reduced calcium mobilization of anergic T cells, which was attributed to Cbl-b-mediated regulation of PLCγ-1 phosphorylation. Loss of Cbl-b in mice results in impaired induction of T-cell tolerance both in vitro and in vivo and shows exacerbated autoimmunity. Moreover, B-cell-specific deficiency of Cbl/Cbl-b shows impaired BCR downmodulation and anergy to self-antigen, and develop spontaneous lupus-like disease presenting with anti-dsDNA, ANA, massive leukocytic infiltrates in multiple organs, and immune complex GN.

$Rc3h1^{san/san}$ mice: Roquin (Rc3h1), a RING-type ubiquitin ligase family member, is a negative regulator of the development of follicular helper T (Tfh) cell, a T helper (Th) cell subset specialized for providing help to B cells

in germinal center. This molecule is identified by a novel forward genetic strategy: Male C57BL/6 mice were treated with ethylnitrosourea, a mutagenic agent, and bred the variant genome sequences to homozygosity and screened for autoimmunity. Mice with M199R mutation within the ROQ domain of Roquin were generated by ENU mutagenesis that resulted in ANA, anti-dsDNA, glomerulonephritis, necrotizing hepatitis, anemia, and immune thrombocytopenia. This mouse displays increased germinal center formation and expansion of memory/effector $CD4^+$ T cells, particularly Tfh cells.

Cytokines and Their Receptors

Mice that are deficient in IL-2 and IL-2R have disrupted immunological homeostasis that eventually leads to fatal autoimmune manifestations. Specifically, both IL-2-deficient mice and IL-2Rα-deficient mice develop autoimmune hemolytic anemia and colitis with lymphoproliferation, expansion of effector/memory phenotype T cells, polyclonal hypergammaglobulinemia, and autoantibodies. IL-2Rβ−/− mice likewise develop anemia, splenomegaly, and lymphoadenopathy, but not colitis. Activation-induced cell death (AICD) is central for the elimination of activated autoreactive cells, and this depends on IL-2 signaling. Defective AICD obviously plays a role in the development of autoimmunity. Humans with SLE have defective AICD that appears to be multifunctional: defective TNF-α and IL-2 production (Kammer and Tsokos 2002). IL-2 plays a central role in the development and maintenance of regulatory T (Treg) cells, which have been proven to be of pathogenic relevance in the development of autoimmune disease.

BAFF-transgenic or *TACI-knockout mice*: The tumor necrosis factor/ receptor (TNF/TNFR) system participates in the homeostasis of the immune system in different ways. Among them, TNFSF13B (BAFF, BlyS) and its receptor TNFRSF13B (TACI) is implicated in the development of autoimmune disease. BAFF is critical for B-cell survival and BAFF-transgenic or TACI-knockout mice have a lupus-like disease. Moreover, serum BAFF is elevated in both BWF1 and MRL/*lpr* mice, and blocking BAFF function with a soluble TACI-IgGFc protein can inhibit proteinuria and prolong survival.

Interferon-gamma (IFN-γ-transgenic mice): IFN-γ is required for the development of lupus as this cytokine-deficient lupus-prone animal produces significantly reduced production of autoantibody and develops reduced glomerulonephritis. Transgenic mice with a normal genetic background overexpressing IFN-γ in the epidermis develop lupus-like syndrome with antinuclear antibodies and glomerulonephritis with the deposition of immune complex.

Complement and Complement Receptor Proteins

C1q-deficient mice: Activation of classical pathway typically starts by interaction of C1q with immune complexes. The complement system also has an important role in clearing immune complex from circulation. It can also bind apoptotic cells and helps to eliminate these cells from tissue (Carroll 2004). More than 90 % of individuals with C1q and C1r/C1s deficiency develop an SLE-like disorder, while 10–20 % of individuals with C2 deficiency develop SLE. These phenotypes in humans do not parallel in full those in mice. Deficiency of C1q in C57BL/6 mice does not lead to the development of autoimmunity. By contrast, C1q-deficient MRL/MpJ mice display accelerated disease onset and increased levels of antinuclear antibodies and of glomerulonephritis, particularly in females, which developed severe crescentic glomerulonephritis. Moreover, C1q-deficient mice on B6 × 129 genetic background were shown to develop higher levels of autoantibodies compared to strain-matched controls and to develop glomerulonephritis by 8–10 months of age.

CR1/CR2-deficient mice: The B6/*lpr* mouse develops minor autoimmune features. Deficiency in this strain of the complement receptor 1 and complement receptor 2 (CR1/CR2, CD35/CD21), encoded by Cr2 gene, permits development of intense autoimmune features. These receptors are important in the elimination of B cells that display reactivity

with self-antigens. Patients with SLE have around 50 % lower levels of these receptors on their B cells. MRL/*lpr* mice exhibit lower levels of these receptors on B cells prior to the onset of clinical disease. Also, the congenic interval corresponding to *Sle1c*, one of the SLE susceptibility loci, *Sle1*, contains the Cr2 gene.

C4-deficient mice: Since disruption of the C1q, C4, and CR1/CR2 leads to reduced selection against autoreactive B cells and to impaired humoral responses, C1 and C4 could act through CR1/CR2 to enhance humoral immunity and suppress autoimmunity, but each complement component appears to act independently (Manderson et al. 2004). High titers of spontaneous ANA and SLE-like autoimmunity develop in C4-deficient mice and most male mice but not in Cr2−/− animals. The fact that the clearance of circulating immune complexes is impaired in pre-autoimmune C4−/−, but not Cr2−/−, mice favors the role of nuclear antigen-ANA immune complexes in the development of autoimmune disease.

Clearance of Dead Cells

DNaseI-deficient mice: Effective degradation of nucleotides from dead cells and digestion of cellular components by macrophages allow non-inflammatory clearance and recycle of dead cells. DNaseI is the major nuclease present in the blood, urine, and secretions. DNaseI deficiency in non-autoimmune background mice was reported to increase the incidence of SLE manifestations, including positive ANA, anti-DNA, and immune complex glomerulonephritis. Reduced DNaseI activity is observed in the sera of lupus patients and contributes to SLE susceptibility (Tanaka and Miyake 2007).

MFG-E8-deficient mice: Deficiency in the clearance of apoptotic cells is proposed to be one of the causes of SLE. Unengulfed apoptotic cells are present in the germinal centers of the lymph nodes of some SLE patients, and macrophages from these patients often show a reduced ability to engulf apoptotic cells. Milk fat globule-EGF factor-8 (MFG-E8) protein functions as a bridging protein between phosphatidylserine on apoptotic cells to avb3 or avb5 integrins on phagocytic cells. MFG-E8 is primarily expressed on CD68-positive tangible body macrophages within germinal center. MFG-E8-deficient female mice in B6 × 129 gene background develop SLE-like autoimmune disease with anti-dsDNA, ANA, and glomerulonephritis by 40 weeks of age.

Mer^{KD} mice: TAM family members (Tyro3, Axl, and Mer), which are tyrosine kinase receptors expressed on antigen-presenting cells (APCs), promote clearance of apoptotic cells and mice expressing a kinase-dead mutant of Mer (Mer^{KD}) develop SLE-like autoimmunity. TAM receptors negatively regulate the innate immune reaction and TAM-deficient dendritic cells overproduce IL-6, IFN and TNFα, which might be responsible for the induction of autoimmunity.

Innate Immune Cell Signaling

DNA and RNA in apoptotic material can activate B cells and dendritic cells through TLR9, TLR7, and TLR8. As described above, overexpression of TLR7 is responsible for the development of autoimmune diseases in BXSB mice. These results indicate that TLR signaling is linked to the development of autoimmune disease and aberrant activation of innate immunity may contribute to systemic autoimmune diseases including RA and SLE.

TANK-deficient mice: TANK (also known as I-TRAF) is a TNF-receptor-associated factor (TRAF) – binding protein and binds to TRAF1, 2, 3, 5, and 6, all of which are crucial for TLR signaling. TANK is a negative regulator of proinflammatory cytokine production induced by TLR signaling and TANK-deficient mice spontaneously develop lupus-like autoimmune diseases with fatal glomerulonephritis, ANA, and anti-dsDNA. Autoantibody production in TANK-deficient mice is abrogated by antibiotic treatment or the absence of IL-6 or MyD88, indicating that TANK controls TLR signaling by intestinal commensal microbiota (Kawagoe et al. 2009).

Zc3h12a-deficient mice: Zc3h12a is an RNase activated by TLR signaling that promotes the degradation of mRNA. Zc3h12a-deficient mice have early mortality associated with severe hemolytic anemia, lymphoproliferation, and

ANA with increased number of activated B cells, T cells, and plasma cells due to the excessive cytokine transcription such as IL-6 and IL-12.

Induced Models

Information has been acquired over many years from the study of autoimmunity and SLE-like disease which develops in mice after the injection of immune cells of chemicals.

The *isoprenoid alkane pristane* (2, 6, 10, and 14 tetramethylpentadecane) induces autoantibodies characteristic of SLE, including anti-Sm, anti-dsDNA, and anti-ribosomal P in BALB/c and SJL/J mice. Pristane induces type I IFN production from Ly6C^{hi} monocyte through toll-like receptor-7 (TLR7) and myeloid

differentiation factor-88(MyD88) pathway and triggers autoantibody production. Also, IL-12, IFN-γ, but not IL-4 are involved in the development of pristine-induced lupus, indicating that T helper type 1 (Th1) responses are dominant. For unexplained reasons, the *lpr* and *gld* mutations protect mice from the production of antibodies routinely induced by pristine. In addition to nephritis, hemorrhagic pulmonary capillaritis and arthritis have also been observed in pristine-treated mice. The arthritis symptoms in this model include synovial hyperplasia, periostitis, and progressive marginal erosions. Pristane-induced arthritis is TNFα mediated, as the treatment with neutralizing anti-TNFα antibody ameliorates the arthritis symptoms (Beech et al. 1997).

Graft-versus-host induced models of systemic autoimmunity involve the injection of parent cells into F1 offspring and clarified early events in the induction of autoimmunity. When lymphocytes from DBA mice are transferred into (B6 X DBA) F1 mice, donor $CD4^+$ cells are stimulated by recipient MHC class II cells, which presumably present a chromatin-associated nuclear antigen and produce initially IL-2 and later on IL-4 and IL-10, while the generation of $CD8^+$ CTL cells is silenced. These responses result in chronic GVHD with autoantibody- and immune-complex-mediated glomerulonephritis. When B6/H-2^{bm12} lymphocytes, whose MHC class II locus confers a three amino acid substitution in H-2^b, are transferred into (Carroll 2000) B6 hosts, they also develop chronic GVHD with autoantibodies and GN. This model works equally with opposite donor and recipient.

Conclusion

Animal models of systemic human autoimmune disease have served useful information for understanding autoimmunity. Human systemic autoimmune diseases are highly heterogeneous both at the clinical and pathogenic level to the point that the field is not served properly by lumping them along antedated criteria-counting approaches. A critical review of the animal models (Table 1) has been used to understand disease processes and perform preclinical trials of putative new drugs and biologics.

Definition

Antibodies that react against self-antigens of the organism that produced them.

Introduction

Systemic lupus erythematosus (SLE) is a heterogeneous disease involving many organs, accompanied by immunological abnormalities, particularly antibodies against self-structures. Over 100 autoantibodies have been related to this disease, though few are of truly diagnostic importance (Isenberg et al. 2007; Wandstrat et al. 2006). However, after more than 50 years of research, their real value in SLE remains only partly understood.

History

The first description of autoantibodies occurred in the early 1900s. Ironically, Paul Ehrlich having postulated the notion of "horror autotoxicus" – implying the unlikely prospect that the body's immune system would cause self-harm, was also the first to describe autoantibodies – antibodies to red blood cells (now known to be associated with hemolytic anemia). Hargreaves first described the lupus erythematosus cell – a polymorphonuclear leucocyte with a large phagocytized inclusion body – in the bone marrow aspirates of patients with SLE and 14 years later, antibodies to nuclear antigens (ANAs), more specifically against double-stranded DNA (anti-dsDNA), were identified (Holman 2011).

In the past 50 years, SLE has been associated with many autoantibodies which react with different components of the cell; however, anti-dsDNA antibodies have become the hallmark of SLE, partly because they can be detected in the serum of 70 % these patients (Isenberg 2004).

Relation to Autoimmunity Diseases

The first tangible proof of the likely pathogenicity of autoantibodies in lupus was reported in 1967 in kidney biopsies from patients with lupus nephritis and since then, many clinical correlations have been reported (reviewed in Isenberg et al. (2007)).

However, their real role in autoimmune diseases is often unclear. For example, antibodies to some self-antigens (e.g., nucleic acids, phospholipids, and erythrocytes) participate in the physiological homeostasis, facilitating the clearance of apoptotic cells and oxidized lipids. In addition, ANAs have been detected in up to 20 % of healthy people, though usually in low titers (Isenberg 2004; Almqvist et al. 2011; Pisetsky 2011). Some authors relate this finding to the difficulty in distinguishing "physiologic" from pathogenic autoantibodies, while others believe it represents an autoimmune predisposition. Furthermore, some lupus antibodies were identified up to 9.4 years before SLE symptoms developed and may also be found in the serum of

patients with other diseases (e.g., multiple myeloma). Moreover, some lupus-prone mice display accelerated disease despite having low titers of anti-dsDNA antibody (Wandstrat et al. 2006; Almqvist et al. 2011; Arbuckle et al. 2003).

Therefore, to be associated definitively with the pathogenicity of SLE, autoantibodies must be able to induce disease after passive transfer; they must be isolated from affected organs and linked to specific genes. Although injection of denaturated DNA into healthy animals does not normally generate anti-dsDNA antibody, when combined with histones and binding proteins, autoantibodies may develop. The passive transference of monoclonal anti-dsDNA autoantibodies also induces glomerulonephritis in some normal mice, and these antibodies have also been found in the glomeruli of patients with active lupus nephritis. Finally, the expression of V-genes in transgenic mice induces high-affinity anti-dsDNA autoantibody production, although their expression in normal mice did not induce autoimmune disease (Almqvist et al. 2011; Pathak and Mohan 2011; Ehrenstein et al. 1995; Rekvig et al. 2012).

Origin of Autoantibodies

Potential Triggering Events

Several studies have provided evidence of the role of genetic and environmental factors in triggering autoantibody development. A wide variety of genetic disturbances in innate and acquired immunity result in deficient clearance of immunostimulatory material and can predispose individuals to SLE (Pisetsky 2011).

Increased expression of Fcγ receptor type I on monocytes has been related to lupus nephritis, and polymorphisms in Fcγ RIIB have been associated with SLE in some ethnic groups. In addition, the familial occurrence of SLE and the lupus concordance rates for homozygotic twins (around 25 %) and for heterozygotic twins (2–3 %) also suggest a susceptible genetic background (Pisetsky and Vrabie 2009).

However, the susceptibility loci involved are heterogeneous and do not explain the presence of autoantibodies in healthy subjects. An environmental trigger a likely stimulus. The worldwide female prevalence of SLE (usually 9:1) suggests a hormonal influence in autoimmune susceptibility, but beside the extensive exposure of nuclear antigens during pregnancy, no other gender-specific events have been identified.

Reports of anti-DNA antibody in patients with infections due to *Escherichia coli* or *Klebsiella spp.* make infectious agents a probable trigger for autoantibody development (Isenberg 2004). In fact, bacterial DNA and polymerases have immunological activity, via host cells' Toll-like receptors (TLR). The TLR-9 is important to the production of anti-dsDNA and type-1 interferon. Interestingly, autoantibodies to U1-ribonucleoprotein (U1-RNP) recognize epitopes with strong homology to Influenza B, Herpes simplex-1, and Epstein Barr virus proteins. Even though polyclonal B-cell activation after an infection could explain autoantibody development, their isotypes (mainly IgG2) differ from those in patients with SLE (primarily IgG1 and IgG3 isotypes) (Pisetsky 2011; Pisetsky and Vrabie 2009).

Models of Autoantibodies Development

Triggered by environmental factors or genetic predisposition, the production of autoantibodies seems to be antigen driven. This requires intracellular antigens, like DNA, to become exposed to the immune system. Apoptosis has been proposed to be the event in which self-antigens are cleaved, becoming surface accessible and thus exposing previously cryptic immunogenic epitopes (Isenberg et al. 2007; Almqvist et al. 2011; Yung and Chan 2008).

Normally, in major necrotic events, "backup" mechanisms ensure the elimination of the dying cells, avoiding their presentation in lymphoid tissues. However, in SLE patients, there is an impaired clearance of self-antigens. Genetic defects for DNase I, serum amyloid protein P, and tyrosine kinase have been linked to the development of antinuclear antibodies in murine studies. Moreover, deficiency of C1q, (that promotes phagocytosis of chromatin) leads to an SLE-like disease and anti-C1q autoantibodies have been associated with lupus nephritis. SLE patients also have smaller and impaired

phagocytic cells with shorter life spans, culminating in lengthy exposure of self-antigens. Apoptotic blebs release microparticles into the blood stream, displaying nucleosomal molecules and promoting immune complex (IC) formation. High concentrations of self-antigens are presented to T- and B-lymphocytes. In healthy subjects, auto-reactive T- and B-cells are efficiently removed in early stages of their development, but in SLE patients, defective checkpoints on pre-B-cell development allow auto-reactive B-cells to survive and engage BCR specific to DNA (Almqvist et al. 2011). Moreover, underlying defects of T-lymphocyte antigen receptor signaling can also lead to the generation of auto-reactive T-cells. DNA derived from activated T helper cells induces the production of anti-dsDNA antibodies, and nucleosomes can stimulate T-cells to produce cytokines and help B-lymphocytes to differentiate. An essential step follows auto-reactive B-cell proliferation – BCR gene rearrangement – switching from IgM low-affinity isotype (found in healthy subjects) to the IgG high-affinity isotype (found in SLE patients). Increased levels of BAFF and Th17 cell subset favor these events in SLE patients. When high-affinity autoantibodies bind to their driving antigen, the FcγR-mediated phagocytosis by dendritic cells induces the production of cytokines (e.g., IL-8, IL-1β, TNF-β, IL-18, and IFN-α) essential for presentation of antigens and clonal expansion of B-cells. This rebound effect is strong proof of the likely pathogenic role of autoantibodies in maintaining and amplifying inflammation (Isenberg et al. 2007; Almqvist et al. 2011; Pathak and Mohan 2011; Yung and Chan 2008; Muñoz et al. 2010; Waldman and Madaio 2005).

Since autoantibodies are present in both patients and healthy people, the onset of clinical symptoms is not simply related to the quantity of autoantibodies but to their acquisition of pathogenic properties.

Pathogenic Features of Antigens and Autoantibodies

Research in the pathogenicity of SLE is mainly focused on the two participants of antigen-antibody interaction: (1) specific immunogenic characteristics of a limited subset of self-antigens and (2) intrinsic pathogenic properties of autoantibodies.

Specific Immunogenic Characteristics of Self-Antigens in SLE

The development of autoantibodies to a limited subset of self-antigens, mostly DNA- and RNA-associated macromolecules, suggests that, in SLE patients, these particles may be more immunogenic than in healthy subjects. Antibodies to dsDNA are linked to renal involvement unlike those to single-stranded DNA, confirming the importance of the structure of the target. Moreover, sequences of DNA enriched with particular oligonucleotides provide strong ligands to intracellular TLR-9 and -7, intensifying inflammatory cytokines production and B-cell proliferation. Anti-dsDNA antibody seems to bind a specific sequence in the *N*-methyl D-aspartate receptor (NMDAR), a neuronal glutamate receptor, in patients with neuropsychiatric lupus. In contrast, substitution of arginine for glycine in the sequence of beta-2-glycoprotein-I (B2GPI) is related to the pathogenicity of antiphospholipid antibody syndrome (APS) (Isenberg et al. 2007; Rekvig et al. 2012; Núñez-Álvarez and Cabiedes 2011).

Intrinsic Pathogenic Properties of Autoantibodies in SLE

More recently, the findings of specific properties of autoantibodies in SLE patients have provided information about their role as active pathogenic agents.

Immunoglobulin Isotype and Physical Properties While healthy individuals have low-affinity IgM isotype anti-dsDNA autoantibody, SLE patients display high-affinity IgG isotype autoantibodies. In fact, the positively charged IgG2 and IgG3 subclasses have been associated to lupus nephritis, suggesting that during disease development, autoantibodies undergo isotype switch and affinity maturation (Pisetsky and Vrabie 2009; Muñoz et al. 2010).

Antiphospholipid antibodies have also been found in healthy subjects and patients with infectious and neoplastic diseases, who do not develop APS. A switch from the IgM isotype (that does not bind B2GPI) to the IgG isotype seems to occur in patients. Interestingly, high-affinity may determine which autoantibodies induce glomerulonephritis in mice models (Ehrenstein et al. 1995).

Specific Complementarity Determining Regions Besides their isotype, the amino acid sequences in the variable regions of antibodies can also induce their high avidity. Arginine, asparagine and lysine were found in high percentages in the complementarity determining regions (CDR) of anti-dsDNA antibody, probably by somatic hypermutation. The specific position of these residues within the sequence was also critical to increase antigen affinity, suggesting that during B-cell expansion, the clones containing arginine in their CDR-VH genes would develop into anti-DNA antibody producers (Isenberg et al. 2007; Rahman et al. 2002).

Cross-Reactivity The ability of some antibodies to bind to several host molecules may influence pathogenicity. In fact, negatively charged structures like alpha-actinin, laminin, heparan sulfate, and type-IV collagen have been suggested as glomerular targets for cationic charged anti-dsDNA antibodies, leading to direct damage and local IC formation. The intrinsic features of autoantibodies seem to be linked to the pathogenic role of autoantibodies in SLE and may also explain the differential autoantibody accumulation in target organs and why some autoantibodies are more prone to induce IC formation than others (Yung and Chan 2008; Waldman and Madaio 2005).

Mechanisms of Disease

The precise mechanism by which autoantibodies cause tissue inflammation and damage in systemic lupus erythematosus remains uncertain, but four main pathways have been proposed (Rekvig et al. 2012):

1. Induction of circulating immune complexes that deposit in target organs and activate complement and inflammation
2. Penetration into living cells
3. Binding to cell surface promoting cytolysis or cytotoxicity – by anti-Ro/La, anti-P ribosomal, antilymphocyte, antierythrocyte, and antiphospholipid antibodies
4. Cross-reactivity with extracellular molecules (like heparan sulfate and fragmented chromatin) – by anti-chromatin, anti-dsDNA, and antiphospholipid antibodies

Deposition of Circulating Immune Complex in Target Organs

In active disease, patients have higher levels of circulating IC compared to inactive disease and their deposition in tissues may explain the decrease in anti-dsDNA antibody levels observed in some patients before SLE flares occur. In addition, deficiencies of C4a (which prevents IC precipitation) and reduced expression of CR1 (a complement-binding receptor that clears ICs) were associated with the development of lupus nephritis. However, the concentration of circulating ICs in SLE patients is relatively low and it has been hard to demonstrate their passive glomerular trapping as the primary event for disease. For example, the administration of preformed ICs to healthy mice did not result in glomerular deposition or clinical disease. Current opinion is that IC formation occurs in situ, rather than in circulation, probably following deposition of chromatin or exposure of nucleosomes in target tissues (Rekvig et al. 2012; Yung and Chan 2008; Åhlin et al. 2012).

Penetration into Living Cells

It was long presumed that anti-DNA antibodies could only bind to extracellular (post-apoptotic) chromatin and that the findings of immunoglobulins in Hargreaves' cells and glomerular deposits were artifacts of fixation techniques. However, since 1978, it has been accepted that anti-dsDNA, U1-RNP, Sm, Ro, and La antibodies might on occasion penetrate living cells

(via Fc receptor), entering the nucleus (probably through their CDR3 region) and induce cell growth or apoptosis. Interestingly, after being internalized, autoantibodies can return to cells surface and become antigens for immunoglobulin deposition and T-cell activation (Yung and Chan 2008; Waldman and Madaio 2005).

Binding to Cell Surface

In order that autoantibodies bind directly to cells surfaces, antigens must be expressed in the outer membrane. This mechanism has been linked to the development of antiphospholipid, anti-ribosomal-P antigen, anti-Ro/La, and antierythrocyte antibodies. The binding of beta-2-glycoprotein-I (B2GPI) to phospholipids increases the affinity of anti-B2GPI antibodies to cell membranes, allowing them to bind several cell types. For example, anti-B2GPI/B2GPI complexes link to apolipoprotein E receptor 2 on platelets inducing thrombin activation, but can also stimulate monocytes, in vitro, enhancing expression of tissue factor and, during embryonic development, they bind to negatively charged trophoblasts' phospholipids impairing their invasive capacity and ultimately leading to miscarriage, a common feature of antiphospholipid syndrome. They can also interact with the neuronal tissue. Anti-ribosomal-P antibodies bind directly to the surface of T-lymphocytes, monocytes, hepatoma, and neuroblastoma cells. A neuronal surface P antigen was identified as a potential target for autoantibodies from neuropsychiatric lupus patients (Rekvig et al. 2012; Yung and Chan 2008; Núñez-Álvarez and Cabiedes 2011).

Cross-Reactivity with Extracellular Molecules

Numerous cross-reactions of anti-dsDNA antibody with different constituents of glomerular basement membrane, matrix, and podocytes have been described, explaining the existence of distinct histologic and clinical patterns of lupus nephritis. Moreover, the wide distribution of these antigens in the body can also explain the multisystemic damage that characterizes SLE. Among the several glomerular candidates, the alpha-actinin-4 from the podocytes cytoskeleton is a possible target for anti-DNA antibody cross-reaction. However, the phenomenon of cross-reactivity does not explain how high-affinity allows countless interactions with several epitopes, unless there is an intermediary agent, providing a high-affinity epitope to antibodies while anchors to target tissues. This link seems to be the circulating nucleosomes, released after apoptosis and binding to glomerulus surface molecules, exposing their DNA to autoantibodies, leading to the formation of specific dense deposits found in nephritic kidneys (Isenberg et al. 2007; Almqvist et al. 2011; Yung and Chan 2008; Waldman and Madaio 2005).

The Final Pathway: Complement Cascade Activation and Cytokine Production

Several of the mechanisms discussed previously culminate in the deposition and consumption of complement, which marks active lupus nephritis. Anti-dsDNA antibody and ICs stimulate TLR-9 and the Fc receptor promoting cytokine production, notably alfa-IFN, amplifying the inflammatory process.

Types of Autoantibodies in SLE

Several autoantibodies have been described in patients with SLE but, at present, only the anti-dsDNA, Sm, and antiphospholipid autoantibodies are included in the classification criteria of the American College of Rheumatology.

Antibodies to DNA

Several studies concluded that both mammalian and bacterial DNA activate the immune system and do not need to be fragmented to become immunogenic. In fact, the histone-1/nucleosome complexes, rather that free DNA, appear to be the real target for the anti-dsDNA antibodies (Pathak and Mohan 2011; Yung and Chan 2008).

Anti-dsDNA antibodies are present in approximately 2/3 of patients with lupus and in less than 0.5 % of healthy people or patients with other autoimmune diseases (Isenberg 2004). Variability of prevalence is probably related to

different assays and to the existence of three types of autoantibodies to DNA. The anti-single-stranded DNA antibody recognizes bases, nucleosides, oligonucleotides, and the ribose-phosphate backbone of denaturated DNA. The anti-double-stranded DNA antibody, the most frequent type, binds to the ribose-phosphate backbone of both single- and double-stranded DNA molecules, in their right-handed helical conformation, called B-DNA. The anti-z-DNA antibody binds to the rare left-handed helical conformation of the molecule of DNA (Z DNA).

At least three clinical methods can detect and quantify anti-dsDNA antibodies: *Crithidia luciliae* indirect immunofluorescence (CLIF), ELISAs, and radioimmunoassays (RIAs), namely, the Farr assay. The last is considered to be the gold standard due to its strong specificity for high-affinity anti-dsDNA antibodies. However, ELISAs are widely used, given their convenience, lack of the use of radioactive reagents, low cost, and good sensitivity to detect anti-dsDNA antibodies (Wandstrat et al. 2006; Heidenreich et al. 2009).

Over 80 % of the patients who have elevated levels of anti-dsDNA antibody develop clinically active disease within 5 years after their detection. Despite the lack of agreement of different assays, several authors were able to prove the relationship of anti-dsDNA levels with lupus activity. Several authors have suggested a sharp fall in anti-dsDNA antibody levels precedes a flare and might reflect its deposition in the glomeruli (Isenberg 2004).

In addition to reflecting the disease activity, treating patients according to anti-dsDNA antibody levels may prevent more flares rather than treating them only accordingly to clinical symptoms. Furthermore, there is a danger of overprescribing steroids in these patients, and anti-dsDNA and nucleosome antibodies have shown good correlation with clinical responses to B-cell depletion therapy (Isenberg et al. 2007; Tew et al. 2010).

In terms of prognosis, the presence of anti-dsDNA antibodies was recently identified as the best predictor for renal outcome in patients with new-onset lupus nephritis (Manson et al. 2009).

Antibodies Anti-nucleosomes

The complex organization of DNA offers a variety of targets to autoantibodies, notably histones, either in their individual form or grouped with DNA, forming nucleosomes. The nucleosome may well be the major antigen in SLE. Interestingly, in murine studies, the anti-nucleosome antibody appears before anti-dsDNA antibody and this autoantibody has also shown good correlation with disease activity, especially to lupus nephritis. Anti-histone antibodies may target individual histones components, notably H1, H2a, H2b, H3, and H4, but given the exposed position of H1, the anti-H1 antibody shows the best specificity, being found in up to 60 % of SLE patients. It has also been linked to particular manifestations (e.g., leukopenia and hemolytic anemia) and to drug-induced SLE caused by hydralazine and procainamide (Isenberg 2004; Yung and Chan 2008; Waldman and Madaio 2005; Manson et al. 2009).

Antibodies Anti-RNA

The RNA molecule is a target for autoantibodies that bind conformational epitopes of RNA, U1-snRNA, and tRNA. The linking of these autoantibodies to the cell replication machinery reinforces the potential of viruses to act as triggers of autoimmune disease. The frequency of anti-RNA antibodies in SLE patients ranges from 15 % to 25 %, varying according to the detection assays (Åhlin et al. 2012; Rahman and Isenberg 2008).

Antibodies Anti-extractable Nuclear Antigens

Anti-spliceosomal Antibodies: Anti-Sm, and Anti-Mo (Anti-ribonuclear Protein Antibodies)

The first autoantibody to intracellular molecules extracted in saline solution and not related to histones was identified in 1966. After finding that these molecules were nuclear antigens related to SLE, this autoantibody was named anti-Sm, (after the first two letters of the patient in whom it was found). A second nuclear antigen, a ribonucleoprotein (U-RNP), was late identified as another component of the spliceosome. The spliceosome is a protein complex ring that splices nuclear RNA into messenger RNA. Anti-Sm

antibodies recognize U1-, U2-, U4-, U5-, and U6-ribonucleoproteins, while anti-U1-RNP antibodies bind to the specific U1 ribonucleoprotein, exposed during cell apoptosis. According to some authors, the anti-U1-RNP antibody has the best sensitivity for SLE but insufficient specificity. In contrast, anti-Sm antibodies are present in around 10 % of Caucasian SLE patients and 30 % of those of Afro-Caribbean origin. A pathogenic role of anti-U1-RNP antibody in SLE remains unclear, although it is linked to myositis, esophageal dysmotility, Raynaud's phenomenon, and a photosensitivity rash. On the contrary, the anti-Sm antibody is associated with glomerular damage in some series and can fix complement in immune complexes. The prognostic value of overall anti-spliceosome antibodies remains unclear, although some authors relate anti-Sm antibody to worst prognosis of renal, vascular, and pulmonary disease (Isenberg et al. 2007; Rahman and Isenberg 2008; Greidinger et al. 2000).

Anti-Ro and Anti-La Antibodies

The targeting of exocrine glands by autoantibodies from the serum of a patient with Sjögrens syndrome led to the discovery of the Ro (SS-A) and La (SS-B) ribonucleoproteins. Ro consists of two peptides with 60 and 52 kDa that bind to cytoplasmic RNA and La is a phosphoprotein that binds to a variety of host and viral RNA. Unlike the anti-Sm antibodies, which are highly specific for SLE, anti-Ro and La autoantibodies have been reported with higher frequencies in Sjögren's syndrome and undifferentiated autoimmune rheumatic disease (UARD). The prevalence of anti-La antibody in SLE patients is less than 15 %, while anti-Ro antibody ranges from 25 % to 40 %, according to the assay used. For example, the anti-Ro 60-kDa antibody is seen mostly in SLE, while the anti-Ro 52-kDa antibody is almost exclusively found in Sjögren's syndrome and UARD. Their frequencies also depend on the detection assays used, given their susceptibility to be denaturated. Thus, ELISA and Western blot are the most efficient assays. Anti-Ro antibodies have been related to a high frequency of mucocutaneous symptoms, sicca syndrome, and photosensitivity. Intriguingly, anti-La antibodies were related to late-onset SLE and low incidence of renal complications (Isenberg et al. 2007; Rahman and Isenberg 2008; Peene et al. 2002).

A particular feature of these antibodies is their association with congenital heart block (CHB) and neonatal lupus, both prototypes of maternal-fetal autoimmune disease. These maternal autoantibodies pass through the placenta of about 1:20 mothers and bind to Ro/La antigens exposed in fetal cardiomyocytes, during apoptotic heart remodeling. They further disappear from the serum of infants at 6–8 months of age. Interestingly, although their mothers have these autoantibodies, they rarely develop SLE symptoms during or after pregnancy. These findings and the discordance of CHB in twins confirm that the pathogenic role of these autoantibodies is not understood (Isenberg et al. 2007; Zuppa et al. 2008).

Antibodies to Glycoproteins and Phospholipids

This heterogeneous family of autoantibodies recognizes several types of phospholipids, annexin V, prothrombin, protein C, and protein S, although their major target seems to be B2GPI. In 1995, the anti-B2GPI antibody was unequivocally related to thrombotic events and recurrent fetal losses. Secondary APS is mainly associated with SLE. In fact, lupus anticoagulant and anti-cardiolipin antibodies were found in patients with SLE. The pathogenic mechanisms of antiphospholipid antibodies are related to procoagulant and anticoagulant mechanisms, platelet activation, and inflammation. The association of IgG anti-cardiolipin antibodies with an increased risk of renal disease and of subendothelial deposits of anti-cardiolipin and anti-B2GPI antibodies to heart valve dysfunction and Libman-Sacks endocarditis reinforces the important linkage between antiphospholipid antibodies and cardiovascular and thromboembolic events in SLE patients (Isenberg et al. 2007; Núñez-Álvarez and Cabiedes 2011; Rahman and Isenberg 2008).

Antineuronal Antibodies

Antineuronal antibodies were first described in SLE patients in 1978, but their real role in neuropsychiatric lupus (NPSLE) remains unclear. Their overall prevalence in SLE patients is less than 10 %, increasing to 70–90 % in neuropsychiatric lupus. However, they lack specificity for SLE diagnosis, since they were reported in several neurologic diseases and can be detected using different sources of neuronal antigens, although the most promising target is the NMDA receptor, found mainly in the hippocampus and amygdala. These autoantibodies enter the cerebrospinal fluid by passive transfer through a permeabilized blood–brain barrier, or by direct intrathecal production, interfering in synaptic transmission or inducing apoptotic cell death. The mechanisms of their pathogenicity and the definitive relationship with SLE activity remain to be proven (Núñez-Álvarez and Cabiedes 2011; Rahman and Isenberg 2008; Colasanti et al. 2009).

Antibodies Related to Hemolytic Anemia and Immune Thrombocytopenia

Hematological disturbances are important manifestations of SLE, particularly, autoimmune hemolytic anemia due to autoantibody-mediated destruction of red cells, which may be present in the first years of the disease and related to thrombocytopenia (Evan's syndrome), lupus nephritis, and central nervous system manifestations. Although the prevalence of antibodies to red cells in SLE patients is found in <10 %, interestingly, these patients represent a subgroup with a fairly good prognosis, showing a good response to treatment. Up to 25 % of patients with SLE develop moderate to severe thrombocytopenia, by several mechanisms, including anti-platelet antibodies, ICs, antiphospholipid antibodies, and microangiopathy. These autoantibodies are found in less than 10 % of SLE patients, although their frequencies vary according to the detection techniques. Several membrane molecules have been suggested as potential targets, notably the glycoproteins IIb/IIIa and IV (Núñez-Álvarez and Cabiedes 2011).

The anti-dsDNA autoantibody was also correlated to thrombocytopenia, probably by a cross-reactivity phenomenon and CDR3 complementarity to glycoprotein IIIa, which was suggested to be an epitope mimicking dsDNA (Al-Shahi et al. 1997).

Antineutrophil Cytoplasmic Antibodies

Antineutrophil cytoplasmic autoantibodies (ANCAs) were first described in patients with necrotizing glomerulonephritis and have been associated mostly with the vasculitis, (e.g., polyangiitis with granulomatosis and microscopic polyangiitis). They bind to the myeloperoxidase and proteinase-3 of neutrophils contained in vessel walls, inducing their degranulation and further inflammation of the vessels. The phenomenon of vasculitis occurs in 35 % of patients with SLE, and ANCAs were frequently associated to nephritis and serositis. Higher levels of anti-myeloperoxidase antibodies seem to predict clinical relapse in SLE patients and longer active phases of the disease, reflecting long-standing inflammation. However, the role of ANCA in the pathogenesis of SLE remains uncertain since some patients with high ANCA levels do not develop SLE and most authors cannot dissociate the effects of ANCA from those of other antibodies found concomitantly in SLE patients (Sen and Isenberg 2003).

Anti-C1q Antibodies

Since the first discovery of an IgG against the circulating complement C1 complex in a patient with acquired angioedema, this antibody has been found in some patients with SLE and correlated with the duration and activity of this disease, especially in pediatric patients. There is also a strong correlation of the anti-C1q autoantibody levels to the activity of class III/IV lupus nephritis. Rising levels may predict renal flares.

Autoantibodies in Clinical Practice

Autoantibodies represent the hallmark of SLE and their use in clinical routine is of most importance in diagnosis, disease monitoring, and response to treatment evaluation.

The current revised ACR classification criteria include four autoantibodies: antinuclear, anti-Sm, anti-dsDNA, and antiphospholipid antibodies. All tests for anti-dsDNA antibody (*Crithidia luciliae*, BINDAZYME, FARRZYME) have moderate sensitivity and generally good specificity for SLE diagnosis, and are often best correlated with lupus nephritis. Other autoantibodies, notably anti-C1q and anti-nucleosome antibodies, are also linked to renal disease. In contrast, anti-Sm antibodies, though useful diagnostically, are not linked to renal disease (Isenberg et al. 2007; Heidenreich et al. 2009).

ANAs are a useful guide to the possibility of lupus in appropriate settings. For example, in a young woman presenting with polyarthritis and rash, whose rheumatoid factor is negative, the finding of positive ANA is likely to facilitate a lupus diagnosis. However, ANA positivity has been found after many infectious diseases and (usually in low titers) in some healthy people. Thirty to forty percent of lupus patients have antiphospholipid antibodies, but only 10–15 % have the clinical features (blood clots and miscarriages) usually associated with these antibodies (Isenberg et al. 2007; Núñez-Álvarez and Cabiedes 2011).

Other lupus antibodies may offer a guide to likely clinical features. Anti-RNPs are often linked to more overlap features (e.g., Raynaud's, myositis): anti-Ro to photosensitivity and neonatal lupus and anti-La to concomitant Sjögren's syndrome (Isenberg et al. 2007; Wandstrat et al. 2006; Peene et al. 2002; Zuppa et al. 2008).

The frequency of monitoring is also important. In terms of diagnostic confirmation, some autoantibodies are relatively stable over time, so it is not cost-effective to recheck them. Probably, around 15 % of SLE patients lose ANA positivity after diagnosis. Increasing titers of anti-dsDNA antibody accompanying a complement fall may predict exacerbations of renal and other disease manifestations. Measuring these antibodies is thus helpful in monitoring disease activity. However, there is a group of patients with persistently very high levels of anti-dsDNA antibody who remain clinically well, suggesting that not only are the levels important but also the isotype and subclass of immunoglobulin are essential to induce damage.

In conclusion, lupus patients have been associated with a wide variety of autoantibodies, though few are present in >30 % of these patients. Some are helpful diagnostically, while others point to likely clinical features. However, the precise mechanisms determining which antibodies will be truly pathogenic remain to be determined.

Lupus

Definition of SLE

SLE (systemic lupus erythematosus) is a complex, unpredictable waxing and waning autoimmune disease. It is characterized by unchecked immune responses that cannot be explained by known or treatable infection. Chronic and recurrent flares of disease can potentially damage many vital organs in the body

leading to significant impact on quality of life, morbidity and mortality (Renau and Isenberg 2012; Flower et al. 2012; Alarcón et al. 1999; Jakes et al. 2012).

Clinical Manifestations

The commonest features of lupus (found at some time in most patients with SLE) are polyarticular inflammatory arthritis and certain characteristic skin rashes. The arthritis has classic rheumatic features such as morning stiffness, bilateral symmetric pattern, and involvement of proximal hand and finger joints. As such, it may resemble rheumatoid arthritis, although it tends to be non-erosive. Nevertheless, severe ligament involvement (Jaccoud's arthropathy) can occur, leading to disabling dysfunction of the joints. There are a number of inflammatory rashes ranging from a relatively mild malar rash (acute cutaneous lupus, which can sometimes occur as a prodrome to systemic flares) to an exquisitely photosensitive and sometimes widespread pruritic rash (subacute cutaneous) and to deep, painful, and disfiguring chronic manifestations, including severely scarring discoid rashes. The classification criteria include many of the other clinical features of lupus, including other mucocutaneous manifestations, seizures and psychosis, serositis, renal involvement, hematologic and serologic abnormalities (Tan et al. 1982; American College of Rheumatology website 1997; Petri et al. 2012). However, patients can develop disease in almost any organ. Raynaud's syndrome, peripheral and central neuropathies, vasculitis, myositis, carditis, pneumonitis, autoimmune hepatitis, and cerebritis can all occur without warning.

The set of classification criteria for SLE most commonly used to define patients for recent clinical trials is the 1997 update of the 1982 American College of Rheumatology Revised Criteria for Classification of Systemic Lupus Erythematosus) (American College of Rheumatology website 1997). These criteria have recently been reevaluated by the Systemic Lupus International Collaborating Clinics against a modified system (Petri et al. 2012). Both are almost equally valid in describing a population that expert physicians would agree have SLE. The major changes in the newer SLICC 2012 criteria are improvements of logic. For example, it is less easy to be falsely classified with systemic disease when there are only a few focal skin criteria using the 2012 criteria. On the other hand, it is easier to receive a systemic classification with a more localized manifestation that puts a vital organ at risk such as when there is documented lupus renal involvement.

Although the term SLE has evolved to connote widespread bodily involvement, confusion has arisen by misguided attempts to separate primary lupus syndromes and overlap syndromes from SLE as if they represent non-intersecting diseases. Several serious and even life-threatening primary lupus disorders such as discoid lupus, the antiphospholipid syndrome, or acquired, autoimmune microangiopathy may occur without any other features of lupus, and in these patients SLE classification criteria would not be met. However, these disorders cannot be distinguished, either by pathology or clinical features, from manifestations of SLE. Patients with lupus may also develop, in addition to classic lupus pathology, clinical problems traditionally assigned to other diseases such as polymyositis or Sjogren's syndrome. Although such patients are often categorized as having overlap syndromes, many are assigned more than one diagnosis, without evidence that these individuals really experience two, unrelated forms of autoimmunity.

Why is this important? Treatment approvals by regulatory agencies are increasingly restricted to the types of patients in whom clinical trials are performed, such as recently occurred with the first lupus treatment approved in more than 50 years, belimumab (Medscape Summary 2011). Patients with certain overlap syndromes and/or primary lupus syndromes are frequently excluded from trials for "SLE" and may in turn be denied access to new treatments that might have helped them. The simpler and yet more comprehensive term, lupus, therefore may apply better to all meaningful patients: those who meet classification criteria for SLE, those with moderate to

severe primary lupus syndromes, and those with lupus overlap syndromes that most likely arise from one, integrated pathophysiologic process in that given individual. All of these patients have serious illness which might benefit from the targeted agents being developed toward ameliorating lupus pathology.

Costenbader et al. (2002) proposed the Boston weighted criteria for SLE to allow a more inclusive classification to include true lupus patients who may not meet the ACR criteria. This may be an important step in the right direction. These criteria have been used in several studies since then, most importantly in the large CDC epidemiologic effort that is currently underway, through which it may be compared to both the 1982 and SLICC classification schemes (Lim et al. 2009).

The term "lupus," however, should not be used to describe people who have autoantibodies without clinical autoimmune illness (which frequently occur transiently in infections or with no associated illness in older people), nor should the term "lupus" apply to those with the disorder known as fibromyalgia. There is no evidence that fibromyalgia shares pathology with lupus, but this has sometimes caused a great deal of confusion, since many lupus patients experience symptoms similar to fibromyalgia such as depression, fatigue, and body aches, despite the fact that there are various (and multifactorial) causes for such symptoms. The law of parsimony suggests that when these symptoms occur in a lupus patient, it is probably not fibromyalgia and when they occur in a fibromyalgia patient, it is definitely not lupus.

Diagnosis Based on Pathogenesis: Science Is Entering the Clinic

Lupus has long been considered a prototype disease of multisystem autoimmunity. However, autoimmunity is a nearly outdated term today, implying a feral immune system which is storming the individual it is supposed to serve. Nothing can be less therapeutic to a patient than the often heard message they receive that their body is "attacking itself." However, it is far more logical to assume that all immune responses are defensive, not aggressive, since they do occur inside the body of the host. Damage to organs then can be looked at as a collateral event, caused by a system that is out of balance, not rogue. In fact, the growing understanding of immunity supports this model of disease better than the self-flagellating version (Elkon and Casali 2008; Shlomchik et al. 2001).

The immune system is a complex army of interacting pieces with multiple feedback loops capable of dialing up or dialing down the movement of troops to ensure a flexible response to external threats (such as microorganisms and toxins) and internal threats (such as neoplasms and bodily debris). All immune responses are capable of doing some damage to the host, but this is normally kept in reasonable check by appropriate upregulation of immune suppressive elements and vascular sanitation systems which eliminate those triggers that might perpetuate inflammation. Lupus patients, those who can be thought to share a common diagnosis, appear to share a syndrome in which there may be persistent loops of immune triggering events coupled to inadequate immune down-modulation and incomplete elimination of the triggering elements.

This feature is shared by patients with SLE and with primary organ limited lupus such as primary cutaneous lupus, autoimmune hemolytic anemia, immune thrombocytopenia, autoimmune TMHA syndrome (microangiopathy), and the antiphospholipid syndrome (Asherson et al. 2008). Overlapping types of immunologic imbalance can also be found in diseases that are currently thought of as being "not lupus" (Theander and Jacobsson 2008; Finke et al. 2009; Rai and Wakeland 2011). Notable examples include Sjogren's syndrome, polymyositis, and autoimmune thyroiditis, all of which have manifestations that can occur, indistinguishable from their primary forms, in patients who meet the various classification criteria for SLE. Similar immune imbalance is not shared, however, by most people who present with an isolated positive ANA, osteoarthritis, depression, fibromyalgia, or chronic fatigue, all of whom

have some risk of being misdiagnosed with lupus. Thus, a case can be made, based on pathogenesis, that lupus, a disease that was originally defined at a time when very little was known about the underlying immune disorder, might be both underdiagnosed and overdiagnosed even by the best clinical standards.

In a circular fashion, the following are some of the elements that seem to play a role in significant subsets of lupus patients (Elkon and Casali 2008; Shlomchik et al. 2001; Pathak and Mohan 2011)

1. Activation of the innate immune system which may have a role in the increased interferon alpha signals seen in most children and about half of all adult patients with lupus.
2. Activation of specialized cells (especially but not limited to plasmacytoid dendritic cells) which make interferon alpha.
3. Stimulation of interferon alpha inducible genes, some of which might be genetic variants which are caused by or lead to increased lupus activity. The signaling pathways thus triggered then set off a cascade of inflammatory events.
4. Cell debris caused by vascular or organ inflammation is not disposed of quickly enough by a defective reticuloendothelial system. This leads to perpetuation of the interferon alpha cycle as ribonucleotides stimulate Toll-Like Receptors, leading to further signals to accentuate the interferon alpha pathways.
5. Autoantibodies against intracellular structures, which may play beneficial roles in a measured immune response, are increased, depositing in tissues and activating complement.
6. During this process, adaptive immune responses ramp up, activating both B cells, which play multiple roles in inflammation along with the stimulation of even more autoantibody production.
7. T cells, which tend to evolve in an asymmetric fashion leading to increased TH17 cells and decreased T suppressor cells.

Both B cells and T cells have complex interactions with myeloid cells (neutrophils, monocytes, macrophages) and myeloid-like cells in the skin, kidneys, and other organs, which add to inflammatory processes in the vasculature and solid organs, particularly the skin and kidneys. At the same time, these cells seem to underperform in their functions at cleaning up debris from dead and dying cells which then litter the vasculature, leading to perpetuation of the immune response. The combination of a relative weakness in immune-dampening and immune clearance elements coupled with ongoing triggers for inflammation favors the type of immune imbalance that characterizes a lupus flare.

Optimal Diagnosis Combines Clinical Features with Strategic Diagnostic Testing

Given the complexity of the disease and the unique ways in which it might manifest in different people, the diagnosis of lupus should only be made by an experienced rheumatologist based on a combination of clinical history, clinical findings, physical examination and blood tests, and/or additional diagnostic procedures. Diagnostic testing is evolving now, but remains limited, necessitating good clinical pattern recognition at the present time.

People with mild autoimmune syndromes are sometimes told they have SLE because a weak or circumstantial history may have been coupled to a positive ANA test which in and of itself does not signify any illness. Conversely, people with significant lupus may go many years without a diagnosis because no one has thought of this explanation for their unpredictable and sometimes sequential symptoms. Classification criteria are useful in understanding the range of features that may be most common in this disease, but they need to be distinguished from strict diagnostic criteria. A skilled rheumatologist may diagnose a primary or systemic lupus without strict adherence to the Classification Criteria and similarly may determine that a patient with minor manifestations of an adequate array of such features to meet the classification criteria does not have clinically significant lupus and does not warrant the diagnosis.

For many patients, a careful clinician might suspect lupus for some time before arriving at a definitive diagnosis. Although this can be frustrating to a patient who understandably wants a clear answer and definitive solution to what might be wrong, this is often the best way to ensure a person is properly monitored and treated without risking a lifelong misdiagnosis.

The Most Important Element of Diagnosis: Prognosis

What is in a name? Once a diagnosis is given, it is important for the clinician and the patient to understand that the severity of disease on a given day, in a given year, and over a lifetime will widely vary from person to person and may also change in an unpredictable manner in a single patient. This uncertainty embedded in the diagnosis can be quite frightening, so an important part of the diagnostic process (and in the communication of this process to the patient), is to generate a reasonable prediction of expectations and formulate a meaningful rationale for treatment choices.

Of course there is no crystal ball to predict for any individual with lupus what the final outcome of their disease will be. Race, lifestyle, current blood test results, and history may be identical today for two patients, one of whom will always have mild disease and the other who will develop severe disease. Nevertheless some modeling of demographic, serologic, and clinical risk for major flares, organ damage, and overall poor prognosis (if untreated) can be performed based on certain clinical features (Renau and Isenberg 2012; Flower et al. 2012; Alarcón et al. 1999; Jakes et al. 2012). For example, Ro (SSA) and La (SSB) antibodies, which are classic features of Sjogren's Syndrome, are associated with risk for subacute cutaneous lupus, and neonatal lupus syndromes (Buyon and Clancy 2003). Antibodies to dsDNA are associated with risk for renal disease and other severe lupus manifestations (Merrill and Buyon 2005). Anticardiolipin (or related prothrombotic antibodies) confer increased risk for thrombotic manifestations (Asherson et al. 2008). Younger patients and those of Hispanic, African, or Asian background may be at risk for more severe disease (Alarcón et al. 1999; Jakes et al. 2012).

However, none of these risks are 100 % and the absence of these features does not eliminate risk. Therefore, rather than using this prognostic knowledge to falsely reassure or upset people, this kind of profiling might suggest directions for monitoring and therapy and/or suggest that more aggressive treatments will be considered earlier for some patients and provide a rationale for giving milder treatments and/or simply monitoring others.

Given strong evidence for increased risk for atherosclerosis and accelerated atherosclerosis in patients with lupus (Kao et al. 2003), diagnostic attention to all conventional risk factors for heart disease and stroke is a cornerstone of treatment, and it may be best to ensure that patients are not undertreated for the inflammatory process. This should be the same for patients with mild, moderate, or severe disease, since chronic, even low-grade inflammation may play a major role in this major cause of long-term morbidity and mortality.

Conclusion

The concept of multisystem autoimmunity which underlies the name of systemic lupus erythematosus can be confusing and sometimes misleading. There are in fact a range of clinically significant lupus syndromes all of which are sometimes linked to multiple organ disease, but many of which can also stand alone as a *forme fruste* syndrome, without additional organ involvement. Other diseases that are not considered to fall within the range of SLE or lupus have major overlapping pathophysiology and clinical features and may even occur in patients with lupus.

The danger in restricting clinical trials to those patients who meet classification criteria for SLE is that treatments might be withheld from significant subsets of people who need them. It is also problematic that some people who are quite

unlikely to benefit from new medications developed for lupus, such as those with fibromyalgia or chronic fatigue, are sometimes misdiagnosed with lupus, indeed they sometimes legitimately meet the classification criteria by a technicality without having significant inflammatory pathology. For this reason, the diagnosis and care of patients with lupus should be in the hands of a clinician with significant training and experience in this disease.

An understanding of the pathophysiology of autoimmune diseases may help to inform diagnosis of lupus. Also intrinsic to the diagnostic process is an appreciation for certain imperfect, but nevertheless helpful prognostic features of the disease, since this may help to plan the best approaches to monitoring and treatment for individual patients. Diagnostic attention to all potential risk factors for atherosclerosis, a major cause of morbidity and mortality in this population, is equally important.

Lupus: Few Approved Treatments, Disappointing Trial Results

As discussed in the entry entitled "▶ Systemic Lupus Erythematosus, Clinical Features and Diagnosis," there are currently few FDA-approved treatments for lupus. There are exactly four. These are antimalarials, corticosteroids, aspirin, and, after a 50-year lag period, the monoclonal anti-BlyS antibody, belimumab, was approved in April 2011. Given the paucity of effective and affordable approved treatments, the standard of care for most patients remains treatment with off-label medications, many of which are supported only by rudimentary anecdotal literature (Dooley and Ginzler 2006). This situation might have rapidly resolved in the last 15 years, given the number of agents entering protocolized registrational development programs specifically for lupus. But this has not happened yet.

Even for belimumab, now approved by the FDA and other worldwide regulators, the differences between treatment and placebo groups in the pivotal Phase III trials were modest (Navarra et al. 2011; Furie et al. 2011). This should not have been surprising, regardless of how effective a treatment might be, since in these year-long studies, belimumab or placebo was added to a fluid roster of background medications, allowing significant adjustments in background treatment for substantial periods at the start of the study. It was thought at the time that this approach would provide the most ethical trial design, and address problems with high dropout rates in previous studies by allowing adequate treatment in both placebo and treatment arms for sustained, 52–76 week studies. However, given a natural ceiling on the percentage of patients likely to respond to any targeted treatment, these large Phase III trials which ensured a high "placebo" or background response were mounted under an understanding that the effect size was likely to be modest.

Therefore, regulatory approvals were given for this treatment in the context of small but scientifically persuasive differences between aggressively treated arms. Unfortunately, since then, there has been only modest progress in marketing the treatment. Community confusion over the data might be part of the problem. Additionally, resistance and road blocks have arisen from the third party payers based on the small effect size, the most notable example coming from the British National Institute for Health and Clinical Excellence (NICE) which supervises coverage for treatments and failed to approve belimumab payments for the entire UK (NICE website report 2011).

In addition to the limited success of belimumab, most of the Phase II and III trials of novel biologics for lupus have failed in clinical trials completely (Merrill 2009; Bruce 2010; Xiong and Lahita 2011).

This has left many questions unanswered. Is belimumab limited in efficacy and are all of these other treatments completely ineffective for lupus? Were the esoteric outcome measures being used in this complex disease too problematic to interpret? Were there potentially illuminating subsets of these heterogeneous patients that have not to date been well enough characterized? Was the ubiquitous use of a potpourri of

background medications in these many trials interfering with the assessment of the drugs under study? Although some exploratory analysis of failed trials suggests that any of these hypotheses might be true (Merrill 2009; Bruce 2010), the definitive answer is simply not known. The community is left in the aftermath of so many disappointing trials with at best (in the case of belimumab) modest and at worst (in the case of several other theoretically promising biologics, no evidence that these treatments work. On the other hand, the evidence that these agents do not work seems equally unsubstantiated, as will be discussed below.

The First Wave of Trials

The first modern wave of registrational multicenter clinical trials for SLE to study products aimed for the market were begun in the mid- to late 1990s. These included studies of the weak androgen dehydroepiandrosterone (DHEA) (Genelabs), an antagonist of CD40 Ligand, IDEC 141 (IDEC, later to become Biogen-IDEC) and multiple trials of the anti-dsDNA antagonist Riquent (La Jolla Pharmaceutical Company), all of which failed to meet their study endpoints (Petri et al. 2002; Kalunian et al. 2002; Cardiel et al. 2008).

The Phase II program DHEA was initially designed as a steroid withdrawal study, allowing patients with mild or no disease activity to undergo a taper supplemented by study medication or placebo. Steroid tapering was found to be quite successful in both the treatment and placebo groups, although some benefits were later found for those patients with at least mild disease activity (SLEDAI greater than two) at entry. Potential modest benefits of DHEA for bone mineral density were observed, but with overall disappointing results in a population that may not have been very ill to begin with, the development program was ended.

Although Biogen and IDEC later merged, they were both developing antagonists of CD40 Ligand in the 1990s. The Biogen program was halted prematurely but the IDEC study was completed, finding virtually no difference in any measurement between treatment and placebo (Kalunian et al. 2002). Since there was a substantial improvement in the placebo group, it was speculated that perhaps, the patients were not really sick enough to determine differences in this trial, reflecting the outcomes seen in the DHEA trials.

Riquent was an oligonucleotide construct on a polyethylene platform which targeted antibodies to anti-dsDNA. It was originally designed as a "toleragen," aimed at cross-linking surface antibodies on B cells, with the aim of selectively killing only the B cells that trigger production of harmful autoantibodies. However, the treatment also seemed to bind the far more prevalent epitopes on circulating anti-dsDNA antibodies, and it is likely these became, for all practical purposes, its real target. Could a significant decrease in anti-dsDNA antibodies prevent a new flare of renal disease?

The Riquent trials which began in the 1990s but lasted well into the next decade were primarily based on a flare design. Patients who were well at baseline, but with a history of renal disease and measurable anti-dsDNA antibodies, were randomized to treatment vs. placebo and tracked for renal and other types of flares. There was no difference between treatment and placebo in these studies (Cardiel et al. 2008) and eventually the treatment was dropped.

Although there was little to no evidence that any of these therapies had clinically significant efficacy, one important cautionary generalization emerged from these early studies, underscoring thinking in the design of future trials: If patients were not significantly ill to start with, it might be difficult to assess efficacy of a treatment. Therefore, in the next wave of trials, the primary effort was directed at including only patients with significant baseline disease activity.

The Second Wave of Trials

Both active nephritis patients and significantly ill non-nephritis patients were considered appropriate patients for the second wave of trial designs,

but in each case, it seemed clear that significant background medications would need to be given to ensure the safety of these patients. Therefore, it can be generalized that the "not so sick" patients of the first wave were now going to be replaced by more acutely ill and more aggressively treated patients. The results were the same. Most trials designed in this way found no differences between treatment and placebo in primary or secondary endpoints (Merrill 2009; Bruce 2010).

As has been widely discussed, the liberal background treatments used in these trials, especially some protocols containing mandated high-dose steroids, may have been excessive and at the very least were virtually guaranteed to narrow the gap between even a highly effective treatment and placebo. Two programs with more success were the Phase III belimumab studies as discussed above (van Vollenhoven et al. 2012) and the Phase II epratuzumab study (Wallace et al. 2010). In both of these cases, there were less mandated aggressive steroids than in some of the other studies. Additionally, some evidence supported the hypothesis that a greater effect size could be distinguished when either the sickest subsets of patients or those with less aggressive background therapy were analyzed separately (11,14,18). Thus, the overall narrow ratio of illness to treatment that plagued the first wave of trials may not have been completely solved in the second wave of trials, since overall, both the illness factor and the treatment factor were increased together.

The Next Wave: Can Background Treatments Be Decreased?

One possibility similar to the design that seemed to work well in the epratuzumab Phase IIb trial is to leave patients on their background medications at entry (with or without some limited optional steroids at entry) but without allowing an increase in immune suppressants, and then to have a primary outcome visit at a relatively early time point (as soon as the treatment agent is thought to work). Once the primary endpoint date is reached, patients who have not done well could then be treated for ongoing disease with increased medications and followed for the full year for safety. Sustainability of response could also be monitored in those who do not require additional treatments.

An alternative approach is to give steroids to the patients at entry, but immediately withdraw the background immune suppressants. Steroid tapering would be aimed at the expected time that it should take the test treatment to work. As soon as a patient has a significant flare, immune suppressants can be restarted, but since the subject will be considered a permanent nonresponder at that point, this cannot confound the primary outcome measure. This design has been tried in two small pilot studies and at least one Phase II trial with results forthcoming in the near future (clinicaltrials.gov listing a; clinicaltrials.gov listing b; clinicaltrials.gov listing c).

The latter design would obviously be inappropriate for patients with active nephritis or any severe organ-threatening disease, even with close monitoring, but could be appropriate for clinically stable patients with significant arthritis and/or rash. From an ethical point of view, there are pros and cons to designs in which background medications are withdrawn and to those in which they are left in place. The greatest risk in withdrawing immune suppressants seems likely to be lupus flares. However, if the patients are entered who are not responding to the medication they are taking at baseline, if enough steroid is given to improve their condition, and if it is not withdrawn too quickly or until the test treatment would be expected to work, there is only a minimal time during which an induced flare would be allowed to continue.

Compare this to a design in which a patient must stay on ineffective therapy for a year with minimal rescue options and the withdrawal study would be a far more comfortable option for the patients. Additionally, the benefit of the withdrawal option, besides eliminating the confounding biologic effects of disparate medications, might be fewer additive infection risks. This should not be underestimated since

unacceptable infection levels have caused the termination of trials for at least two biologics that were added to aggressive background immune suppression (pharmastrategy blog 2010; Ginzler et al. 2012).

Biology May Be Destiny in Lupus Trials

Given the known biologic and clinical heterogeneity of lupus patients (as discussed in the entry "▶ Systemic Lupus Erythematosus, Clinical Features and Diagnosis"), it is unlikely that any given targeted treatment will work for all patients with lupus or in any given patient under all circumstances, especially with the potentially confounding impact of background therapies. In any unselected group of patients, this puts a ceiling on potential efficacy. But does this mean that biologic subsets more likely to respond might be identified? Without hoping that any approach to select among these complex patients is likely to be 100 % effective, it seems likely that subsets who are more likely to respond to given targeted treatments than an unselected lupus population could certainly be sorted out. Interestingly, belimumab may have gained its modest success only because of a biologic prescreening of patients with significant titer autoantibodies for entry into the Phase III trials who might logically be more likely to benefit from B cell targeted therapy such as this agent. The potential for various disturbances in immune equilibrium by different background treatments, any one of which could be interfering with the observable effects of a given test treatment, may become an important variable in the design of future trials.

Another important consideration is the possibility that interruption of one pathway among the complex disordered signals in SLE could initiate additional problems. The underlying biology of response and nonresponse may differ among certain subsets of patients but it would make sense to try and characterize these changes early in the development process for a new biologic in order to optimize patient selection for the later, more expensive pivotal trials.

The Measurement Is the Message

Another unresolved issue in lupus clinical trials is whether the endpoints being measured are either accurate or clinically meaningful. In trials which included aggressive background treatments and an endpoint that defined nonresponse, at least in part, by a single mild flare (one BILAG B) at any given visit, the response rates for both the treatment and placebo patients were extremely low (20–30 %) (Merrill et al. 2010a, b). However, exploratory exploration of alternative endpoints showed that overall disease activity improved in both treatment and placebo groups in these studies. Although exploratory endpoints must be interpreted with caution, this illustrates the adage that the answers received depend on the question asked.

In the belimumab and epratuzumab studies, nonresponse depended on a more significant (and likely more clinically meaningful) measurement of disease (Wallace et al. 2010; van Vollenhoven et al. 2012). Both used composite responder indices and, importantly, a landmark analysis. Unlike the previous failed trials in which a minor flare midway through the study rendered permanent nonresponse, these studies allowed those with transient interim flares to be contenders for response at the subsequent visit and, most importantly, the primary endpoint date. Although there are issues with landmark analysis, not the least of which is the consistency of responses throughout the year, this can be partially addressed with a multiple landmark analysis, as was done for both the belimumab and epratuzumab trials.

Conclusions

On the basis of data from recent clinical trials in lupus, it can be hypothesized that there have been excessive background treatments used in many studies. Given the likelihood that there is a ceiling on the percentage of unselected, heterogeneous lupus patients likely to respond to any given targeted biologic, allowing an aggressive

standard of care in the background risks a high rate of "placebo group" efficacy, which, coupled to the potential for either positive or negative interactions with the mechanism of the test drug, is likely to minimize potential differences between placebo and even an effective treatment. In revisiting the ethics of a trial design in which patients are given novel biologics in addition to close to optimal standard of care, the downsides of excessive immune suppression, including risks for infection, should also be considered.

Optimal ethics would dictate a trial design that is both optimally safe from the point of view of disease flares and infectious risk, and optimally compatible with an interpretable efficacy assessment. If immune suppressant withdrawal could be coupled to a steroid burst and taper, this would ensure patient comfort and safety as the trial begins. If patients could then be treated in a timely manner at the time of any significant flare, but nevertheless allowed to continue in the study as a designated "nonresponder," this might become an even more ethical trial design than those which enforce the continuation of treatments that are not working at baseline and withhold rescue therapy during the latter phases of the study.

With an evolving understanding of variables introduced by the heterogeneous underlying biology of lupus patients, the impact of background treatments on the pathways affected by investigational biologics, and optimal endpoints to appropriately distinguish clinically meaningful differences between an effective treatment and placebo, it can be hoped that trial designs will become more effective and interpretable in the near future.

Synonyms

Neonatal autoimmune disease; Neonatal lupus

Definition

Neonatal lupus is a condition affecting newborns born to mothers with systemic lupus erythematosus who have anti-Ro and anti-La antibodies. The most important clinical manifestation of neonatal lupus is congenital heart block.

Introduction

Neonatal lupus is the archetype of a group of diseases known as neonatal autoimmune diseases. The neonatal autoimmune diseases include neonatal lupus, neonatal phospholipid syndrome, neonatal Graves disease, neonatal polymyositis and dermatomyositis, neonatal Behcet's disease, and neonatal Kawasaki disease (Chang 2012). The maternal autoantibodies in neonatal lupus are directed against the ribonucleoproteins (RNP) SS-A (Ro), SS-B (La), and less commonly U1-RNP (Harley et al. 1985). In neonatal antiphospholipid syndrome, the relevant antibodies are directed against cardiolipin and β2-glycoprotein-1. In many of these other neonatal autoimmune disease, the offending autoantibody has not been determined.

Historical Background

Congenital heart block was first described in 1901 (Morquio 1901). The first reports of an association between congenital heart block and maternal systemic lupus erythematosus appeared in 1966 (Hull et al. 1966). It was not until about a decade later that autoantibodies were detected in Sjogren's syndrome and systemic lupus erythematosus (SLE). These autoantibodies were originally found by immunodiffusion and were designated the precipitins SS-A, SS-B, and rheumatoid arthritis precipitins. Two antigenic Ro polypeptides were then reported, a 60 kd and a 52 kd polypeptide. These were designated as Ro60 and Ro52. An antigenic determinant of La that is implicated in congenital heart block is a 48kd protein which shares no homology with the SS-A/Ro polypeptides. The function of SS-B/La involves a role in maturation of RNA polymerase III transcripts and in the termination of transcription, and it appears to exist in a complex with 5S rRNA and tRNA, as well as

the SS-A/Ro polypeptides. An association between maternal autoantibodies to SS-A/Ro and SS-B/La was reported in the mid-1980s (Harley et al. 1985). More recently, anti-U1-RNP antibodies have been associated with neonatal lupus.

Epidemiology/Prevalence

The incidence of congenital heart block is estimated to be about 1 in 20,000 live births. Neonatal lupus occurs in about 1–2 % of offspring of mothers with systemic lupus erythematosus and who possess anti-Ro or anti-La antibodies. If the mother has previously had a child with neonatal lupus (presenting with congenital heart block, cutaneous manifestations, or both), the incidence of disease increases 10-fold (Buyon et al. 1998). A US registry of 325 neonates born to antibody positive mothers revealed a mortality rate of 17.5 % and a 10 year survival rate of 86 %. In neonates with only isolated heart block, the fatality rate was 7.8 %. Seventy percent of neonates required pacing. Risk factors for fatality include hydrops fetalis and endocardial fibroelastosis (Izmirly et al. 2011).

Clinical Presentation

The classical presentation of neonatal lupus is congenital heart block. Other cardiac manifestations may include cardiomyopathy, fetal pericarditis and myocarditis, endocardial fibroelastosis, transient prolonged QT interval, and sinus bradycardia. Structural cardiac anomalies such as patent ductus arteriosus (Stephensen et al. 1981), ventricular septal defects, atrial septal defects, and pulmonary valve stenosis are not commonly seen in neonatal lupus but have also been reported.

Cutaneous manifestations may occur in about 25–50 % of cases. These are usually self-limiting and resolve by about 6–8 months of life, corresponding approximately to the time when maternal antibodies disappear from the neonatal circulation. The rash is generally described as erythematosus annular lesions about 1 cm in diameter or as arcuate macules with slight central atrophy and raised active margins. The physical location of the rash usually includes the scalp and periorbital areas but may also involve other parts of the body including the trunk. In some cases there is a typical "Raccoon's eye" or "Owl's eye" appearance. The rash can be exacerbated by exposure to sunlight. Histologically, the rash has been described as similar to subacute cutaneous lupus erythematosus. Alternatively, the rash can present as telangiectasias.

Other system involvement includes the hepatic system, the neurological system, and the hematologic system. Hepatic manifestations can present in three ways, with the most mild being a transient elevation of liver transaminases. The most severe form is fulminant liver failure and the third form is hepatobiliary cholestasis without or with only mild elevation of liver enzymes. The hematologic manifestations can include thrombocytopenia, anemia, or neutropenia. Macrocephaly and hydrocephalus have been reported as neurological manifestations of neonatal lupus (Silverman and Jaeggi 2010). Chondrodysplasia punctata has also been reported as a skeletal manifestation.

Diagnosis and Differential Diagnosis

Unlike SLE, criteria for the diagnosis of neonatal autoimmune disease do not exist. The diagnosis, however, is not difficult to make from a clinical standpoint. The presence of anti-Ro or anti-La antibodies in a mother of a neonate with congenital heart block is easily detectable and reflects a high likelihood of the correct diagnosis. The search for these antibodies requires a high index of suspicion. Other non-cardiac manifestations may support the diagnosis, and the family history of having a previous child with neonatal lupus also helps, since the incidence of neonatal lupus increases about 10-fold in the face of a previous child with the disease.

The differential diagnosis of the rash may include urticaria, seborrheic dermatitis, erythema

annulare centrifugum, erythema multiforme, annular erythema of infancy, erythema marginatum, and tinea corporis. The presence of an immune response to the 50kd La protein as well as U1-RNP seem to confer risk of developing cutaneous symptoms, while antibodies to the classical 60kd Ro and 52kd Ro proteins are more likely associated with complete heart block (Yukiko 2000).

Other Neonatal Autoimmune Diseases

Another well-described neonatal autoimmune disease is neonatal antiphospholipid syndrome. It is a rare disease but can be associated with a significant increase in fetal and neonatal mortality. There have been very few reports of thrombosis as a result of antiphospholipid syndrome, but more commonly, morbidity is related to poor fetal growth, premature labor, preeclampsia, and thrombocytopenia (Abrahams et al. 2012). The pathophysiology of neonatal antiphospholipid syndrome is not well understood.

Pathogenesis

The role of autoantibodies in the pathogenesis of neonatal lupus is still undetermined. The search for a cross reacting cardiac antigen has revealed that L-type calcium channels may interact with the anti-Ro or anti-La antibodies and that this may impact normal cardiac conduction, leading to heart block. But this still does not explain why only a small percentage of neonates born to mothers with these autoantibodies develop congenital heart block.

The primary theory behind the pathogenesis of neonatal lupus involves the concept of apoptosis. Apoptosis is already believed to play a role in both systemic lupus erythematosus and drug-induced lupus, albeit through different pathways and with different effects (Chang and Gershwin 2011). In the case of neonatal lupus, apoptosis may lead to the migration of Ro and La antigens from the nucleus to the cell surface, thus presenting them for binding with autoantibodies from the mother. The timing of these events may be a potential reason why not all mothers with these autoantibodies bear a child with congenital heart block. However, even if an interaction between maternal autoantibodies and the corresponding antigens in the fetus or neonate occurs, that does not necessarily indicate that this is the pathogenesis of disease. One theory is that Ro and La have no other significance other than they lead to the generation of an immune complex with the corresponding maternal autoantibodies, and rather, it is the resulting inflammation in the heart tissues in proximity to these immune complexes that results in damage to structures instrumental in cardiac pacing, such as the atrioventricular node. Another possibility is that there is immunologically cross reactivity between the molecules Ro and La and critical proteins that are engaged in normal cardiac conduction, as in the case of the aforementioned L-type calcium channels (Boutjdir 2000). Interestingly, β2-glycoprotein 1 appears to confer a protective effect for the development of congenital heart block in anti-Ro and anti-La positive mothers (Reed et al. 2011).

Further studies have defined a p200 epitope of Ro52 that encompasses amino acids 200–239 as a target of autoantibodies. p200-autoantibodies have been found to be present at higher levels in mothers of children with all degrees of severity of atrioventricular block (Strandberg et al. 2008). While this may not help establish a cause and effect relationship between the autoantibodies and disease nor may it not help explain the role of Ro52 in the pathogenesis, it does have the potential to provide clinicians with a serologic marker that can help define the risk of developing congenital heart block.

The role of T cells in the development of neonatal lupus is complex. The populations of the various T cell subtypes in cord blood have been studied, and it appears that regulatory T cells are deficient, which contradicts the belief that the neonatal immune system is overall tolerogenic. In other words, reduced regulatory T cell function allows for a more immunogenic immune system. However, this may actually

reflect a window of opportunity to develop autoimmune disease, which occurs when there is a sufficiently unregulated T cell response coupled with the appearance of maternal autoantibody in the fetus and the appearance of autoantigen on the surface of apoptotic cardiac cells. It is only when these conditions are met that autoimmunity occurs. This theory is highly speculative, but it is interesting to note that Setiady et al. were able to artificially manipulate the development of autoimmune ovarian disease (AOD) in mice by transfer of adult populations of T cells either rich or deficient in CD4 + CD25+ regulatory T cells (Setiady et al. 2005).

Neonates have also been shown to have increased inhibitory receptor expression on their immune cells, probably to facilitate the development of tolerance. Examples of these inhibitory receptors are CD31, leukocyte-associated immunoglobulin (Ig)-like receptor-1 (LAIR-1), signal-regulatory protein alpha (SIRPa), CD200, and others. While there is no evidence that these are reduced in neonates who develop congenital heart block, this is a valid consideration for future investigations into the role of T cells in this disease.

Innate immunity may play a role in neonatal lupus. Pattern recognition receptors such as toll-like receptors (TLRs) are an integral part of the innate immune system, which is critical for early protection against dangerous entities, such as microbes. A role of TLRs in rheumatic diseases stems from a defective ability to distinguish between self and dangerous antigens, and nucleic acids have been found to be able to act as ligands for TLRs. In the case of neonatal lupus, it is possible that the formation of an interaction between TLRs and Ro or La leads to activation of innate immunity and the production of a not necessarily healthy response to the nuclear antigen, leading to clinical manifestations of heart block and other signs of neonatal lupus.

This role of TLR in the pathogenesis of neonatal lupus may perhaps explain why antimalarial drugs such as hydroxychloroquine may have clinical benefits, since these drugs have been shown to inhibit interferon-γ-dependent TLR-7 activation, and TLR-7 has been found to play a role in mediating inflammation in congenital heart block patients (Clancy et al. 2010a).

Genome-wide association studies (GWAS) have identified two candidate loci at the HLA region 6p21 and the non-HLA region 21q22 to be risk alleles for the development of congenital heart block (Clancy et al. 2010b). Earlier HLA studies suggest that HLA-Cw3 may be associated with neonatal lupus, but this association has not been confirmed.

Prognosis

The progression of congenital heart block is variable. In the cases of milder forms of congenital heart block, there is usually no progression to more severe forms. However, neonates who have second degree heart block or worse will usually progress to complete heart block. Over 90 % of this group of neonatal lupus patients will eventually require cardiac pacing. Management and treatment measures, as outlined below, are not successfully in reversing this trend. In cases were heart block is severe, there may be involvement of cardiac muscle, leading to cardiomyopathy and fibrosis with a corresponding significantly higher morbidity and mortality. It is not yet clear whether neonates with congenital heart block are more prone to developing autoimmune diseases later in life. It is also not known if there is an increased incidence over that which would be expected from the family history of the mother alone. Interestingly, neonates with congenital heart disease can be born to mothers without lupus who have antibodies to Ro and La, and these women almost always develop autoimmune disease subsequently. In these cases, the diagnosis of neonatal lupus may be the first indication of autoimmune disease in the mother.

A 25-year follow-up study of the long-term prognosis of congenital heart block indicates that the majority of patients are able to lead normal and productive lives and are able to carry a child to term (Capone et al. 2012). Most cases are diagnosed at birth and pacemaker management is instituted early. Clearly, if there

is associated myocardial disease that is not treated, then the morbidity and mortality increases significantly.

Management

The management of neonatal lupus is generally supportive. Agents used have included corticosteroids, intravenous immunoglobulin (IVIg), and hydroxychloroquine. Results are inconclusive. Studies using corticosteroids have not demonstrated that prenatal administration to the mother or postnatal administration can prevent the progression of heart block (Friedman et al. 2009). However, there is some indication that the morbidities of heart block, including pericarditis, myocardiopathy, pleural effusion, hydrops, and other serious complications may be prevented. One must also consider the potential adverse effects of corticosteroids on the fetus, depending on the dosage administered.

The use of intravenous immunoglobulin (IVIg) has also been extensively studied in the treatment of congenital heart block. IVIg 400 mg/kg given in the second trimester (12–24 weeks) did not reduce the incidence of 2nd or 3rd degree cardiac block (Pisoni et al. 2010).

Based on previous experience with the use of antimalarials for rheumatic diseases, hydroxychloroquine has also been studied in neonatal lupus. Early studies showed that hydroxychloroquine was able to reduce the risk of congenital heart block if it was given before 16 weeks of gestation. Furthermore, in a historical cohort study of 257 pregnancies to mothers with positive anti-SSA/Ro titers and a history of a previous child with congenital heart block, being treated with hydroxychloroquine was associated with a significantly reduced risk of recurrent congenital heart block (7.5 % recurrence rate in the hydroxychloroquine-treated group versus 21.2 % in the non-treated group) (Izmirly et al. 2010).

Mothers who are at potential risk for developing a child with neonatal lupus should be screened for autoantibodies to Ro and La. Fetal echocardiograms should be performed to determine if heart block exists and for any complications of heart block. Cardiac pacing is an important facet of the treatment of neonatal lupus, both postnatally and prenatally with invasive fetal pacing to prevent hydrops. Overall, about 60–70 % of congenital heart block patients will ultimately require cardiac pacing. This figure is higher in patients with 2nd or 3rd degree heart block.

Family counselling and planning are important aspects of the management strategy for neonatal lupus. The family should be educated on the probability of having a child with neonatal lupus and how this may impact the family. If the mother has had a history of a previous child with neonatal lupus, then she should be counselled regarding the much higher risk of having another child with congenital heart block. The parents should also be advised on how the fetus may be monitored during the prenatal period and what to expect after the child is born. Mothers with systemic lupus erythematosus can have very successful pregnancies but need to be informed of the risks with a great deal of sensitivity, empathy, and support.

Conclusion

The most important clinical manifestation of neonatal lupus is heart block. This is the main cause of death. Other clinical manifestations are usually self-limiting and do not usually result in mortality or long-term morbidity. The cardiac manifestations of neonatal lupus can be variable, ranging from first-degree heart block to complete heart block. Hydrops fetalis is a significant complication if heart block occurs in the prenatal period.

The pathogenesis of neonatal lupus is unknown. Molecular mimicry mechanisms involving autoantibodies to Ro and La may or may not play a role in pathogenesis, and other mechanisms may be involved, including apoptosis, maternal microchimerism, and genetic factors.

The management of neonatal lupus involves supportive care. Studies using corticosteroids,

intravenous gamma globulin have yielded equivocal results. The use of hydroxychloroquine appears to be more efficacious. The more severe cases of congenital heart block ultimately require cardiac pacing.

Definition

Systemic lupus erythematosus (SLE) is a chronic autoimmune disease which afflicts mainly women in the reproductive years and leads to significant morbidity and mortality. The disease follows an unpredictable relapse-remission type of course with variable phases of disease quiescence interrupted by sporadic flares of intense disease activity. The production and deposition of autoantibodies and inflammatory cell infiltration lead to damage of multiple target organs such as the skin, kidneys, and brain. Deregulation of both innate and adaptive arms of the immune system contributes to the disease pathogenesis. While the exact cause of SLE is not known, a combination of genetic and environmental factors (UV radiation, drugs, hormones, etc.) is thought to be responsible for the onset and severity of disease.

X Chromosome and Sex Hormones

Ninety percent of patients afflicted with SLE are women, indicating that the female gender is an important factor in disease development. The gender bias in SLE reflects the role of sex chromosomes as well as sex hormones. A skewed X chromosome-inactivation pattern, sex hormone defects, and reproductive history are factors that contribute to the breakdown of tolerance leading to autoimmunity (Selmi et al. 2012). Several X chromosome defects have been reported in patients with SLE. These include gene translocation causing triplication of genes, X duplication with an increased incidence of SLE in males with Klinefelter's (XXY) syndrome, and demethylation of genes such as CD40L on the X chromosome, resulting in overexpression of CD40L. The importance of the X chromosome was shown in a pristane-induced model of lupus wherein the XX sex chromosome complement conferred increased susceptibility to disease over the XY^{-} mice (Selmi et al. 2012).

The disease manifests predominantly in the reproductive phase such that before puberty, the female to male prevalence is 3:1, which increases to 9:1 after the onset of puberty, implicating the role of sex hormones in disease pathogenesis. Further, evidence points to an increased estrogenic environment in both men and women with SLE. Historically, animal studies using both NZB/NZW and MRL/lpr mouse models of lupus have shown that lupus-prone female mice succumb to disease sooner than male mice. Early studies performing gonad removal (ovaries or testicles) with subsequent improvement or worsening of disease suggested the important role of hormones. Female mice survived longer after ovariectomy than castrated male mice. Administration of estrogen worsened the disease, while androgen supplements improved the disease in both female or male castrated mice (Lahita 1999, 2011). While serum estrogen levels are not significantly altered in patients with SLE, androgen levels are found to be significantly lower. There appears to be an increase in estrogen metabolism in SLE. Increased levels of the feminizing 16-hydroxyestrone and estriol metabolites occur in the serum of patients resulting from an increased oxidation of the androgen precursor dehydroepiandrosterone (DHEA). On the other hand, androgen levels specifically DHEA are low in lupus patients. Besides estrogen, the female hormone prolactin is associated with worse renal disease in lupus-prone mice, while the prolactin inhibitor bromocriptine improved disease and prolonged survival in these mice (Lahita 1999).

Estrogen and Immune Responses

Estrogen is known to regulate the immune system by modulating cytokine production. Cytokine abnormalities are an important component in the aberrant immune response in patients with SLE. The immune response in SLE is characterized by a switch from a T helper (Th) 1 to a Th2 type of cytokine environment such that cytokines interleukin (IL)-4, IL-6, and IL-10 are increased while IL-2 and IFN-γ are decreased in serum from patients. High doses of estrogen are known to promote Th2 cytokine (IL-4, IL-10, TGFβ) production. In contrast, estrogen suppresses the Th1 (IL-12, TNF-α, IFN-γ) cytokines. In the lupus-prone NZB/NZW mice, high serum estrogen levels correlated with low IL-2 levels. Furthermore, estrogen treatment increased TNF-α and IL-6 levels after lipopolysaccharide (LPS) challenge in both normal and lupus-prone MRL/lpr mice, and these effects were reversed by the selective estrogen receptor modulator tamoxifen. Animal studies have shown that mice treated with synthetic estrogen were susceptible to *L. monocytogenes* bacterial infection and their splenocytes produced less IL-2, while increased IL-17 production was seen in splenocytes from estrogen-treated mice (Salem 2004; Kassi and Moutsatsou 2010).

While hormones especially estrogens are important contributors in the expression of disease, their exact molecular role and mechanisms of action are still poorly understood. Some of the first direct molecular evidence into the role of estrogen in autoimmunity came from studies performed in non-autoimmune mice transgenic for the heavy chain of a pathogenic anti-dsDNA antibody. Estrogen upregulates expression of the antiapoptotic molecule Bcl-2 and promotes survival of autoreactive B cells, allowing their escape from tolerance induction (Cohen-Solal et al. 2008). Furthermore, estrogen enables the survival and persistence of autoreactive T cells by downregulating FasL and suppressing activation-induced cell death of human SLE T cells (Lang 2004). Studies performed in human peripheral blood T cells have shown that estrogen increases the expression of calcineurin mRNA and the encoded protein phosphatase (PP) 2B activity in an estrogen receptor-dependent manner. PP2B induces dephosphorylation of the nuclear factor of activated T-cell (NFAT) transcription factor and subsequent nuclear translocation and binding to target genes such as CD40L. Estrogen may contribute to the increased T-cell cognate help to autoreactive B cells, as estradiol administration was shown to upregulate the expression of CD40L in T cells from lupus patients but not healthy individuals (Rider and Abdou 2001). Exposure of normal human peripheral blood T cells to estradiol led to increased expression of the transcriptional repressor cyclic AMP response element modulator (CREM) alpha and suppression of IL-2 cytokine production (Moulton and Tsokos 2012).

Dendritic cells (DC) are initiators of the innate as well as adaptive immune responses and abundantly express the pattern recognition toll-like receptors (TLR). TLR7- and TLR9-deficient lupus-prone mice exhibit reduced disease, indicating that TLRs are important in lupus pathogenesis. DCs are defective in SLE in both humans and mice, exhibiting an overstimulated phenotype and function, with increased expression of major histocompatibility complexes (MHC) as well as costimulatory molecules CD80/86 (Kis-Toth and Tsokos 2010). Estrogen can modulate DC differentiation and function in several ways – alter the expression of MHC proteins, costimulatory molecules, or TLR; regulate cytokine production by DCs directly or indirectly via other cell types; and modulate migratory function through changes in cytokine or chemokine production. Furthermore, estrogen is required for the activation and differentiation of DCs, specifically those bearing features of a Langerhans cell-like DC (Nalbandian and Kovats 2005).

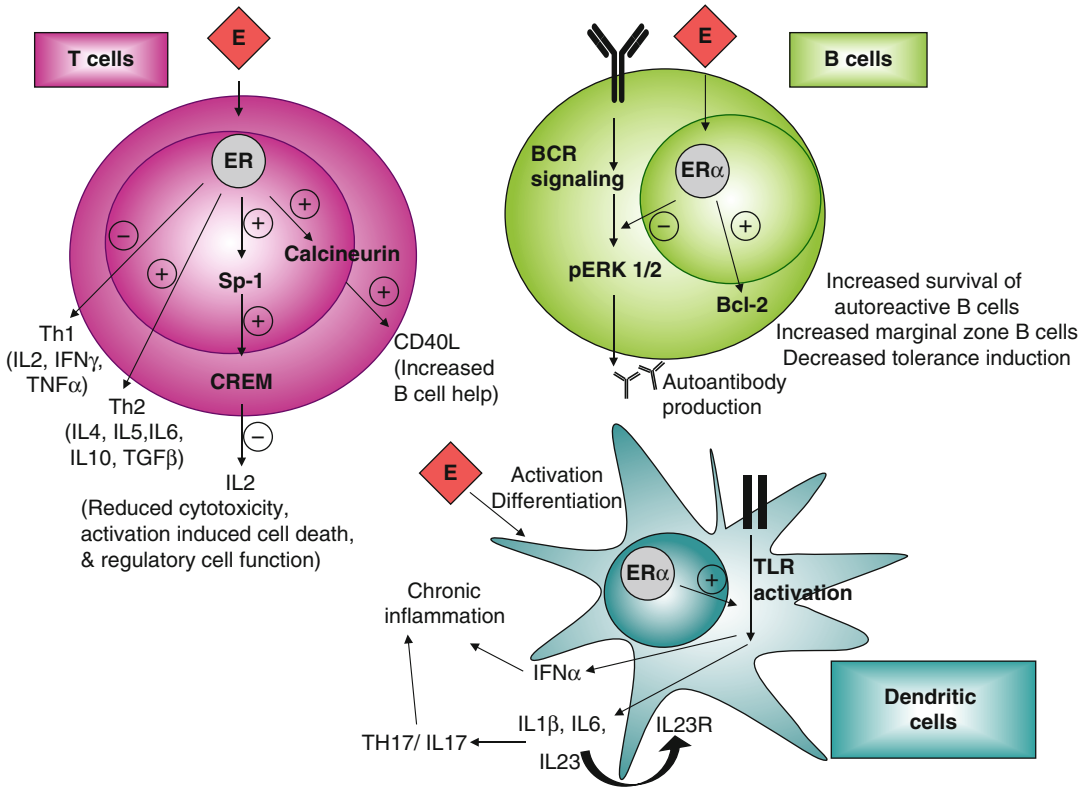
Besides the direct role of estrogen on the immune system, another interesting theory proposes that the regulatory mechanisms that normally control the estrogen-induced excitation of the immune response may be abnormal in SLE patients. To this end, DNA microarray analysis of genes expressed in the peripheral blood

mononuclear cells (PBMC) during the menstrual cycle of healthy women was compared to those from women with SLE and showed interesting differences. Specifically tumor necrosis factor receptor superfamily member 14 (TNFRSF14) (synonym: Herpes virus entry mediator HVEM) was found to be increased in correlation with increasing serum estrogen levels in healthy women but not in SLE patients. TNFRSF14 is a ligand for B and T lymphocyte attenuator (BTLA), an inhibitory receptor which dampens lymphocyte activation and is important in maintaining immune homeostasis. These results suggest that the mechanisms that regulate the immune-activating effects of estrogen may be defective in SLE patients (Sekigawa et al. 2010).

Estrogen Receptors

SLE patients experience increased disease activity and flares during pregnancy; however, in some studies, hormone levels were found to be lower in pregnant women with SLE as compared to healthy pregnant women. Thus, it is unclear if hormones alone determine disease activity (Walker 2011), rather the sensitivity of immune cells to hormones may be equally or more important. In this regard, the role of estrogen receptors (ER) and their contribution to disease are emerging. ER alpha (α) and beta (β) belong to the steroid hormone receptor superfamily and are intracellular receptors expressed in most immune cells including T cells, B cells, monocytes, and dendritic cells (Fig. 1). Estradiol diffuses through the cell membrane and binds to the ER which leads to the homo- or heterodimerization of the ER which then bind with high affinity to consensus estrogen response elements (ERE) sites within target genes, thus functioning as transcription factors to regulate gene expression. Besides the direct binding to target genes, ER-mediated regulation of gene transcription can occur indirectly via other proteins and can be ligand dependent or independent. The ER can act as a transcriptional co-activator and bind to other transcription factors such as specific protein 1 (Sp1), activator protein (AP)-1, or nuclear factor kappa-light-chain enhancer of activated B cells (NF-κB). Besides the conventional intracellular ER, membrane-bound G protein-coupled receptors (GPR30) and cytoplasmic receptors have been identified which upon estrogen ligation can induce rapid intracellular calcium fluxing and intracellular signaling in various cell types. Interestingly, the ER can function in gene regulation in a ligand-independent manner – for example, extracellular stimuli such as insulin, IGF1, EGF, and TGF-β can lead to ER phosphorylation by MAP kinases and result in gene transactivation (Nilsson et al. 2001).

ER-α is required for hematopoietic and stromal development of a full-sized thymus in both male and female mice, and estrogen regulates CD4+CD8+ double-positive T-cell development which requires both ERα and ERβ. Estrogen can stimulate the production of regulatory T cells as it induced the expression of FoxP3 and IL-10 genes and promoted conversion of CD4 CD25- T cells to CD4CD25+ T regulatory cells, and this conversion was blocked by the ER antagonist ICI 182, 780. Several studies have highlighted the role of the ERs in lupus (Cunningham and Gilkeson 2011). In murine lupus studies, the ERα appears to be critical in disease pathogenesis; deficiency of ERα alone led to autoantibody production and reduced renal disease and prolonged survival in lupus-prone mice. Studies using estrogen receptor α- and β − deficient animals have shown that while both receptors regulate B-cell maturation, ERα engagement is responsible for the estrogen-induced dampening of the BCR signaling and B-cell selection and thus an important trigger for autoimmunity (Cohen-Solal et al. 2008; Cutolo et al. 2010). A ligand-independent role of the ER in the innate immune response in SLE has recently been proposed. Reduced TLR9-mediated inflammatory cytokine (IL-6, MCP-1, IL-1b, and IL-23) production was observed from DCs of both wild-type and lupus-prone ERα-deficient mice. Further, ERα-deficient DCs failed to upregulate IL-23R compared with wild-type DCs, suggesting that ERα may modulate the TLR induction of the IL-23/IL-17 pathway. These studies suggest



Systemic Lupus Erythematosus, Gender and Hormone Influences, Fig. 1 Diagram illustrating select roles of estrogen and estrogen receptors in the T cells, B cells, and dendritic cells in SLE (Adapted from Moulton and Tsokos 2012 with permission)

a cross talk between the ER and the TLR signaling that may occur in the absence of estrogen (Moulton and Tsokos 2012).

Hormone Therapy

While estrogen and estrogen receptors are potential culprits in SLE, estrogen has significant health benefits especially in bone metabolism and is crucial in osteoporosis treatment in postmenopausal women. Clinical trials have administered hormone replacement therapy in postmenopausal women and shown benefits in osteoporosis. The Safety of Estrogens in Lupus Erythematosus National Assessment (SELENA) studies, large multicenter randomized placebo-controlled clinical trials comprised of two separate arms – one of hormone replacement therapy and the other of combined oral contraceptive therapy in women with SLE. Results of these trials showed that hormone replacement therapy in postmenopausal women with SLE was associated with a small risk of mild to moderate flares. Historically, women with SLE were prohibited from using oral contraceptives for fear of exacerbating disease. However, the SELENA trials found that the use of combined estrogen-progesterone oral contraceptives in premenopausal women did not significantly increase the risk of flares in women with stable disease. However, caution must be exercised when considering hormone therapy in patients with SLE. For example, exogenous estrogen therapy should be avoided in patients with antiphospholipid antibodies due to the increased risk of thrombosis. Clinical trials have shown some utility of prescribing DHEA to patients in

terms of tapered prednisone doses, improved disease activity, and fewer flares. These studies indicate that the use of oral contraceptives and hormone therapy may be beneficial and warranted at least in some patients with SLE (Schwarz and Lohr 2006; Lateef and Petri 2012).

While the role of hormones and their receptors in autoimmunity and lupus disease pathogenesis is beginning to be uncovered, further molecular mechanistic studies are needed to understand and modulate these important contributors of disease.

Definition

Systemic lupus erythematosus (SLE) is a complex, autoimmune disease characterized by the presence of antibodies to nuclear components. Genetic and environmental factors interact and contribute to the immunologic manifestations and development of disease, which can involve the skin, joints, hematologic system, kidneys, nervous system, mucosal and serosal membranes, and/or other organs.

Introduction

The importance of a genetic component in the pathogenesis of SLE has been implied for several decades based on early epidemiologic and genetic studies, particularly in multiplex families (Deng and Tsao 2010). Initial work confirmed several genetic signals utilizing methods such as linkage analysis and candidate gene association analysis. Our understanding of the genetic contribution to pathogenesis of disease in SLE has been greatly advanced, especially by recent genome-wide association (GWA) studies in populations of European and Asian ancestries (Sestak et al. 2011). In the vast majority of cases, SLE fits the common disease-common variant hypothesis, in which non-rare risk variants lead to a modest magnitude of risk (odds ratios of 1.1–2.5) and account for a portion of overall genetic susceptibility to disease. High-throughput genotyping platforms designed to identify common variants have been used in, to date, seven GWA studies (four in European-derived populations, three in Asians) and in a series of large-scale replication studies of individuals of European, Asian, African-American, and Amerindian/Hispanic descent. Many loci identified or confirmed by these studies are located either within or near genes encoding products with functional relevance to the pathogenesis of SLE (Guerra et al. 2012), providing an opportunity to potentially elucidate disease pathophysiology, predict disease course, and suggest drug targets. The nature of the complex pathophysiology of SLE has been underscored by many promising genetic susceptibility candidates from nearly all aspects of the immune system. In the summary below, those SLE susceptibility genes which have reached genome-wide significance, after correcting for multiple testing (Pe'er et al. 2008), are described.

Common SLE Susceptibility Genes Among Ancestral Backgrounds

Most identified SLE-associated risk loci are common genetic variations shared among multiple ancestral populations, suggesting their likely role in disease susceptibility and pathogenesis worldwide (Lee and Bae 2010; Scofield and Kaufman 2012). The variability between ancestral groups in frequencies of certain disease manifestations, including decreased risk of lupus nephritis in European backgrounds compared with Amerindian, Asian, and African-American descent (Richman et al. 2012), may be explained by divergent genetic effects of SLE susceptibility genes. For example, an increased effect size for several SLE loci has been observed in Amerindian compared with European ancestry (Sanchez et al. 2010) and in southern Europeans compared with central Europeans (Alonso-Perez et al. 2012). Variability in allelic frequency, differences in allelic linkage, the impact of gene-gene interactions, and particular environmental exposures may all contribute to such observed differences in ancestral groups, as well as limits of study design. Ongoing research in this area may ultimately provide important insight into both the common pathways leading to SLE manifestations, as well as more personalized risk profiles based on specific ancestral and genetic background.

Genotype-Phenotype Effects in SLE

Genotype effects may have an impact on SLE manifestations and disease course. For instance, an association between certain SLE susceptibility

genes, such as *ITGAM* (integrin alpha M or CD11b), *TNFSF4* (tumor necrosis factor superfamily, member 4), and *STAT4* (signal transducer and activator of transcription 4) (Sanchez et al. 2011), with the development of lupus nephritis has been suggested by several studies. Robust evidence has shown the *ITGAM* R77H risk allele conferring higher risk for lupus nephritis in case-only analyses of SLE patients of European and Asian ancestry. This integrin variant results in impaired phagocytosis and antigen-presenting cell adhesiveness to ICAMs (intercellular adhesion molecules) and complement factor iC3b, possibly resulting in decreased immunosuppressive effects and increasing SLE susceptibility. The possibility of "autoantibody propensity loci" which may further influence disease subphenotype is supported by the association between *IRF5* (interferon regulatory factor 5) risk haplotype, autoantibody production, and increased interferon (IFN)-α activity, whereby the impact of *IRF5* haplotypes on IFN activity is influenced by the presence of specific autoantibody subsets (Bronson et al. 2012). There may, in fact, be baseline increases in IFN activity based on *IRF5* haplotype leading to increased risk for development of autoantibodies and autoimmune disease (Rullo et al. 2010). Learning more loci to account for heritability will enhance the link between genotype and phenotype in SLE.

Immunological Pathways Affected by SLE Susceptibility Variants

Current understanding of SLE pathogenesis can group several identified SLE susceptibility genes into major immunological pathways. Certain immunological pathways, including the well-established *HLA* genetic region (Relle and Schwarting 2012), are common to multiple autoimmune disorders. A growing number of additional SLE susceptibility genes also predispose to other related conditions. An example to highlight is *TNFAIP3* (tumor necrosis factor, alpha-induced protein 3), which encodes the ubiquitin-modifying enzyme A20, a control mechanism that can terminate prolonged activation of inflammatory responses. The widely expressed A20, a cytoplasmic enzyme, regulates NF-κB (nuclear factor-KappaB)-driven gene expression after TNFR (tumor necrosis factor receptor), IL-1R (interleukin 1 receptor), and TLR (toll-like receptor) signaling, leading to altered dendritic cell homeostasis. Several SNPs in the A20 genomic locus have been found to be associated with chronic inflammation and increased susceptibility to SLE, rheumatoid arthritis, systemic sclerosis, type 1 diabetes, Crohn's disease, and multiple sclerosis (Vereecke et al. 2011).

DNA Degradation, Apoptosis, and Clearance of Cellular Debris

An abundance of self-antigens due to inappropriate disposal of intracellular constituents or infectious agents can initiate and drive aberrant immune responses in SLE. Several variants of genes related to these pathways contribute to both monogenic and polygenic forms of SLE (Table 1). Some examples include:

- *TREX1* (three prime repair exonuclease 1): Deep sequencing of this gene identified novel mutations in patients with SLE but not controls; common variations of *TREX1* are also associated with SLE (Bronson et al. 2012). Deficiency of TREX1, an exonuclease involved in cell death, DNA degradation, and cellular response to oxidative damage, typically leads to Aicardi-Goutieres syndrome, a neurologic condition characterized by increased IFN-α and varied autoimmune phenomenon.
- *ACP5* (acid phosphatase 5, tartrate resistant): Mutations in this gene lead to elevated IFN-α activity and a spectrum of autoimmune diseases including SLE (Bronson et al. 2012). Deficiency of the gene product TRAP (tartrate-resistant acid phosphatase), a protein that functions in lysosomal digestion, is known to cause the syndrome of spondyloenchondrodysplasia.

Systemic Lupus Erythematosus, Genetics, Table 1 Pathway-associated genes: DNA degradation, apoptosis, and clearance of cellular debris

Candidate gene	Putative functional significance	Associated SLE manifestations
ACP5	Overactivation of IFN-α	ANA and anti-dsDNA antibodies, renal disorder, arthritis, thrombocytopenia
TREX1	Removal of nucleic acids	Neuropsychiatric SLE
DNASE1/1L3	Clearance of apoptotic debris	N.D.
ATG5	Formation of autophagosomes	N.D.

N.D. not described, *DNASE1/1L3* deoxyribonuclease 1, *ATG5* autophagy related 5

Immune Complex Clearance and Phagocytosis

Genetic variants that result in lower levels of complement components, a classic feature of SLE pathophysiology, or abnormalities of apoptotic cell clearance may lead to the initiation of the autoimmune response (Table 2). Some examples to highlight include:

- *C1Q*; *C4A/B*: The incidence of SLE or lupus-like manifestation in individuals with a complete deficiency, due to a homozygous mutation, in one of the classical complement pathway genes ranges from 10 % to 93 %, with an extremely strong genetic risk for SLE and glomerulonephritis in young people who are C1q-deficient (93 % penetrant) and deficiency in both C4A and C4B genes (75 % penetrant) individuals (Chen et al. 2010).
- FcγR (Fc fragment of IgG, low affinity receptor) gene variants: With function in immune complex clearance, the role of FcγR variants to risk of SLE is highlighted by several variants, including H131R of *FCGR2A*, F158V of *FCGR3A*, and I232T of *FCGR2B*, which have been associated with SLE susceptibility in several ancestral populations and with specific disease profiles (Li et al. 2009). Investigation of the gene structure of the Fc receptor gene family region is complicated by the presence of gene duplications and copy-number variations. Inconsistencies between FcγRs genetic studies in SLE have been attributed to ethnic differences and disease heterogeneity, as well as genotyping error. Further investigation of functional consequences of the FcγR gene variants in SLE is warranted and will help to characterize their contributions to disease pathogenesis.

Systemic Lupus Erythematosus, Genetics, Table 2 Pathway-associated genes: immune complex processing and phagocytosis

Candidate gene	Putative functional significance	Associated SLE manifestations
C1Q	Reduced handling of apoptotic cell debris and immune complexes	Renal disorder, photosensitivity, neurological disorder
C1R/C1X	Early key regulators of complement cascade	Renal disorder
C2	Early key regulator of complement cascade	Renal disorder
C4A/B	Clearance of immune complex; propagating complement cascade	Arthritis, renal disorder
FCGR2A	Reduced immune complex clearance	Renal disorder, antiphospholipid syndrome, malar rash
FCGR3A/B	Reduced immune complex clearance	Renal disorder
ITGAM	Leukocyte activation and migration	Discoid rash; arthritis; renal, neurological, hematological, and immunological disorders

TLR, IFN, and NF-κB Pathways

Immune complexes consisting of nucleic acid self-antigens are known to bind the pattern recognition receptors TLR7 and TLR9. These receptors activate transcription factors, leading to activation of the type I interferon pathway, an important early proinflammatory mechanism utilized as a response to viral infection.

Systemic Lupus Erythematosus, Genetics, Table 3 Pathway-associated genes: TLR and type I IFN signaling

Candidate gene	Putative functional significance	Associated SLE manifestations
TLR7	Bind nucleic acid-containing immune complexes, induce interferon-alpha response	Anti-RBP antibodies
IRF5	Transcription factor that induces interferon-alpha and downstream gene production	Anti-dsDNA and anti-Ro antibodies
IRF7	Transcription factor that induces interferon-alpha and downstream gene production	Anti-dsDNA and anti-Sm antibodies, immunological disorder
IRF8	B cell differentiation	N.D.
IRAK1	Suppression of TLR response	N.D.
TYK2	Interaction with IFN receptor	N.D.
PRDM1	Hyperproliferation of T cells	N.D.
STAT4	Immune cell signal transduction	Early age at disease onset, renal disorder, anti-dsDNA, antiphospholipid syndrome
TREX1	Removal of nucleic acids	Neuropsychiatric SLE
ACP5	Overactivation of IFN-α	ANA and anti-dsDNA antibodies, renal disorder, arthritis, thrombocytopenia

IRAK1 interleukin-1 receptor-associated kinase 1, *PRDM1* PR domain zinc finger protein 1

Systemic Lupus Erythematosus, Genetics, Table 4 Pathway-associated genes: NF-κB signaling

Candidate gene	Putative functional significance	Associated SLE manifestations
IRAK1	Suppression of TLR response	N.D.
TNFAIP3	Restricts TNF and NF-κB signals	Renal and hematological disorders
TNIP1	NF-κB inhibition	Photosensitivity, vasculitis
UBE2L3	Regulation of the TLR response	Anti-dsDNA antibodies
SLC15A4	NF-κB signaling pathway regulation	Discoid rash
PRKCB	B cell activation, apoptosis induction	N.D.

RBP ribosomal binding protein (included: Sm/RNP, SSA/SSB)

The overly abundant activation of this and downstream pathways in patients with SLE, triggered by either viral or endogenous nucleic acids, leads to the persistent production of interferon-inducible, antiviral genes (Niewold 2011). Several variants have been associated with risk of SLE (Table 3); for example, a functional 3′ untranslated region (UTR) SNP of the X-linked *TLR7* that confers elevated TLR7 expression and an increased IFN response has been associated with SLE in East Asians (Shen et al. 2010), which was subsequently confirmed in European-American, African-American, and Hispanic populations (Deng et al. 2011). Variation in genes coding for transcription factors downstream of TLRs, including IRF5, IRF7, and IRF8, has been associated with SLE susceptibility (Bronson et al. 2012). Several additional genes within or downstream of the type I IFN pathway have been associated with risk of SLE (Table 3), including *STAT4*, *IFIH1* (interferon induced with helicase C domain 1), *TYK2* (tyrosine kinase 2), and *PRDM1* (PR domain zinc finger protein 1) (Bronson et al. 2012). Genes that play a role in the NF-κB pathway downstream of TLR engagement have also been associated with increased SLE susceptibility in multiple ancestries and are included in the list below (Table 4).

Immune Cell Signaling and Function

After recognition of self-DNA or RNA from dying or damaged cells, autoreactive B cells produce autoantibodies that form immune complexes and drive other proinflammatory

Systemic Lupus Erythematosus, Genetics, Table 5 Pathway-associated genes: lymphocyte function and signaling

Candidate gene	Putative functional significance	Associated SLE manifestations
FCGR2B	232T risk allele reduces inhibitory activity of BCR signaling	232T and risk of SLE susceptibility has been established only in patients of Asian descent
BLK	B cell development	Antiphospholipid syndrome, anti-dsDNA antibodies
LYN	B cell activation	Discoid rash, hematological disorder
BANK1	Attenuates B cell proliferation and survival	N.D.
CSK	Modify kinase activation	N.D.
PRDM1	Hyperproliferation of T cells	N.D.
ETS1	B and T cell differentiation	Early age at disease onset
IKZF1	Perturbed TH1/TH2 balance	Malar rash, renal disorder
AFF1	Development of lymphocytes	N.D.
RASGRP3	Lymphocyte activation	Malar rash, discoid rash, ANA
IL10	Promotes B cell hyperactivity and autoantibody production, downregulates antigen presentation	aCL-IgM, anti-Sm, anti-SSA antibodies; discoid rash; renal and neurological disorders
IL21	TH17 cell response	Hematological disorder
NCF2	Increases B cell differentiation	N.D.
PRKCB	B cell activation, apoptosis induction	N.D.
HLA-DR2 & DR3	Peptide presentation to CD4+ T cells	Anti-Ro/La and anti-dsDNA antibodies
MSH5	Meiotic recombination	N.D.
IRF8	B cell differentiation	N.D.
PTPN22	Reduced removal of autoreactive B cells	N.D.
TNFSF4	Co-stimulation for inhibition of T regulatory cells	N.D.
CD44	Lymphocyte activity	Thrombocytopenia
TYK2	Interaction with IFN receptor	N.D.
STAT4	Immune cell signal transduction	Early age at disease onset, renal disorder, anti-dsDNA, antiphospholipid syndrome

BLK B lymphoid tyrosine kinase, *LYN* tyrosine protein kinase LYN, *BANK1* B cell scaffold protein with ankyrin repeats 1, *CSK* tyrosine protein kinase CSK, *ETS1* Ets-1 protein or p54, *IKZF1* IKAROS family zinc finger 1, *AFF1* AF4/FMR2 family member 1, *RASGRP3* RAS guanyl-releasing protein 3, *IL10* interleukin 10, *IL21* interleukin 21, *PRKCB* protein kinase C, beta, *MSH5* MutS protein homolog 5, *PTPN22* protein tyrosine phosphatase, non-receptor type 22

responses. T cells and additional antigens can further stimulate B cells, leading to hyperactivity with increased autoantibody production. Gene variants involved in B and T cell signaling have been associated with SLE susceptibility in multiple ancestral backgrounds (Vaughn et al. 2012), as described in the list below (Table 5). Additionally, the production of superoxide by NADPH oxidase in leukocytes stimulated by autoantigens may be affected by an amino acid change (H389Q) in *NCF2* (neutrophil cytosolic factor 2), an SLE susceptibility gene encoding a subunit of the NADPH oxidase enzyme, implicating a role for decreased reactive oxygen species in SLE pathogenesis (Jacob et al. 2012).

Neutrophils and monocytes may play an important role in the pathogenesis of SLE, particularly in the formation of NETs (neutrophil extracellular traps) containing DNA and neutrophil-derived proteins which trigger IFN-α and can directly damage cells (Dorner 2012). Variants in genes with function in adhesion and migration of both cell types have been associated with SLE susceptibility in multiple ancestries (Table 6), specifically R77H *ITGAM* and the *ICAM* loci, encoding an ITGAM ligand (Kim et al. 2012).

Systemic Lupus Erythematosus, Genetics, Table 6 Pathway-associated genes: neutrophil and monocyte function and signaling

Candidate gene	Putative functional significance	Associated SLE manifestations
ITGAM	Leukocyte activation and migration	Discoid rash; arthritis; renal, neurological, hematological, and immunological disorders
ICAMs	Ligands for cellular adhesion	N.D.
FCGR2B	B cell differentiation	N.D.
FCGR3A/B	Reduced immune complex clearance	Renal disorder, antiphospholipid syndrome, malar rash
IL10	Downregulates immune responses	aCL-IgM, anti-Sm, anti-SSA antibodies; discoid rash; renal and neurological disorders
IRF8	Lymphocyte differentiation	N.D.

Conclusion

The identification of susceptibility genes for the development of SLE can help to understand both disease pathogenesis and tolerance breakdown in human immunology. To date, several important immunologic pathways have been implicated as responsible for susceptibility to disease, including DNA degradation, apoptosis, immune complex clearance, immune cell signaling and function, and inappropriate activation of the IFN, TLR, and NF-κB pathways. Research probing the dysfunction within these pathways has led to novel medications that may have therapeutic impact in SLE, including anti-IFN-α and anti-BLyS therapies. Several functional variants within these pathways have been determined and explored, such as risk alleles of *TLR7* and *IRF5* which exert control over IFN activity, enhancing our understanding of possible links between genotype and specific disease manifestations. Investigating all genetic backgrounds, including Amerindian, Hispanic, and African-American will lead to discovery of additional risk loci and ultimately greater understanding of common pathways to development of SLE. The development of drug therapy in SLE will be driven by the ongoing discovery of major susceptibility genes which are common among ancestral backgrounds. Next-generation sequencing technology such as whole genome sequencing and whole exome sequencing may help discover novel rare and functional risk variants, as well as provide further insight into SLE pathogenesis and molecular mechanisms of immune tolerance.

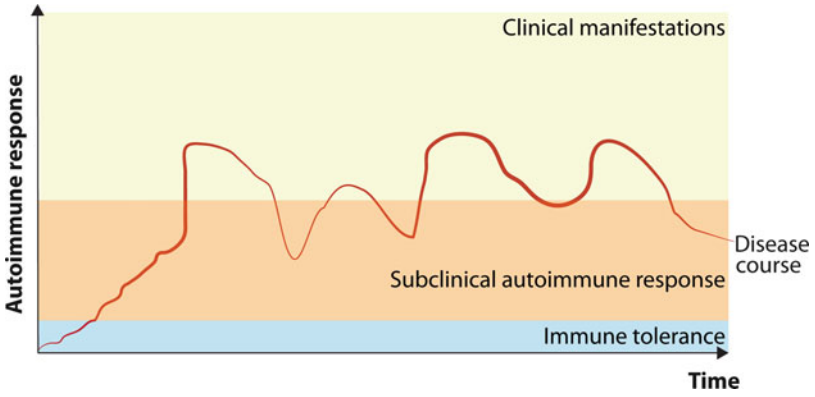
Cause of SLE

Definition

The mechanisms or pathological processes by which a collection of inherited and acquired abnormalities cause SLE.

Systemic lupus erythematosus (SLE) is a chronic autoimmune disease that affects mostly women. Patients with SLE have laboratory abnormalities that indicate that immune tolerance towards self-antigens has broken and



Systemic Lupus Erythematosus, Pathogenesis, Fig. 1 *Development of lupus involves a subclinical chronic autoimmune response and acute bouts of organ inflammation*. Patients with SLE develop a chronic autoimmune response that can be detected by the presence of autoantibodies. This response precedes and underlies the obvious clinical manifestations that occur when products of the autoimmune response cause local inflammation

heterogeneous clinical manifestations that vary according to the involvement of different organs and systems.

One of the characteristics of SLE that has baffled clinicians and has complicated its understanding is that patients with lupus differ very much from each other. Moreover, different pathogenic mechanisms underlie each clinical manifestation. For example, lupus nephritis is caused by the deposition of immune complexes in the renal glomeruli and by the infiltration of lymphocytes into the renal interstitium, whereas thrombocytopenia is caused by antiplatelet antibodies.

In contrast to organ-specific autoimmune diseases (e.g., autoimmune thyroid disease) that are driven by immune responses against components of the affected organ, in lupus most manifestations occur when cellular or soluble components of the immune system activated during the course of a chronic autoimmune response directed towards widely expressed molecules gain access to tissues and cause local inflammation. Lupus nephritis is not caused by an immune response against components of the glomeruli; it is triggered by the deposition of immune complexes in the glomerular mesangium and basement membrane. These immune complexes are not formed by anti-renal antibodies but rather by various autoantibodies that deposit in the glomeruli. Ensuing activation of complement and neutrophils causes glomerulonephritis which is probably modulated by the response of the kidney to the presence of immune complexes and local inflammation (Bagavant and Fu 2009).

Patients with SLE develop a chronic autoimmune response directed mostly against ubiquitously expressed intracellular antigens (e.g., DNA and ribonucleoproteins). This response is present in most – if not all – patients with SLE and causes no clinical symptoms directly. It becomes evident as antinuclear antibodies (ANA). When by-products of this response gain access to tissues (e.g., DNA-anti-DNA immune complexes deposit in the glomeruli), they cause local inflammation that manifests clinically. Thus, SLE has a common, mostly subclinical component (a chronic autoimmune response against widely expressed intracellular antigens) that is necessary but not sufficient to cause the disease and a second heterogeneous component directly involved in causing clinical manifestations.

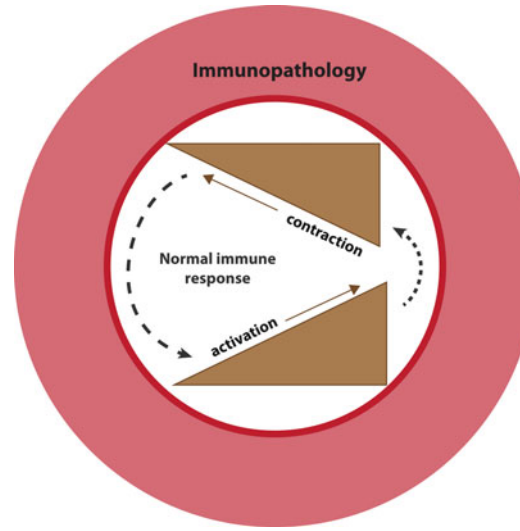
In this regard, the pathogenesis of SLE involves a first step when self-tolerance is broken and the immune system engages a chronic autoimmune response and a second step that determines when and where the products of the underlying autoimmune response will instigate inflammation (Fig. 1).

Genetic and Environmental Factors

Why some individuals develop SLE is still a matter of debate (Tsokos 2011). Early genetic studies demonstrated that SLE has a genetic component: it shows familial aggregation and high concordance rates among twins, and its prevalence and severity vary among different ethnic groups (see ▶ Systemic Lupus Erythematosus, Genetics). Accordingly, genome-wide association studies (GWAS) have identified several markers that are more commonly found in patients with SLE than in healthy controls. Not surprisingly, most of these markers are within (or in close proximity to) genes that encode for proteins involved in the immune response. These markers (single nucleotide polymorphisms or SNP) are mostly found in noncoding DNA regions, and the effects most of them exert on the immune system are still poorly understood. They probably modify the function of the gene they are associated with in a subtle manner. It is important to emphasize that although these SNPs are more common in patients with SLE, they are also frequent in healthy individuals. Therefore, the presence of each is predicted to have a small impact in immune function (since they are found in healthy individuals). Accordingly, the current hypothesis is that lupus is more likely to develop in persons who carry numerous susceptibility SNPs. Each SNP may contribute in a small way to an immune system more prone to inflammation or autoreactivity, but only the combination of several will exceed the threshold of susceptibility to lupus. This model also predicts that different combinations of susceptibility SNPs will be associated with different clinical phenotypes. In this sense, the combination of hereditary traits that fine-tune the immune behavior of an individual can also, under certain circumstances, make that individual prone to develop lupus. How these hereditary traits modulate the immune system and, importantly, how they interact with each other are subject of intense scrutiny.

A great majority of SLE patients are women in the childbearing age; lupus is less common before puberty and after menopause, and in those ages, the difference in frequency between men and women is less marked. Therefore, female sex and in particular female hormones are considered a strong predisposing factor for lupus. Again, a variety of studies have shown that hormones exert broad effects in the immune system, but the exact mechanisms through which female hormones promote autoimmunity are incompletely understood (see ▶ Systemic Lupus Erythematosus, Gender and Hormone Influences).

Thus, the current paradigm is that hereditary factors shape the immune system in such a way that it becomes susceptible of losing immune tolerance upon encountering unknown trigger (s). At some point during the life of the individual with lupus, an external agent is thought to activate the immune response, driving it over the tolerance threshold (Fig. 2). Agents able to cause cellular damage and activate the immune responses such as UV light and in particular viral



Systemic Lupus Erythematosus, Pathogenesis, Fig. 2 *A dysregulated immune response can produce immune-mediated pathology*. The immune system gets activated and expands upon antigenic stimulation. In healthy individuals, immunopathology is avoided by restricting the magnitude and the duration of the immune response and by ensuring that most of the immune cells that have been produced during the response are eliminated during the contraction phase. If the mechanisms that limit the intensity of the immune response are faulty, the elements of the immune response will cause organ damage

infections have been proposed as culprits. Importantly, disease development and tolerance loss probably represent a gradual process induced by multiple events (Liu and Davidson 2012). This is supported by the finding that antibodies against self-antigens are produced in patients with lupus several years before clinical disease is evident and that the variety and amount of these autoantibodies increases slowly until disease becomes overt. Therefore, loss of tolerance, manifested by the production of an immune response against self-antigens, precedes by years the development of organ and tissue injury. This suggests that the autoimmune response is initially of small magnitude but that – in persons who eventually develop disease – it slowly increases until its products (i.e., autoantibodies, cytokines, activated cells) become pathogenic by virtue of specificity (e.g., development of anti-red blood cell antibodies that cause autoimmune hemolytic anemia) or quantity (e.g., immune complexes that deposit in the renal glomeruli) (Fig. 1).

An important concept to understand this hypothesis is the continuous remodeling of the immune system. Lymphocytes (T cells and B cells) activated during an immune response proliferate and increase their affinity to the antigens that triggered the response. Therefore, the immune system repertoire adjusts after each immune bout. By the time lupus becomes clinically apparent, the immune system of an affected individual probably harbors a relatively large number of autoreactive T and B cells that have expanded and gradually accumulated cells that by virtue of number and functionality are able to produce a highly specific and powerful self-aimed immune response. A pathogenic immune response will thus slowly develop in a susceptible person driven by encounters with environmental triggers (Shlomchik et al. 2001).

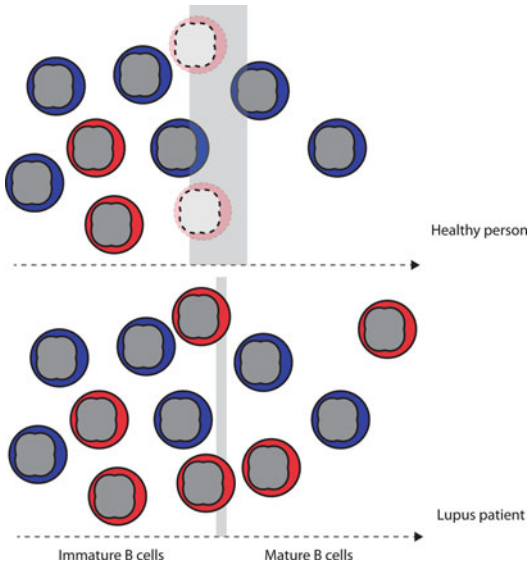
Innate Immune System

The innate immune system, and in particular antigen-presenting cells (APC), probably plays a major role in the development of SLE. APCs are responsible for detecting pathogens and for initiating and modulating the ensuing immune response. Moreover, they handle self-antigen-rich cellular debris that should be presented to the adaptive immune system in a noninflammatory fashion (i.e., as innocuous self-antigens). The responses of APCs to antigens are determined by a number of factors such as the local abundance of cytokines and signals that indicate the presence of a noxious agent (i.e., molecules associated to infectious agents or produced by stressed cells). These cues induce functional and phenotypic changes in the APC and deeply affect the manner it presents the antigen to T cells. Normally, self-antigens are presented as such, and T cells able to recognize them are deactivated; this process maintains self-tolerance. When antigens are associated to pathogens, antigen presentation elicits the activation and proliferation of T cells, triggering an efficient, proinflammatory immune response that will eliminate the source of the antigen. Evidence from animal models and from patients that lack key molecules responsible for the clearance of cellular debris indicates that when the load of self-antigens is not adequately handled by the innate immune system, autoantigens may elicit immune responses. In fact, apoptotic cells are thought to be an important source of autoantigens in SLE. This process may represent a primary defect that promotes the development of lupus but may also facilitate established disease. Patients with SLE have antibodies that are directed against self-constituents. Therefore, apoptotic cells may become coated by these autoantibodies and their recognition by the immune system affected. An APC will not interpret an antibody-coated particle as self. In this way, autoantibodies contribute to the amplification of the autoimmune pathology and to the breach in tolerance towards self-antigens. Another factor that may play a role in patients with ongoing disease is that the presence of an inflammatory environment may facilitate the activation of APCs and their presentation of self-antigens in a proinflammatory manner. For instance, immune complexes present in patients with SLE can stimulate APC activation through immunoglobulin receptors.

Humoral Immune Response

Each B cell creates a unique antibody through a process of random gene rearrangement. This process allows the production of a large array of different antibodies, some of them autoreactive. After immature B cells create and express a unique immunoglobulin (as B cell receptor), they undergo a selection process designed to eliminate self-reactive B cells before their maturation into immunocompetent cells. This process has been shown to be altered in patients with SLE. Thus, more autoreactive B cells are present in patients with SLE (Fig. 3).

Autoantibodies are the most commonly observed immune alteration in patients with lupus (see ▶ Systemic Lupus Erythematosus, Autoantibodies). SLE autoantibodies have high affinity and have been produced by cells that have participated in a full-blown immune response.



Systemic Lupus Erythematosus, Pathogenesis, Fig. 3 *Autoreactive B cells are inadequately eliminated in patients with SLE*. Since immunoglobulin production depends on random genetic rearrangement, a fraction of B cells creates autoreactive immunoglobulins. These potentially harmful cells (*red cells*) are eliminated before becoming mature (*upper panel*). This process is defective in patients with lupus (*lower panel*) that have more mature autoreactive cells in their B cell repertoire

Although the autoantibody response in SLE is broad and directed against numerous specificities, several hallmark antigens are intranuclear complexes comprised of nucleic acids and proteins. This might be important from the pathogenic point of view, since B cells can be stimulated by DNA and RNA through toll-like receptors. In fact, evidence obtained in animal models of lupus suggests that nucleic acids contained in immune complexes can deliver a second signal to the B cell, complementary to the signal conveyed by the immunoglobulin. Thus, nucleic acid-containing immune complexes might be able stimulate B cells without the need of T cell-derived help providing an alternative pathogenic amplification pathway independent of T cell help and regulation.

Autoantibodies produced by patients with SLE have been shown to be pathogenic through different mechanisms. Autoantibodies form immune complexes with antigens derived from injured or apoptotic cells and can be detected in sera of patients with lupus. They can deposit in certain vascular beds (e.g., renal glomeruli) where they induce inflammation by activating complement and engaging immunoglobulin receptors in neutrophils and other inflammatory cells. When present, anti-red blood cell and antiplatelet antibodies cause hemolytic anemia and autoimmune thrombocytopenia. Autoantibodies can also induce tissue damage by mechanisms different than immune complex deposition. In experimental models, autoantibodies isolated from patients with lupus have been shown to bind to placenta and ischemic intestine and trigger inflammatory responses that cause, respectively, fetal resorption and ischemia-reperfusion-mediated tissue injury. Autoantibodies can also bind to surface receptors and alter cellular function. For example, some anti-DNA antibodies cause neuronal apoptosis by promoting the prolonged activation of glutamate receptors, while anti-T lymphocyte antibodies can significantly alter T cell function and cytokine production by activating intracellular pathways that modify the activation of transcription factors. In pregnant patients with

lupus, autoantibodies (e.g., anti-Ro) may cross the placenta and cause fetal damage (Diamond and Volpe 2012).

Cellular Immune Response

T cells regulate immune responses through the release of cytokines and the expression of membrane-bound factors that affect the behavior of other immune and nonimmune cells. They also induce cellular apoptosis in cells affected by intracellular pathogens such as viruses. In lupus patients, the function of T cells is altered: their activation process and gene expression profile are abnormal. This is reflected in an aberrant cytokine production profile and altered effector functions (Crispin et al. 2010).

When activated, lupus-derived T cells exhibit an abnormally rapid and elevated surge in intracellular calcium accompanied by increased phosphorylation of signaling proteins. This is caused by alterations in the composition of proteins associated to the T cell receptor and to structural changes in the plasma membrane. These changes have profound consequences, because when a lupus T cell is stimulated by an antigen, its response, in terms of gene expression and cellular behavior, is abnormal. Gene transcription is controlled by a multilayered process that includes DNA methylation and posttranslational histone modifications. DNA methylation is decreased in T cells from lupus patients. This alteration is responsible for the overexpression of a number of genes. Interestingly, two drugs that cause drug-induced lupus (i.e., procainamide and hydralazine) induce DNA demethylation. Therefore, an altered activation process along with defects in gene regulation affects T cell function in patients with SLE.

One of the most obvious T cell defect is the skewed cytokine production. Since cytokines are probably the most important conduit used by T cells to deliver signals, aberrant cytokine production implies faulty immune regulation. Production of interleukin 2 (IL-2) is impaired in SLE T cells. This defect has been associated with several T cell abnormalities that not only determine autoimmune pathology but also impair the development of protective immune responses against pathogens. On the other hand, decreased IL-2 has been postulated to be involved in quantitative and qualitative abnormalities in regulatory T cells. Moreover, activation-induced cell death, a mechanism that allows the contraction of expanded clones of activated lymphocytes at the end of an immune response, also depends on the presence of IL-2. On the other hand, production of IL-17, a proinflammatory cytokine, is increased in patients with lupus. Importantly, IL-17-producing T cells infiltrate kidneys from patients with lupus nephritis causing local inflammation.

T cells regulate the production of antibodies by directly stimulating B cells and by producing cytokines that modulate B cell function. T cells from patients with SLE exhibit an enhanced capacity to stimulate B cells. Moreover, characteristics of the autoantibodies found in patients with SLE indicate that the B cells that produce them have received T cell stimulation (Craft 2011).

In summary, SLE is a complex disease that develops over time in individuals who harbor an inherited predisposition kindled by undefined environmental factors. Discrete defects in virtually every cell of the immune system contribute to shape an immune system that is more inflammatory and more prone to tolerance breaches. At some point, the immune system crosses the threshold of immune tolerance and develops a self-aimed immune response that gradually grows. This subclinical phase is manifested solely by the presence of antinuclear antibodies. The intensity of the autoimmune response increases until its products reach tissues and organs causing inflammation and clinical disease.

Lupus treatment; Treatment of SLE

Definition

SLE is a systemic autoimmune disease that is treated with high-dose immunosuppressive medications during acute flares to prevent permanent organ damage. Less toxic medications are used during disease quiescence to prevent future flares. Besides the direct immunologic damage to organs and tissues, accelerated atherosclerosis and metabolic bone disease often accompany the disease and/or result from chronic use of toxic medications.

General Principals

Systemic Lupus Erythematosus (SLE) is characterized by periods of high disease activity (flares) and periods of clinical quiescence. The flares can be of varying severity, affect different organ systems, and can, if left untreated, lead to permanent organ damage (Tsokos 2011). SLE flares are treated with high-dose immunosuppressive medications, while less toxic immunomodulatory medications are used for flare prevention (most commonly used medications are described in Table 1). In addition, patients with SLE have oftentimes comorbid conditions, due to the disease itself and/or medications, that can result in significant disability.

Treatment of Acute SLE

SLE flares can be mild, moderate, or severe depending on the organs that are involved, the severity of inflammation, and the potential for permanent organ or tissue damage.

The treatment of severe organ or life-threatening SLE flares follows the paradigm established in patients with severe lupus nephritis (WHO class III and IV). Following the diagnosis of the type of lupus nephritis, treatment is started with high doses of corticosteroids (prednisone 1 mg/kg p.o. per day). If the disease is very active and especially if the kidney function is compromised, corticosteroids can initially be given intravenously at high doses (Methylprednisolone 1,000 mg IV per day for 3 days). Corticosteroids alone although efficacious have a suboptimal long-term effect with a significant proportion of the patients becoming hemodialysis dependent. Cyclophosphamide given monthly I.V. (0.5–1 mg/kg) when added to corticosteroids was found to be very effective in improving renal outcomes. More recently, mycophenolate mofetil, an oral immunosuppressive, was shown to be as good as cyclophosphamide in inducing remission of glomerulonephritis in SLE patients (reviewed in (Houssiau 2012)).

Initially cyclophosphamide treatment was given in two phases, a 6-month induction phase and a maintenance phase. Given significant toxicity of cyclophosphamide, other immunosuppressive medications are now routinely used instead of cyclophosphamide in the maintenance phase. Currently azathioprine (typically 2 mg/kg)

Systemic Lupus Erythematosus, Treatment, Table 1 Commonly used medications in SLE

Medication	Indication	Dose	Significant side effects
Hydroxychloroquine	Dermatitis and arthritis, pregnancy	200–400 mg/d po	Retinopathy (rare-yearly ophthalmologic exam); Muscle toxicity (very rare)
Azathioprine	Maintenance in lupus nephritis and other manifestations; can be used in pregnancy	50–150 mg (2 mg/kg) po	Liver and bone marrow toxicity
Prednisone	Acute flares; can be used in pregnancy	5 mg–60 mg po; IV bolus	Diabetes, hypertension; osteoporosis; weight gain; cataract; glaucoma
Cyclophosphamide	Lupus nephritis; other severe manifestations	0.5–1 mg/m2 IV q monthly	cytopenia; hemorrhagic cystitis; secondary cancers; infertility
Mycophenolate mofetil	Lupus nephritis; other manifestations	500–1,500 mg po bid	Diarrhea; cytopenia
Belimumab	mild-moderately active autoantibody positive SLE	10 mg/kg IV monthly	Infusion reactions; hypersensitivity; diarrhea
Methotrexate	arthritis	7.5–20 mg p.o. weekly	Bone marrow, liver, and lung toxicity; nausea, oral ulcers; folic acid can mitigate some of the side effects

or mycophenolate mofetil (2,000 mg per day) are the preferred maintenance treatment following the induction phase (current treatment guidelines published in (Bertsias et al. 2012)). Corticosteroids are used in a tapering fashion. The exact length of the maintenance phase of treatment is still unclear, but most experts agree that at least 2 years of treatment is required. These regimens coupled with better supportive care have improved the outcome of patients with nephritis from 90 % 5-year mortality to <10 % 10-year mortality.

By extrapolation from the nephritis trials, the combination of cyclophosphamide and corticosteroids is used also for the treatment of severe extrarenal flares as well. In particular multi-system disease, vasculitis, alveolar hemorrhage, and neuropsychiatric lupus are treated in the same fashion as nephritis with induction of remission using cyclophosphamide or mycophenolate together with corticosteroids followed by a maintenance phase. Class V nephritis, characterized by profound proteinuria without significant inflammation, is also generally treated with mycophenolate mofetil and varying doses of corticosteroids.

For less severe manifestations/flares of the disease such as pericarditis, pleuritis and, thrombocytopenia, the preferred treatment is moderate to high doses of corticosteroids (0.5–1 mg/kg of prednisone p.o.). Oftentimes an immunomodulator, such as azathioprine or mycophenolate mofetil, is added shortly after the initial phase to allow for a corticosteroid taper. The exact length of treatment with steroids, timing of introduction of an immunomodulator, and the length of the treatment are largely based on empiric data. Other modalities that can be used in SLE include intravenous immunoglobulin in patients with thrombocytopenia, dapsone and thalidomide for refractory skin disease, and plasmapheresis for alveolar hemorrhage.

Milder flares that cause organ inflammation but do not generally lead to organ damage are treated in a less aggressive way. Although corticosteroids are very effective in these cases, they should be avoided or used sparingly because of side effects. For arthritis and cutaneous disease the mainstay of treatment is the antimalarial drug hydroxychloroquine. Nonsteroidal anti-inflammatory drugs such as ibuprofen or diclofenac are also often used to alleviate symptoms of arthritis. In more severe cases of arthritis, methotrexate can be very effective. Skin rashes

often respond to local corticosteroids ointments; intra-lesional steroid injections and topical tacrolimus are used in more persistent skin rashes.

Flare Prevention

The most common readily recognizable cause of SLE flares is sun exposure. Ultraviolet light can cause skin rashes as well as constitutional symptoms in SLE patients. Strict sun protection is therefore part of the strategy to avoid SLE flares in most patients but especially in patients with known photosensitivity and/or skin disease. Physical or psychological stress, pregnancy, and viral illnesses may also precede an SLE flare although their cause-effect relationship is not established.

Despite preventive measures, a significant proportion of SLE patients flare at a high enough rate to require continuous treatment. As this treatment is chronic, less toxic medications are preferred. The most commonly used preventative medication in SLE is hydroxychloroquine, as it has a very good risk to benefit ratio.

If hydroxychloroquine does not prevent flares or the patient has continuous disease activity, immunosuppressive medications such as azathioprine, mycophenolate, or low-dose prednisone can be added to the regimen. As mentioned above, methotrexate can also be useful especially in patients with persistent or recurrent arthritis.

Prevention and Treatment of Comorbidities and Medication Toxicity

As is the case in several chronic inflammatory conditions, SLE patients display accelerated atherosclerosis, partly due to the disease itself and partly due to medication effects (Roman et al. 2003). Obesity, diabetes, and hypertension are common in SLE patients: Corticosteroids are the main but not the only contributors to these metabolic abnormalities; renal disease can cause hypertension and hypercholesterolemia; antiphospholipid antibodies can cause thromboembolic events. SLE patients should therefore be strongly encouraged to exercise regularly and avoid smoking. The blood pressure and the cholesterol level should be kept within normal limits and proteinuria should be addressed with the use of angiotensin converting enzyme inhibitors.

Corticosteroids are also largely responsible for osteopenia and/or osteoporosis in SLE patients. It is recommended that patients on chronic steroid treatment take supplemental calcium and vitamin D. Patients who have no contraindications to antiresorptive agents should also take bisphosphonate especially if they take more than 5–7.5 mg of prednisone a day.

Given that most medications used in SLE are immunosuppressive, the patients should be vaccinated against influenza yearly. Age-appropriate immunizations should also be done, although immunizations with live viruses should be avoided. SLE is associated with cancers especially lymphoma, while cyclophosphamide treatment predisposes to bladder cancer. Hence, periodic screening for development of symptoms and signs of malignancy, and age-appropriate malignancy laboratory screening including urinalysis for hematuria should be done in all SLE patients.

The patients should also be monitored for development of liver toxicity (mainly with methotrexate and azathioprine), bone marrow suppression (methotrexate, azathioprine, mycophenolate mofetil, and cyclophosphamide), and gastrointestinal complications such as mucosal or peptic ulcers, nausea, and diarrhea (nonsteroidal anti-inflammatories, prednisone, azathioprine, methotrexate, and mycophenolate mofetil). Yearly ophthalmologic exam is recommended to diagnose hydroxychloroquine maculopathy and screen for the development of cataracts and glaucoma in patients with high steroid exposure (Peponis et al. 2010).

As most SLE patients are women of childbearing years, several fertility issues arise with their treatment. Medications that can be used in patients that are pregnant or wish to become pregnant include hydroxychloroquine, prednisone, and azathioprine. Cyclophosphamide can cause infertility, which is more common in older women; concomitant use of leuprolide

may mitigate this risk. As estrogens have been associated with SLE, birth control pills have been thought as unsafe to use by SLE patients. Newer studies though have shown that they are probably safe to use in patients with low disease activity, but their safety during flares is still unclear (Sanchez-Guerrero et al. 2005). Use of birth control pills should also be avoided if the patient has high levels of antiphospholipid antibodies.

Emerging and Experimental Treatments

No new treatments had been approved for SLE for several decades until the approval of belimumab in 2011 (Furie et al. 2011). Belimumab is a monoclonal antibody that neutralizes the B Lymphocyte stimulator cytokine (BLyS), a pro-B cell growth factor that is thought to be important in the production of (auto)-antibodies in SLE. Following two large clinical trials, patients treated with monthly infusions of belimumab had less flares and needed less corticosteroids to manage their disease. Belimumab was only shown to be useful in patients with mild to moderate disease as patients with the more difficult to treat acute nephritis and central nervous system disease were excluded from the trials. Its effect overall on disease activity can be characterized as modest.

Difficult to treat SLE is not that uncommon. High-dose chemotherapy with or without stem cell transplantation can be helpful in patients with severe refractory SLE. Rituximab, an anti-CD20 antibody, can be helpful in select cases of SLE such as thrombotic thrombocytopenic purpura or immune thrombocytopenia. Thalidomide and dapsone are oftentimes used for severe skin disease. Calcineurin inhibitors are effective in SLE but due to unfavorable side effect profile especially renal toxicity are reserved as third or fourth line medications.

Several medications targeting B cells (epratuzumab, atacicept), T cells (abatacept), and soluble cytokines (tocilizumab) are being investigated for the treatment of SLE. Epratuzumab, an anti-CD22 antibody, showed some effect in phase II trials and is currently being investigated in phase III trials. Atacicept targets APRIL and BLyS, two B cell-related cytokines, caused severe infections when used in combination with mycophenolate. Abatacept is a fusion protein CTLA4-Ig that prevents T cell activation and although showing no effect in short-term trials, is being investigated in longer-term clinical trials.

Conclusions

The treatment of acute SLE consists of high doses of corticosteroids and immunosuppressives to prevent permanent organ damage. This initial induction of remission phase is followed by long-term maintenance treatment that aims at using the lowest possible dose of corticosteroids alongside an immunosuppressive medication. The choice of maintenance immunosuppressives depends on the severity of the disease and the organs involved. Hydroxychloroquine remains the drug of choice for prevention of future flares. Finally, although the monoclonal antibody belimumab was recently approved for the treatment of SLE, targeted SLE treatment remains in its infancy.

Synonyms

Memory $CD8^+$ and $CD4^+$ T cells; Memory T lymphocytes

Definition

T cell memory arises from a complex molecular process in which a naïve T lymphocyte encounters its cognate antigen, expands in numbers, and acquires long-lived and functionally improved features. This process results in the most efficient reactivation of such T lymphocyte upon another encounter with the same antigen.

Introduction

Over the past decade, many studies have investigated the role of cells, pathways, and molecules that regulate this complex process. Differentiation of naïve T cells into fully functional long-lived memory T cells comprises several steps that include initial activation (priming), proliferation (expansion), and massive apoptosis (contraction), after which the cells that survived remain in the host and differentiate into long-lived memory cells (Cui and Kaech 2010; Harty and Badovinac 2008; McKinstry et al. 2010). Unraveling the molecular basis of T cell memory development is highly significant with regard to the development of novel vaccines and cell-based immunotherapies. The current state of knowledge on the mechanisms regulating the steps of T cell memory formation, maintenance, and protective abilities is summarized in this entry (Fig. 1).

Programming Naïve T Cells to Become Long-Lived Memory Cells

T cells that have successfully completed thymic selection exit to the blood and peripheral tissues and constitute the pool of host naïve T cells. Differentiation of such naïve, "antigen-inexperienced" T cells into long-lived "antigen-experienced" memory T cells is a complex multistep process that involves priming, expansion, contraction, and memory formation. During the first phase of this process, i.e., priming and proliferation, the majority of naïve T cells differentiate into effector cells while only a small proportion will become long-lived memory T cells.

T Cell Priming

The signals: Optimal T cell priming and differentiation into memory cells requires three

T Cell Memory, Fig. 1 Schematic representation of the steps controlling T cell memory formation and protective immune responses

signals, namely, antigen, costimulation, and inflammation. Each of these signals has an impact on T cell differentiation. Amount and duration of antigen presentation (signal 1) and subsequent T cell receptor (TCR) triggering largely determines the extent of T cell expansion. Costimulation (signal 2) that requires upregulation of cell-surface costimulatory molecules such as CD80 and CD86 on antigen presenting cells (APCs), which present T cell cognate antigens, is critical in driving potent T cell activation through engaging its major coreceptor CD28 on T cells. Finally, inflammatory factors (signal 3) such as IL-2, IL-12, IFN-γ, IL-4, IL-6, IL-10, TGF-β, or IFN-αβ, through signaling on the T cells, mostly modulate their ability to express specific sets of effector functions and to differentiate into distinct T cell subsets (Harty and Badovinac 2008; Littman and Rudensky 2010).

The cells providing the signals: Dendritic cells (DCs), a subset of mononuclear myeloid cells expressing high levels of the cell-surface integrin CD11c, are specialized APCs exhibiting the most potent ability to prime naïve T cells. Seminal reports established their unique functional features among the different subsets of APCs in efficient detection of microbial molecules, uptake, and presentation of antigens derived from microbial pathogens to T cells. Experiments were performed both in vitro and in vivo and compared the ability of the distinct APCs to activate naïve T cells. The most compelling evidence came from the generation of an in vivo conditional depletion system in which $CD11c^+$ cells expressed the human diphtheria toxin receptor (DTR), allowing for their selective elimination upon diphtheria toxin (DT) injection (Jung et al. 2002). Results demonstrated that DCs possess unique and optimized features for the priming of naïve T cells. Thus, upon recognition of pathogen-derived products through specialized family of innate immune receptors – namely, the pattern recognition receptors, PRRs – DCs undergo maturation and subsequently express high levels of major histocompatibility complex and of costimulatory molecules and secrete inflammatory cytokines, all of which are required for optimal T cell priming (Iwasaki and Medzhitov 2004). Other innate immune cells such as tissue-resident macrophages, blood phagocytes like neutrophils and monocytes that are rapidly recruited to infected foci, or even non-hematopoietic cells (stromal, epithelial, or endothelial cells) can also provide important inflammatory molecules at the time of T cell priming. Importantly, $CD4^+$ T cells, also defined as "helper" T cells (Th), are essential for optimal $CD8^+$ T cell priming and further differentiation because they contribute to DCs maturation, in particular through CD40 (on DCs)/CD40L (on $CD4^+$ T cells)-mediated costimulation. $CD4^+$ T cell help is particularly important for $CD8^+$ T cells primed in an environment with little inflammatory cytokines.

The dynamics of T cell priming in situ: Interaction of mature DCs with naïve T cells recognizing their cognate antigen takes place in secondary lymphoid organs (SLO), e.g., spleen and draining lymph nodes. Using intravital imaging by biphoton microscopy, the dynamics of DC-mediated T cell priming was visualized in living mice and revealed that naïve T cells and DCs presenting their cognate antigen encounter each other inside SLO by wandering in contact with a network of fibroblastic reticular cells (FRCs) and through complex and multiple chemotactic cues (Germain et al. 2012). The kinetics of naïve T cell priming involves three major dynamic phases in which T cells undergo intermittent contacts with cognate-antigen-loaded DCs, form stable interactions in clusters constituted of T cells surrounding individual DCs, and finally resume their motility prior to initiating multiple rounds of proliferation (Mempel et al. 2004).

T Cell Expansion, Effector Differentiation, and Contraction

The widely accepted view is that inflammation plays a key role in driving naïve T cell differentiation into highly effector cells that also exhibit a short-life potential and do not survive for extended period of times in the host. Effector T cells are characterized by upregulation of the

cell-surface lectin KLRG-1 and the IL-2 receptor CD25 as well as the loss of the chemokine receptor CCR7 and L-selectin CD62L (Cui and Kaech 2010; Sallusto et al. 1999). One important attribute of effector $CD8^+$ T cells is their ability to become cytolytic, express high amounts of granzyme B and perforin, and secrete inflammatory cytokines like IFN-γ and TNF-α.

In the case of effector $CD4^+$ T cells, a specific pattern of secreted cytokines is associated with distinct lineages of $CD4^+$ Th cells, such as Th1 cells producing IFN-γ/TNF-α/IL-2, Th2 cells producing IL-4/5/13 (Th2), Th17 cells producing IL-17/22, or follicular helper T cells (T_{FH}) producing IL-21 and regulating B cell effector responses. These effector cell types are usually associated with different diseases, in particular, strong Th1-type immune responses are promoted upon viral and intracellular bacterial infections; Th2-type immune responses are found upon parasitic worm infections or allergic diseases (e.g., asthma); and Th17-type immune responses are described during fungal and extracellular bacterial infection or autoimmune inflammatory diseases.

While the inflammatory context, e.g., which combination of cytokines are present at the time of initial T cell priming, is a critical inducer of T cell effector fate, expression of transcriptional regulators ultimately convey the priming signals and regulate the fates of the differentiating T cells. Some of the most important of these transcription factors controlling the differentiation of $CD8^+$ T cells are T-bet, eomesodermin (Eomes), Blimp-1, and BCL-6. Their roles have some redundancy (T-bet, Eomes) as well as clear antagonizing effects (Blimp-1, BCL-6) that regulate the balance between terminal effector and memory $CD8^+$ T cell fates in vivo (Crotty et al. 2010). T-bet but also the transcriptional regulators GATA-3, RORγT, or BCL-6 drive the differentiation of naïve $CD4^+$ T cells into distinct subsets of effector $CD4^+$ T cells, respectively, the Th1, Th2, Th17, and T_{FH} cells (Littman and Rudensky 2010).

After primary expansion, most T cells (>95 %) undergo programmed cell death. Current thinking is that T cell contraction is programmed early on during the initial priming. Inflammatory cytokines such as IFN-γ and IL-12 are strong contributors, possibly through the modulation of the level of anti-apoptotic molecules like BCL-2 inside T cells.

Memory Formation

Naïve T cells undergoing priming acquire the potential to differentiate into effector cells and memory cells. Adoptive transfers of one single naïve $CD8^+$ T cell of known antigenic specificity or its tracking through unique genetic barcoding indeed demonstrated that an individual $CD8^+$ T cell has the intrinsic potential to differentiate into various functional subsets of T cells following antigen-driven activation (Stemberger et al. 2007). One explanation supported by some reports is that T cells undergo asymmetric division during initial activation, leading to distinct effector or memory fates. Other elegant genetic tagging experiments in which activated $CD8^+$ T cells that express the cytolytic marker granzyme B became permanently labeled established that memory T cells may arise from effector cells (Jacob and Baltimore 1999).

Differentiation of fully functional long-lived memory $CD8^+$ T cells requires the presence of $CD4^+$ T cells, since memory $CD8^+$ T cells generated in the absence of $CD4^+$ T cells poorly re-expand upon recall stimulation. One mechanism accounting for this observation is that "helpless" memory $CD8^+$ T cells express increased amounts of proapoptotic molecules such as the TNF-related apoptosis-inducing ligand TRAIL (Cui and Kaech 2010; Harty and Badovinac 2008).

While strong inflammation during priming promotes T cell differentiation towards terminal effector cells, the nature of the infection will select for memory T cells with distinct functional features. For instance, during acute infections, in which microbial pathogens are eliminated from the host, memory cells come in at least two flavors, namely, effector (T_{EM}) and central (T_{CM}) memory T cells. Both subsets of memory T cells exhibit different properties: T_{CM} express CD62L and CCR7 for efficient trafficking to SLO and exhibit a high proliferative

capacity, while T_{EM} ($CD62L^{low}CCR7^{-}$) presence is largely restricted to nonlymphoid peripheral tissues in which they can express rapid effector functions contributing to early host protection (Sallusto et al. 1999). Expression of high levels of the cell-surface marker KLRG-1 on $CD8^+$ T cells further marks terminally differentiated "short-lived" effector cells (SLEC) within the T_{EM} subset, by opposition to $KLRG1^{low}$-activated T cells that give rise to long-lived memory cells (Cui and Kaech 2010). T_{CM} ultimately represent memory cells that persist in immunized hosts. While Th1- and Th2-committed $CD4^+$ T cells can form long-lived memory, it is less clear whether the other subsets of $CD4^+$ T cells (Th17, T_{FH}) per se persist in the host as true long-lived memory cells.

In contrast to acute infections, in the course of chronic infections, the fate of memory T cells is different. Seminal studies comparing two clonal variants of the lymphochoriomeningitis virus (LCMV) that either induce an acute or a chronic infection in mice established that repeated high level of antigenic stimulation of memory T cells in a low inflammatory context makes them dysfunctional and defined as "exhausted" memory T cells (Barber et al. 2006). These important findings were confirmed in human immunodeficiency and hepatitis B and C virus-infected patients. Constantly, TCR-triggered memory T cells express very high levels of inhibitory receptors such as PD1, one of the main markers characterizing T cell exhaustion.

Mechanisms of Long-Term Memory T Cell Maintenance

Memory T cells can persist in the host for very long period of time, and these unique features are achieved through several mechanisms that are discussed below.

The cytokines IL-7 and IL-15: These cytokines are among the most important contributors to memory T cell maintenance with IL-7 and IL-15 respectively involved in survival and homeostatic turnover (Surh and Sprent 2008). In the course of a primary microbial pathogen infection, while the majority of activated effector T cells downregulate cell-surface expression of the IL-7 receptor (IL-7R/CD127), a small subset expresses high cell-surface levels. Adoptive transfer experiments of this subset of cells into a recipient host demonstrated that they differentiated into long-lived memory cells; however, IL-7R expression per se is not instructive of the process. Since IL-7 is constitutively secreted at relatively fixed amounts by FRCs in SLO, modulation of IL-7 levels remains limited, suggesting that regulation of IL-7 signals may mostly occur through fine-tuning of cell-surface IL-7R expression by the lymphocytes. Downstream effectors of IL-7 signaling inside memory T cells include anti-apoptotic molecules such as Bcl-2 which undergo upregulation. IL-15 plays a critical role for memory T cell maintenance. IL-15 mostly acts by promoting homeostatic proliferation of the memory T cells that express high cell-surface levels of the IL-15Rβ chain (CD122). Upon adoptive transfer into $IL\text{-}15^{-/-}$ recipients, memory T cells are rapidly lost, demonstrating IL-15 signals absolute requirements for memory T cell maintenance. Reports have also shown that IL-15 is *trans*-presented by distinct APCs – namely, DCs and macrophages (MPs) – to $CD8^+$ T cells, and the different APCs exhibit specific roles: MPs support effector $CD8^+$ T cell transition to the memory stage and T_{EM}/T_{CM} homeostasis, while DC-derived IL-15 appears restricted to T_{CM} (Mortier et al. 2009). Of note, the long-term maintenance of memory $CD8^+$ T cells induced after acute infections requires the presence of $CD4^+$ T cells even though the mechanisms involved still need to be clarified.

Several transcription factors involved in T cell development ultimately regulate the maintenance and reactivation of memory T cells. These include transcriptional regulators such as BCL-6, the T cell factor 1 (TCF-1), or the inhibitor of DNA-binding 2 (Id2). Common mechanisms shared by these factors include promoting the expression of anti-apoptotic molecules like BCL-2 and the IL-15 receptor CD122 involved in homeostatic proliferation.

Metabolic switch: T cells undergoing priming, expansion, and memory differentiation are experiencing dramatic energetic changes to accommodate their rapidly evolving status. Recent reports revealed that upon differentiation into memory T cells, expanding T cells switch from an anabolic (glycolysis) to a catabolic metabolism by inducing fatty acid oxidation (FAO) (Pearce et al. 2009). This process is required for their long-term maintenance and also suggested to depend on IL-15 and on the transcription factor eomesodermin. The use of FAO as the main source of energy correlates with acquisition of resting quiescent features by the memory T cells.

Antigen and major histocompatibility complex molecules: While naïve T cells require frequent contacts with major histocompatibility complex molecules and endogenous peptides, memory T cells can persist in the host for very long period of time in the absence of major histocompatibility complex presented cognate antigens. This idea was supported by adoptive transfer experiments of memory T cells purified from immunized hosts to mice genetically deficient for major histocompatibility complex class I or class II molecules in comparison to wt mice, and the numbers of memory cells was shown to remain comparable. This represents another important adaptative feature of memory T cells.

Mechanisms of Protection

T cell memory is an essential part of the adaptive immune system of the host. It allows hosts to most efficiently resist to microbial pathogens against which they have been previously immunized. Several mechanisms account for this: memory T cells specific for an immunizing antigen are present in much higher numbers than their naïve counterparts (up to 200 times); they exhibit distinct activation thresholds and requirements and acquire enhanced effector functions and improved abilities to be mobilized during inflammation.

Memory T cells are present in much higher numbers than their naïve counterparts in immunized hosts as a consequence of their initial clonal expansion but also because they survive for extended times through expression of anti-apoptotic genes, homeostatic proliferation and metabolism switch, and loss of major histocompatibility complex antigen dependence. They also constitutively express "ready-to-go" cell-cycle-related kinases and effector cytokines and chemokines stored as mRNA and proteins, which make them able not only to rapidly initiate proliferation but also to deliver protective effector functions (Veiga-Fernandes et al. 2000). Importantly, memory T cells express increased levels of chemotactic receptors and adhesion molecules that are essential to efficiently reach infected foci and mediate host defense (Sallusto et al. 2000).

Immunological protection, e.g., microbial pathogen killing, can be achieved through several mechanisms. Memory $CD8^+$ T lymphocytes recognize and kill infected or tumor cells through delivery of cytotoxic granules into target cells and/or triggering of cell-surface death receptors. Memory $CD4^+$ T lymphocytes are best characterized as important sources of effector cytokines and chemokines that promote both activation and recruitment of antimicrobial innate immune effector cells (McKinstry et al. 2010). Such mechanism, which can also be achieved by memory $CD8^+$ T cells in some instances (Narni-Mancinelli et al. 2007), allow for rapid and efficient amplification of the host-protective immune response. Along these lines, the concomitant expression of multiple effector functions by memory T cells is strongly correlated to protection both in humans and in mice models (Seder et al. 2008). Successive immunizations with a same vaccine promote the acquisition of a core genetic program by memory cells that includes high transcription of effector and chemokine genes and receptors, as well as anti-apoptotic genes (Cui and Kaech 2010). Interestingly, in hosts sequentially infected with multiple microbial pathogens, the global size of the memory T ($CD8^+$) compartment increases while only a minimal loss of pathogen-specific memory cells was observed. Overall, while many distinct processes exposed above account for heightened

memory T cell-mediated host protection, achieving multifunctional potential is likely the most relevant to hosts' survival.

Conclusions

While tremendous insights have been gained in the complex process of T cell memory formation over the past decade, the fine understanding on how these events take place in situ in a living host and the cell-cell interactions and molecular cues that govern these processes in a timely manner are still poorly defined. Whether a specific set of innate immune sensing receptors inside APCs drives the differentiation of memory T cells at the time of priming is an open possibility. Likewise, which combinations of signals lead to the differentiation of memory T cells acquiring specific functions and the complex interaction of transcription factors regulating these processes needs to be precisely determined so that the design of T cell-dependent vaccination and therapeutic strategies will be rationally improved.

TGF-β

Estrella García-González and Enrico Selvi
Rheumatology Unit, Department of Clinical Medicine and Immunological Sciences, University of Siena, Siena, Italy

Synonyms

Transforming growth factor-beta (TGF-β)

Definition

TGF-β is a dimeric polypeptide growth factor which belongs to a family of growth factors that share a cluster of conserved cysteine residues held together by intramolecular disulfide bonds (Elgert 2009a).

It is produced by cells which express receptors for it, which include most human cells.

TGF-β regulates many biological functions including the proliferation and differentiation of cells, embryonic development, wound healing, and angiogenesis (Elgert 2009a).

Mechanism of Action

TGF-β exists in three isoforms: TGF-β1, TGF-β2, and TGF-β3. Each isoform is encoded by a distinct gene and is expressed in a tissue-specific manner. TGF-β1 is expressed mainly in endothelial, hematopoietic, and connective tissue cells. TGF-β2 is produced in epithelial and neuronal cells, and TGF-β3 is produced mainly in mesenchymal cells. All three isoforms are highly conserved in mammals, suggesting a critical biological function for each one (Elgert 2009a; Santibanez et al. 2011).

To regulate cellular processes, TGF-β binds three high-affinity cell-surface receptors known as TGF-β receptor I, II, and III. The TGF-β type III receptor is the most abundant (Elgert 2009a).

After binding the specific receptor, TGF-β intracellular signaling occurs predominantly by phosphorylation of cytoplasmic proteins belonging to the Smad family. The last Smad-phosphorylated complex is shuttled into the nucleus where it regulates the expression of target genes by direct binding to the gene promoter and/or through an interaction with other transcriptional factors (Liu and Feng 2010). In addition to the canonical Smad pathway, TGF-β can also regulate cellular processes through Smad-independent pathways that include the activation of other signaling molecules such as mitogen-activated protein kinase (MAPK), Akt, or nuclear factor κB (Santibanez et al. 2011; Liu and Feng 2010).

Role in Immunity

TGF-β is produced by all leukocytes, promoting their differentiation and inhibiting their proliferation and activation. Furthermore, TGF-β provides leukocyte chemotaxis by regulating expression of adhesion molecules (Elgert 2009a; Santibanez et al. 2011).

Although TGF-β had been classified as an immunosuppressive cytokine by inhibiting T lymphocyte activation, recent observations indicate that the proinflammatory cytokine interleukin-6 switches the transcriptional program initiated by TGF-β, inducing development of Th17-activated lymphocytes (Miossec et al. 2009). Th17 cells can rapidly initiate an inflammatory response and facilitate clearance of infections. In addition, unregulated Th17 responses or overproduction of interleukin-17 is associated with chronic inflammation as well as autoimmunity and autoinflammatory conditions (Miossec et al. 2009).

Role in Cancer

TGF-β regulates cellular proliferation in a cell-specific manner. In most epithelial, endothelial, and hematopoietic cells, it is a potent inhibitor of cell proliferation, arresting the cell

cycle in the G1 phase. Thus, in normal conditions TGF-β has a tumor-suppressive role (Elgert 2009b; Finn 2008). In addition, TGF-β is able to protect cells from tumorigenesis by inducing apoptosis (programmed cell death) and by maintaining genomic stability (inhibiting the production of mitogenic factors) (Finn 2008).

Paradoxically, TGF-β becomes a pro-oncogenic factor in cancer cells in which mutations in TGF-β signaling confer resistance to the tumor-suppressive role of TGF-β. Resistance to TGF-β cell cycle control allows cancer cells and surrounding stromal cells (fibroblasts) to proliferate and in turn to produce more TGF-β. The overproduction of TGF-β leads to immunosuppression and angiogenesis and increases the invasiveness of the tumor by activating fibroblasts, immune cells, and endothelial and smooth-muscle cells (Elgert 2009b; Finn 2008). By suppressing activation of infiltrating immune cells, TGF-β allows tumor cells to escape host immunosurveillance. In addition, with the induction of angiogenesis, TGF-β stimulates growth of late-stage tumors, thereby facilitating invasion and metastasis (also enhanced by TGF-β-mediated cell motility) (Finn 2008; Chiang and Massague 2008).

Role in Fibrosis

TGF-β is one of the most potent regulators of the production and deposition of extracellular matrix (ECM). It stimulates fibroblasts and other cells to produce ECM proteins and cell-adhesion proteins, including collagen, fibronectin, and integrins. In addition, TGF-β reduces production of enzymes that degrade the ECM, including collagenase, heparinase and stromelysin, and increases production of proteins that inhibit ECM degrading enzymes (Smith 2003; Border and Noble 1994; Gabrielli et al. 2009).

Although TGF-β is essential for wound healing, overproduction of TGF-β can result in excessive deposition of scar tissue and fibrosis. Thus, abnormal TGF-β signaling results in fibrotic diseases such as pulmonary fibrosis, liver cirrhosis, and systemic sclerosis. In these pathologies, the aberrant upregulation of TGF-β in an autocrine/paracrine manner leads to a constitutive activation of fibrogenesis. Together with other profibrotic cytokines, TGF-β orchestrates excessive ECM synthesis and deposition, thereby promoting early fibrosis without normal remodeling of tissue, a process that is subsequently maintained by other profibrogenic cytokines, including connective-tissue growth factor (CTGF) (Border and Noble 1994; Gabrielli et al. 2009; Mori et al. 1999).

Definition

The emerging area of renal clinical pharmacology has uncovered the complicated nature of drug selection and dosing in chronic kidney diseases. This is particularly relevant to optimizing treatment-related outcomes for patients with glomerulonephritis. The pharmacokinetics and pharmacodynamics of drugs need to be fully understood in order to adequately dose and assess the therapeutic benefits of existing and novel treatments.

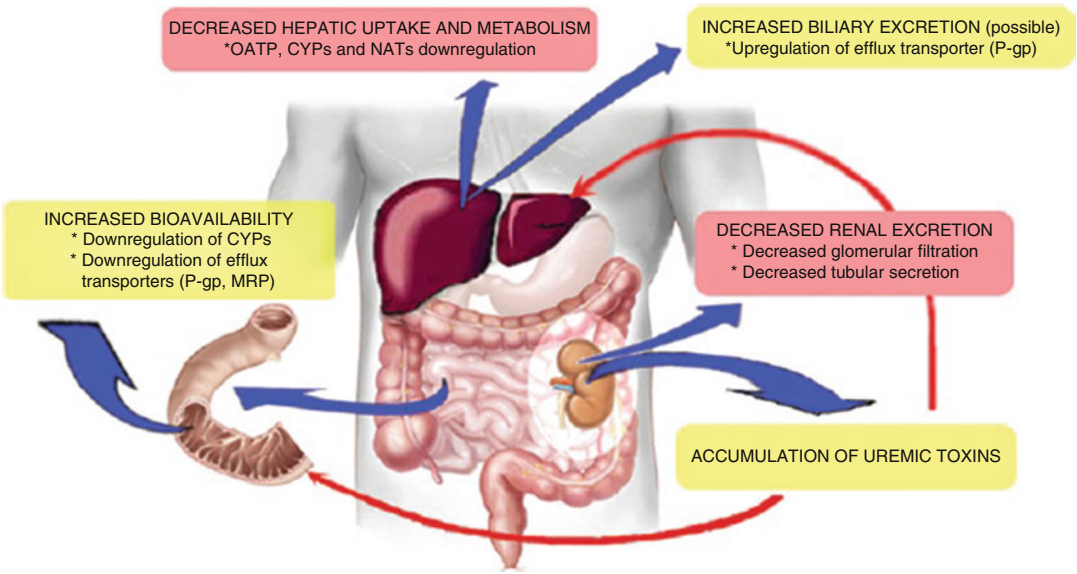
Background

In 2010, more than 20 million people in the USA aged 20 years and older were reported to have chronic kidney disease (NKUDIC 2011). This statistic represents greater than 10 % of the entire population. Diabetes mellitus is the leading cause of kidney disease in the United States, and with its rising incidence, there is a corresponding rise in diabetic kidney disease. Similar associations with kidney disease are also anticipated with the rising incidence and prevalence of hypertension, obesity, hyperlipidemia, and aging in the US population.

The US trends between primary diseases and kidney disease are mirrored on a global level. Research throughout the world supports a high prevalence of kidney disease (Chadban et al. 2003; Jafar et al. 2005; Choi et al. 2006). A study from Korea, using microalbuminuria as a marker for kidney disease, found a prevalence of microalbuminuria of 2.8 %, 10.1 %, and 16.0 % in normoglycemic, normotensive patients; hypertensive patients; and diabetic patients, respectively (Choi et al. 2006). The AusDiab Kidney Study found that approximately 16 % of the adult Australian population has some degree of kidney injury, as defined by proteinuria, hematuria, and/or glomerular filtration rate (GFR) (Chadban et al. 2003). A small study in Pakistani patients designed to evaluate the accuracy of commonly used equations for estimating GFR found that 26.7 % of men and 32.5 % of women (overall prevalence 29.9 %) age 40 years and older had a reduced GFR (Jafar et al. 2005). The global trends in increasing prevalence rates of kidney disease necessitate a thorough understanding of therapeutic interventions to slow disease progression, as well as improvements in methods of treating concomitant comorbidities.

Therapeutic Considerations in Kidney Diseases

Therapeutics are complicated in kidney diseases (Fig. 1). Typical reasons for this include reductions in glomerular filtration rate, loss of proteins in the urine, and alterations in cellular components of blood, serum proteins, and electrolytes. Many medications or their metabolites are dependent on the kidneys for elimination from the body. There is a highly correlated relationship between glomerular filtration rate and drug dosage and/or administration frequency requirements. Historical published data from the ESRD population show altered interactions between drugs and plasma proteins. This is particularly relevant for patients receiving drugs that exhibit significant protein-binding characteristics. A classic example is phenytoin, where there is an elevated free fraction of the drug in patients with ESRD. Some data also support enhanced clearance of highly protein-bound drugs in patients with glomerulonephritis. Baseline alterations in electrolytes due to chronic kidney disease can influence the toxicity profile of many medications. Additional emerging data demonstrate changes in the activity



Therapeutic Considerations in Kidney Diseases Due to Glomerulonephritis, Fig. 1 Potential mechanisms for altered drug disposition in kidney diseases (Nolin et al. 2008)

of drug metabolism and drug transport pathways in patients with chronic kidney diseases (Nolin et al. 2008; Joy et al. 2012) (Fig. 1). The existing data support reductions in activity in many drug metabolism pathways in primary and secondary kidney diseases. These established and evolving clinical paradigms demonstrate the potential for significant inaccuracies in therapeutic dosing regimens in chronic kidney disease patients. The existing and emerging awareness of the complicated nature of drug selection and dosing in chronic kidney disease provides evidence that clinicians must increase their understanding of clinical pharmacology in the context of kidney disease.

The etiology of the kidney disease needs to be considered in order to predict the physiological aspects that may contribute to altered disposition of drugs. Patients with glomerulonephritis can have significant perturbations in serum albumin secondary to loss of proteins through the urine. They can also exhibit loss of protein-bound drug in the urine. Many of these patients have reductions in GFR as well. The relationship between drug exposure and pharmacodynamic response in patients with kidney disease can be confounded by whether the disease etiology is primary or secondary (Joy et al. 2009a). Further complicating drug therapy, disparate patterns of kidney injury exist, and variable rates of progression within different compartments of the kidney may occur depending, at least in part, on the etiology of disease. Inconsistency between methods of determining and calculating renal function may lead to differences in drug dosing and, therefore, response. The primary focus of this chapter is on therapeutic considerations specific to the pharmacokinetics and pharmacodynamics of drugs used in patients with glomerular diseases.

Glomerular Diseases and Treatment Considerations

The primary glomerular diseases represent the third leading cause of end-stage renal disease in the United States. This group of diseases (Table 1) comprises several entities, such as IgA nephropathy, focal segmental glomerular sclerosis (FSGS), lupus nephritis, and idiopathic membranous nephropathy. Since some causes of vasculitis also lead to glomerulonephritis, they are included in Table 1.

Therapeutic Considerations in Kidney Diseases Due to Glomerulonephritis, Table 1 Causes of glomerular disease (Hunder 2013; Hebert 2012)

IgA nephropathy
Thin basement membrane disease
Hereditary nephritis
Mesangial proliferative glomerulonephritis
Systemic lupus erythematosus
Post-infectious glomerulonephritis
Membranoproliferative glomerulonephritis
Rapidly progressive glomerulonephritis
Fibrillary glomerulonephritis
Minimal change disease
Focal glomerulosclerosis
Membranous nephropathy
Diabetic nephropathy
Primary amyloidosis/light chain deposition disease
Benign nephrosclerosis
Vasculitis
Churg-Strauss syndrome (also known as allergic granulomatosis and angiitis)
Granulomatosis with polyangiitis (formerly known as Wegener's disease)
Microscopic polyarteritis
Anti-glomerular basement membrane (anti-GBM) disease
Henoch-Schönlein purpura
Essential cryoglobulinemic vasculitis
Hypersensitivity vasculitis
Vasculitis secondary to connective tissue disorders
Vasculitis secondary to viral infection

Chlorambucil
Therapeutic antibodies
Rituximab (anti-CD20)
Belimumab (anti-BLyS)

Many of the drugs currently used for the treatment of glomerular diseases (Table 2) were originally approved to treat rheumatologic diseases, malignancies, or prevention of rejection in transplant patients. Therapeutic dosing regimens were initially selected based on the ranges of doses used for the treatment of the approved indications. Subsequent modifications in dosing regimens have come about through clinical trials that have endpoints of efficacy and/or toxicity. A limitation to repurposing medications to new populations is the lack of understanding of the clinical pharmacology of the therapeutic agents in those populations. This is particularly relevant in patients with chronic kidney disease and, more specifically, in patients with glomerulonephritis. In fact, increased systemic clearance of these drugs has been observed in the setting of glomerulonephritis compared with reference diseases (Joy 2011; Joy et al. 2009b, c, d; Joy et al. 2010a). The enhanced systemic clearance has been observed for both small molecules and therapeutic proteins. As clearance is subdivided into "renal clearance" and "nonrenal clearance" fractions, it is important to understand the relevance of each clearance route on overall systemic clearance. Interestingly, both renal and nonrenal clearance enhancements have been reported in kidney diseases due to glomerulonephritis. Enhancements in renal clearance can occur secondary to increases in the activity of apical drug efflux transporters on proximal tubule cells and secondary to loss of protein-bound drugs in cases of proteinuria. Since eGFR is usually negatively impacted by glomerulonephritis, augmented renal clearance cannot be attributed to increases in eGFR. Enhancements in nonrenal clearance can occur secondary to increases in free fraction of drugs, resulting in an increased propensity to undergo drug metabolism, and may occur secondary to enhancement of certain drug metabolism pathways. The role of systemic inflammation on renal and nonrenal clearance pathways in glomerulonephritis has not been evaluated.

Additionally, the contribution of edema in patients with massive urinary protein excretion to a medication's volume of distribution and clearance has not been elucidated. Understanding alterations in the pharmacokinetics and pharmacodynamics of drugs in glomerulonephritis is central to personalizing patient therapies based on acceptable therapeutic targets. Smarter prescribing should result in better treatment-related outcomes across patient populations. A thorough understanding of clinical pharmacology in kidney diseases should reduce the potential for adverse drug effects and drug interactions. The following sections of this chapter provide information concerning the existing published pharmacology data on several medications commonly used in the treatment of glomerulonephritis.

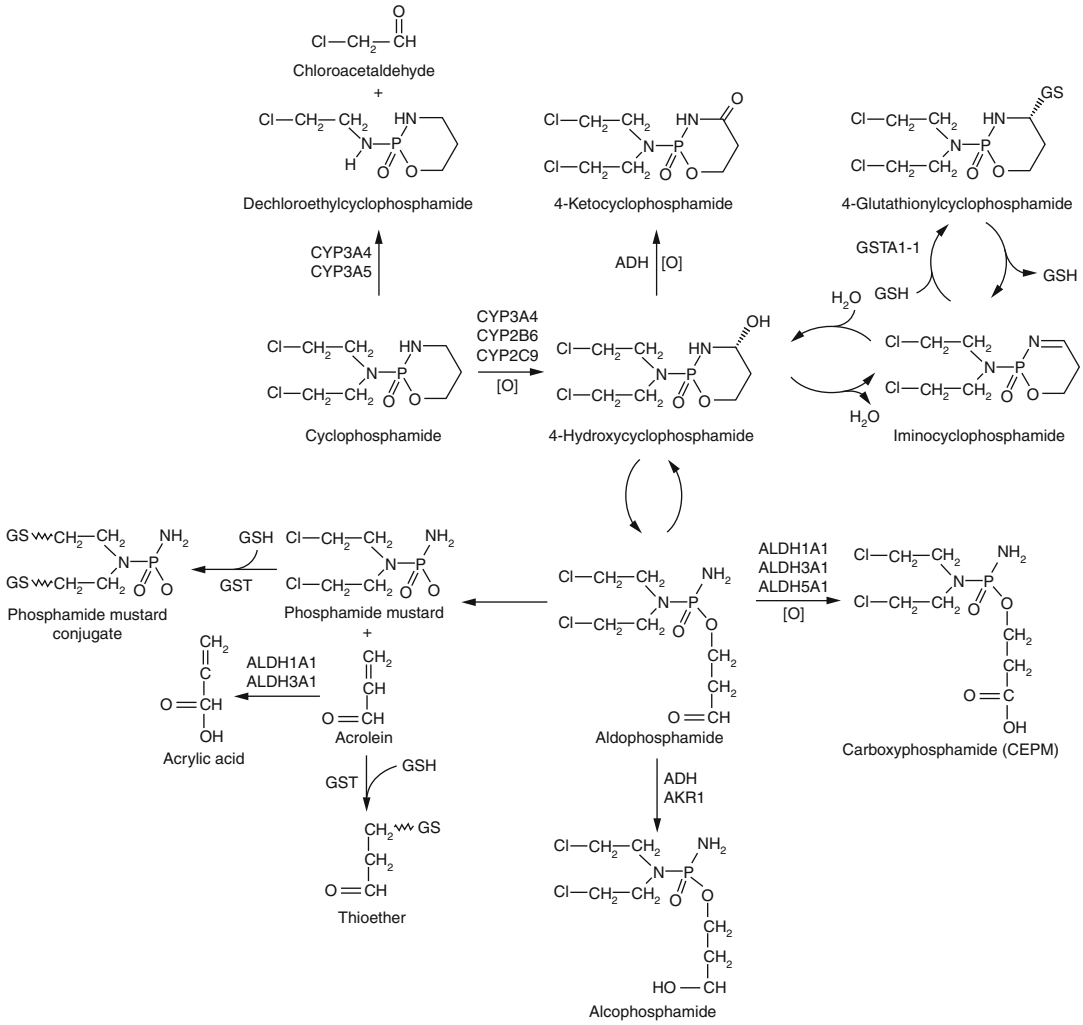
Treatments of Glomerulonephritis

Cyclophosphamide

Cyclophosphamide is used in the treatment of rapidly progressive forms of glomerulonephritis, including forms of small-vessel vasculitis (SVV) and lupus nephritis. One of the first accounts of cytotoxic therapy in the treatment of granulomatosis with polyangiitis (GPA; formerly Wegener's granulomatosis) was by Fahey et al. in the early 1950s (Fahey et al. 1954). The report was published in a 1954 volume of the *Lancet* and described a 38-year-old man with GPA who was treated with nitrogen mustard. Since that time, a number of cytotoxic therapies, including cyclophosphamide, azathioprine, chlorambucil, and methotrexate, have been used in the treatment of various immune-mediated diseases. Cyclophosphamide has remained the mainstay of treatment of many forms of glomerulonephritis. Previous studies in animals have demonstrated cyclophosphamide's immunosuppressant activity, independent of its antimitotic (i.e., cytotoxic) characteristics in the treatment of malignancy.

Cyclophosphamide is an oxazaphosphorine that is related to the nitrogen mustard family of alkylating agents. Cyclophosphamide is a prodrug that undergoes complex metabolic alterations in the liver and other tissues via multiple enzymatic pathways, including cytochrome P450s, aldehyde dehydrogenases, alcohol dehydrogenases, and glutathione sulfotransferases (Fig. 2). Of the multiple metabolites generated from the cyclophosphamide prodrug, 4-hydroxycyclophosphamide (4-OH-CPA) is the active metabolite that can be readily measured in plasma. It is in equilibrium with its tautomer, aldophosphamide, the aldehyde intermediate between 4-OH-CPA and the ultimate cytotoxic metabolite, phosphoramide mustard. When cyclophosphamide is used as an antitumor agent, phosphoramide mustard is thought to be the primary active antitumor metabolite, mediating tumor destruction by alkylation and resultant cross-linking of DNA in tumor cells. The 4-OH-CPA metabolite can also undergo further metabolism by aldehyde dehydrogenase to carboxyphosphamide (CEPM), which is nontoxic (Fig. 2). Studies in patients with severe aplastic anemia revealed that cells with high levels of aldehyde dehydrogenase, such as early hematopoietic progenitors, are comparatively resistant to cyclophosphamide. Alternatively, lymphocytes, which are relatively deficient in aldehyde dehydrogenase, are highly susceptible to cyclophosphamide, contributing to cyclophosphamide's effectiveness as an immunosuppressant.

Although cyclophosphamide has proven to be useful in the treatment of glomerulonephritis due to both SVV and systemic lupus erythematosus (SLE), treatment response remains variable between patients. For example, African-American race has been shown to be an independent predictor of poor outcome (i.e., decreased renal survival) in patients with lupus nephritis (Dooley et al. 1997). A clear interpretation of treatment responses had until the time of this study been confounded by the designs of previous trials. The earlier studies included predominantly Caucasian patients and did not distinguish among histological types of renal lesions. The more recent study by Dooley et al. demonstrated that renal survival in African-Americans with diffuse proliferative glomerulonephritis was markedly worse than in non-African-American patients with the same lesion. All of the patients



Therapeutic Considerations in Kidney Diseases Due to Glomerulonephritis, Fig. 2 Metabolic scheme for cyclophosphamide (Drug Metabolism Reviews (was Fig. 3 in 2005))

in the study were being treated with corticosteroids, with similar tapering schedules in African-Americans and non-African-Americans. Most patients were continued on steroid therapy for greater than 12 months. The study utilized modified NIH criteria for dosing of cyclophosphamide in lupus nephritis. Patients were treated with 0.5–1.0 g/m^2 cyclophosphamide once a month for 6 months, with dose adjusted to patients' nadir white blood cell counts. Quarterly cyclophosphamide infusions were continued dependent on the renal response of each patient. Overall, the median cumulative dose of intravenous cyclophosphamide was lower in African-Americans than in non-African-Americans due to a higher incidence of ESRD in African-Americans in the 6 months after kidney biopsy. Otherwise, there was no difference in dose or duration of treatment in patients who did not progress to ESRD within the first 6 months. The reported 58 % 5-year renal survival among African-Americans demonstrates that, even among patients who are ostensibly experiencing the same clinical condition and undergoing the same treatment, the outcome can be quite different. The complex

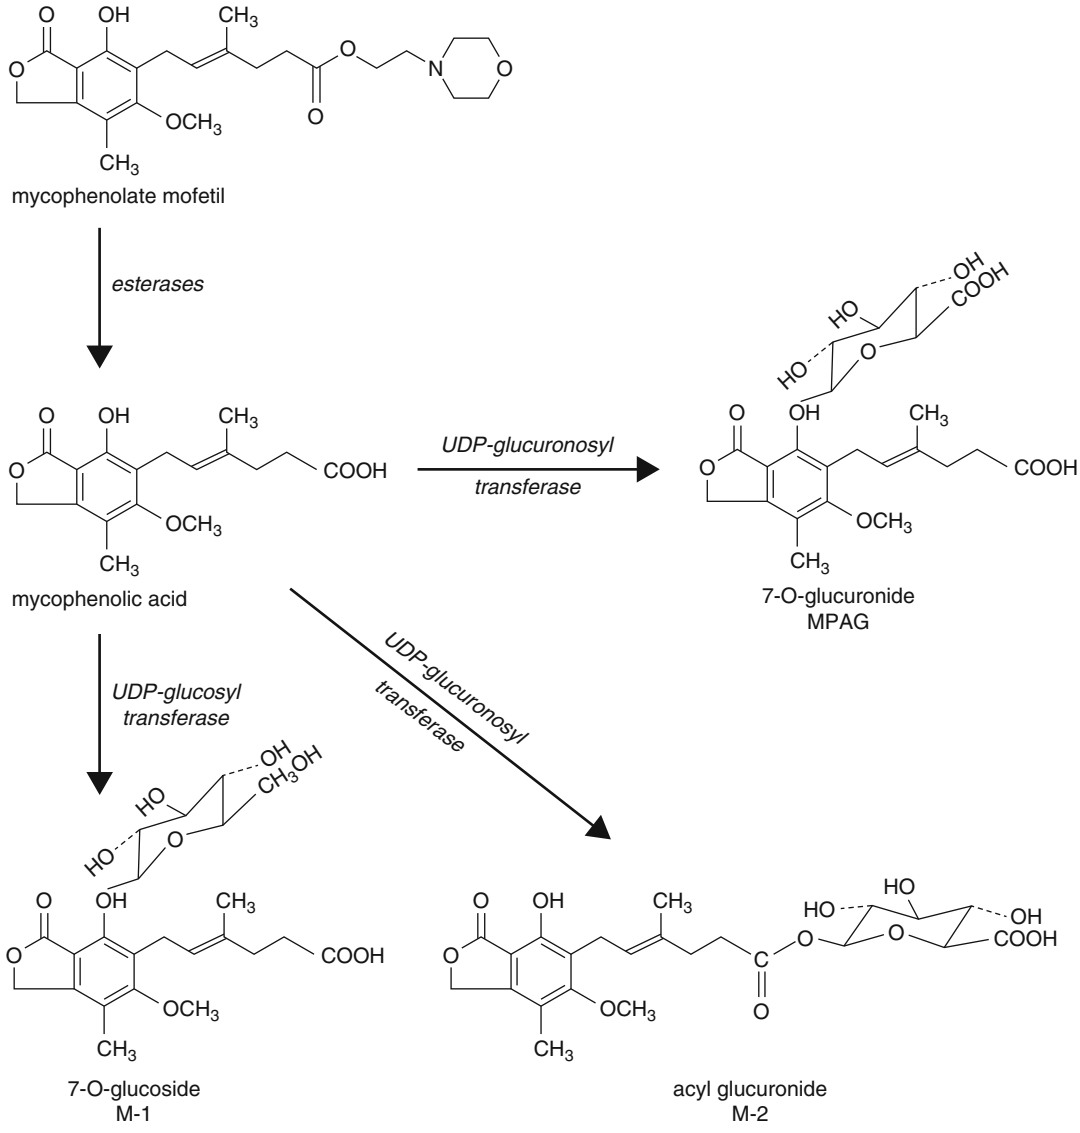
routes of metabolism and the pharmacokinetic variability of cyclophosphamide in these patients must be considered as a possible underlying source of this variability in treatment-related outcomes.

The influence of eGFR on the pharmacokinetics of cyclophosphamide has been reported (Haubitz et al. 2002). As compared to controls with eGFR ≥80 mL/min, patients with eGFR of 25–50 mL/min and 10–24 mL/min had total clearance and renal clearance values that were significantly reduced. These reductions resulted in cyclophosphamide exposures that were nearly double the values found in patients with eGFR ≥80 mL/min. Subsequent studies have reported on the pharmacokinetics of cyclophosphamide and 4-OH-CPA in patients with lupus nephritis and SVV (Belfayol-Pisanté et al. 2000; de Miranda Silva et al. 2009; Joy et al. 2012). In the Joy et al. study, the glomerulonephritis patients had relatively preserved eGFR, so the study focused on the influence of clinical factors such as serum albumin and urinary protein excretion on pharmacokinetics (Joy et al. 2012). Reductions in serum albumin resulted in reduced exposure to 4-OH-CPA. Additionally, urinary protein loss resulted in higher exposure to cyclophosphamide as compared to 4-OH-CPA. Refinement of the established relationships between eGFR, serum albumin, and urinary protein excretion to 4-OH-CPA exposure will enable a patient-directed approach to designing therapeutic regimens with cyclophosphamide.

There is considerable interest in the field of pharmacogenomics due to its contribution to drug pharmacokinetics and the promise of individualizing therapy to reduce variability in treatment responses. The pharmacogenetics of drug metabolism pathways involved in the breakdown of cyclophosphamide has been explored in patients with glomerulonephritis (Takada et al. 2004; Helsby et al. 2010; Joy et al. 2012). Takada et al. reported on the risk of premature ovarian failure and probability of reaching renal outcomes in lupus nephritis patients receiving cyclophosphamide (Takada et al. 2004). Patients exhibiting heterozygosity or homozygosity at the *CYP2C19 G681A* locus had reduced risk of premature ovarian failure. Patients who were homozygous for *CYP2B6 C1459T* or *CYP2C19 G681A* had increased probability of ESRD and doubling of serum creatinine. However, these homozygous variants have a low frequency in SLE populations, and the heterozygous variants did not associate with cyclophosphamide-induced lupus nephritis remissions (Winoto et al. 2011). These studies did not report on pharmacokinetics for either cyclophosphamide or 4-OH-CPA. The study by Joy et al. reported on the influence of the *CYP2B6 G516T* variant on the pharmacokinetics of cyclophosphamide. Variants had decreased maximal concentration (Cmax) in plasma after a dose and decreased elimination rate constant. Several trends were noted for the *ABCB1*/*MDR1* C3435T variant. The *ABCB1*/*MDR1 C3435T* variant exhibited a lower elimination rate constant and lower Cmax for cyclophosphamide. This study did not report on patient-related outcomes. Using both in vitro studies of liver samples from a biobank and plasma samples from 16 patients with SLE, Helsby et al. examined the role of the *CYP450* enzymes *CYP2B6* and *CYP2C19* in the bioactivation of cyclophosphamide (Helsby et al. 2010). They also examined the relationship of the 4-hydroxylation of cyclophosphamide to loss-of-function alleles in *CYP2B6* and *CYP2C19* in patients with lupus nephritis. Their studies suggest that one or more loss-of-function alleles in either *CYP2B6* or *CYP2C19* result in decreased bioactivation of cyclophosphamide. A few other studies have implicated variants of *CYP2B6* (Xie et al. 2006; Nakajima et al. 2007) and *CYP2C19* (Timm et al. 2005; Ekhart et al. 2008) in the decreased clearance of cyclophosphamide. The described studies support the approach of employing in vivo assessments of function of proteins and/or pharmacokinetics in evaluating the influence of genetic polymorphisms on any cyclophosphamide treatment-related outcomes.

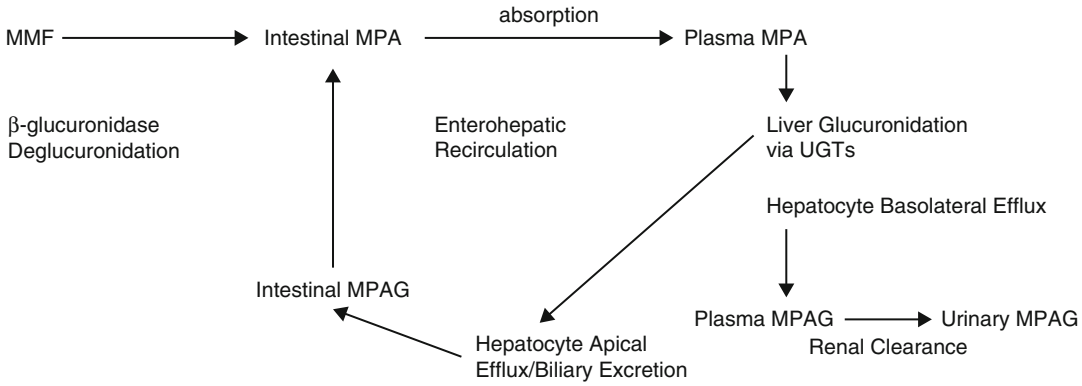
Mycophenolate

Mycophenolate, a drug commonly used in both induction and maintenance regimens of various forms of glomerulonephritis, is available as either the mofetil ester or the sodium salt. Mycophenolic acid (MPA) is the therapeutically



Therapeutic Considerations in Kidney Diseases Due to Glomerulonephritis, Fig. 3 Metabolic scheme for mycophenolate (Shipkova et al. 1999)

active moiety of both dosage forms. Mycophenolic acid is metabolized by a number of uridine diphosphate glucuronosyltransferase (UGT) enzymes to inactive glucuronide metabolites (MPAG) (Fig. 3). Over 90 % of the administered dose of mycophenolate is excreted in the urine, mostly as MPAG. The disposition of MPA is complicated, as MPAG undergoes active renal tubular secretion, as well as deglucuronidation in the intestines to result in a physiologic re-dosing of MPA known as enterohepatic recycling (Fig. 4). This later phenomenon is demonstrated by the appearance of two MPA peak concentrations, separated by several hours, after administration of the drug. The deconjugation process results in an estimated 40 % exposure (AUC) being attributable to enterohepatic circulation. Significant reductions in both eGFR and tubular secretion can lead to increased plasma levels of MPAG, which in turn



Therapeutic Considerations in Kidney Diseases Due to Glomerulonephritis, Fig. 4 Disposition pathway for mycophenolic acid (MPA)

can result in higher plasma concentrations of MPA through the availability of increased substrate for enterohepatic circulation. With regard to relevance of altered serum albumin concentrations and urinary protein excretion, about 97 % of MPA and 82–88 % of MPAG are bound to albumin (Joy et al. 2009c, d). At high concentrations of MPAG, such as might occur when there is impaired renal clearance, binding of MPA and MPAG to albumin is reduced. Studies have demonstrated reduced protein binding of MPA, with a bound fraction on the order of 94 % in patients with glomerulonephritis as compared with a mean of 97.5–99 % in renal transplant patients. The increased unbound concentration of MPA would contribute to enhanced pharmacologic and adverse effects.

Some studies evaluating the pharmacokinetics of MPA and/or its metabolites in patients with glomerulonephritis have been published (Mino et al. 2008a, b; Neumann et al. 2008; Joy et al. 2009c, d; Djabarouti et al. (2010), Lertdumrongluk et al. 2010; Sam and Joy 2010; Zahr et al. 2010; Mino et al. 2011a, b; Sagcal-Gironella et al. 2011). These studies suggest increased apparent oral clearance and corresponding decreased AUC for MPA in patients with glomerulonephritis versus renal transplant recipients. A study of patients with lupus nephritis looked at the influence of urinary protein excretion on the pharmacokinetics of MPA (Joy et al. 2009c). Patients with urinary protein excretion of $\geq$1 g/day had significantly increased apparent oral clearance and reduced AUC as compared with those with a urinary protein excretion $<$1 g/day. Higher urinary protein excretion was associated with reduced MPA trough concentrations in plasma. Multiple regression analyses were performed to determine which of several clinical factors in patients with glomerulonephritis (i.e., urine protein-to-creatinine ratio, creatinine clearance, serum albumin, age, race, gender, or steroid dose) had the greatest influence on the pharmacokinetics of MPA. Elevated creatinine clearance and reduced serum albumin significantly contributed to the apparent oral clearance of MPA. A glomerulonephritis population pharmacokinetics study that included patients with lupus nephritis and SVV demonstrated significant covariate effects of creatinine clearance and serum albumin on the pharmacokinetics of MPA and MPAG (Sam and Joy 2010). Importantly, this later study demonstrated that renal and nonrenal clearance parameters were affected by the creatinine clearance.

Lertdumrongluk et al. reported on the relationship between AUC and response to MPA in Asian patients with severe lupus nephritis (Lertdumrongluk et al. 2010). The patients in the study by Lertdumrongluk and colleagues were all Thai, and 85 % had nephropathy due to lupus. Treatment success, as defined by eGFR, inactive urine sediment, and reduction in urinary protein excretion, was associated with MPA exposures of $>$45 mg h/L. A study by

Zahr et al. reported on the relationship between MPA AUC and lupus disease activity as assessed by the SLE Disease Activity Index (SLEDAI) (Zahr et al. 2010). MPA exposure was negatively correlated with the results of the SLEDAI. The study reported that MPA plasma exposure levels of ≥35 mg h/L were associated with the lowest risk of active lupus. An additional study evaluated the relationship of MPA AUC to disease activity via the British Isles Lupus Assessment Groups Index (BILAG) in patients with childhood-onset lupus (Sagcal-Gironella et al. 2011). The patients in this study were of different races, and most of them had nephritis. The authors reported decreased (i.e., improved) BILAG scores on MPA therapy when AUC values were ≥30 mg h/L. A study of patients with SVV and lupus nephritis reported on the association between MPA trough plasma concentrations ≥3.5 mg/L and maintenance of disease remission (Neumann et al. 2008).

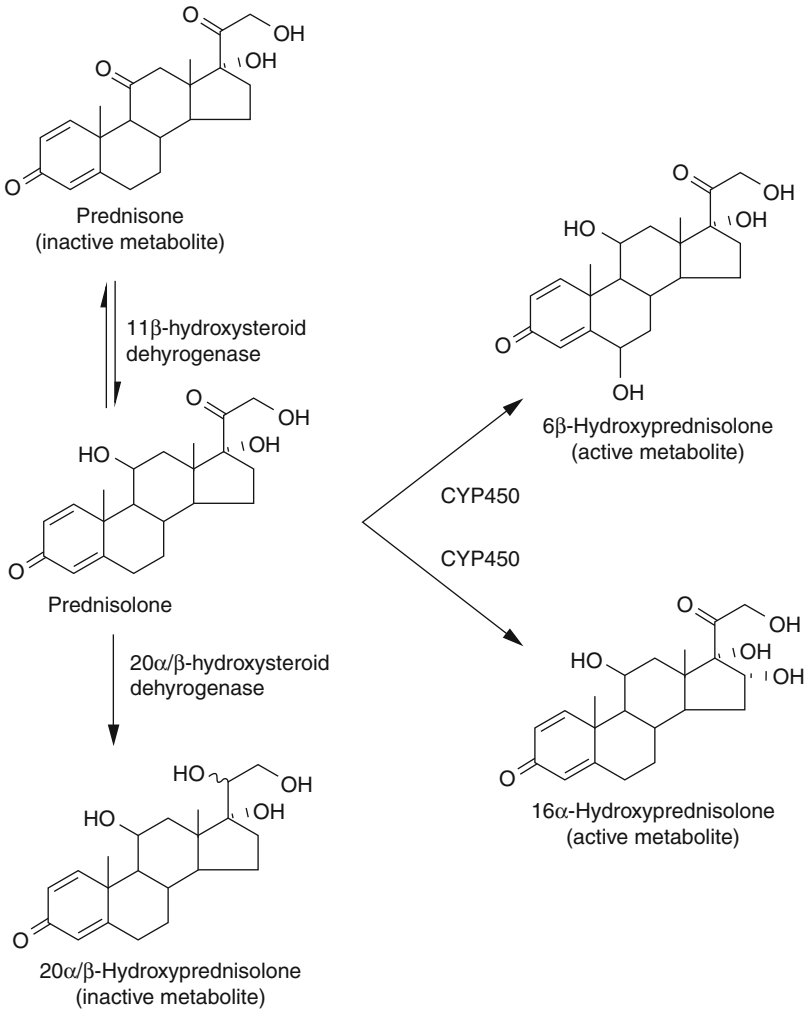
The influence of pharmacogenetics on MPA treatment responses in patients with glomerulonephritis has not yet been reported. However, it appears that polymorphisms in gene(s) encoding uridine diphosphate glucuronosyltransferases (UGTs) can influence the pharmacokinetics of MPA and MPAG (Joy et al. 2010a). Further research is needed to define the influence of pharmacogenomics on MPA efficacy and safety. The evolving data concerning the role of clinical covariates on MPA pharmacokinetics and MPA exposure targets to treatment responses provide evidence that personalized MPA therapy may be beneficial to patients with glomerulonephritis.

Glucocorticoids

The glucocorticoids are the most frequently used medications in the treatment of autoimmune diseases, including glomerulonephritis. Glucocorticoids have numerous mechanisms of action that contribute toward effectiveness in the treatment of autoimmune diseases, including suppression of inflammation, inhibition of T- and B-cell immunity, and alteration in the genetic regulation of proinflammatory cytokines. Despite their widespread use in glomerulonephritis, there is a dearth of information regarding the pharmacokinetics of glucocorticoids. Studies of prednisone and prednisolone, the most commonly used glucocorticoids, are complicated by the nature of their metabolism (Frey and Frey 1990) (Fig. 5). Prednisone is a prodrug that is orally administered. Prednisolone is not stable as an oral formulation and hence is available as a parenteral product employing various salts. Prednisolone is the active form of the drug. The 11beta-hydroxysteroid dehydrogenase is responsible for converting the prodrug prednisone to prednisolone. A subsequent dehydrogenase step results in the formation of an inactive metabolite. However, metabolism via cytochrome P450s results in the formation of additional active metabolites. Notably, both prednisone and prednisolone undergo reversible metabolism resulting in formation clearance of prednisolone from prednisone and vice versa. This section will review basic glucocorticoid pharmacokinetics, as well as the available data pertaining to nephrotic syndrome and glomerulonephritis.

A study by Garg and Jusko attempted to evaluate the pharmacokinetics of prednisone and prednisolone in healthy male subjects (Garg and Jusko, 1994). In this double-blind, randomized, two-way crossover study, subjects were treated with oral prednisone (0.8 mg/kg) and parenteral prednisolone sodium phosphate (equivalent to 0.66 mg/kg of the free base). Regardless of the product evaluated, prednisolone concentrations exceeded that of prednisone at each time point evaluated. Poor oral absorption of prednisone accounted for the lower bioavailability of prednisolone derived from prednisone. The formation clearance of prednisolone from prednisone was 10-times greater than the formation clearance of prednisone from prednisolone.

These findings conflict somewhat with those of an earlier study by Rocci et al. (Rocci et al. 1982). The pharmacokinetics of prednisone and prednisolone were evaluated in six children with nephrotic syndrome. The exposure of prednisolone was significantly higher after oral prednisone than after intravenous prednisolone, suggesting that the oral absorption of prednisone



Therapeutic Considerations in Kidney Diseases Due to Glomerulonephritis, Fig. 5 Metabolic scheme of prednisone and prednisolone (Foye's Principles of Medicinal Chemistry Fig. 33.12; Miller et al. (2008))

and its subsequent conversion are not altered in children with nephrotic syndrome. They also reported increased apparent clearance of prednisolone as compared to previous reports in children with asthma. Renal clearance of both prednisone and prednisolone were found to be normal, suggesting that loss of protein-bound drug in the urine was not problematic. However, since steroids are highly lipophilic and bind to lipoproteins as well as to transcortin and albumin, assessing the influence of proteinuria on renal clearance may be difficult to fully characterize.

Several published studies in nephrotic patients sought to determine if glucocorticoid pharmacokinetics correlated with clinical response or side effects. A study by Rostin et al. demonstrated that the AUC and peak plasma concentrations of prednisolone were highly correlated with serum albumin concentrations, as might be expected for a drug that is bound to albumin (Rostin et al. 1990). These results supported a previous study reporting lower serum prednisolone concentrations in patients with nephrotic syndrome (Frey and Frey 1982). However, correlations of pharmacokinetic parameters to clinical effectiveness could not be identified by Rostin and colleagues.

An earlier study sought to identify a relationship between pharmacokinetic factors and steroid responsiveness in children with nephrotic syndrome (Gatti et al. 1984). Children were assessed during the active phase of disease

and during remission. The authors noted that total serum prednisolone levels during the active phase of disease were significantly lower than during remission. The free fraction of prednisolone was found to correlate negatively with serum albumin levels and was increased during the active phase of disease. However, free prednisolone levels were not significantly different during the active phase and remission, suggesting that the concentration of prednisolone available at pharmacologic sites of action is not different according to disease activity. A recent study reported the pharmacokinetics of prednisolone in eight patients with childhood-onset lupus without changes in GFR (Sagcal-Gironella et al. 2011). The authors sought to correlate drug exposure with disease activity. The results demonstrated that high AUCs were associated with low disease activity as measured by the BILAG. While the limited studies (with small patient numbers) of prednisolone pharmacokinetics in nephrotic syndrome and lupus suggest some alterations and correlation with disease activity, there are multiple patient confounders that have not been appropriately assessed. There are no publications describing the role of pharmacogenomics in drug disposition genes on prednisone and prednisolone responses in glomerulonephritis. This is relevant since numerous dehydrogenases, CYPs, and drug transporters are important for the disposition of these agents. Patients prescribed glucocorticoids for the treatment of glomerulonephritis are often on other medications with documented drug interactions that may alter response or safety. Glucocorticoids are known to induce the metabolism of numerous medications, resulting in altered therapeutic efficacy and safety of the victim drug.

Monoclonal Antibodies

Monoclonal antibodies are increasingly being investigated to treat diseases associated with glomerulonephritis. Rituximab is a monoclonal antibody that received US Food and Drug Administration approval on April 29, 2011, for treatment of GPA and microscopic polyangiitis (MPA), two forms of anti-neutrophil cytoplasmic autoantibody (ANCA)-associated vasculitis. A second monoclonal antibody, adalimumab, has been studied in patients with FSGS (Joy et al. 2010b). Infliximab has been used as a third-line agent to treat refractory lupus nephritis.

All subclasses of human IgG have a molecular weight of 145 kD, approximately twice the molecular weight of albumin (67 kD). Based on the molecular weight, therapeutic antibodies would not be expected to be excreted in the urine. However, proteinuric kidney diseases, such as glomerulonephritis, can result in urinary excretion of large amounts of proteins. While albumin is the predominant constituent of the proteins found in the urine, there is evidence of loss of other macromolecular proteins, especially in the setting of nephrotic-range proteinuria ($\geq$3 g protein/day). A study of pediatric patients with nephrotic syndrome due to minimal change disease (MCD), focal glomerulosclerosis (FGS), or membranoproliferative glomerulonephritis (MPGN) found that many patients with MCD and FGS had significantly decreased serum levels of immunoglobulins (Ellis and Buffone 1981). For patients with MCD, there were only minimal urinary immunoglobulins, suggesting either decreased production or increased systemic clearance via nonrenal routes. Conversely, patients with FGS had high urinary IgG excretion relative to serum levels. These data provided the first suggestion that nephrotic patients have increased systemic clearance of immunoglobulins through renal and nonrenal routes of elimination.

Rituximab is an intravenously administered, CD20-specific chimeric murine/human monoclonal antibody that selectively targets B cells at all phases of maturation, with the exception of the earliest and latest phases, including plasma cells. CD20 is a B-cell differentiation marker not found on most other cells, and it is not found in the circulation. Rituximab represents a promising rational treatment for many forms of autoimmune disease, since it selectively targets B cells. In the case of ANCA-associated glomerulonephritis, rituximab targets the B cells that have been clearly demonstrated to play a pathogenic role in the development and recurrence of disease.

Clinical studies have reported that rituximab is non-inferior to cyclophosphamide for initial therapy or recurrence of either GPA or MPA in both short-term (Jones et al. 2010; Specks and Stone 2010) and long-term follow-up (Jones et al. 2011; Specks et al. 2011). The antibody is composed of two heavy chains of 451 amino acids and two light chains of 213 amino acids, with a resultant molecular weight of 145 kD. This size is consistent with normal human IgG molecules, which generally have a weight of 146 kD (IgG1, 2, and 4), or in the case of IgG3 of 170 kD. Pharmacokinetic data for rituximab in patients with kidney disease of any etiology is generally lacking. There are few case reports suggesting that target levels of the drug can be achieved both in patients with chronic kidney disease, as well as end-stage renal disease, without adverse effect (Castro et al. 2001; Jillella et al. 2002). However, significant data supporting these observations are unavailable. Multiple studies have shown rituximab to be highly effective in reducing proteinuria secondary to several disease entities, and there is evidence that rituximab can reverse glomerular pathology in patients with nephrotic-range proteinuria. Studies to determine the influence of proteinuria on renal and nonrenal clearance and other pharmacokinetics parameters, as well as to determine targets for drug exposure and therapeutic dosing strategies, are needed to maximize beneficial effects and minimize potential adverse effects.

Adalimumab is a subcutaneously administered, fully humanized recombinant monoclonal antibody of the IgG1 subclass, with high affinity for tumor necrosis factor alpha (TNFα). It comprises 133 amino acids and has a molecular weight of approximately 148 kD, similar to that of rituximab. The recently reported FONT Study (Novel Therapies for Resistant FSGS) was designed to investigate the pharmacokinetic characteristics, tolerability, and safety of pharmaceutical agents with potential for antifibrotic activity (Joy et al. 2010b). Adalimumab was one of the drugs studied in the setting of patients with resistant primary FSGS. The FONT investigators found a twofold higher apparent clearance and twofold lower AUC in the proteinuric patients with FSGS as compared to previous reports in patients with rheumatoid arthritis. A shorter time to maximum plasma concentration (Tmax) and lower maximum plasma concentration (Cmax) were also reported as compared to patients with rheumatoid arthritis. Preliminary unpublished data suggest increased renal and nonrenal clearance of adalimumab in FSGS. The data also suggested that patients who were able to achieve a predefined targeted trough plasma concentration (Ctrough) demonstrated a better therapeutic response as defined by decreased urinary protein excretion and increased eGFR. The data demonstrating the pharmacokinetics of adalimumab in patients with proteinuria suggest the need for thorough clinical pharmacology studies when therapeutic proteins are being considered for use in proteinuric kidney diseases in order to appropriately define and meet targeted exposure criteria to maximize treatment responses.

The drugs discussed here represent only a few of the medications now available as part of the armamentarium for treatment of SVV, SLE, and other forms of glomerular disease. Discussion of these particular drugs highlights some of the issues that remain in understanding how best to utilize them. Of particular importance is a better understanding of the clinical pharmacology (pharmacokinetics) of these drugs, particularly in the setting of the diseases that they are used to treat. By further elucidating the specifics of altered drug-related parameters (clearance, volume of distribution, AUC), clinical factors (proteinuria, GFR, serum albumin) and level of inflammation, and the role of genetic factors and drug interactions, drugs investigated for use in glomerulonephritis may show even greater promise for ameliorating or even curing a number of diseases that continue to cause significant morbidity and mortality.

Translational Aspects of Membranous Nephropathy

William G. Couser
Division of Nephrology, University of Washington, Seattle, WA, USA

Synonyms

Chronic kidney disease; Class V lupus nephritis; Idiopathic nephrotic syndrome; Membranous glomerulonephritis; Nephrotic syndrome; Proteinuria

Definition

Membranous nephropathy (MN) refers to a pathologic pattern of injury to the filtering units in the kidney, the renal glomeruli, characterized by minimal changes (early) or glomerular basement membrane (GBM) thickening (later) by light microscopy; diffuse, finely granular deposits of IgG and complement C3 exclusively along the outer surface of the capillary wall by immunofluorescence microscopy (IF); and corresponding diffuse electron-dense deposits in an exclusively subepithelial distribution by electron microscopy (EM) (Couser and Cattran 2010; Fervenza et al. 2008). MN is a pathologic diagnosis made when a renal biopsy is performed to evaluate the cause of an unexplained increase in excretion of protein in the urine. In such patients MN is the underlying disease in 10 % of children, 33 % of adults, and 40 % of adults over 60. About 80 % of cases of MN are without obvious etiology (idiopathic, IMN) (Couser and Cattran 2010a; Fervenza et al. 2008). Most of these are autoimmune caused by glomerular deposition of an IgG_4 autoantibody to M-type phospholipase A2 receptor (PLA2R), a membrane glycoprotein expressed in the kidney only by glomerular podocytes that line the outer surface of the glomerular capillary wall (Beck et al. 2009).

In the remaining 20 % of cases, the lesion of MN develops in a setting of some systemic disease (secondary MN) (Table 1). In secondary MN, the antigens involved are non-glomerular but may also be self-antigens as seen, for example, in lupus (class V lupus nephritis) (Couser and Cattran 2010a; Fervenza et al. 2008).

Epidemiology

In the USA, the incidence of end-stage renal disease (ESRD) due to MN is about 460 patients/year, which represents 0.4 % of the total end-stage renal disease (ESRD) population (Couser and Cattran 2010; Fervenza et al. 2008). Since only about 20 % of all patients with MN now progress to ESRD, the real incidence of MN is likely about 2,300 patients per year in the USA or about eight patients/million population/year (Couser and Cattran 2010a; Fervenza et al. 2008).

The risk for MN is increased threefold in Caucasian patients with HLA-DR3, and associations with HLA-B8 and HLA-B18 have also been reported. The risk of progressive loss of renal function in Caucasians is increased with HLA-DR5 and HLA-DR3. In Japan, MN is associated with HLA-DR2. Some Caucasian patients have a deletion of C4 with the HLA-B8–DR3 haplotype (Couser and Cattran 2010). Familial MN is rare and is usually seen in children. Genome-wide association studies have also identified a link between IMN and the gene for PLA2R. The presence of both HLA and PLA2R risk alleles increases the odds of developing IMN almost 80 fold (Stanescu et al. 2011).

Translational Aspects of Membranous Nephropathy, Table 1 Causes of secondary membranous nephropathy (Adapted with permission from Couser and Cattran (2010). All permissions were obtained through ScienceDirect at www.sciencedirect.com)

Groups	Common	Uncommon
Immune diseases	Systemic lupus erythematosus, diabetes mellitus	Rheumatoid arthritis, Hashimoto's disease, Graves' disease, mixed connective tissue disease, Sjögren's syndrome, primary biliary cirrhosis, bullous pemphigoid, small bowel enteropathy syndrome, dermatitis herpetiformis, ankylosing spondylitis, graft-versus-host disease, Guillain–Barré syndrome, bone marrow and stem cell transplantation, anti-GBM and ANCA-positive crescentic glomerulonephritis
Infectious or parasitic diseases	Hepatitis B	Hepatitis C, syphilis, filariasis, hydatid disease, schistosomiasis, malaria, leprosy
Drugs and toxins	Gold, penicillamine, nonsteroidal anti-inflammatory drugs	Mercury, captopril, formaldehyde, hydrocarbons, bucillamine agents
Miscellaneous	Tumors, renal transplantation	Sarcoidosis, sickle cell disease, Kimura disease, angiofollicular lymph node hyperplasia

The list excludes conditions where only a single case has been reported or where the lesions were atypical of membranous nephropathy

Clinical Features

Common clinical features in IMN are summarized in Table 2. In adults, about 70 % of patients with IMN present with nephrotic syndrome, a clinical diagnosis made when the measured urine protein excretion exceeds 3.5 g/day or the ratio of protein to creatinine in a random urine sample exceeds 3.0 (Couser and Cattran 2010a; Fervenza et al. 2008; Hladunewich et al. 2009). Renal function is normal at presentation in over 90 %. Many such patients exhibit other disease manifestations including reduced serum albumin levels, elevated lipid levels, and peripheral edema, collectively referred to as nephrotic syndrome. About 25 % present with elevated but lower levels of protein excretion. Sixty percent of these patients progress to nephrotic syndrome, usually in the first year after diagnosis, and 10 % of all IMN patients never become nephrotic (Hladunewich et al. 2009). Spontaneous remissions with disappearance of the proteinuria without therapy occur in about 32 % in an average of 14 months (Couser and Cattran 2010a; Fervenza et al. 2008; Hladunewich et al. 2009).

About 80 % of cases of MN represent "idiopathic" primary renal diseases, and most are now recognized to be consequent to an autoimmune mechanism caused by development of an autoantibody to a podocyte membrane protein (phospholipase A2 receptor (PLA2R)) (Couser and Cattran 2010a; Beck et al. 2009; Fervenza et al. 2008) (see below). About 20 % of patients have secondary MN which may also involve nonrenal self-antigens (lupus) or exogenous non-self-antigens as is presumed to occur in MN associated with hepatitis B and C virus

Translational Aspects of Membranous Nephropathy, Table 2 Clinical features of idiopathic membranous nephropathy (Adapted with permission from Couser and Cattran (2010). All permissions were obtained through ScienceDirect at www.sciencedirect.com)

Rare in children – < 5 % of total cases of nephrotic syndrome
Common in adults – 15–50 % of total cases of nephrotic syndrome, depending on age. Increasing frequency after age 40 years, commonest cause in adults >60
Males > females in all adult groups
Caucasians > Asians > African–Americans > Hispanics
Nephrotic syndrome in 60–70 %
Normal or mildly elevated BP at presentation
"Benign" urinary sediment
Nonselective proteinuria
Tendency to thromboembolic disease
Secondary causes: infection, drugs, neoplasia, systemic lupus erythematosus

infection, various chronic parasitic infections, drug exposures, malignancies, and (in infants) allergy to cow's milk (Couser and Cattran 2010a; Fervenza et al. 2008; Hladunewich et al. 2009). The commonest causes of secondary MN are listed in Table 1. An increased incidence of MN has been reported in association with other autoimmune diseases, particularly type I diabetes, anti-GBM disease, ANCA-associated vasculitis, and lupus. Lupus MN is anti-PLA2R negative, but the nature of the autoantibody in these secondary autoimmune forms of the disease is otherwise unknown.

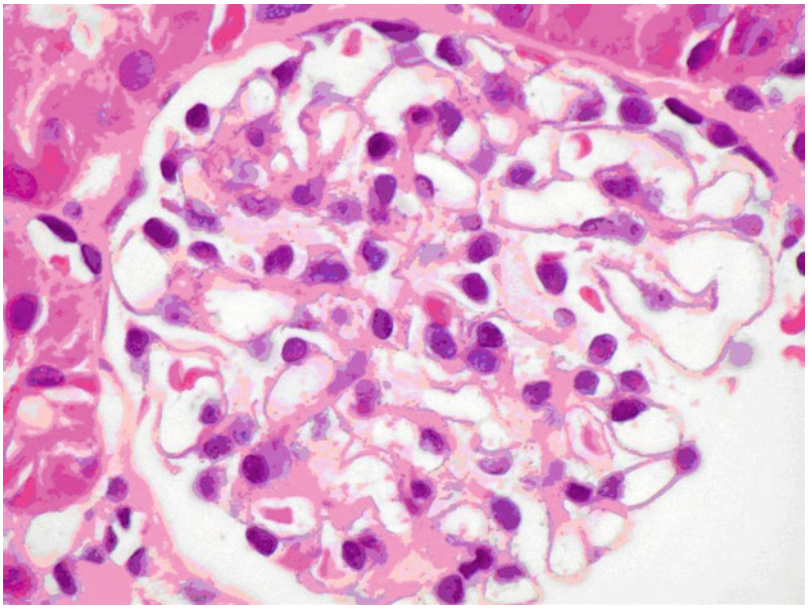
The clinical consequences of MN can be considered as both short and long term. In the short term, they reflect the result of an increased loss of albumin and other serum proteins in the urine that can lead to hypoalbuminemia with salt and water retention resulting in edema and even anasarca, a high risk for development of thrombotic and thromboembolic events (10–40 %) due to loss of coagulation inhibitors in the urine and increased risk of infection due primarily to urinary loss of immunoglobulins (Couser and Cattran 2010a; Fervenza et al. 2008; Hladunewich et al. 2009) (Table 2). However, the most feared long-term consequence of MN is progressive loss of renal function leading to ESRD. This course is followed by about 50 % of patients with 35 % developing ESRD within 10 years, 41 % at 15 years, and another 10 % after that (Couser and Cattran 2010a; Fervenza et al. 2008; Hladunewich et al. 2009). The risk of progression is directly related to the level of urine protein excretion over time. Progression occurs in <5 % of patients who never develop nephrotic-range proteinuria, <10 % of those who maintain protein excretions below 4 g/day, 50 % of those with persistent levels of 4–8 g/day, and 70–80 % of those who continue to excrete 8–10 or more grams/day (Couser and Cattran 2010a; Fervenza et al. 2008; Hladunewich et al. 2009). Other risk factors for progression include male sex, elevated blood pressure, and likely persistently elevated levels of anti-PLA2R antibodies.

In secondary MN, the course will vary depending on the etiology and success in treating the underlying primary disease (Table 1). For example, drug-induced disease usually resolves spontaneously with discontinuation of the drug, viral infection-related MN can resolve with successful antiviral therapy, cancer-associated MN has been reported to resolve with removal of the tumor, and lupus-associated MN follows a chronic course that usually parallels the course of the systemic lupus (Couser and Cattran 2010; Fervenza et al. 2008; Hladunewich et al. 2009).

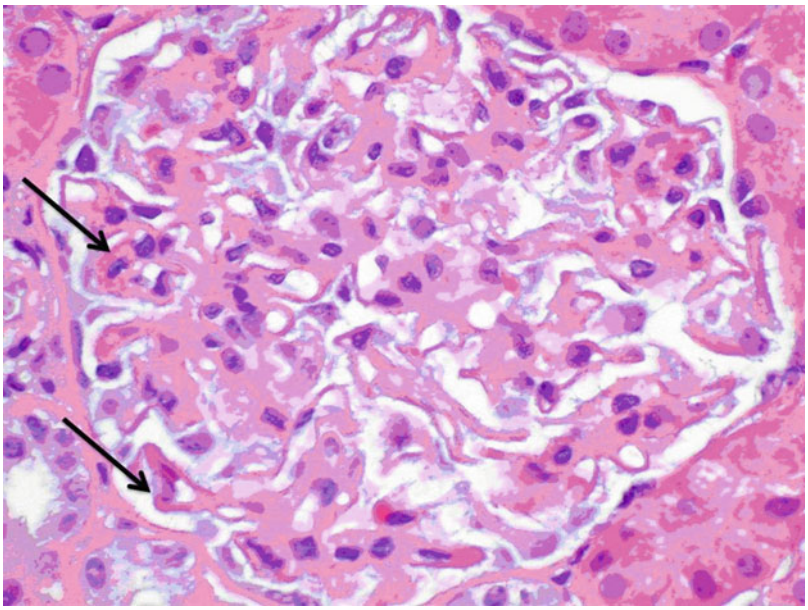
Pathology

As mentioned above, MN is a pathology diagnosis made by study of a diagnostic renal biopsy. The diagnostic pathologic changes are seen only in glomeruli and are uniform involving all glomeruli to the same degree (Couser and Cattran 2010a; Fervenza et al. 2008). By light microscopy, glomeruli may appear entirely normal in early disease (Fig. 1). With progression changes of basement membrane, thickening (hence the term membranous) (Fig. 2) with formation of subepithelial "spikes" of basement membrane on the outer surface of the capillary wall become apparent, particularly when a stain that marks extracellular matrix such as silver methenamine is employed (Fig. 3).

IF reveals diffuse, uniform, (Kanigicherla et al. 2013) finely granular deposits of IgG and C3 along the outer surface of the capillary wall in all glomeruli (Fig. 4) (Couser and Cattran 2010; Fervenza et al. 2008). The predominant IgG subtype in IMN is IgG_4 usually reflecting the deposition of IgG_4 anti-PLA2R antibody, although lesser deposits of IgG_1 and IgG_3 may be seen (Beck et al. 2009). The presence of primarily IgG_1 or IgG_3, IgM or IgA, suggests a secondary cause, particularly lupus, in which a "full house" IF pattern is typical (Couser and Cattran 2010a; Fervenza et al. 2008). Complement deposits include C3, C4, and C5b-9 but not C1q consistent with complement activation by either the MBL or alternate complement pathways (see below) (Couser 2012; Cybulsky 2011). PLA2R is also a constituent of the subepithelial deposits in most cases studied (Beck et al. 2009). A variety of nonrenal antigens



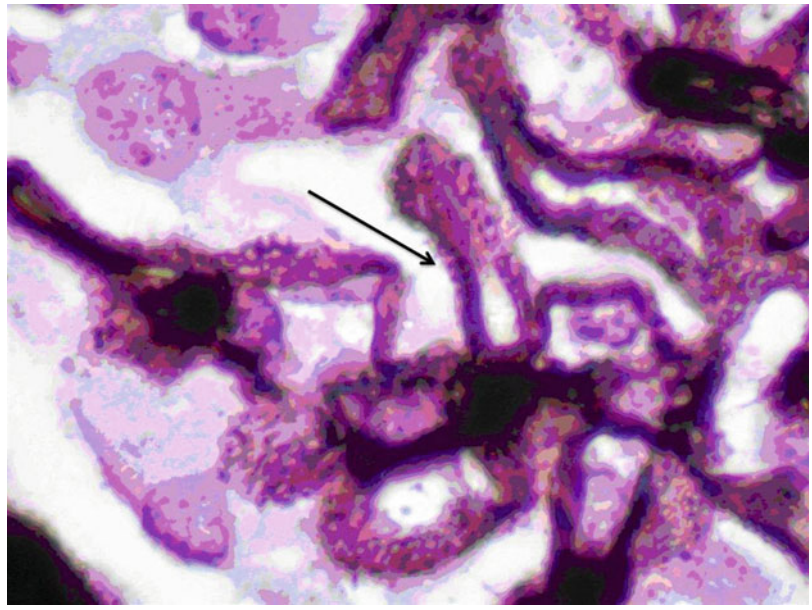
Translational Aspects of Membranous Nephropathy, Fig. 1 Light micrograph of early membranous nephropathy exhibiting normal architecture and peripheral capillary basement membranes of normal thickness. This light microscopic appearance in a patient with nephrotic syndrome can be indistinguishable from normal or minimal change disease (Silver methenamine; magnification X400)



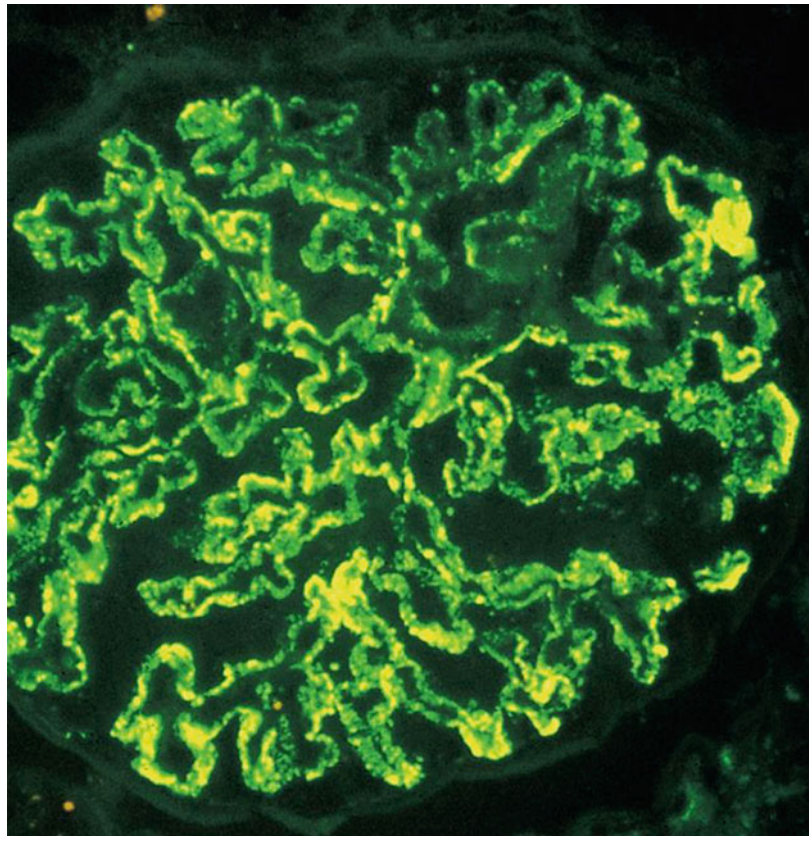
Translational Aspects of Membranous Nephropathy, Fig. 2 Morphologically advanced MN. There is a uniform increase in the thickness of the glomerular capillary walls throughout the glomerulus (Membranous change, *arrows*) without any increase in glomerular cellularity (Periodic acid–Schiff; magnification 400X)

have been identified by IF in the deposits in secondary MN including hepatitis B virus, nucleosomes in lupus MN, and tumor-associated proteins in MN associated with malignancy (Couser 2012).

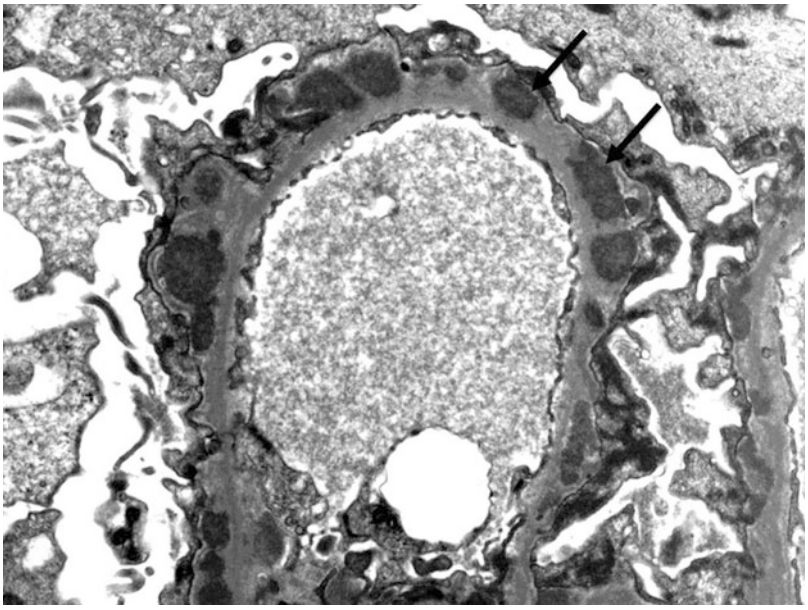
EM in IMN confirms the exclusively subepithelial localization of electron-dense deposits, which are often in slit, pore regions between adjacent podocyte foot processes (Fig. 5). GBM thickening is seen with progression, and the deposits gradually are incorporated within new GBM and then become more electron-lucent as they are resorbed before disappearing. This has led to classification of



Translational Aspects of Membranous Nephropathy, Fig. 3 Light microscopic appearance of a glomerulus in chronic IMN stained with silver methenamine to reveal the characteristic "spikes" projecting from the outer, subepithelial aspect of the basement membrane (*arrow*). Spikes are seen in more advanced disease (Magnification X1000)



Translational Aspects of Membranous Nephropathy, Fig. 4 Typical pattern of immunofluorescence staining for IgG in MN showing diffuse, finely granular deposits along the outer (subepithelial) aspect of the glomerular capillary wall. Similar staining can be seen with stains for C3, C5b-9, and, in active MN, for PLA2R (X400)



Translational Aspects of Membranous Nephropathy, Fig. 5 Low-power electron micrograph of MN showing typical discrete electron-dense deposits (*arrows*) along the outer (subepithelial) aspect of the glomerular capillary wall. Spikes of basement membrane can be seen projecting between deposits to form the spikes seen on silver staining. There is widespread effacement of overlying podocyte foot processes (X 18,000)

the EM changes into stages 1–4, which reflect the activity and chronicity of the disease (Couser and Cattran 2010a; Fervenza et al. 2008). Additional biopsy findings that are suggestive of secondary disease and rarely seen in IMN include electron-dense deposits in subendothelial or mesangial locations, significant mesangial cell proliferation, prominent deposition of IgG_1 and IgG_3, and tubuloreticular structures by EM. The other characteristic finding by EM is swelling and effacement, or "fusion," of podocyte foot processes, similar to findings in most proteinuric glomerular diseases that occur consequent to primary podocyte injury (Fig. 5) (Couser and Cattran 2010; Fervenza et al. 2008). With time there is detachment of damaged cells where protein flux becomes greatest and development of podocytopenia, another feature common to several chronic progressive proteinuric nephropathies.

In patients with persistent proteinuria and progressive disease, glomeruli eventually become scarred and sclerotic, and an interstitial mononuclear cell infiltrate develops between glomeruli followed by interstitial fibrosis as occurs in all chronic progressive glomerular diseases (Couser and Cattran 2010; Fervenza et al. 2008; Hladunewich et al. 2009).

Pathogenesis

The studies over a period of 50 years that have led to our current understanding of the pathogenetic mechanisms that underlie IMN represent a remarkable tribute to the value of basic, translational, and clinical research pursued by physician–scientists in finally unlocking the underlying autoimmune pathogenesis of an important human renal disease. They are well summarized elsewhere (Couser 2012; Beck and Salant 2010; Ronco and Debiec 2010). Attempts to clarify how the subepithelial immune deposits of IgG and complement form in MN began in the 1960s with models of acute and chronic serum sickness induced in rabbits immunized with bovine serum albumin (BSA). It was shown that chronic administration of native BSA sufficient to maintain a slight excess of antigen over antibody led to formation of low molecular weight, low avidity, and circulating soluble immune complexes coincident with the appearance of glomerular immune deposits of both antigen and antibody that were primarily subepithelial in distribution (Couser 1985). The deposits were believed to reflect the passive trapping of preformed immune complexes that penetrated to the subepithelial side of the glomerular filter to

precipitate beneath the podocyte layer (Couser 1985). However, in these BSA-serum sickness models, substantial deposit formation also occurred in mesangial and subendothelial locations, unlike the deposits in IMN, which were exclusively subepithelial. Moreover, subsequent studies were unable to verify that immune complexes of the proposed size were able to transit the capillary wall intact to deposit in the subepithelial space or that circulating immune complexes were even present in IMN in man (Couser 1985). Finally, other studies showed that subepithelial formation of BSA–anti-BSA immune deposits were independent of circulating immune complexes and depended largely on the electrical charge of the BSA antigen which appeared to localize independently of antibody and lead to subsequent "in situ" immune complex formation (Couser 1985).

Another model of MN had been described in 1959 by Walter Heymann who immunized rats with an antigenic preparation derived primarily from renal proximal tubular brush border that was later termed fraction 1A (Fx1A). Heymann found, over 4–6 months, that these rats developed a lesion that was virtually indistinguishable clinically and pathologically from IMN in man (active Heymann nephritis) (Couser 2012; Beck and Salant 2010; Kerjaschki 2004). Others later were able to induce the same deposits within days by injecting rabbit IgG antibodies to Fx1A (passive Heymann nephritis, PHN). However, these deposits were not accompanied by proteinuria until later in the disease when rat antibodies to the deposited rabbit IgG developed and a new process of deposit formation intervened. Based on the rabbit BSA-serum sickness studies, both the active and passive Heymann models were presumed to reflect chronic trapping of circulating immune complexes containing tubular antigens (Couser 1985). However, the mechanisms of tissue injury induced by immune deposit formation in glomeruli had only been defined in models of anti-GBM nephritis where complement activation, C5a chemotactic factor generation, and neutrophil recruitment were central (Couser 2012; 1985). They were unknown in traditional immune complex nephritis including the serum sickness or Heymann models where complement deposition also occurred but in the absence of any corresponding neutrophil infiltrate or inflammatory changes.

In the late 1970s, the PHN model was successfully modified to exhibit proteinuria that was induced by deposition of the injected heterologous anti-Fx1A IgG within 5 days (before the animals began to deposit a secondary antibody to the initial heterologous IgG) allowing the study of how the primary nephritogenic antibody caused glomerular injury without producing morphologic evidence of inflammation. This was eventually achieved with a high-titer sheep antibody to Fx1A that induced nephrotic-range proteinuria in rats within 3–4 days, a short enough interval to allow the mediators of glomerular injury to be defined. Two unexpected observations immediately followed. The first was that when the sheep anti-Fx1a antibody IgG used to induce proteinuric PHN was added to a non-recirculating, bloodless perfusate in a physiologic isolated perfused kidney system, within 1–2 h, it induced exactly the same deposits seen in 3–4 days following intravenous injection in the intact animal (Couser et al. 1978). This finding, reported almost simultaneously by Couser et al. and by the group led by Philip Hoedemaeker in the Netherlands using an ex vivo perfusion system, excluded any role for circulating immune complex trapping in producing the lesion of IMN and proved that the deposits instead formed in situ when antibody bound to some fixed glomerular antigen. Similar findings were obtained using rat antibody eluted from the kidneys of animals with active Heymann nephritis. The Heymann antigen, based on the exclusive localization of the deposits beneath podocyte foot processes, was hypothesized to be a constituent of the podocyte, and MN was therefore postulated to be an autoimmune disease (Couser et al. 1978; Couser 1985). Extensive later studies by Kerjaschki and Farquhar in the 1980s confirmed this and identified the antigen in Heymann nephritis as megalin, a normal constituent of the rat podocyte membrane (Kerjaschki 2004). However, megalin is not expressed in human podocytes. Another 25 years elapsed before it

was finally shown that IMN in man could result from the same mechanism involving in situ deposit formation by an anti-podocyte antibody as first in the Heymann models in rats.

The second unanticipated observation was that the injury (proteinuria) was entirely complement dependent despite the fact that no inflammatory cells were present thus excluding the only recognized role of complement in tissue injury – that is, attracting neutrophils via release of chemotactic C5a leading to neutrophil-mediated damage (Cybulsky 2011; Salant et al. 1980; Couser et al. 1985). It was speculated that this new role for complement might be due to glomerular formation of the complement membrane attack complex, C5b-9, which could insert into lipid bilayers of resident glomerular cells and activate these cells to release mediators such as oxidants and proteases that could, in turn, injure the capillary wall and cause proteinuria (Salant et al. 1980). This hypothesis was later confirmed ex vivo in isolated perfused kidneys using sheep anti-Fx1A IgG added to C6- and C8-deficient serum perfusate and in vivo using selective C6 depletion in the intact animal (Cybulsky 2011; Couser and Nangaku 2006). The initial demonstration that C5b-9 could mediate immune tissue injury was later extended to models of immune injury to both endothelial and mesangial cells as well and has since been verified in complement-mediated immune damage in several other disease states including neurons in multiple sclerosis, cardiac cells in myocardial infarcts, retinal epithelium in acute macular degeneration, and renal tubular cells in progressive proteinuric nephropathies of both immune and nonimmune origin (Cybulsky 2011).

Debiec and Ronco provided the first documentation of a fixed podocyte antigen causing IMN in humans in 2002 when they studied an infant with MN and nephrotic syndrome born to a mother with a genetic deficiency in neutral endopeptidase (NEP). They showed that NEP was expressed on podocytes of the infant and that the MN lesion resulted from alloimmunization with deposition of maternal anti-NEP antibody – which could also transfer MN to normal animals (Ronco and Debiec 2010). However, this mechanism proved applicable only to the alloimmunization setting and is not operative in typical adult IMN. However, in 2009, Beck and Salant utilized microdissection of glomeruli from patients with IMN, microelution of deposited antibody, and proteomic technology to demonstrate that the deposited IgG, primarily IgG4, in IMN was reactive with another podocyte membrane protein PLA2R (Beck et al. 2009). Moreover, 70–80 % of IMN patients studied had circulating anti-PLA2R antibody which not only correlated clinically with proteinuria but disappeared before remission and returned with relapse (Beck et al. 2009; Ronco and Debiec 2010; Hofstra et al. 2011). These findings, now confirmed by several other laboratories, bring full circle the observations made initially in the Heymann models of MN in rats to explain the pathogenesis of IMN in man.

In addition to membrane proteins NEP and PLA2R, antibodies to other podocyte antigens have also been identified in a minority of patients with IMN including cytosolic constituents such as superoxide dismutase, aldose reductase, and enolase, although the latter likely represent reactive secondary rather than primary disease-inducing antibodies.

Much has also been learned about the mechanism of C5b-9-mediated tissue injury that was first identified in PHN in 1980 (Cybulsky 2011). In contrast to antigen–antibody complexes which form lattices that are capped and shed from the podocyte to create the visible subepithelial deposits beneath the podocyte slit diaphragm, membrane insertion of C5b-9 is followed by uptake of the complex into multivesicular bodies within the cell and extrusion into the urinary space leading to elevated levels of urinary C5b-9 excretion in MN (Couser 2012; Couser and Nangaku 2006). Membrane insertion of C5b-9 in sublytic quantities has a potent agonistic effect on nucleated cells activating several signalling pathways and thereby converting normal glomerular cells to effector cells that produce mediator molecules such as oxidants, proteases, cytokines, growth factors, and several extracellular matrix components that lead (in the case of podocytes) to the membranous changes and spike

formation seen in MN (Cybulsky 2011). C5b-9 also alters cell-matrix interaction favoring detachment, podocyte shedding in the urine, and podocytopenia. It causes DNA damage that prevents completion of the cell cycle and therefore cell proliferation to repair the areas of denuded GBM created by podocyte detachment. The combination of oxidant injury to underlying GBM and podocyte detachment are believed to be the principal mechanisms that underlie the partial disruption of the glomerular barrier to protein filtration and consequent nonselective loss of large quantities of serum proteins in the urine in MN (Couser 2012; Cybulsky 2011).

Studies of models of secondary MN such as cationic BSA-induced chronic serum sickness or the autologous phase of PHN confirm that subepithelial deposits involving nonrenal antigens also form in situ and also cause injury through a C5b-9-dependent process (Couser 2012; Couser and Nangaku 2006).

A final important point in understanding the pathophysiology of capillary wall injury in MN is that sequestration of deposits in the subepithelial space and slow resorption by fully differentiated podocytes results in very delayed resolution of the disease after formation of new deposits ceases. This has been documented experimentally by transplanting MN kidneys (Heymann nephritis) into normal hosts and confirmed in man by the lag of weeks or months between the disappearance of anti-PLA2R antibody from the circulation and the eventual resolution of proteinuria (Hofstra et al. 2011).

Treatment

Any discussion of treatment of IMN must be prefaced with the reminder that less than 50 % of patients in most studies develop progressive disease and many patients need only general antiproteinuric supportive therapy since reducing urine protein excretion to less than 3.5 g/day is associated with a <5 % chance of progression (Couser and Cattran 2010; Fervenza et al. 2008). Thus, treatment to reduce edema with diuretics, correct hyperlipidemia with statins, and control blood pressure and lower protein excretion with renin–angiotensin system blockers titrated to achieve the lowest possible protein excretion is the standard of care for all patients with protein excretions exceeding 1 g/day (Feehally et al. 2012; Hofstra and Wetzels 2012). Studies have also shown that a conservative "watch and wait" approach during 6 months of conservative therapy does not alter the long-term outcome of the disease years later (although initial resolution of nephrotic syndrome is delayed by this approach, a consequence that is likely outweighed by sparing many patients the adverse consequences of immunosuppressive drug therapy) (Hofstra and Wetzels 2012). For patients who fail to achieve a 50 % reduction in protein excretion or have persistent proteinuria exceeding 3.5 g/day after 6 months of conservative therapy, patients who present initially with proteinuria >10 g/day, or patients exhibiting disabling nephrotic syndrome or progressive loss of renal function (evident by a 30 % increase in serum creatinine levels), the risk of progression exceeds 50 % and the addition of immunosuppressive therapy is warranted (Couser and Cattran 2010; Fervenza et al. 2008; Hofstra and Wetzels 2012). Disease-specific immunosuppressive therapy is not indicated in patients who have <3.5 g/day of proteinuria or have already lost substantial renal function – for example, those with eGFR <30 ml/min or serum creatinine >3.5 mg/dl (Feehally et al. 2012; Hofstra and Wetzels 2012).

The best established treatment regimen for IMN is to initiate steroid therapy with intravenous methylprednisolone (30 mg/kg/day to a maximum of 1,000 mg) for 3 days followed by 27 days of oral steroids (prednisone, 0.5 mg/kg not exceeding 60 mg/day) followed by a month of oral cyclophosphamide, 2–2.5 mg/day (adjusted for age and renal function) (Couser and Cattran 2010; Fervenza et al. 2008; Feehally et al. 2012). When this alternating monthly cycle of steroids and cytotoxic drugs is repeated for three cycles (6 months), remissions of proteinuria occur in about 70–80 % of patients vs. about 30 % of controls treated with supportive care only, and the development of ESRD 10 years later is reduced

from 30–40 % to 10 % or less when all patients with IMN are treated (Hofstra and Wetzels 2012; Hofstra and Wetzels 2010; Feehally et al. 2012). Comparable results have been reported at 7 years when the delayed therapy approach described above is employed (Hofstra and Wetzels 2012; Hofstra and Wetzels 2010). Observational studies suggest that treating for 6 months with daily oral cyclophosphamide and steroids achieves comparable results, although the cumulative dose of administered cyclophosphamide is twofold higher. The relapse rate following treatment with these regimens is about 25 %, and relapses are usually treated by repeating the same therapy that induced the initial remission (Feehally et al. 2012).

The only other treatment for MN established to improve long-term outcomes is calcineurin inhibitors (CNI), usually cyclosporine A (CSA), 3.5–5 mg/kg/day in divided doses to maintain blood levels of 120–200 μg/L, combined with low-dose steroids (prednisone 0.15 mg/kg/day) (Couser and Cattran 2010; Fervenza et al. 2008; Feehally et al. 2012). CSA has been shown to induce partial or complete remissions in 40–50 % of cases of IMN and should be employed if Cytoxan/steroid treatment fails, the patient cannot tolerate cytotoxic drugs, or issues such as preservation of fertility are operative (although MN is rarely progressive in young women). Results with Tacrolimus (.05 to .075 mg/kg/day, levels of 3–5 μg/L increasing to 5–8) are comparable, although the incidence of diabetes as a complication is higher. The relapse rate with CNIs is higher (40–50 %) than with cyclophosphamide (25 %) but seems to diminish with longer periods of therapy (Couser and Cattran 2010; Fervenza et al. 2008; Feehally et al. 2012). However, CNI nephrotoxicity is also a problem. Attempting to balance the nephrotoxicity with the increased relapse rate after short-term therapy, current recommendations are to use CNIs only in patients with normal or near-normal renal function (GFR $>$ 40 ml/min), to reduce initial doses every 4–8 weeks after achieving a complete or partial remission to 50 % of the initial dose, to treat for at least 1 year after a complete remission is achieved and 18 months after a partial remission, and to taper the drug slowly over several months (Couser and Cattran 2010; Fervenza et al. 2008; Feehally et al. 2012).

Less well-established treatment options for IMN include mycophenolate mofetil (MMF), B cell depletion with Rituximab and ACTH, and these may be employed in patients resistant to, or intolerant of, cyclophosphamide or CNIs. Pilot studies have suggested MMF, 2–3 g/day for 6 months, may give comparable short-term results to steroids and cyclophosphamide, at least in Asian patients. MMF is equivalent to cyclophosphamide for efficacy in membranous lupus nephritis, but long-term data on preservation of renal function are lacking. Rituximab used in a single dose of 375 mg/M2 i.v. has also been reported to reduce anti-PLA2R antibody levels and induce remission in about 50 % of patients in 1 year (Couser and Cattran 2010; Fervenza et al. 2008; Feehally et al. 2012; Hofstra et al. 2011), but that figure steadily increases to about 90 % by 6 years, and the safety profile is better than that of cyclophosphamide. ACTH therapy was shown to give short-term results equivalent to monthly cycles of cyclophosphamide and steroids with minimal adverse events in one small randomized controlled study but another controlled study comparing the two favored cyclophosphamide. MMF, rituximab, and ACTH all need to be compared to a cyclophosphamide/steroid protocol in properly designed prospective controlled trials with long-term follow-up before their places in the therapeutic armamentarium for IMN can be firmly established. Unfortunately, because of the indolent nature of the disease and slow rate of progression, this will take many years to accomplish by which time other more effective therapies may become available. Of particular potential with regard to IMN are newer B cell depleting drugs and complement inhibitors.

Renal transplantation is effective in patients who do reach ESRD from MN. The disease recurs in about 30 % of allografts and can alter allograft survival (Couser and Cattran 2010; Fervenza et al. 2008; Moroni et al. 2011). De novo MN is also a common cause of nephrotic syndrome in renal transplant recipients. Recurrent MN is associated with return of anti-PLA2R antibody

(Hofstra et al. 2011), but the mechanism of de novo MN in transplants does not involve anti-PLA2R and has not yet been defined. Employing cyclophosphamide as the primary immunosuppressive agent in transplant patients with MN is often recommended.

Treatment options for secondary MN depend on the etiology. Except when the disease occurs in association with other autoimmune diseases such as lupus, anti-GBM antibody disease, or ANCA-associated vasculitis, cytotoxic drug therapy is usually not indicated (Couser and Cattran 2010; Fervenza et al. 2008). Anti-PLA2R antibody is not generally detectable in cases of secondary MN including lupus although up to 30 % of patients with cancer-associated MN tested positive in one study. When MN is secondary to infections, exposure to drugs or toxins, and cancer, it is generally transient, resolves following successful treatment of the primary disease, and rarely progresses.

Transplantation for Autoimmune Liver Diseases

James Neuberger
Liver Unit, Queen Elizabeth Hospital, Birmingham, UK
NHS Blood and Transplant, Bristol, UK

Synonyms

Autoimmune Hepatitis: Chronic Active Hepatitis; Hepatocellular Carcinoma: Hepatoma, Liver Cell Cancer; Primary Biliary Cirrhosis: Chronic Nonsuppurative Destructive Cholangitis; Pruritus: Itching

Definition

The most common autoimmune liver diseases that may lead to liver transplantation are autoimmune hepatitis (AIH), primary biliary cirrhosis (PBC), and primary sclerosing cholangitis (PSC).

Indications for Liver Transplantation: The indications and contraindications for liver transplantation (LT) in autoimmune liver diseases are broadly similar as for other liver diseases. LT may be required to treat patients with end-stage liver disease or to treat intractable symptoms that make the patient's quality of life unacceptable (Carbone and Neuberger 2011). Although survival after transplantation for autoimmune liver disease is very good, with those grafted for PBC having some of the best outcomes, neither the quality nor the length of life is normal. Survival is reduced by many factors, including an increased risk of cardiovascular disease, some malignancies, some infections, recurrent disease, and the specific effects of immunosuppressive agents, such as diabetes and renal impairment (Li and Neuberger 2009).

However, most patients would expect 5-year survival in excess of 85 %.

For those with end-stage disease, a survival benefit of transplantation becomes apparent when the MELD (model for end-stage liver disease) score exceeds 15 (Carbone and Neuberger 2011). Of course, models such as MELD have their limitations, but they do provide an invaluable tool to guide management and an objective basis for allocating donated organs. Those who develop liver cell cancer (hepatocellular carcinoma (HCC)) may also be candidates for transplantation and most centers use the Milan criteria, although this restriction remains controversial.

Other indications for transplantation include intractable encephalopathy and intractable pruritus. Options for treatment of itching include cholestyramine, rifampicin, naltrexone, and even treatment with plasmapheresis or MARS (molecular absorbent recycling system). Lethargy is not an indication for transplantation since while fatigue scores may improve after transplantation, they rarely return to normal. Management should focus on the exclusion of treatable causes of lethargy (such as undiagnosed Addison's disease, thyroid disease, or the impact of inappropriate use of antihistamines to treat pruritus); modafinil

has been used but is not licensed in this indication. The presence of cholangiocarcinoma will usually contraindicate transplantation as recurrence is high although encouraging outcomes are seen in highly selected patients who may follow a regime with brachytherapy and chemotherapy (Ilyas et al. 2011).

Outcomes After Transplantation: Outcomes are usually excellent, but recurrence remains a significant factor affecting both the survival of graft and patient.

Recurrence of PBC: The diagnosis of recurrent PBC (rPBC) is made on the basis of histology, with demonstration of the characteristic nonsuppurative destructive cholangitis. Antimitochondrial antibody (AMA) titers usually fall transiently after transplantation but then rise (Silveira et al. 2010). The subtypes usually remain unchanged. Extrahepatic associated disease associated with PBC (such as thyroid disease or celiac disease) may become apparent after transplant. Liver tests may show a cholestatic pattern, but histological evidence of recurrence may be seen in the presence of normal liver tests. The reported rates of recurrent PBC vary, primarily because of variations in the diagnosis and the use of protocol liver biopsies. Reported rates of recurrence are around 30–40 % at 5 years. Recurrence may lead to graft cirrhosis, but graft loss from recurrence is low (about 4 %). There are few identified risk factors for recurrence: use of ciclosporin is associated with less common and less severe recurrence although no impact of choice of immunosuppressive agents on outcomes has yet been shown. Some reports have suggested that lack of corticosteroids might be associated with recurrence (Silveira et al. 2010). The role of genetic factors on recurrence has yet to be clarified.

There is no effective treatment for recurrence: use of ursodeoxycholic acid (UDCA) 10–15 mg/kg/day is associated with improved liver tests, but no impact has been shown on graft or patient survival or progression of graft damage.

Recurrence of PSC: The diagnosis of recurrent PSC (rPSC) is more complex, and differentiation between rPSC and secondary sclerosing cholangitis is sometimes difficult. The diagnosis of rPSC is made on the basis of multiple non-anastomotic biliary strictures in the absence of other factors: factors that may be associated with non-anastomotic strictures include rejection, graft/host ABO incompatibility, ischemic, hepatic artery thrombosis, and infection (bacterial and viral). Histological features in the graft may also make the diagnosis (Fosby et al. 2012; Carbone and Neuberger 2011). The demonstration of multiple non-anastomotic strictures is commonly made on biliary imaging by magnetic resonance imaging: most patients with PSC have a Roux-en-y biliary drainage procedure as the bile duct is often affected by the disease, and cholangiocarcinoma may develop in the remnant after transplant; as a consequence, endoscopic demonstration of biliary strictures is difficult although percutaneous biliary imaging may be effective. It is unusual to find single dominant strictures; so biliary dilatation is rarely effective.

Treatment is Uncertain: As indicated above, biliary dilatation is technically difficult and rarely effective and is associated with cholangitis. UDCA (10–15 mg/kg/day) may improve liver tests, but no impact on graft survival has been shown. UDCA is not licensed for use in this indication.

As with rPBC, reported rates of recurrence are variable and may reach 50 % at 5 years; unlike rPBC, rPSC may lead to graft loss in 20 % at 5 years. For those few who have had a regraft for rPSC, disease recurrence is variable.

Several studies have assessed risk factors (Fosby et al. 2012): our own study has shown that colectomy either before or during transplantation protects against recurrence, but this has yet to be confirmed in other studies. Other factors that are associated with rPBC include acute rejection and CMV infection.

Most patients with PSC have inflammatory bowel disease affecting the colon, usually ulcerative colitis. The course of colitis is variable (Fosby et al. 2012), with approximately one third improving, one third remaining static, and one third deteriorating. There are no reliable factors that predict the outcome of the colon. All liver transplant recipients have an increased risk of colonic polyps and neoplasm, but this risk is significantly greater in those with colitis. Most centers advocate the

use of annual colonoscopy and a low threshold for surgical intervention; this approach seems sensible but is not evidenced based.

Recurrence of Autoimmune Hepatitis: The diagnosis of recurrent autoimmune hepatitis (rAIH) is based on a combination of factors: transplantation for AIH, high titers of autoantibodies (antinuclear antibodies (ANA) > 1:100 or liver-kidney microsomal antibodies, elevated immunoglobulins (IgG > 1.5 times upper limit of normal), elevated transaminases), and liver histology showing interface hepatitis in the absence of other factors such as rejection and viral infection (Duclos-Vallee and Sebagh 2009; Mendes et al. 2011). A similar condition may be seen in those who were transplanted for conditions other than AIH, and this has been termed de novo AIH (Liberal et al. 2012): it remains uncertain whether this condition truly represents a new syndrome, development of AIH or is just a form of modified rejection. Histological features of rAIH may be found in the presence of normal liver tests and, again, the use of protocol biopsies recommended.

The Risk Factors for rAIH Are Uncertain: The impact of donor and recipient HLA is conflicting. The treatment of rAIH is with the introduction or increase amount of corticosteroids, but fibrosis may progress despite treatment. Use of mycophenolate may also be of help. Most centers advocate the long-term use of corticosteroids in these patients, using doses such as prednisolone 5–10 mg/day, with bone protection measures.

Living Donation and Recurrent Disease: Numbers of patients receiving living donor grafts for autoimmune disease are small, but some studies suggest that recurrence may be more common in such patients (Duclos-Vallee and Sebagh 2009; Ilyas et al. 2011).

Synonyms

Regulatory T cells; Treg

Definition

Regulatory T cells (Treg) (Bregs:IL-10) are important mediators of immune tolerance to

self-antigens or alloantigens, and their impairment may cause autoimmune disease (Sakaguchi et al. 2008). However, the regulatory function of Treg can also limit the immune responses toward pathogens or cancer cells. Regulatory T cells can control immune responses by downmodulating activation and effector functions of various cell types including CD4 and CD8 T cells, B cells, NK cells, NKT cells, and dendritic cells. Several Treg subsets can be differentiated by their phenotype and suppressive mechanisms (Jonuleit and Schmitt 2003). Among these subsets, CD4 + CD25 + Foxp3+ Treg are the most abundant and best characterized Treg population, and their fundamental role in controlling immune responses has been described in various contexts such as autoimmunity, transplantation, and cancer (Sakaguchi et al. 2008). These CD4 + CD25 + Foxp3+ Treg exert their suppressive function mainly through cell contact by membrane-bound molecules but also contact independently through secreted molecules, such as transforming growth factor-beta (TGF-β), interleukin-10, or interleukin-35 (Shevach 2009). The majority of the CD4 + CD25 + Foxp3+ Treg are generated in the thymus; however, these cells may also be generated in the periphery, either by expansion of thymic Treg or by TGFβ-dependent de novo conversion from Foxp3-negative nonregulatory CD4+ T cells (Curotto de Lafaille and Lafaille 2009). Most of the data on CD4 + CD25 + Foxp3+ Treg has been generated in mice, in which these Treg cells can be easily identified by their Foxp3 expression. Characterization of CD4 + CD25 + Foxp + Treg in humans is more difficult, and unambiguous distinction from activated nonregulatory effector T cells requires detection of additional parameters, such as a low expression level of CD127 (Liu et al. 2006). Other Treg subsets are Tr1 cells (Treg Subsets: TR1) and Th3 cells that suppress through contact-independent secretion of interleukin-10 (Treg Subsets: IL-10) or TGF-β, respectively (Jonuleit and Schmitt 2003). Besides the secretion of these cytokines, there are no defined markers that specifically identify Tr1 or Th3 cells. Of note, all activated Treg cells of whatever subset exert their suppressive activity in a nonspecific way, affecting in particular those cells that are in close proximity; however, the activation of Treg cells depends on the specific recognition of cognate antigen through their T-cell receptor.

Treg and Healthy Liver

The liver is increasingly being recognized as an immunological organ that can establish multiple interactions with circulating T cells under the relatively slow blood flow in the sinusoidal network (Racanelli and Rehermann 2006). In the healthy liver, such interactions most often result in the induction of a state of immune tolerance (Carambia and Herkel 2010). The generation of Treg cells through stimulation by liver cells is of central importance for the establishment of hepatic immune tolerance (Thomson and Knolle 2010) (▶ Liver Sinusoidal Endothelial Cells: Role in Immunity and Tolerance). Two major mechanisms seem to account for the hepatic generation of Treg cells: (1) the interleukin 10-dependent generation of Tr1-like cells (Thomson and Knolle 2010) and (2) the TGFβ-dependent generation of CD4 + CD25 + Foxp3+ Treg cells (Lüth et al. 2008). Indeed, both interleukin-10 and TGF-β are expressed in the liver by various cells types and in relative abundance (Carambia and Herkel 2010; Thomson and Knolle 2010). The capacity of the liver to induce Treg is currently being explored for use in induction of specific tolerance to gene products through hepatic gene transfer (LoDuca et al. 2009).

Treg and Autoimmune Liver Disease

Since Treg have the capacity to control autoimmune responses, it is conceivable that a functional or numerical impairment of Treg may contribute to the pathogenesis of autoimmune liver diseases. Indeed, global Treg defects have been reported for patients with autoimmune hepatitis or primary biliary cirrhosis (reviewed in

Czaja and Manns 2010). However, these findings should be interpreted with caution, since the majority of these studies have not been performed with unambiguous Treg markers, leaving the possibility that activated nonregulatory T cells had been assessed. Thus far, the analysis of antigen-specific Treg that recognize relevant autoantigens has been far more difficult, partially because only a few disease-related antigens have been identified (Czaja and Manns 2010) and partially because the antigen-specific Treg frequency in blood is very low (Longhi et al. 2011). Nevertheless, functional antigen-specific Treg can be expanded from the blood of patients (Longhi et al. 2011). Therefore, expanded antigen-specific Tregs may enable specific immunotherapies for autoimmune liver disease.

Treg and Viral Hepatitis

Treg are believed to contribute to the impaired immune responses to virus in patients with chronic infection with hepatitis B virus (HBV) (▶ Acute and Chronic Hepatitis B Virus Infection, Immune Response) or hepatitis C virus (HCV) (▶ Immune Responses to the Hepatitis C Virus) (Rehermann 2007). Indeed, several studies (reviewed in Manigold and Racanelli 2007) indicate that both chronic HBV and chronic HCV infection is associated with increased Treg frequencies in peripheral blood. As most of these studies have not been performed with unambiguous Treg markers, these findings should be interpreted with caution. However, several reports of increased intrahepatic frequencies of viral antigen-specific Treg in chronic viral infection (reviewed in Carambia and Herkel 2010) support the idea that Treg may contribute to impaired antiviral immunity. Moreover, several groups reported a functional suppression of virus-specific T cells by Treg from chronically infected patients (in Carambia and Herkel 2010). Therefore, functional inhibition or depletion of virus-specific Treg may facilitate viral clearance and resolution of hepatitis. However, there is thus far no methodology for the selective targeting of antigen-specific Treg cells. Currently, it seems only possible to inhibit or deplete all Treg irrespective of their specificity; it remains to be seen whether such treatment option is safe and effective.

Treg and Liver Cancer

Although effector T-cell responses to various tumor-associated antigens can be detected in patients suffering from hepatocellular carcinoma (reviewed in Breous and Thimme 2011), these T-cell responses most often cannot effectively deplete the malignant cells. Treg, which are part of the lymphocytic tumor infiltrate, are considered to be a major reason for the poor effectiveness of anticancer immunity (Breous and Thimme 2011). Indeed, pharmaceutical Treg impairment was able to unmask a CD4+ T-cell response to tumor-associated antigen (Greten et al. 2010). Thus, it is conceivable that T-cell-based immunotherapies for the treatment of liver cancer could greatly benefit from combining with a functional inhibition of tumor-associated Treg. However, as mentioned above, it is currently not possible to selectively target antigen-specific Treg, and it is not clear whether a transient nonspecific Treg impairment is both safe and effective.

Conclusions

The suppression of immune responses by Treg serves tissue protection through prevention of autoimmune disease, or through limiting excessive immunity to pathogens. However, the suppressor activity of Treg can also contribute to tissue damage by preventing efficient clearance of pathogens or eradication of malignant cells. Therefore, both, activation and inhibition of Treg activity, have great potential for therapeutic use. Several approaches are currently being explored that can increase or decrease Treg frequency or function. However, to date the development of Treg-based therapies is significantly limited by (1) the lack of suitable methodologies for the selective manipulation of Treg

specifically recognizing defined antigens and (2) the lack of defined antigens that drive pathogenic (auto-) immune responses.

Definition

Inflammatory cells of monocytic lineage present in the neoplastic environment of central nervous system glial tumors.

Basic Characteristics

Introduction

Glioblastoma is a high-grade glial tumor that has remained one of the deadliest human malignancies despite decades of basic scientific and clinical research. In the United States alone, this disease is diagnosed in approximately 10,000 patients per year, and the median survival of newly diagnosed glioblastoma following surgery, radiation, and chemotherapy is about 1 year (Louis et al. 2007). Particularly as new therapeutic avenues are sought, there has been increasing interest in

leveraging the patient's own innate and adaptive immune responses in the fight against glial tumors.

The central nervous system (CNS) has a unique relationship with the immune system that sets it apart from all other organ systems in the body. Notable features include the blood-brain barrier comprises tight endothelial junctions and pericapillary astrocytic processes, the absence of conventional lymphatic vessels, and the relative paucity of major histocompatibility complex expression and antigen-presenting cells. While it would seem that these properties inevitably impact the manner in which the immune system responds to tumors arising in the CNS, many of these classically recognized CNS-specific immunological features may themselves change under neoplastic conditions. Central players in the immune response to glial tumors are both tumor-infiltrating macrophages/microglia (TIMs) and tumor-infiltrating lymphocytes (TILs). The role of TIMs will be discussed in this entry, while a separate entry will review the role of TILs in the immunobiology of glioblastomas.

Microglia, a Mesenchymal Glial Cell of Innate Immunity

Microglia are mesenchymal, hematopoietic-derived glial cells that are the resident mononuclear phagocytes of the CNS. They serve in part as the innate immune system's frontline defense and also play a key role in activating the adaptive immune system. In their quiescent state, their morphology is characterized by ramified processes. In response to infection or injury, microglia change their phenotype into an activated state; they become ameboid in shape, similar to peripherally derived activated macrophages, and they upregulate proteins important in mediating a variety of immune responses. Chief among these are increased expression of MHC class II and costimulatory proteins that aid microglia in their capacity to perform as APCs. Additionally, microglia release proinflammatory cytokines and chemokines, such as TNF alpha (Graeber et al. 2002).

As of yet there is no single specific marker to distinguish microglia from peripherally derived macrophages. Some groups have used the relative expression levels of CD45 as a way to distinguish two subpopulations of CD11b-expressing cells, and there is evidence to suggest that $CD11b^{+}$ $CD45^{low}$ cells are in fact microglia, while a $CD11b^{+}$ $CD45^{high}$ immunophenotype marks other, peripherally derived, macrophages (Badie and Schartner 2001). However, it may be that different activation states impart different immunophenotypes on a given cell type, and such uncertainties have made definitive microglial identification in the context of complex immunobiological environments as yet controversial. Furthermore, the differential expression of CD45 mentioned above was conducted in experiments with rodents, and other groups have not reproduced this difference in human tissue (Hussain et al. 2006).

The Role of Microglia in Glioma Immunobiology

There is evidence that TIMs constitute a large fraction of leukocytes found in glioma tissue, and, by some reports, a large fraction of all cells in these tumors. For example, experiments using flow cytometry with human tissue show that an average of 0.825 % of all cells in resected GBM tissue comprise microglia/macrophages (CD45, CD11b+, CD11c+) versus 0.007 % in normal brain (Hussain et al. 2006). By comparison, in the same study, CD4+ T cells accounted for 0.099 % of cells, and CD8+ T cells accounted for 0.039 % of cells. Other groups, using immunohistochemical methods and manual cell counting have found as many as 30.1 % of glioblastoma cells to be CD11b+, with an average of 10.4 % over 5 nonrecurrent tumor samples (Morimura et al. 1990). Even higher numbers were obtained using other macrophage markers. Certainly, while it is clear that TIMs are indeed present, further analysis is required to definitively quantitate their extent, with particular attention being paid to the manner in which these cells are defined by their immunophenotype and/or other criteria.

Recent data shows that the principle effect of TIMs may be to aid the progression of tumors rather than initiate an immune attack. It has been

shown that microglia may be co-opted by glioma cells to mediate an immunosuppressive effect. For example, driven by glioma cell release of cytokines such as TGF beta, TIMs upregulate B7-H1, which causes programmed cell death of nearby T effector cells. In vitro assays have also shown an upregulation of IL-10 and FASL in TIMs, which suppresses cytotoxic T cell responses (Badie and Schartner 2001). At the same time, proinflammatory cytokines such as TNF alpha are downregulated in microglia when in the presence of glioma cells. Finally, TIMs engage in a number of other activities beneficial to tumorigenesis such as the degradation of extracellular protein networks which facilitates tumor cell migration, as well as the secretion of vascular and tumor cell growth factors, such as epidermal growth factor (EGF) (Graeber et al. 2002; Yang et al. 2010). EGF is known to play an important role in the progression of glioblastomas, and its receptor is frequently both mutated and amplified in primary glioblastomas (Chin et al. 2008).

Therapeutic Promise of TIMs

The majority of current evidence suggests that TIMs are accomplices of the glioma cell and that glioblastomas have recruited them to promote neoplastic disease progression. Is it hopeless, therefore, to pursue these immunological players as potential therapeutic mediators? Current experimental evidence is mixed in that strategies employing both TIM activation and suppression have shown improved survival in animal models of glioma. Injections of CpG oligodeoxynucleotide, which activate TIMs via a toll-like receptor pathway, improve animal survival (Carpentier et al. 2003). At the same time, other groups have shown that the suppression of TIMs, for example, via inhibition of STAT3, can also slow the progression of tumors (Zhang et al. 2009). What seems clear, however, is that manipulating TIMs in some fashion may prove to be an important adjunctive therapeutic modality. However, the best method for utilizing these cells, whether to attack or to stifle malignant gliomas, remains to be elucidated.

Definition

Lymphocytes with expression of T cell markers present in the neoplastic environment of central nervous system glial tumors.

Basic Characteristics

A Diversity of T Cells in the Tumor Microenvironment

Studies have shown that a diversity of inflammatory cell types is present within high-grade gliomas. A basic introduction to the role of monocytic derived cells in the glioma environment is presented in a separate entry (see "► Tumor Macrophages"). In this entry, we focus on T cells in the context of glioma biology. As will be discussed below, T cells exhibiting a variety of immunophenotypes can be found within glioma tissue, although their relative quantities vary depending on the study. Despite the presence of both potential cytotoxic and humoral mediators, however, there is a clear inability of the host to mount an effective response to high-grade glial neoplasms. The numerous factors contributing to this failure have only begun to be understood, and the ability to boost or suppress specific T cell functions in a therapeutic context depends upon a deeper understanding of the role of individual T cell types in the glioma environment.

Tumor Antigen Delivery to T Cells

The basic steps required for an intrinsic cytotoxic T cell response to gliomas include revelation of tumor antigen by neoplastic cells, retrieval and processing of antigen by antigen-presenting cells (APCs); travel of APCs to, and communication with, naive T cells at sites including those likely remote from the tumor itself; travel of T cells back to the site of the tumor; and, finally, activation and persistence of T cell function within the tumor environment. Efforts to reveal the APCs relevant to the endogenous glioma response have pointed to both dendritic cells and macrophage/microglial cells as potentially important players (Dunn et al. 2007). Experimental evidence suggests that intraparenchymal CNS antigens are successfully delivered to cervical lymph nodes by APCs where they interact with T cells able to home to CNS capillaries and into the parenchymal bed. However, the identification of glioma tumor antigens that could potentially initiate a potent T cell effector response requires further investigation. Certainly, antigens that are relatively glioma-specific have been identified and include a variant of the epidermal growth factor receptor (EGFRvIII) that results from an in-frame deletion and is seen in a relatively high percentage of de novo glioblastomas (Dietrich et al. 2010). Other antigens of interest include SART3, whose expression is restricted to gliomas in limited datasets, and IL13Rα2, whose expression profile in normal tissue remains to be clarified (Dunn et al. 2007). Of course, if such antigens are to be employed in the context of immune therapy, their specificity becomes crucial in limiting toxicity to nonneoplastic brain parenchyma.

T Cell Subtypes and Their Role in Gliomas

Experimental evidence has shown that multiple T cell classes are present within the glioma environment. These include CD4+, CD8+, and CD4+ CD25+ cells. The latter immunophenotype, especially when also FOXP3+, is thought to be a marker for T regulatory cells (Tregs) which are of particular interest due to their role as potent immunosuppresive agents (Shevach 2002). The relative proportion of these different cell types varies considerably among different studies. For example, one group that used flow cytometry to characterize the lymphocyte population of 10 glioblastoma resection specimens reported that 17.7 % of cells were lymphocytes. Of these, 25 % were CD3+, and of those, 18.9 % were CD4+ CD25- while 6.2 % were CD4+ CD25+ (El Andaloussi and Lesniak 2006). Studies conducted in the 1980s utilized variable quantitative methodologies. One study that presorted cells with both gross dissection and Percoll gradient centrifugation followed by immunohistochemical labeling found that CD45+ cells accounted for a range of 11–67 % of tumor cells in 4 high-grade gliomas; of these, approximately 42 % were CD4+ cells and 41 % were CD8+ cells

(Farmer et al. 1989). Other studies conducted around the same time used semi-quantitative methods to estimate the extent of lymphocytic infiltration (i.e., slight, moderate, or intense) (von Hanwehr et al. 1984). Clearly, more robust and standardized methods to accurately capture the diversity of lymphocytes present in high-grade gliomas are needed. Adding to the complexity is the variation in human samples themselves, for example, did the patient undergo a previous resection, irradiation, or treatment with immunomodulatory agents? All of these interventions likely have an impact on the immune system players present in a given specimen.

As the relentless progression of virtually all high-grade gliomas would suggest, the ability of the adaptive immune system to mount an effective response is limited. Animal models with spontaneous glioma formation show both a lymphocytic and monocytic response relatively early in the progression of tumors, long before the animals become symptomatic (such analyses are unfortunately limited in the context of human high-grade gliomas that are rarely found incidentally prior to the onset of symptoms). The composition of these infiltrates does indeed include helper cells, cytotoxic cells, and Tregs. The exact role of this adaptive response with respect to tumor evolution remains incompletely understood. Critically, the degree to which an ineffective initial immune response encourages the formation of less antigenic tumor subclones, and the degree to which Tregs generate an immunosuppressive environment are essential areas of ongoing investigation (Tran Thang et al. 2010).

Prognostic Implications of TILs

While it is not unusual to see a lymphocytic infiltrate in high-grade glial tumors and within specimens, this feature is heterogeneous across specimens and often times it is virtually absent. For example, the lymphocytic infiltrate may be robust and perivascular, it may be present diffusely throughout the tumor in smaller numbers, or it may be difficult to appreciate without immunohistochemical aides. The question of whether the presence of TILs itself is of prognostic relevance has been addressed in several studies. Early studies found an increase in survival on the order of months in patients with high-grade gliomas that showed significant perivascular cuffing of lymphocytes (Brooks et al. 1978; Dunn et al. 2007). Subsequent studies have also found positive correlations with survival, whereas others have found either no correlation or even negative correlations (Dunn et al. 2007).

Therapeutic Considerations

Leveraging the adaptive immune system in the treatment of high-grade gliomas is of great interest, especially as tumor-specific antigens become better characterized. Two strategies that will be briefly discussed are active vaccination immunotherapy and adoptive T cell therapy.

Vaccination strategies that employ cultured dendritic cells or utilize direct injection of tumor-specific peptides to induce humoral- and/or delayed-type hypersensitivity immune responses have already been tested in early phase clinical trials (Choi et al. 2009). Specifically, a peptide derived from the EGFRvIII protein described above has been used in vaccination trials that show some promise in extending tumor-free progression with limited toxicity in small numbers of patients (Choi et al. 2009). However, further trials including randomized studies are needed to confirm such benefits. Of concern however is that tumors initially showing definitive expression of EGFRvIII may lose such expression in the face of immunotherapy, with subsequent evasion of any mounted immune response. Alternatively, it may be that the tumor itself initially has heterogeneous expression of a given epitope, generating a survival advantage for those cells lacking expression of the targeted epitope in the context of vaccination. Such cancer immunoediting likely will necessitate the administration of multidimensional therapies that simultaneously attack several tumor antigens, modulate the tumor population to enrich for cells bearing the targeted epitope, and/or alter the tumor microenvironment to increase the efficacy of a given immune response.

Regarding adoptive T cell therapy, numerous strategies for introducing populations of cytotoxic T cells that have been primed and expanded ex vivo

have been tested. Sources for these T cells have varied from autologous memory T cells obtained from the peripheral blood to TILs obtained from the tumor bed itself. The key theoretical benefits of such adoptive strategies in comparison to active immunotherapy is the ability to generate higher percentages of tumor antigen-directed T cells and the ability to manipulate and optimize the T cell phenotype in culture prior to patient introduction (Mitchell et al. 2003). An oft-cited trial utilizing in vitro expansion of autologous tumor bed-derived TILs showed a partial or complete response in three of six patients after 2 years (Quattrocchi et al. 1999). This study, while encouraging, lacked enough power to make strong conclusions about therapeutic efficacy; nevertheless the protocol appeared safe and the relatively low dose of IL-2 used adjunctively appeared well tolerated. More studies are clearly needed with sufficient numbers of patients to account for differences in adjunctive therapies, recurrence status, time since surgery, and the baseline immune status of the patient, among other factors.

The Liver Sinusoid

The liver sinusoids are the blood vessels that make up the microcirculation of the liver. Ultrastructure refers to the morphological cellular features that can be resolved by electron microscopy.

The liver has many immunological roles including production of acute-phase proteins, clearance of waste products generated by systemic inflammation and immune responses, deletion of activated T cells, and induction of tolerance to ingested and self-antigens (Parker and Picut 2012). The liver sinusoids form the interface between circulating blood and the hepatocytes thus are strategically placed to undertake and/or regulate the immune functions of the liver.

The sinusoidal vessels branch off from the terminal portal venules, carry blood between the plates of hepatocytes, and then drain into the central venules (Fig. 1). Each sinusoid traverses a distance of about 1 mm, and there are about one billion sinusoids in a human liver (Fraser et al. 2012). They occupy about 30 % of the liver volume and are a very complex network of vessels with a fractal dimension exceeding two (Warren et al. 2008). The periportal (zone I) sinusoids are more reticular in distribution and become more aligned or anisotropic as they move towards the pericentral (zone III) regions. The sinusoids are only 9–10 μm in diameter (Warren et al. 2008); therefore, blood flow is occasionally interrupted by circulating blood cells that have become blocked within the sinusoids. Moreover leukocytes and lymphocytes force plasma into the extracellular space as they squeeze through the sinusoids – a process termed "forced sieving" (Wisse et al. 1985).

The sinusoids contain four main cell types:

1. Liver sinusoidal endothelial cells (LSECs), which form the endothelial lining of the sinusoids and represent about 70 % of the total population of sinusoidal cells.
2. Kupffer cells, which are the resident macrophages of the liver and occupy the lumen of the sinusoids. They make up about 20 % of the sinusoidal cells but over 80 % of all fixed macrophages in the body.
3. Stellate cells, which are pericytes that lie within the extracellular space between the LSECs and hepatocytes. They are also known as fat-storing cells or Ito cells and represent less than 10 % of the sinusoidal cells.

4. Pit cells, which are natural killer lymphocytes that reside in the sinusoidal lumen and make up less than 1 % of all sinusoidal cells.

Liver Sinusoidal Endothelial Cells

LSECs are the endothelial cells of the hepatic sinusoids. LSECs are very thin and perforated with fenestrations that characterize the ultrastructure of the LSEC. Fenestrations are transcellular pores 50–150 nm in diameter, which occupy up to 20 % of the cell membrane surface of the LSEC (Fig. 2). These pores are not bridged by a diaphragm nor is there any underlying basement membrane in healthy livers; therefore, fenestrations provide unimpeded access of plasma in the sinusoid to the extracellular space (termed the space of Disse). About three quarters of fenestrations are found within clusters containing scores of fenestrations that have been called sieve plates because of their sieve-like appearance. A single-cultured LSEC may have many tens of sieve plates, representing perhaps many thousands of fenestrations per cell (Cogger and Le Couteur 2009).

Fenestrations cannot be resolved using standard light microscopic methods; therefore, they have been visualized primarily using transmission and scanning electron microscopy. Structured illumination light microscopy (SIM) can also visualize fenestrations and sieve plates in isolated rat LSECs without any of the preparation techniques required for electron microscopy (Cogger et al. 2010). This method confirmed that fenestrations are about 100 nm in diameter (123 ± 24 nm) with 26 ± 14 fenestrations in each sieve plate (Fig. 2).

Fenestrations are dynamic structures. The size and number of fenestrations have been influenced by various vasoactive hormones, cytokines, pharmaceutical agents, and physiological factors such as portal pressure, liver regeneration, and nutritional status. In particular, vascular endothelial growth factor (VEGF) and substances that disrupt the actin cytoskeleton increase the number and/or diameter of fenestrations (Cogger and Le Couteur 2009). Fenestrations are reduced in chronic liver disease, diabetes mellitus, and old age, while large gaps develop following acute toxic insults such as oxidative stress and acetaminophen poisoning (Cogger et al. 2004; Le Couteur et al. 2005).

The major physiological role of fenestrations appears to be the transfer of substrates between hepatocytes and the sinusoidal blood and hepatocytes. This includes particulate substrates with diameters less than that of the fenestrations (e.g., lipoproteins) or soluble substrates (Fraser et al. 2012). The loss of fenestrations that occurs in chronic liver disease and aging provides a mechanism contributing to the impairment of hepatic clearance seen in these conditions (Le Couteur et al. 2002, 2005).

(**c**) Scanning electron micrograph of a sinusoid perforated with fenestrations. (**d**) Transmission electron micrograph of liver sinusoidal endothelial cell showing fenestrations (*arrow*) and clathrin coated pits (*asterix*) (Source: Biogerontology Laboratory of the ANZAC Research Institute by Victoria Cogger, Alessandra Warren and Jennifer O'Reilly)

Fenestrations may also have a role in the ability of the liver to induce immunological tolerance. Hepatocytes have been shown to be tolerogenic antigen-presenting cells (Bertolino 2008; Holz et al. 2010). Electron microscopy revealed that resident lymphocytes and circulating naïve CD8+ T cells make direct contact with hepatocytes via fenestrations, a process termed trans-endothelial hepatocyte lymphocyte interaction (TEHLI) (Warren et al. 2006). Thus, fenestrations might regulate the first step in the development of immune tolerance by hepatocytes.

Electron microscopy also reveals numerous caveolae and clathrin-coated pits on both luminal and abluminal membranes of LSECs (Fig. 2d). These underpin the key role of the LSEC in endocytosis. The LSEC is responsible for the clearance of most blood-borne waste macromolecules including soluble IgG immune complexes, bacterial CpG, heparin, collagen and procollagen products, advanced glycation end products, chondroitin, acetylated LDLs, and hyaluronan. The LSEC carries pattern-recognition endocytosis receptors (mannose receptor and stabilin1/2) and the endocytic Fc gamma receptor IIb2 combined with a highly efficient endocytic machinery (Sørensen et al. 2012).

Kupffer Cells

The Kupffer cells are the major fixed macrophages in the body. Both Kupffer cells and LSECs form the scavenger cell system ("dual cell principle") with LSECs representing the professional pinocyte, clearing the blood of waste colloids and soluble macromolecules, while the Kupffer cell represents the professional phagocyte, eliminating larger particles including cells and bacteria (Sørensen et al. 2012). The Kupffer cell also produces cytokines such as TNF-α and interleukin-6 in response to inflammatory stimuli (Arii and Imamura 2000; Naito et al. 2004).

Kupffer cells are large ameboid cells that adhere to the luminal surface of the LSECs (Fig. 3). There are many more Kupffer cells in

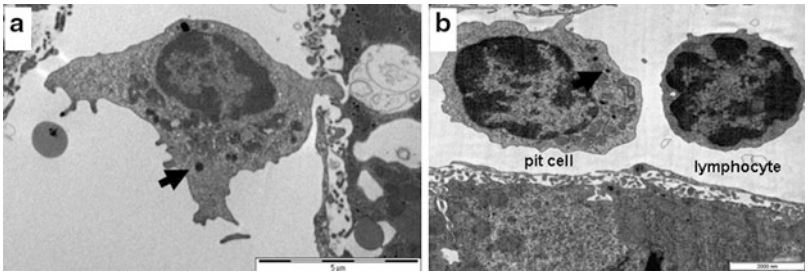
the periportal region of the sinusoid than the pericentral region. They have numerous projections (lamellipodia, microvilli), many of which attach to the LSECs and even extend through fenestrations into the extravascular space. Kupffer cells and their lamellipodia increase in number and size after activation. The cytoplasm contains large numbers of endocytic vesicles and lysosomes which also increase with Kupffer cell activation (Naito et al. 2004).

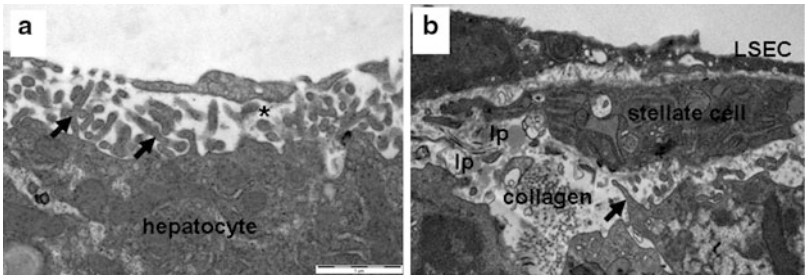
The role of Kupffer cells has been studied by depleting the liver of Kupffer cells with agents such as gadolinium chloride or clodronate liposomes. These studies have shown that Kupffer cell activation is a pivotal mechanism for many conditions including ischemia reperfusion injury, acetaminophen toxicity, and fatty liver. With aging there is an increase in basally active Kupffer cells; however, these do not respond effectively to inflammatory stimuli (Hilmer et al. 2007).

Stellate Cells

Hepatic stellate cells are pericytes that lie in the extracellular space between the LSEC and hepatocytes termed the space of Disse. They are spindle or star-shaped cells with long cytoplasmic extensions that surround the sinusoids (Fig. 4). The characteristic structural features of stellate cells are large lipid droplets containing vitamin A and triglycerides. In fact, over 80 % of vitamin A in the body is stored in stellate cells as retinyl palmitate, and this generates a distinctive autofluorescence (Senoo 2004; Senoo et al. 2007).



Ultrastructure of the Liver Sinusoid, Fig. 5 (**a**) Transmission electron micrograph of a large granular lymphocyte in the sinusoidal lumen containing electron dense vesicles in the cytoplasm consistent with pits (*arrow*). (**b**) Pit cell and lymphocyte in the sinusoid (Source: Biogerontology Laboratory of the ANZAC Research Institute by Victoria Cogger, Alessandra Warren and Jennifer O'Reilly)



Ultrastructure of the Liver Sinusoid, Fig. 6 Electron micrographs of the space of Disse. (**a**) Normal space of Disse containing hepatocyte microvilli (*arrow*) and extracellular matrix (*asterix*). (**b**) Space of Disse containing lipoproteins (*lp*) and collagen (Source: Biogerontology Laboratory of the ANZAC Research Institute by Victoria Cogger, Alessandra Warren and Jennifer O'Reilly)

In various liver diseases such as hepatic cirrhosis and fibrosis, stellate cells become activated. This is associated with loss of the lipid droplets and the development of a myofibroblastic appearance. There is increased rough endoplasmic reticulum and Golgi apparatus associated with increased production of extracellular matrix substances such as collagen (Senoo et al. 2007). On the other hand, old age is associated with increased numbers of nonactivated stellate cells that are swollen with large lipid droplets (Warren et al. 2011).

Pit Cells

Pit cells are large granular lymphocytes found in the lumen of the sinusoid (Fig. 5). The characteristic ultrastructural feature is the presence of "pits" or spherical dense granules about 200 nm in diameter within their cytoplasm that contain perforin and granzymes. They also contain rod-cored vesicles and tend to have kidney-shaped nuclei. Functionally, pit cells are natural killer cells (NK) with cytotoxic activity against tumor cells which provides protection against liver metastases. Natural killer T cells (NKT) are ultrastructurally similar to pit cells but also express the T cell receptor on their cell membrane (Nakatani et al. 2004; Parker and Picut 2012).

Space of Disse

The space of Disse is the extracellular space that lies between the LSEC and the surrounding hepatocytes (Fig. 6). The space contains extracellular matrix proteins and microvilli that project from the hepatocytes, some of which span the entire space of Disse and extend through fenestrations

into the lumen of the sinusoid. Plasma enters the space of Disse via fenestrations and flows in a retrograde direction towards the lymphatic vessels in the periportal regions to form hepatic lymph. Unlike other extravascular spaces, the space of Disse does not contain significant amounts of basal lamina, although continuous basal membranes develop in old age and various liver diseases (Le Couteur et al. 2005). There are only occasional collagen bundles which increase markedly in liver disease and diabetes mellitus. Sometimes smaller lipoproteins are seen in the space of Disse (Fraser et al. 2012). In some forms of hepatitis, inflammatory cells such as neutrophils enter the space of Disse via fenestrations (Warren et al. 2007). Peliosis refers to the situation where erythrocytes are found in the space of Disse in conditions such as heart failure and acetaminophen toxicity.

Definition

Vasculitis is a pathological process defined by leukocyte invasion and fibrinoid necrosis of the vessel wall. Any size vessel can be affected, and vasculitis may be associated with thrombotic occlusion, stenosis, or aneurysmal dilatation of the blood vessel.

Introduction

Systemic vasculitis occurs either as a primary autoimmune disorder or as a secondary manifestation of another disease process (Tables 1 and 2). Primary systemic vasculitis is classified according to the predominant size of vessel involved and the presence of circulating antineutrophil cytoplasmic autoantibodies (ANCA) (Fig. 1) (Jennette 2011; Watts et al. 2011). Small vessel vasculitides, especially those associated with ANCA, often involve the kidneys. Less commonly, large vessel vasculitides such as polyarteritis nodosa and Takayasu arteritis can involve the kidneys.

ANCA-associated vasculitis (AAV) is a relatively rare systemic disease, but accounts for 50 % of all systemic vasculitis presentations. The major AAV subgroups are granulomatosis with polyangiitis (GPA) (formerly called Wegener's granulomatosis) and microscopic polyangiitis (MPA).There is increasing evidence that ANCA is associated with the disease pathogenesis and that the two ANCA subtypes, proteinase 3-ANCA (PR3-ANCA) and myeloperoxidase-ANCA (MPO-ANCA), define clinical subgroups that differ in their survival, renal and cardiovascular outcomes, and renal histology.

AAV has a predilection for the kidney with more than 75 % of patients having renal involvement. These patients are at risk of progressing to end-stage renal failure if not treated promptly. The clinical manifestation of small vessel vasculitis in the kidney is often a rapidly progressive (crescentic) glomerulonephritis. This results from a glomerular capillaritis leading to a segmental, necrotizing glomerulonephritis with epithelioid crescent formation. For those with AAV, immune deposits are typically minimal or absent (pauci-immune) as opposed to Henoch-Schönlein purpura or cryoglobulinemia where immune deposits are present (Jennette et al. 1994).

In the past, untreated systemic vasculitis was often fatal, with only 20 % of patients survived at 1 year. The combination of cyclophosphamide and corticosteroid induces remission in up to 90 % of patients. Nevertheless, the survival of

AAV patients is still worse compared to age- and sex-matched controls. The age of many patients at diagnosis, late presentations with advanced renal failure, histological severity, and the toxicity of current drugs contribute to poor outcomes, with ESRD or death occurring in 17 % of AAV patients at 1 year.

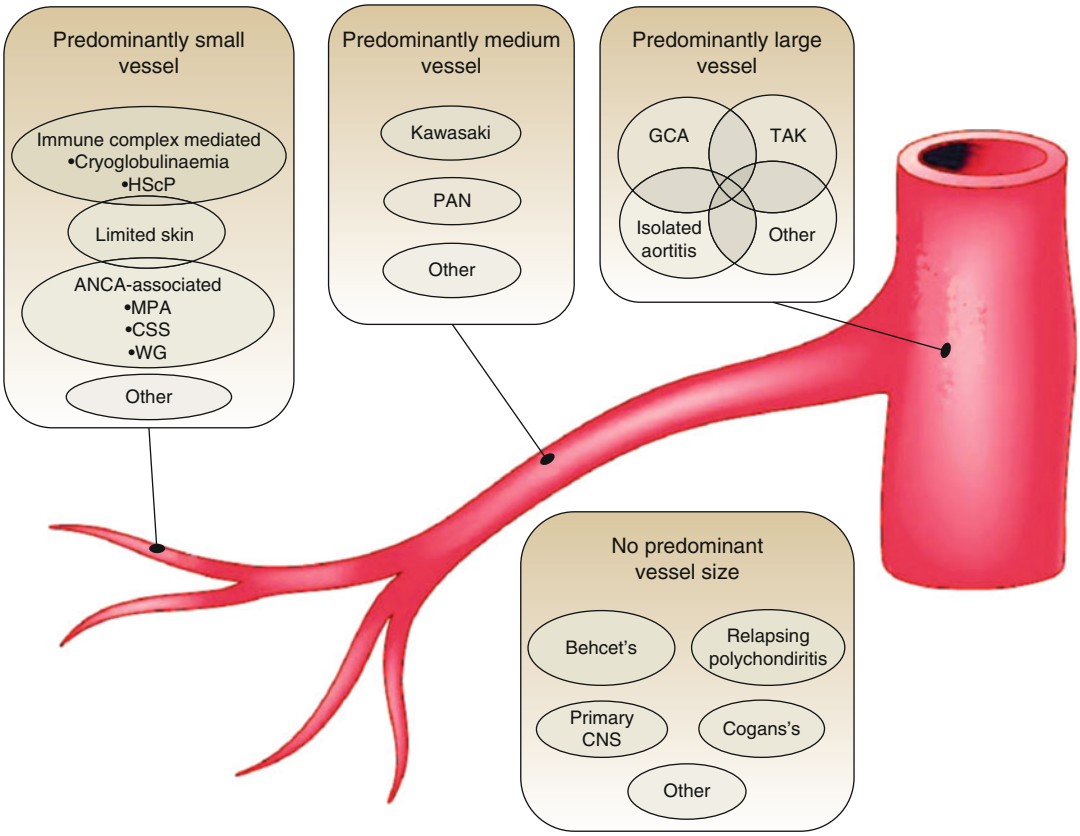
AAV is now characterized by a chronic relapsing and remitting course, with 50 % of patients relapsing within 5 years. Since the 1980s, there has been a growing awareness of the late toxicity of cyclophosphamide that includes infertility, bladder, and hematological malignancies. The advent of newer therapies, especially rituximab, as well as the use of adjunctive therapies such as plasma exchange and intravenous methylprednisolone has improved outcomes and reduced the need for cyclophosphamide.

Nomenclature, Definitions, and Classification of Primary Systemic Vasculitis

Primary systemic vasculitis syndromes were initially described as discrete clinicopathological entities: Henoch-Schönlein purpura in 1837, polyarteritis nodosa in 1866, Takayasu arteritis in 1910, microscopic polyangiitis in 1923, Wegener's granulomatosis (GPA) in 1936, and Churg-Strauss angiitis in 1951. An International Consensus on the terminology of vasculitis syndromes resulted in the 1992 Chapel Hill statement (Table 3), which forms the basis for current classification systems. The availability of ANCA testing, especially with modern solid-phase assays, has been a major step in the diagnosis and monitoring of vasculitis and has provided insights into pathogenesis and classification (Savige et al. 1999).

Epidemiology and Demography of AAV

The incidence of primary systemic vasculitis is 40/million/year with AAV comprising 15–20/million/year. An apparent increased incidence of AAV has been explained by improved detection, especially in the elderly, but where long-term epidemiology studies have been performed, no increase in incidence has been seen. Prevalence rates of AAV range from 90 to 400/million (Lane et al. 2005). Although the



Vasculitis and the Kidney, Fig. 1 Revised draft classification scheme for primary vasculitis (Used with permission. Watts R, Suppiah R, Merkel P, Luqmani R. Systemic vasculitis – is it time to reclassify? The way forward in approaching a diagnosis of vasculitis. *Rheumatology*, 2001;50:643–645)

disease can occur at any age, there is a skewing of the age distribution towards older age groups for both GPA and MPA with peak age of onset being 65–74 years. The majority of young patients with AAV have GPA and PR3-ANCA (Fig. 2). Older patients have worse renal function and there is also an increased proportion of these patients being diagnosed with crescentic glomerulonephritis on kidney biopsies (from 5 % in those <60 years to over 11 % in those >60 years of age). The relative frequencies of GPA and Churg-Strauss syndrome, but not MPA, are influenced by latitude with GPA and Churg-Strauss syndrome being more frequent in colder climates in both the North and South hemispheres. In addition, there are ethnic differences with GPA being less common in eastern Asian and black populations. Reports in Japan and China suggest that MPA is more common than GPA as was MPO-ANCA-associated disease compared to PR3-ANCA-associated disease.

Genetics

Genetic associations have been reported with polymorphisms of cytotoxic T lymphocyte associate antigen 4 (CTLA4), tyrosine-protein phosphatase non-receptor type 2, the third complement component, and the Fc gamma RIII immunoglobulin receptor. Familial segregation of GPA carries a relative risk of 1.6 for first degree relatives. Most associations have been with genes that encode proteins that are involved in the immune response such as the human leukocyte antigen (HLA) proteins, PTPN22m,

Vasculitis and the Kidney, Table 3 The chapel hill consensus conference definitions of the antineutrophil cytoplasmic antibody-associated vasculitides (Adapted from Jeanette (1994))

GPA (Wegener's granulomatosis)
Granulomatous inflammation involving the respiratory tract
Necrotizing vasculitis affecting small to medium-sized vessels (e.g., capillaries, venules, arterioles, and arteries)
Necrotizing glomerulonephritis is common
Microscopic polyangiitis
Necrotizing vasculitis, with few or no immune deposits, affecting small vessels (i.e., capillaries,venules, or arterioles)
Necrotizing arteritis involving small- and medium-sized arteries may be present
Necrotizing Glomerulonephritis is Very Common
Pulmonary capillaritis often occurs
Churg-Strauss syndrome
Eosinophil-rich and granulomatous inflammation involving the respiratory tract
Necrotizing vasculitis affecting small- to medium-sized vessels
Associated with asthma and eosinophilia

CTL4, and others. HLA-DPB1*0401 has been found to be a strong and reproducible risk factor for GPA but not MPA. In addition, some studies have suggested an association between AAV and the rare z allele of SERPINA which encodes for α-1 antitrypsin, a serine protease inhibitor that inhibits, among other targets, the enzymatic activity of PR3-ANCA. Deficient α-1 antitrypsin phenotypes develop more aggressive PR3-ANCA-associated vasculitis (Savage 2011).

Etiology, Pathogenesis, and Pathology

Environmental Associations

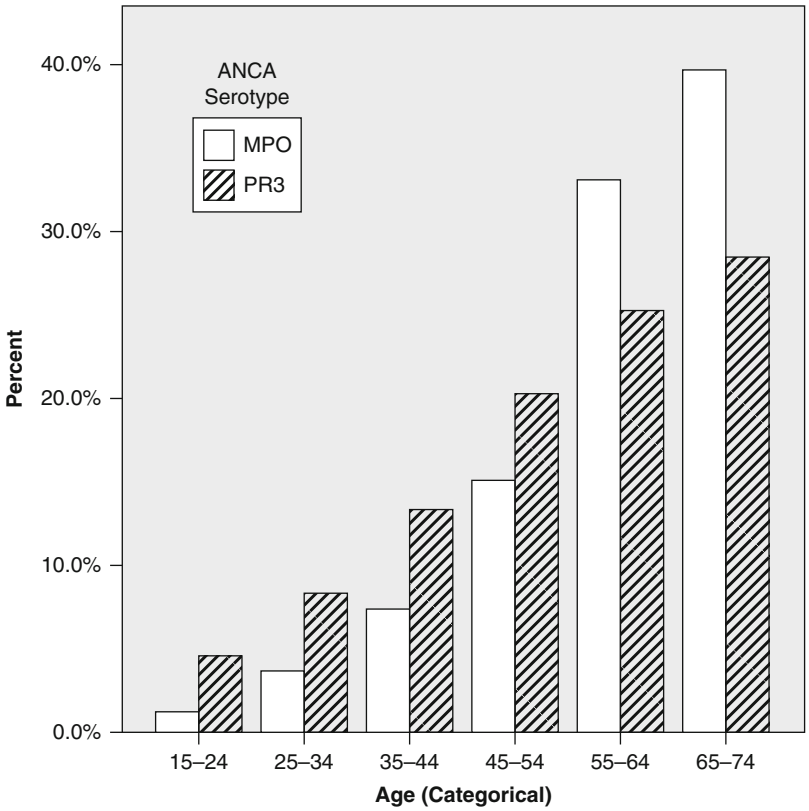
AAV has been associated with silica exposure and an increased incidence of MPO-ANCA vasculitis was reported in Kuwait in 1991 after the first Gulf war and after the Kobe earthquake in 1995. Whether other occupational exposures are etiologically related, such as heavy metals or insecticides, is unclear. Infections have also been linked to the pathogenesis of vasculitis (Hogan et al. 2007).

Pathogenic Role of ANCA

ANCA were identified in the 1980s as diffuse granular (cANCA) or perinuclear staining (pANCA) on indirect immunofluorescence (IIF). Proteinase 3 (PR3) and myeloperoxidase (MPO) antigens were subsequently identified as targets of cANCA and pANCA, respectively, and can be measured by ELISA. It should be noted however that 5–10 % of patients with small vessel vasculitis are ANCA negative. The pathogenic role of ANCA has been controversial because the pathology observed in AAV can occur without circulating ANCA, immune deposits are rarely present, and ANCA often persist without disease activity.

Neutrophils contain the target antigens for ANCA (PR3/MPO/LAMP) and are central in the development of vasculitis. Experimental studies have demonstrated that ANCA induce neutrophil activation, superoxide, and cytokine release and can cause neutrophil-mediated endothelial cytotoxicity. ANCA require neutrophil priming with tumor necrosis factor (TNF) which leads to translocation of proteinase 3 or myeloperoxidase from primary azurophilic granules in the cytoplasm to the cell membrane. In addition to binding to cell surface autoantigen, ligation of the Fc component of the ANCA antibody to neutrophil Fc receptors is necessary for intracellular signaling and cell activation. The interplay between chemokines, neutrophils, and ANCA IgG leads to the preferential recruitment of neutrophils to the microvascular sites (Hewins and Savage 2003).

Spontaneous and induced animal models (Xiao et al. 2002; Hamano et al. 2006) have demonstrated the ability of ANCA to cause a pauci-immune renal vasculitis in susceptible animal strains. Both immunocompetent and Recombinant Activating Gene (RAG-2) deficient mice that lack functioning T and B cells, receiving anti-myeloperoxidase antibodies, develop clinical features resembling those seen in human AAV, such as necrotizing vasculitis with crescentic glomerulonephritis. The evidence in humans is indirect, with drugs such as propylthiouracil causing drug induced AAV. Propylthiouracil



Vasculitis and the Kidney, Fig. 2 Age distribution of 735 AAV patients from 6 European Vasculitis Study Group (EUVAS) trials stratified according to ANCA subtype. The upper age limits of these trials are 75–80

accumulates within neutrophil granules and is thought to cause vasculitis possibly by increasing the immunogenicity of myeloperoxidase. Another possible example of the pathogenicity of ANCA includes case reports of a newborn child who developed glomerulonephritis and pulmonary hemorrhage after being born to a mother who had active MPO-ANCA vasculitis (Kallenberg 2011; Savage 2011).

The Innate and Adaptive Immune Response and the Infectious Link

The involvement of the respiratory tract in GPA has focused attention on the interaction between respiratory tract infection and a dysregulated immune response. Nasal colonization with *Staphylococcus aureus* is common (60–70 %) in patients with GPA and is associated with a higher relapse rate (relative risk of 7.2) (Kallenberg 2011). Treatment with sulfamethoxazole/trimethoprim reduces relapse rates by 60 %.

A possible role of *S. aureus* superantigens in stimulating the adaptive immune response has been suggested. The α-toxin from *S. aureus* is a potent activator of NLRP3 suggesting a potential link between infections and the proinflammatory effects of vasculitis. Bacterial strains expressing toxic shock staphylococcal toxin are implicated in relapsing disease (Stegeman et al. 1994). Damage to the respiratory tract resulting from vasculitic inflammation impairs its ability to eradicate microbial infection, and a cycle of vasculitis and recurrent infection develops. Cytokine-induced upregulation of endothelial adhesion molecules promotes leukocyte adhesion and injury and provides an additional mechanism by which inflammation secondary to infection can stimulate vasculitis.

Alternations within in the T cell populations include markedly reduced levels of T helper cells, skewing towards effector memory T cells, altered expression of co-stimulatory molecules, and

increased numbers of activated T cells. T cells in granulomatous lesions are overrepresented by a CD4+, CD28- subset which release gamma interferon and TNFα and have cytotoxic potential. A pathogenetic role for cytotoxic T cells has been shown in larger vessel arteritis and similar mechanisms are also likely to be important in smaller vessel disease (Weyand and Goronzy 2003). Circulating markers of T cell activation including the soluble interleukin 2 receptor are elevated. Deficient or dysfunctional Tregs and TH17 subsets have also been implicated. In experimental models, animals lacking IL-17A are protected against anti-MPO glomerulonephritis. Recent studies showing that a novel CD8+ T cell transcription signature can predict the likelihood of relapse in ANCA vasculitis suggest that changes in the T cell compartment can influence the course of disease (Fig. 3) (Abdulahad et al. 2009; Kallenberg 2011; Savage 2011).

The success of B cell depletion therapy with rituximab has highlighted a central role of B cells in pathogenesis. B cells which are present in granulomata and at sites of vasculitic injury have specificity for ANCA autoantigens and demonstrate features of affinity maturation.

Infections have also been implicated in the formation of the new type of ANCA directed against the human lysosomal associated protein (h-LAMP2). Kain et al. have suggested that anti-LAMP2 antibodies are important in the development of vasculitis with evidence of molecular mimicry between LAMP2 and the bacterial adhesion protein Fim-H found in gram-negative bacteria. Another infectious link is the production of anti-PR3 antibodies via an anti-idiotypic effect due to surface homology between the middle portion of complementary PR3 (cPR3) and proteins in *S. aureus* (Savage 2011).

Complement

Although AAV causes a "pauci-immune" glomerulonephritis, the complement system appears to be important in pathogenesis because C5 and Factor B knockout mice are protected against disease. C5a is an anaphylatoxin known to prime neutrophils for ANCA- induced respiratory burst, and mice that are deficient for the C5a receptor have been shown to be protected against glomerulonephritis (Savage 2011).

Pathology

AAV predominantly affects small blood vessels, capillaries, arterioles, and venules but may also affect muscular arteries and rarely larger arteries. Capillaritis in the glomerular tuft results in capillary thrombosis and infarction. This appears on biopsy as segmental fibrinoid necrosis and a secondary crescentic reaction within Bowman's capsule containing monocytes and epithelial cells. This progresses to involve the whole tuft and destroy the glomerulus. In addition, there is peri-glomerular and tubulointerstitial inflammation which may contain giant cells. There is considerable variety in the severity and proportion of fibrotic lesions between glomeruli. Obsolescent glomeruli and fibrotic crescents reflect previous vasculitic events and are associated with tubulointerstitial scarring. Capillaritis in pulmonary alveoli causes capillary rupture and hemorrhage into the alveolar space.

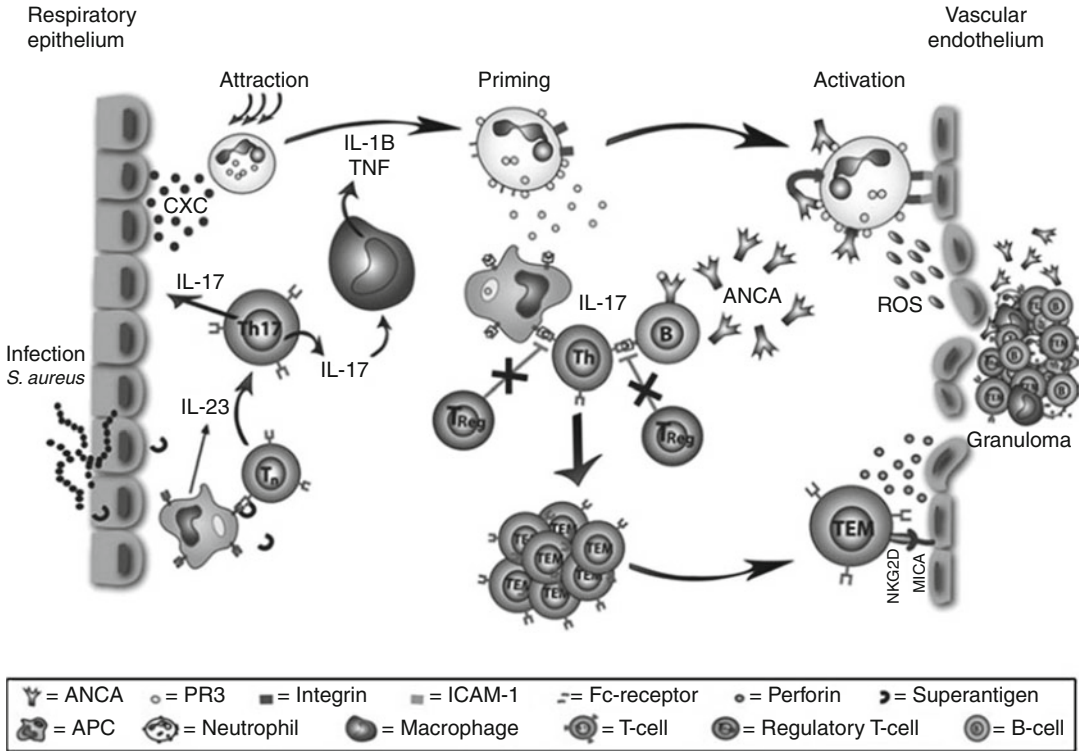
Approach to Diagnosis

Patients with primary systemic vasculitis vary in the pattern and severity of organ involvement, in their response to therapy, and in their subsequent disease course and prognosis. Diagnosis depends on the triad of clinical features, the serology and histology, and the exclusion of secondary causes. Appropriate treatment aims to obtain and sustain disease remission, but relapses are common, and refractory disease or chronic, persistent low-level disease activity represent therapeutic challenges (Hellmich et al. 2007).

Clinical Features

ANCA-Associated Vasculitis

Patients with ANCA-associated vasculitis typically have a prodromal phase of several months with constitutional symptoms such as fever, night sweats, polymyalgia, and weight loss. Half of all patients have chest and ear/nose/throat symptoms, and around 90 % have renal involvement. Other potentially affected organs include the



Vasculitis and the Kidney, Fig. 3 A proposed model representing innate and adaptive immune mechanisms that are supposedly involved in the pathogenesis of antineutrophil cytoplasmic autoantibody (ANCA)-associated systemic vasculitis (AASV). Superantigens and peptidoglycans from *Staphylococcus aureus* stimulate antigen-presenting cells (APC) in the respiratory tract to produce interleukin (IL)-23, which then induce proliferation of Th17 cells and release of IL-17. IL-17 acts further on both respiratory epithelium and tissue macrophages. In response to IL-17, bronchial epithelial cells secrete CXC chemokine that attract neutrophils to the infected tissue, whereas macrophages release proinflammatory cytokines, such as IL-1b and tumor necrosis factor (TNF)-a. These inflammatory cytokines cause priming of neutrophils (membrane expression of proteinase-3 (PR3)) and upregulation of adhesion molecules on their surface as well as on the vascular endothelium. Subsequently, primed neutrophils adhere to the endothelial cells. Released PR3 can be processed and presented by APC to Th cells. As regulatory T cells (TReg) fail to inhibit this autoimmune response in Wegener's granulomatosis, autoreactive T cells might undergo repeated stimulation by PR3-pulsed APC resulting in a pool of effectory memory T cells (TEM). Further, PR3-stimulated Th cells act on B cells and enhance the production of ANCA. Subsequently, ANCA activates neutrophils that adhere to endothelial cells, which results in local production of reactive oxygen species (ROS) and release of proteolytic enzymes that damage vascular endothelial cells. Moreover, the expanded population of CD4+ TEM cells, resulting from persistent activation of Th cells by PR3, upregulate their NKG2D protein and migrate to the peripheral blood and remain in the circulation during remission. When the disease becomes active, MICA protein will be upregulated on several vascular endothelial cells, especially in the kidney, which attract TEM cells to the inflammatory areas. The MICA protein on the target cells can bind to NKG2D on the TEM cells, which in turn enhances their cytotoxic function to kill the target cell in a perforin and granzyme-dependent way ending up in vasculitis (Used with permission from Abdulahad W, Stegeman C, Kallenberg C. Review article: The role of CD4+ T cells in ANCA-associated systemic vasculitis. Nephrology. 2009; 14: 26–32)

skin, eyes, lungs, and heart and the nervous system. Common presentations of AAV are summarized in Table 4.

Renal vasculitis is the most common cause of the syndrome of rapidly progressive glomerulonephritis (RPGN), accounting for 50–80 % of all cases. This syndrome consists of acutely deteriorating renal function and crescentic glomerulonephritis on kidney biopsy. Renal vasculitis is differentiated from other causes of

Vasculitis and the Kidney, Table 4 Common manifestations of ANCA-associated vasculitis (Adapted from Berden et al. (2012))

General	Malaise, myalgias, arthralgias, weight loss, headache, fevers, flu-like illness, headaches
Ear, nose, and throat	Increasing bloody-purulent nasal discharge with crusting (not responding to antibiotics)
	Slowly developing nasal stenosis with mid-facial pain
	Hearing loss
Eye	Unexplained conjunctivitis
	Uveitis, episcleritis
	Unilateral proptosis
	Paresis of the cranial nerves (especially oculomotor) nerves
Lungs	Cough and shortness of breath
	Possibly with bloody-purulent sputum (not responsive to antibiotics)
	Bilateral infiltrates on radiography (not responsive to antibiotics)
	Non-tuberculous cavitating lesions
	Alveolar hemorrhage
Skin	Bursts of small cutaneous vasculitis elements
	Purpura
	Ulcers
	Pyoderma gangrenosum
Kidneys	Hemproteinuria
	Worsening renal function
Nerves	Mononeuritis multiplex

glomerulonephritis by circulating immune reactants and renal immunofluorescence studies. For those with active renal vasculitis, urinary abnormalities will be presented and should therefore be sought in all patients with unexplained illness or where there is a suspicion of vasculitis. In these patients, hematuria and proteinuria is present, but may be confused with prostatic disease or urinary tract infection if the urine is not closely examined. The presence of red cell casts on urine microscopy reflects severe glomerular injury and is usually associated with crescentic glomerulonephritis.

Some 5 % of AAV patients present with simultaneous renal vasculitis and anti-glomerular basement membrane (GBM) disease (Levy et al. 2004). They are older, have more severe renal disease, and are more likely to have pulmonary involvement than other AAV cases. The serology demonstrates ANCA, usually MPO-ANCA positivity and anti-GBM antibodies. Renal histology reveals an aggressive crescentic glomerulonephritis, typically involving all glomeruli with linear IgG deposition on immunofluorescence.

Henoch-Schönlein Purpura

Henoch-Schönlein purpura occurs more frequently in children (15 cases/100,000 children/year) than adults (annual incidence 1/1,000,000). In adults it often pursues a relapsing course (Coppo et al. 1999). Nephritis occurs in 50–80 % in adults and 20–40 % in children. Patients can present with isolated hematuria, proteinuria, acute nephritis, or nephritic syndrome. By definition, extrarenal features of vasculitis including purpura, arthritis, and gastrointestinal involvement are present, but differentiation from other vasculitic syndromes requires the demonstration of IgA deposition on skin or renal biopsy. The renal presentation in Henoch-Schönlein purpura overlaps with that of IgA nephropathy but is more likely to pursue a rapidly progressive course and to have extra-capillary glomerular necrosis with crescents on biopsy.

Polyarteritis Nodosa and Takayasu Arteritis

Involvement of muscular arteries in the kidney in polyarteritis nodosa leads to regional infarction and hypertension (Fig. 4). The association of polyarteritis nodosa with microscopic vessel involvement, such as necrotizing glomerulonephritis, has been called "polyangiitis overlap syndrome" but is now classified as microscopic polyangiitis. A minority of patients with Takayasu arteritis have disease below the diaphragm (Class IV) which may involve the renal arteries causing renal artery stenosis, hypertension, reduced renal size, and renal impairment (Fig. 5).

Investigations

Investigations for AAV aim to rule out secondary causes of vasculitis and diseases that mimic vasculitis. More specific tests are done to confirm the diagnosis and determine the extent of

Vasculitis and the Kidney, Fig. 4 Arteriogram of a patient with polyarteritis nodosa showing numerous micro-aneurysms of renal vessels

involvement. This would usually involve serology, biopsy of relevant sites, and imaging studies (Table 5). Referral to a nephrologist, otolaryngologist, pulmonologist, ophthalmologist, or neurologist may be necessary to determine involvement of specific organs.

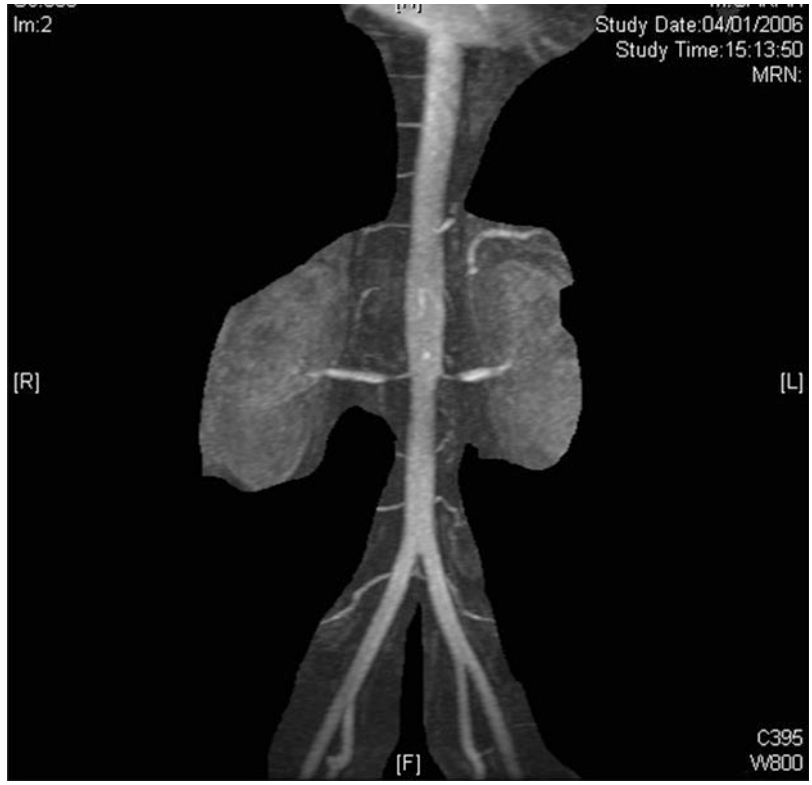
Serology

ANCA is now tested using a combination of IIF and ELISA. An international multicenter observational study found that IIF is more sensitive, but ELISA is more specific, and so IIF is usually used for screening and ELISA is used to confirm positive IIF results. ANCA positivity confirmed by a positive PR3-ANCA or MPO-ANCA has a predictive value above 95 % for the diagnosis of AAV with renal involvement in a patient with suspected nephritis. A minority (5–10 %) of patients with a pauci-immune, necrotizing, crescentic glomerulonephritis are ANCA negative, and ANCA is negative in other vasculitis syndromes, such as Henoch-Schönlein purpura or large vessel vasculitis. ANCA positivity by IIF (i.e., C-ANCA or P-ANCA) with negative PR3-ANCA and MPO-ANCA is still compatible with a diagnosis of AAV, but other chronic inflammatory processes that can produce a "false-positive" C-ANCA or P-ANCA need to be considered such as sinusitis or ulcerative colitis.

Although ANCA testing is widely used for the diagnosis of vasculitis, there is often confusion concerning the value of a negative result and the interpretation of positive results. A negative result has little value. In part, this is influenced by variable assay performance and differing referral practices. The role of ANCA in monitoring is more controversial with the best evidence suggesting that ANCA positivity during the remission phase indicates a higher risk of subsequent relapse.

Kidney Biopsy

Renal histology enables a more secure diagnosis to be made and is recommended for all patients with potential renal vasculitis. In the presence of ANCA positivity (both C-ANCA or P-ANCA and PR3-ANCA or MPO-ANCA), over 95 % of biopsies will show renal vasculitis, so it has been argued that biopsy is unnecessary. However, biopsy also permits diagnosis of concurrent conditions, such as anti-GBM disease or IgA nephropathy, and carries prognostic significance. Biopsy is strongly recommended when PR3-ANCA or MPO-ANCA is negative. The prognostic value of renal biopsy for ESRD may be helpful but is not sufficiently well determined to influence treatment in a particular individual. Microscopic hematuria persists for many months after the commencement of therapy for renal vasculitis despite normalization of the inflammatory markers CRP and ESR. It is unclear how well hematuria correlates with histological activity and what the criteria for repeat biopsy should be. The typical renal biopsy features in ANCA-associated vasculitis are a pauci-immune necrotizing glomerulonephritis with crescent formation. The histological severity of glomerular lesions is classified into focal, crescentic, fibrotic, and mixed groups with the risk of ESRD being lowest for focal and highest for fibrotic disease subgroups.



Vasculitis and the Kidney, Fig. 5 Takayasu arteritis with renal artery involvement (type IV). The angiographic classification of Takayasu arteritis involves 5 stages: type I: branches of the aortic arch; type IIa: ascending aorta, aortic arch, and branches of the aortic arch; type IIb: ascending aorta, aortic arch, and its branches and thoracic descending aorta; type III: thoracic descending aorta, abdominal aorta, and/or renal arteries; type IV: abdominal aorta and/or renal arteries; type V: features of types IIb and IV

Differential Diagnosis

Secondary causes of vasculitis and diseases mimicking vasculitis need to be excluded before a diagnosis of primary systemic vasculitis can be made (Table 2). Chronic inflammatory disorders such as bacterial endocarditis or rheumatoid arthritis can mimic vasculitis or induce a systemic vasculitis syndrome, such as an ANCA-associated vasculitis. Chronic bacterial infection may be obvious, as in cystic fibrosis or bronchiectasis, but occult endocarditis or abdominal sepsis should be considered. Tuberculosis and other non-vasculitic causes of pulmonary cavities can mimic GPA.

For those presenting with deteriorating renal function, other causes of rapidly progressive glomerulonephritis and acute renal failure need to be considered. Radiological assessment of renal size is typically normal in vasculitis; reduced renal size points to more chronic causes of renal disease. The presence of microscopic hematuria and proteinuria is nonspecific, occurring in other forms of renal and lower urinary tract inflammation and infection. Nephrotic range proteinuria may be found during the recovery phase of ANCA-associated vasculitis and in vasculitis associated with immune complexes, such as in cryoglobulinemia or Henoch-Schönlein purpura.

Treatment

AAV patients with renal vasculitis will usually progress to end-stage renal disease unless treated promptly. The progression of renal disease in rarer vasculitides, such as in Henoch-Schönlein purpura, has been less well studied and the role of therapy less established. The induction phase, of 3–6 months, aims to control active features of vasculitis. This is followed by the maintenance or remission phase, which could last 2–4 years, during which treatment is continued. Treatment is then slowly withdrawn but indefinite follow-up is required for the early detection of late relapse and the management of irreversible damage caused by the disease and its treatment. A major problem

Vasculitis and the Kidney, Table 5 Investigations for suspected primary systemic vasculitis

To exclude other causes (including secondary causes of vasculitis)	
Antinuclear antibody (ANA)	Antiphospholipid antibodies
Anti-GBM antibodies	
Complement levels	Serum electrophoresis
Consider infections	Viral (hepatitis B/C/HIV)
	Chronic Bacterial, e.g., endocarditis (ECHO) and
	blood cultures
Further confirmatory tests	
ANCA (MPO/PR3)	Cryoglobulins
Urine Dipstick and Microscopy	Renal biopsy (histology/ immunofluorescence/EM)
Renal ultrasound	Chest X-ray
Nerve conduction studies or electromyography	Angiogram
Biopsies of other sites: ENT, nerve, skin, lung	CT (chest/sinuses/head)
Peripheral eosinophilia	MRI
Bronchoscopy	
Referral to other specialists	
Nephrology	Renal biopsy
Ophthalmologist	? Episcleritis/uveitis
Ear, nose, and throat surgeon	? Assessment of ear, nose, and throat Involvement
	For example, granulomas, inflammation
	Hearing tests
Pulmonologist	Bronchoscopy

with current treatment is treatment toxicity that range from the risk of infections to hematological and urothelial malignancies.

Induction Therapy

Cyclophosphamide was introduced in the 1960s, and the combination of cyclophosphamide and corticosteroids now remains the "standard of care" for renal vasculitis. In the induction phase, cyclophosphamide is continued for 3–6 months, by which time vasculitis will have been controlled in 90 % of patients. Close monitoring of the full blood count is required for the early detection of cytopenias and appropriate dose adjustment. Prednisolone is commenced at high dose and tapered.

Additional treatment with high-dose intravenous methylprednisolone, 1,000–3,000 mg, is widely used for renal vasculitis without a firm evidence base and may be commenced on suspicion of the diagnosis before ANCA testing or renal histology is available. Plasma exchange improves the chances of renal recovery in those presenting in renal failure, with a serum creatinine >500 μmol/L (Jayne et al. 2007), but it is uncertain whether it also has a role in renal vasculitis with deteriorating renal function below this level or in severe non-renal presentations, such as diffuse alveolar hemorrhage.

Treatment intolerance or severe infections are the most common causes of treatment failure in the induction phase. Progressive disease is treated first with intravenous methylprednisolone and/or plasma exchange. If this fails or there is treatment intolerance or active disease persists beyond 6 months, then agents used for refractory vasculitis are employed (see below).

Rituximab has been directly compared to cyclophosphamide for remission induction in two randomized trials (Jones et al. 2010; Stone et al. 2010). They each demonstrated non-inferiority of rituximab as compared to cyclophosphamide in terms of efficacy, but neither trial demonstrated an early safety benefit of reducing or avoiding cyclophosphamide exposure.

Maintenance Therapy

The goals of maintenance therapy are to prevent disease relapse with less risk of drug toxicity then during the induction phase. Cyclophosphamide is withdrawn and replaced by azathioprine. Methotrexate is an alternative if serum creatinine is less than 1.8 mg/dl (Jayne et al. 2003; De Groot et al. 2005). Prednisolone is either continued in conjunction with an immunosuppressive or is withdrawn during the maintenance phase.

Thromboprophylaxis

Thromboembolic events, including pulmonary emboli, myocardial infarction, and stroke occur in 7–15 % of patients during the first year. Thromboprophylaxis may have an important role, although this has not yet been proven.

The Treatment of Refractory Vasculitis

Refractory vasculitis occurs rarely during the induction phase, but is more common later in the disease course, and is manifested by multiple relapses or a state of persistent disease activity. The re-administration of conventional agents including intravenous methylprednisolone, plasma exchange, and cyclophosphamide can control most acute cases of refractory disease. However, their use may be complicated by intolerance, intercurrent infection, or concern over cumulative cyclophosphamide exposure.

Other approaches to refractory disease include intravenous immunoglobulin (IVIg), B cell depletion, and T cell depletion. IVIg reduces levels of vasculitic activity in persisting or relapsing, reduces ANCA production, and is a useful adjunct short term, permitting reduction in immunosuppressive or steroid dosing. This is desirable in the face of active infection, in patients at high risk of infection, and in pregnancy. B cell depletion with rituximab has been shown to be more effective than further cyclophosphamide for relapsing or refractory disease and may be the preferred agent in this setting. T cell depletion with Alemtuzumab (CAMPATH 1-H), a humanized monoclonal anti-CD 52 that selectively depletes lymphocytes, has been shown to induce remissions in difficult to treat AAV, although relapses and adverse events are common.

Adverse Events of Therapy

The major early risk of combined cyclophosphamide and prednisolone treatment is sepsis, often associated with leukopenia which increases the septic risk more than fourfold. Older age and uremia greatly increase the risk of sepsis. A causal sequence of cyclophosphamide-induced neutropenia, sepsis and death, has been established, and cyclophosphamide dosing should aim to minimize neutropenia. Other side effects include hemorrhagic cystitis and infertility. Late risk includes urothelial and hematological malignancies. Steroid-related side effects are very frequent and include fluid retention, weight gain, hypertension, diabetes, and steroid-induced bone disease.

Prognosis and Outcomes

A recent study looking at the long-term outcome of AAV reported 1, 2, and 5 year survival rates of 88 %, 85 %, and 78 %, respectively, with a mortality ratio of 2.6 when compared to age- and sex-matched controls (Flossmann et al. 2011). The most common causes of early death were infection and active vasculitis; later deaths were caused by malignancy and cardiovascular events.

Creatinine at presentation remains the strongest predictor of both patient and kidney survival for renal vasculitis. Those presenting in renal failure have a particularly poor outcome, and earlier diagnosis is likely to improve outcome more than improved therapies.

For those presenting with renal impairment who respond to therapy, there is a gradual improvement in renal function over the first year. GFR may then remain stable for many years even if recovery is to a GFR below 30 ml/min. In this setting, vasculitis relapse with renal involvement carries a high risk of ESRD.

Cardiovascular events are common during periods of active vasculitis and may be caused by the increased pro-thrombotic tendency. There is a threefold increased risk of cardiovascular events in ANCA-associated vasculitis, which has been attributed to direct and indirect effects of vasculitis on blood vessels, chronic inflammation, and the consequences of chronic renal failure and medications.

Malignancy risk is increased approximately twofold. A wide distribution of malignancies is seen, with bladder malignancies overrepresented reflecting cyclophosphamide exposure. Rates of urothelial malignancy have fallen considerably over the last decade due to lower cyclophosphamide exposures. The extent to which pulsed intravenous cyclophosphamide regimens increase the risk of bladder malignancy is not known (de Groot et al. 2001).

The risk of relapse declines with time but follow-up should remain lifelong because late relapse can still occur with potentially devastating consequences. Treatment withdrawal is the strongest relapse predictor; other predictors are a diagnosis of GPA, PR3-ANCA, cardiovascular

disease due to vasculitis, persisting ANCA positivity, a previous history of relapse, or nasal colonization with *Staphylococcus aureus* in GPA. Worse renal disease, especially with a creatinine >200 μmol/L, is a predictor of a lower relapse risk (Walsh et al. 2012). ANCA levels are not closely related to disease activity, but the persistence of ANCA at 6 months after induction therapy or a rising ANCA level indicate relapse is more likely.

End-Stage Renal Disease and Transplantation

In renal-limited vasculitis, treatment with immunosuppression and prednisolone can be withdrawn once ESRD is reached. However, continued therapy may be required to control extrarenal vasculitic disease. Relapse rates of AAV are lower in patients with ESRD, but relapse, especially of the respiratory tract, may still occur. ESRD vasculitis patients have a higher incidence of infection which complicates therapy. The success of renal transplantation in AAV is similar to that for other nondiabetic causes of ESRD (Schmitt and van der Woude 2003). Transplantation reduces the risk of vasculitic relapse and can proceed in the face of a persistently positive ANCA.

Management of Other Vasculitic Syndromes Involving the Kidney

Henoch-Schönlein purpura: although nephritis is not prevented by prednisolone, this is commonly used to treat active renal disease, often in combination with an immunosuppressive. Plasma exchange has the rationale of removing IgA and IgA containing immune complexes and may be considered when there is deteriorating renal function.

Cryoglobulinemic vasculitis: when associated with hepatitis C, therapy is directed at controlling viral replication. Prednisolone may be required for initial therapy of inflammatory manifestations such as nephritis. Hepatitis C-negative, "essential," cryoglobulinemia is treated with glucocorticoids, with or without an immunosuppressive, and plasma exchange. Rituximab has led to remissions in refractory hepatitis C-associated and essential cryoglobulinemia.

Takayasu arteritis: prednisolone and an immunosuppressive are used to arrest progression of vascular disease, but renal artery involvement requires specific therapy if there is evidence of functional decline in the affected kidney. The stenoses are less amenable to angioplasty and stenting than in atheromatous renovascular disease, but this option may still be effective. Renal autotransplantation appears to be a useful alternative.

Controversies in Treatment of Vasculitis and Future Goals

The first consensus treatment guidelines were published in 2007 and highlight areas where evidence is lacking and no clear direction can be given. The duration of cyclophosphamide induction therapy has been reduced to less than 6 months, but it is not known whether much shorter courses followed by an alternative immunosuppressive will be as effective. Similarly, corticosteroid dosing has not been formally tested and there is a trend for doses to be reduced more rapidly. The duration of maintenance immunosuppression and corticosteroid therapy varies widely between 6 months and over 4 years. The short-term benefit of plasma exchange on renal recovery has been demonstrated, but it is not known whether this expensive intervention influences long-term mortality or ESRD rates; there is also controversy over its role in other severe vasculitis presentations, such as rapidly progressive glomerulonephritis without advanced renal failure, and in lung hemorrhage with respiratory failure.

Of the newer drugs under evaluation, rituximab is emerging as both safe and effective for obtaining sustained disease remission and may replace current regimens with long-term immunosuppression and corticosteroids. If rituximab use becomes widespread, this will reduce cyclophosphamide-related toxicity, but

it is unclear whether glucocorticoid exposure will also be reduced and what the implications of rituximab are on maintenance regimens or long-term outcomes.

Vasculitis: Behçet

Petros P. Sfikakis
First Department of Propedeutic & Internal Medicine, Athens University Medical School, Athens, Greece

Synonyms

"Silk Road" disease; Adamantiades-behçet disease

Definition

During the 1930 annual meeting of the Medical Association of Athens, the Greek ophthalmologist Benediktos Adamantiades presented a 20-year-old male patient with relapsing iritis, genital ulcers, and arthritis. Seven years later the Turkish dermatologist Hulusi Behçet described three patients with the tri-symptom complex of oral and genital ulcerations and hypopyon uveitis (Zouboulis and Keitel 2002). This condition is currently considered as a distinct, chronic, relapsing multisystem inflammatory disorder which affects the small and large vessels of the venous and arterial systems and is characterized by mucocutaneous, ocular, arthritic, vascular, and central nervous system manifestations.

Epidemiology

Behçet disease exists worldwide, but it is more prevalent in Mediterranean, Middle Eastern, and Far Eastern countries across the ancient trading route known as the "Silk Road." The highest rate (4 in 1,000 adults) is found in Turkey, followed by Israel, Northern China, Iran, Korea, Japan, Saudi Arabia, Iraq, Morocco, and Egypt. However, recent findings suggest that in Western Europe it is a more common disease than previously thought, perhaps as a result of underdiagnosis, exceeding even the prevalence of polyarteritis nodosa (Yazici et al. 2008).

Pathogenesis and Genetic Factors

Behçet disease can be viewed as a condition linking autoinflammation and autoimmunity (McGonagle and McDermott 2006). Since its etiology and pathogenic mechanisms remain essentially unknown (Mendoza-Pinto et al. 2010), some authors prefer to designate it as a syndrome instead of a disease. No specific immune cell type can be recognized in vasculitic lesions, immune complex deposition is rarely seen, and although both innate and adaptive immune responses are augmented, autoantibodies are usually absent. In addition to the distinct epidemiological features, a genetic contribution to the disease is supported by the high sibling recurrence risk ratio and the strong association with HLA-B51. However, this HLA association accounts for less than 20 % of the genetic risk (Gul and Ohno 2012). In two large genome-wide association studies, the HLA-B51 association was confirmed and a second, independent association within the MHC Class I region was found. Moreover, interleukin-10, interleukin-23 receptor, and interleukin 12 receptor β2 were identified as susceptibility loci, whereas the disease-associated interleukin-10 variant (rs1518111 A allele) was associated with diminished mRNA expression and low protein production (Mizuki et al. 2010; Remmers et al. 2010). Given the anti-inflammatory effects of interleukin-10, these findings support a role for this cytokine in the uncontrolled activation of innate and/or adaptive immune responses seen in these patients. An important role of TNF-mediated interactions in the perpetuation of inflammation is also supported by the impressive clinical responses after therapy with anti-TNF antibodies in many patients (Sfikakis et al. 2007; Arida et al. 2011).

Clinical Spectrum

As shown in the Table 1, there is a wide range of clinical manifestations in Behçet disease. For a number of these features, there is significant difference in prevalence between different ethnic

Vasculitis: Behçet, Table 1 Frequency of clinical manifestations of Behçet disease

Oral ulcers	97–99 %
Genital ulcers	85 %
Papulopustular lesions	55 %
Erythema nodosum	45 %
Uveitis	35–70 %
Arthritis	35–60 %
Superficial thrombophlebitis	25 %
Deep vein thrombosis	5–10 %
Aneurysms	3–8 %
Central nervous system involvement	10–25 %
Epididymitis	5–15 %
Gastrointestinal involvement	5–25 %

groups (Yazici et al. 2007). Recurrent oral ulcers, the cardinal disease feature, are usually painful and appear in the tongue, pharynx, buccal, and labial mucosal membranes, either as single or multiple lesions, which heal within 1 week without scarring. Genital ulcers resemble oral ulcers but are usually larger and deeper, and appear on the scrotum, less frequently on the penis, or on the vulva and vagina in women.

Skin lesions most often include erythema nodosum-like lesions, as well as pseudofolliculitis and acneiform nodules which can appear all over the body and they are not always hair follicle-associated.

Ocular involvement may be severe and any part of the eye can be affected. Anterior uveitis with or without hypopyon, vitritis, and relapsing inflammation of the posterior segment with vasculitis, retinitis, optic disc swelling, and cystoid macular edema may occur.

Joint involvement is usually a monoarthritis affecting the knee or the ankle or oligoarthritis. Erosive changes are rare. Superficial thrombophlebitis is transient and can be misdiagnosed as erythema nodosum.

Thrombosis may occur in many different sites including the chambers of the heart, veins (iliofemoral, superior or inferior vena cava, pulmonary, axillary, brachial, and hepatic), and dural sinus. Arterial aneurysms may develop at the abdominal aorta, iliac, femoral, popliteal, carotid, and renal arteries and can rupture suddenly. Central nervous system involvement includes parenchymal and non-parenchymal (cerebral venous thrombosis or arterial aneurysm) lesions.

Epididymitis is manifest by testicular pain and is mostly self-limited.

Gastrointestinal involvement is particularly frequent in patients from the Far East; single or multiple deep penetrating ulcers develop mostly in the terminal ileum, the ileocecal region, and the colon. These lesions may mimic Crohn's disease.

Diagnosis

The diagnosis of Behçet disease is entirely clinical and requires the exclusion of other diagnoses based on clinical presentation. A careful past medical history is mandatory due to the relapsing-remitting course of the disease. There is no pathognomonic or specific laboratory test and HLA-B51 testing is not recommended for diagnostic purposes. The differential diagnosis is wide and depends on the given constellation of clinical manifestations. For example, multiple sclerosis should be ruled out in patient with central nervous involvement and uveitis, Takayasu's arteritis in a patient with arterial lesions, or inflammatory bowel disease in a patient with intestinal involvement and arthritis.

According to the widely accepted international criteria (Criteria for diagnosis of Behcet's disease 1990), a patient can be diagnosed with Behçet disease (with a sensitivity of 85 % and specificity of 96 %) if, in the absence of other explanations, the patient has recurring oral ulcerations (aphthous or herpetiform) observed by the physician or the patient at least three times in a 12-month period, plus at least any two of the following:

(a) Recurrent genital aphthous ulceration or scarring
(b) Eye lesions: anterior uveitis, posterior uveitis, cells in the vitreous by slit lamp examination, or retinal vasculitis observed by an ophthalmologist
(c) Skin lesions: erythema nodosum, pseudofolliculitis, papulopustular lesions, or acneiform nodules in postadolescent patients not on corticosteroids

(d) A positive pathergy test (nonspecific skin hyper-reactivity in response to minor trauma) read by a physician at 24–48 h

Natural Course and Prognosis

Behçet disease is rarely seen in children or in the elderly. The typical onset occurs in the third or fourth decade of life, but recurrent oral ulceration, which is most often the first symptom, may begin many years before the diagnosis is established. A male preponderance in seen in Mediterranean and Middle Eastern countries, but women are more commonly affected in the Far East. Familial cases have been reported (Kural-Seyahi et al. 2003). A remitting and relapsing course is characteristic of the disease, which abates in the majority of patients after 20 years. However, morbidity and mortality are significant. Ocular involvement is the leading cause of morbidity and, if left untreated, may result in blindness in more than 70 % of those affected. Young males have the worst prognosis and major vessel and neurological involvement, both of which may occur even 10 years after diagnosis, are the main causes of death (Saadoun et al. 2010). HLA-51 status has no prognostic significance.

Management

Management must be individualized, balancing the risks of therapy with the putative efficacy of a given approach. The aim of treatment is to maintain quality of life, prevent irreversible damage (which usually occurs early in the course of disease, especially in the high-risk group of young men) and prevent exacerbations of urogenital, cutaneous, and joint manifestations.

For self-limited manifestations such as oral ulcers, genital ulcers, papulopustular lesions, erythema nodosum, arthritis, epididymitis, and superficial thrombophlebitis, the aim is to control symptoms. Collaboration between different specialties and the use of immunosuppressive agents are mandatory for serious organ involvement, such as ocular involvement, major vessel disease, central nervous system, and gastrointestinal involvement. Adequately powered, randomized, and controlled clinical trials are few.

Corticosteroids, colchicine, cyclosporin-A, interferon-a, and cyclophosphamide, alone or in combination, are used but none of these represents a cure. Among the various immunosuppressive drugs, azathioprine remains the most useful (Yazici et al. 1990). The introduction of anti-TNF monoclonal antibodies during the last decade represents a significant advancement in the management of patients with severe, refractory manifestations and especially in relapsing sight-threatening involvement of the posterior eye segment (Sfikakis et al. 2001; Arida et al. 2011). Thalidomide, antibiotics, antiviral agents, methotrexate, sulfasalazine, chlorambucil, FK506, mycophenolate mofetil, rituximab, anti-IL-1 therapy, and stem cell transplantation have been used with variable results.

Evidence-based recommendations for the management of Behçet disease, supplemented where necessary by expert opinion, have been developed by a multidisciplinary expert committee based on systematic literature search through December 2006 (Hatemi et al. 2008). The following recommendations related to the eye, skin, mucosal, and joint disease are largely evidence-based: Any patient with inflammatory eye disease affecting the posterior segment should be on a treatment regime, which includes azathioprine and systemic corticosteroids. If the patient has severe eye disease defined as more than 2 lines of drop in visual acuity on a 10/10 scale and/or retinal disease (retinal vasculitis or macular involvement), it is recommended that either cyclosporine A or infliximab be used in combination with azathioprine and corticosteroids; alternatively interferon-alpha with or without corticosteroids could be used. The decision to treat skin and mucosa involvement will depend on the perceived severity by the physician and the patient. Topical measures (i.e., local steroids) should be the first line of treatment for isolated oral and genital ulcers as well as for acne-like lesions. Colchicine should be preferred when the dominant lesion is genital ulceration or erythema nodosum. Azathioprine, interferon-α, and TNF

antagonists may be considered in resistant cases. In most patients arthritis can be managed with colchicine.

The following recommendations on vascular disease, neurological and gastrointestinal involvement are based largely on expert opinion and uncontrolled evidence from open trials and observational studies: For the management of acute deep vein thrombosis, corticosteroids, azathioprine, cyclophosphamide, or cyclosporine is recommended. For the management of both pulmonary and peripheral arterial aneurysms, cyclophosphamide and corticosteroids are recommended. Anticoagulants, antiplatelet or fibrinolytic agents are not recommended; these agents may result in fatal bleeding, in the event of a coexisting pulmonary arterial aneurysm. Anticoagulants, antiplatelet, or fibrinolytic agents may cause fatal bleeding if a coexisting pulmonary arterial aneurysm dissects or ruptures. Therefore, these agents should be avoided (Hatemi et al. 2008). However, some experts recommend anticoagulation for venous thrombotic events.

For the management of gastrointestinal involvement, agents such as sulfasalazine, corticosteroids, azathioprine, TNF antagonists, or thalidomide should be tried before surgery, except in emergencies. There are no controlled data to guide the management of central nervous involvement. Due to its potential neurotoxicity, cyclosporine A should not be used in Behçet disease patients with central nervous system involvement unless necessary for intraocular inflammation. For brain parenchymal involvement, corticosteroids, interferon-alpha, azathioprine, cyclophosphamide, methotrexate, and TNF antagonists may be effective. For dural sinus thrombosis corticosteroids are recommended. Dural sinus thrombosis should be treated with corticosteroids (Hatemi et al. 2008) although anticoagulation is also recommended by some experts.

[2]Department of Rheumatic and Immunologic Diseases, Cleveland Clinic Main Campus, Lerner College of Medicine, Cleveland, OH, USA

Synonyms

Granulomatosis with polyangiitis; Wegener's granulomatosis

Definition

Granulomatosis with polyangiitis (GPA) is a small and medium-sized vessel vasculitis that is associated with antineutrophil cytoplasmic antibodies (ANCA) in over 80 % of cases. Tissue injury involves both parenchyma and vessels. Vascular injury is not a feature of all lesions. While GPA commonly involves the upper respiratory tract, lungs, and kidneys, any organ system can be affected. Clinical course varies, depending on distribution of organs affected and rate of progression. If not treated or inadequately treated, GPA is usually life-threatening.

Genetic Background

Strong genetic associations with GPA have not been found, and familial cases are rare. Nonetheless, the relative risk for GPA in 1st degree relatives is 1.56 (Knight et al. 2008). Increasing numbers of genetic polymorphisms have been found to be associated with GPA, many of which are integral to the immune system. The strongest HLA associations have been seen with HLA DPB1*0401 and even stronger with the extended haplotype HLA DPB1*0401/RXRB03 (Table 1) which regulates apoptosis and is located in the MHC class II region (Jagiello et al. 2004). Several other gene alleles related to apoptosis have been reported to be associated with GPA although less strongly than with HLA DPB1*0401/RXRB03. This suggests that alterations in regulation of apoptosis in antigen-presenting cells may play a role in the etiology of GPA.

PTPN22 affects the signalling threshold of the T-cell receptor, binding intracellular tyrosine kinases and regulating phosphorylation of key kinases. The PTPN22 620W allele has been associated with T-cell activation and has been associated with a number of autoimmune diseases including type 1 diabetes, seropositive rheumatoid arthritis, and systemic lupus erythematosus. An increase in the PTPN22 620W allele has been seen in ANCA-positive GPA patients. Significant increases in this allele were not found in ANCA-negative patients compared with controls (Jagiello et al. 2005).

The neutrophil membrane expression pattern of proteinase 3 (PR3) is bimodal with either high or low expression patterns. This appears to be genetically determined as there is a stronger correlation between the expression patterns in monozygotic twins than dizygotic twins. Patients with ANCA-associated vasculitis have been found to have higher expression of PR3 on neutrophils. Overexpression of the G allele in the A-564G polymorphism of the PR3 gene leads to increased expression and is associated with GPA (Gencik et al. 2000). Since surface expression of PR3 on neutrophils is important to the formation of anti-PR3-ANCA complexes, this is a genetic link which could contribute to pathogenesis in a predisposed host.

Cytotoxic T-lymphocyte-associated protein4 (CTLA4) is found on $CD4^+$ T cells which controls interactions with B cells and dendritic

Adapted from Willcocks et al. Arthritis Res Therapy. 2010;12:202

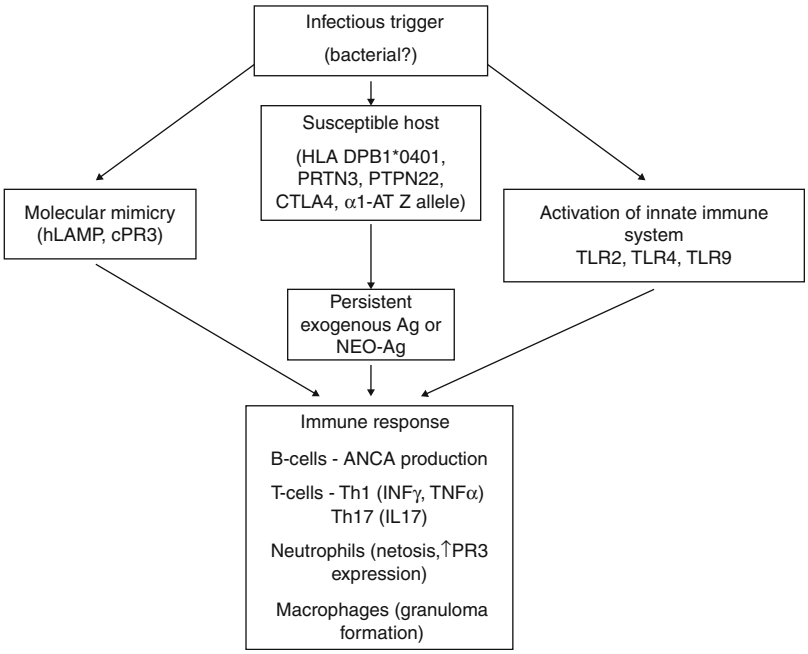
cells. As opposed to CD28 which enhances activity of T cells, CTLA4 is responsible for downregulating T-cell activation. A microsatellite polymorphism of the CTLA4 gene can result in longer alleles. Messenger ribonucleic acid (mRNA) produced from longer alleles is less stable and results in less CTLA4 production. The longer alleles are seen more frequently in GPA patients compared to healthy controls (53 % vs 30 %) (Zhou et al. 2004). In addition, there is a higher frequency of a single nucleotide polymorphism in the promoter region (CTLA4-318T) of CTLA4 in GPA patients (Giscombe et al. 2002). Reduction of inhibition of T-cell activation mediated by CTLA4 could produce an extreme T lymphocyte response.

Alpha 1-antitrypsin (α1-AT) serves an important role in neutralization of free PR3. The plasma level of α1-AT is controlled by codominant alleles. The M allele is the wild-type allele, while Z and S alleles have been associated with α1-AT deficiency. Furthermore, the Z allele has been associated with α1-AT polymer formation which accumulates within the endoplasmic reticulum. These polymers have known proinflammatory effects. In a recent large study from the United Kingdom, the Z allele was shown to have a higher association with GPA relative to healthy controls (HR = 2.54, CI 1.78–3.64, $p < 0.0001$). In patients with ANCA-associated vasculitis with the Z allele, there was a significantly reduced serum α1-AT concentration as well as evidence of polymer formation in the kidney of a patient with MZ phenotype with active crescentic glomerulonephritis. This is suggestive of a role for this allele in pathogenesis. However, the low frequency of the Z allele in GPA (4–8 %) argues against it playing a role in the majority of patients (Morris et al. 2011).

While genetic associations have been found that may contribute to dysregulation of the immune system, given the low prevalence of disease in first-degree relatives they each likely play a limited role. It remains plausible that the predisposition to GPA is related to polygenic factors that have not yet been identified (Fig. 1).

Environmental Factors

The high prevalence of systemic features and symptoms that mimic infection in the upper and lower airway has led many authors to suggest a role for an airborne trigger in GPA. An infectious etiology was suspected in the earliest descriptions of this disease by both Klinger (1931) and Wegener (1990). Early studies by Raynauld and colleagues suggested a higher incidence of new onset disease in spring and winter (Raynauld et al. 1993). However, data from the National Institutes of Health show no seasonal variation in regards to hospitalizations for GPA



Vasculitis: Granulomatosis with Polyangiitis (Wegener's), Fig. 1 Proposed model of pathogenesis

(Cotch et al. 1996). Clustering of cases within specific geographic regions is also suggestive of an environmental trigger(s) (Cotch et al. 1996).

Nasal carriage with *Staphylococcus aureus* has been shown to increase the risk of GPA relapse. Patients carrying a *S. aureus* strain that produces the super antigen toxic shock syndrome toxin-1 have the highest risk of relapse (Popa et al. 2007). In addition, treatment with trimethoprim-sulfamethoxazole (T/S) reduces the risk of relapse. It is tempting to attribute the effect of T/S to elimination of *S. aureus* in the upper airways; however, T/S may also have a primary anti-inflammatory effect through inhibiting formation of oxygen-derived radicals in activated neutrophils and/or immunosuppressive effects through antagonism of folic acid metabolism (Stegeman et al. 1996). Because T/S has been shown to reduce only upper airway symptoms, not pulmonary, renal, or other relapses, there is some question whether the benefit of T/S was actually on sino-nasal infection reduction and not disease relapse.

Infections have also been implicated in the formation of ANCA antibodies. Many infectious agents, including those associated with endocarditis, chronic infections, and parasites (Pudifin et al. 1994), have been variably associated with antibodies to either PR3 or MPO, and other lysosomal enzymes (Bonaci-Nikolic et al. 2010). Molecular mimicry is one proposed mechanism through which infections can induce ANCA. For instance, antibodies to lysosomal membrane protein-2 (LAMP-2) represent a newly described subtype of ANCA. Human LAMP-2 (hLAMP-2) antibodies, highly prevalent in pauci-immune focal necrotizing glomerulonephritis (FNGN), have been shown to activate neutrophils. hLAMP-2 may mediate damage to endothelium in vitro in concert with polymorphonuclear cells (PMNs) or independent of PMNs. It has also been shown to cause pauci-immune FNGN in rodents. hLAMP-2 has considerable homology to the adhesion molecule FimH found on fimbriated bacteria. Rats immunized with FimH develop pauci-immune FNGN and develop antibodies to hLAMP-2 (Kain et al. 2008). Further studies of serum from untreated patients with ANCA-associated vasculitis associated with pauci-immune FNGN from multiple cohorts have shown a high frequency of antibodies hLAMP-2 at presentation in three separate

assays (80–90 %). The antibodies become undetectable with treatment and are frequently detectable again in over half of patients during relapse (Kain et al. 2012). These finding suggest a role for anti-LAMP-2 antibodies in pathogenesis and provide a link between bacteria and disease. The observations need to be confirmed by larger cohorts.

Furthermore, *S. aureus* has homology with the middle portion of complementary PR3 (cPR3) and can induce cPR3 antibodies. cPR3 is elevated in up to one third of PR3-ANCA-positive patients and found in animal models to generate anti-PR3-ANCA through an anti-idiotype immune response (Hewins et al. 2011).

These examples demonstrate several potential mechanisms through which infections could trigger vasculitis through systemic activation of granulocytes, molecular mimicry between bacterial and host proteins, and induction of antibodies by bacterial super antigens (Fig. 1).

There has been less convincing evidence regarding noninfectious triggers. Some studies have implicated silica exposure as well as farming as risk factors. The majority of these studies have utilized questionnaires which are subject to recall bias. Other studies using population registries have reported no correlation between various occupations including those having high risk for silica inhalation (e.g., farming) and GPA (Lane et al. 2003; Knight et al. 2010). To date, there is not enough convincing evidence to implicate a particular noninfectious trigger in pathogenesis.

ANCA

ANCA is associated with GPA in about 80 % of cases. ANCA is also present in most patients with microscopic polyangiitis (MPA) and in about 38 % of cases of eosinophilia with granulomatosis and polyangiitis (EGPA or Churg-Strauss vasculitis). Because up to 20 % of GPA patients can be ANCA negative, questions have been raised about test sensitivity vs. the existence of a truly ANCA-negative GPA subset. If the latter were not a result of test inadequacy, one would have to conclude that ANCA is not essential to disease etiology but may still be important in pathogenesis (i.e., enhancing an established immuno-inflammatory process). ANCA targets proteins within the primary (azurophilic) and secondary granules of neutrophils, within lysosomes of monocytes, and in some cases, proteins that reside only in the cytoplasm. Those antigens most relevant to vasculitis are proteinase 3 (PR3), myeloperoxidase (MPO), and possibly hLAMP-2. While most patients with GPA are PR3-ANCA positive, up to 20 % of patients may have ANCA directed to MPO (and conversely for MPA, wherein 80 % of those positive are anti-MPO and up to 20 % are anti-PR3).

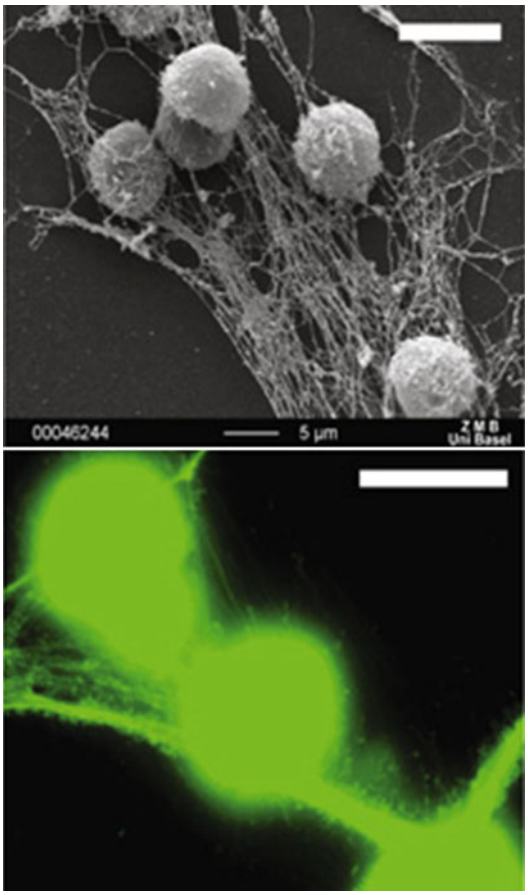
Experimental models have supported a role of PR3-ANCA antibodies in the pathogenesis of GPA. In vitro PR3-ANCA is able to activate neutrophils to produce oxygen species and release lytic enzymes. However, the neutrophils must be "primed" through tumor necrosis factor (TNF)-α, interleukin (IL)-1β, or complement factor C5a. TNF-α has several effects on neutrophils including upregulation of PR3 and other Ag-enzymes on the cell surface, making it available to PR3-ANCA. The expression of PR3 on neutrophils is variable among individuals and seems genetically determined. There are currently no good animal models for GPA to help directly link PR3-ANCA antibodies to pathogenesis. However, there are better animal models of small vessel vasculitis induced by MPO-ANCA. When splenocytes from MPO-deficient mice immunized with MPO are transferred to $Rag2^{-/-}$-immunodeficient mice, the recipients develop glomerulonephritis, granulomatous inflammation, and systemic necrotizing vasculitis. While this proof of concept model is compelling, patients with GPA are not $Rag2^{-/-}$ equivalents. Similar models with PR3-ANCA do not induce similar phenotypic changes (Kallenberg 2008).

Most of the PR3-ANCA in GPA patients with active disease has been shown to interfere with the enzymatic activity and with complex formation between PR3 and α1-antitrypsin, an inhibitor of PR3. Epitopes on PR3 targeted by ANCA include both those dependent on the 3D

structure of PR3 and those reactive to linear epitopes. A better understanding of ANCA-targeted epitopes is likely to improve our understanding of GPA disease expression (van der Geld et al. 2004).

NETosis (Neutrophil Extracellular Chromatin Traps, NETs)

Recently a newly recognized process that involves neutrophil cell death has shed light on the capture and killing of invading extracellular microbes. The process involves release of nuclear or mitochondrial chromatin from PMNs undergoing cell death, independent of apoptosis (Fig. 2). These structures also contain cytoplasmic and granular antimicrobial proteins. NETs are formed in response to a variety of proinflammatory stimuli (LPS, IL-8, and TNF) and microorganisms. In vitro, isolated neutrophils primed with TNF-α formed NETs more frequently when incubated with purified IgG from individuals with small vessel vasculitis compared to IgG from normal controls. In vivo evidence also supports the formation of NETs in kidney biopsies from patients with small vessel vasculitis with active kidney disease, and these NETs are coated with MPO and PR3. DNA NETs have been demonstrated to cause acute damage to small blood vessels during sepsis and may have a pathological role in small vessel vasculitis as well. Indeed, *S. aureus* is known to strongly induce NET formation (Kessenbrock et al. 2009). This observation lends additional support to the hypothesis that infection may be the initial trigger for disease.



Vasculitis: Granulomatosis with Polyangiitis (Wegener's), Fig. 2 *Top panel* – High resolution scanning electron microscopy of neutrophil NET's. *Bottom panel* – Syntox green staining showing high concentration of DNA in NET's (Gupta et al. 2010)

Toll-Like Receptors

Toll-like receptors (TLR) are essential to innate immunity for surveillance of pathogens. TLRs sense pathogen-associated molecular patterns (PAMPs) such as bacterial cell wall components and bacterial DNA and initiate the immune response. TLR2 and TLR4 have been shown to be especially important in the defense against *S. aureus*. TLR9 recognizes CpG motifs which are prevalent in bacterial DNA. In vitro, B cells from GPA patients stimulated by CpG and IL-2 produce higher levels of PR3-ANCA and MPO-ANCA (Hurtado et al. 2008). This was supported by an in vivo experiment in which mice were immunized with MPO and administered either a TLR2-ligand or TLR9-ligand. There was a clear enhancement of anti-MPO immunity and development of antibody-driven glomerular injury with either ligand (Summers et al. 2011). TLR2 is primarily involved in the promotion of the Th17 response, while TLR9 is important in the Th1 response and production of interferon-γ. In GPA, a shift toward a Th17 response has been

observed. These findings are supportive of a role of Toll-like receptors in the pathogenesis of GPA and suggest presence of a bacterial trigger. In a small series of 6 kidney biopsies from ANCA-positive GPA patients, there was evidence of increased TLR2, TLR4, and TLR9 compared to no expression of these molecules in disease controls (Batsford et al. 2011). Further studies of expression in TLRs in target tissues may provide further insight into pathogenesis.

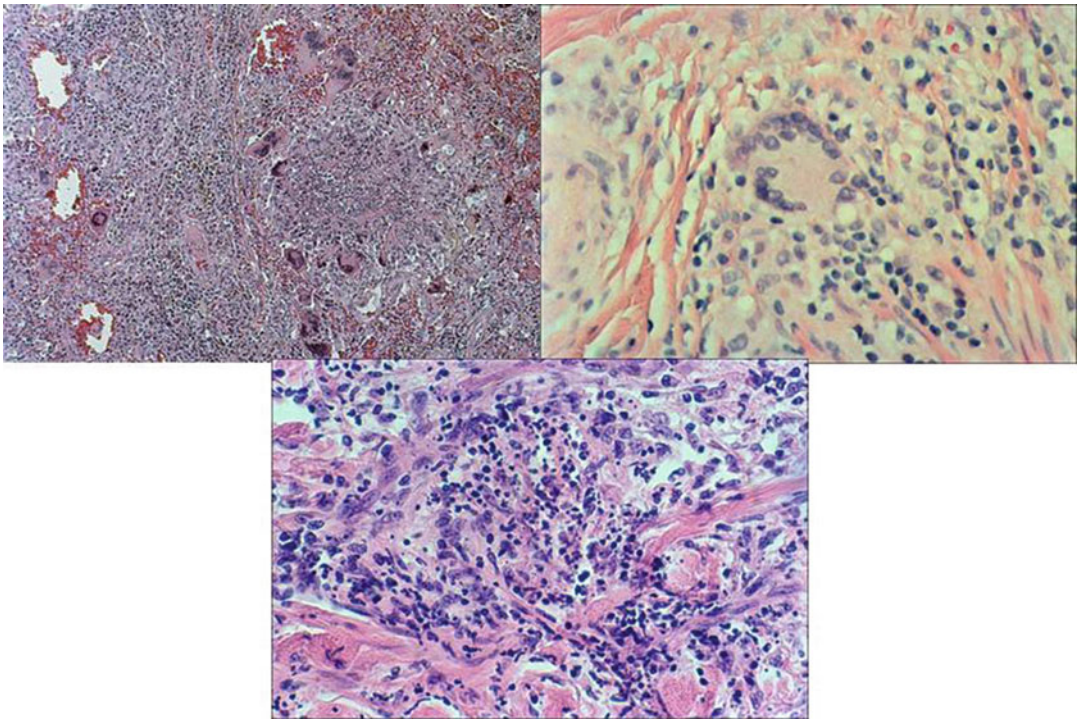
Granuloma Formation

GPA is much more commonly found to be associated with granuloma formation than other forms of small vessel vasculitis. Granulomas may be part of the inflammatory process in any tissue. The histological definition of a "granuloma" should not be used synonymously with a mass lesion or nodule and assumed to exclude the presence of vasculitis. In GPA, vasculitis may or may not be included in inflammatory lesions, whether or not granulomas are present. Granulomas are aggregates of mononuclear cells including activated macrophages, epithelioid cells (with or without giant cells) surrounded by T lymphocytes, B lymphocytes, and plasma cells. There may be an admixture of PMNs and eosinophils (Fig. 3). Thus, the cell content of a granuloma may be quite pleomorphic. It is the presence of activated macrophages and clustering of inflammatory cells that defines a granuloma. Granuloma formation is the body's response to poorly degraded intracellular pathogens (such as mycobacteria or fungi) or inert materials (silica or talc). Granuloma formation is common to sarcoidosis, Crohn's disease, Churg-Strauss syndrome, and Takayasu's arteritis. T lymphocytes, in response to antigen-presenting cells, are shifted toward a T-helper 1 (Th1) response. Th1 cells secrete high levels of IL-2, TNF-α, and interferon (IFN)-γ. This results in macrophage maturation and activation which can then form granulomas. Structurally, granulomas can appear similar to germinal centers seen in lymph nodes. This suggests that the granulomas may function similar to lymphoid organs in perpetuating the immune response. IL-12 is important in the differentiation of T cells into Th1 cells and is present in higher concentrations in patients with active and inactive GPA than controls. The presence of granulomas does not diminish a role for B cells and antibodies in GPA (Schilder 2010).

Clinical Features

Most patients (56–90 %) with GPA will develop otolaryngeal manifestations at some point during their disease (Wegener's Granulomatosis Etanercept Trial (WGET) Research Group 2005; Stone et al. 2010; Hoffman et al. 1992). The most common manifestations are inflammation of the sinuses and nasal mucosa. A history of recurrent sinus infections "refractory" to antibiotics is common. Visual exam of the nasal mucosa may reveal inflammation, ulcers, or nasal septal perforation. With chronic damage, the nasal mucosa may appear atrophic or "cobblestoning" may be present. Saddle nose deformities may appear with chronic damage of the nasal cartilaginous structures. Inflammation within the middle ear can be confused with infectious causes of otitis media. Hearing loss is most often conductive in nature; however, sensorineural deafness can also occur with cranial nerve VIII involvement. Eye manifestations may include conjunctivitis, episcleritis, retro-orbital mass, uveitis, scleritis, and retinal hemorrhages. Damage to the nasolacrimal ducts can lead to excessive tearing. Mouth sores are typically painful. Rarely, the gingiva can appear red, friable, and granular, giving the appearance of "strawberry gingiva." Subglottic stenosis may develop in approximately 10 % of patients (Wegener's Granulomatosis Etanercept Trial (WGET) Research Group 2005; Hoffman et al. 1992). Symptoms and signs of subglottic stenosis may include a history of difficulty with intubation, dyspnea in the absence of lung lesions, and stridor.

Pulmonary manifestations are present as an initial manifestation in up to half of patients; however, up to 85 % of patients eventually developing lung abnormalities. Pulmonary involvement may be asymptomatic or may



Vasculitis: Granulomatosis with Polyangiitis (Wegener's), Fig. 3 Lung biopsy from patient with GPA. (1) This lung biopsy contains areas of intense pleomorphic cellular inflammation and many giant cells. (2) Under higher power one can see an area of mostly mononuclear cell infiltrate with activated macrophages that have formed giant cells. Adjacent to these findings on the left side of the image is a necrotic vessel (vasculitis). (3) In another lung biopsy in GPA activated macrophages are part of a more pleomorphic population, including neutrophils, many of which have undergone lysis (leukocytoclasis)

present dramatically requiring ventilatory support. Frequent symptoms include cough, hemoptysis, and pleuritic chest pain. Diffuse alveolar hemorrhage requires aggressive treatment and if severe may lead to ventilator dependency. Endobronchial inflammation, stenosis, and ulcerations may occur as well. About one third of patients will have radiographs showing infiltrates or nodules without any specific symptoms. Therefore, it is important to screen patients with GPA for pulmonary disease.

Glomerulonephritis (GN) is a presenting manifestation in approximately 20 % of patients with GPA and will eventually affect 80 % of patients. The earliest sign of GN is asymptomatic microscopic hematuria and red blood cell casts in the urine. Kidney biopsies typically reveal necrotizing pauci-immune glomerulonephritis. Permanent kidney damage may develop rapidly. About 10 % of patients may develop end-stage renal disease (Hoffman et al. 1992; Villa-Forte et al. 2007). Patients receiving kidney transplantation have fewer relapses and a lower mortality compared to those who continue on dialysis. Graft survival in GPA is similar to that of other causes of end-stage kidney disease with 5-year graft survival reported as high as 93 % (Geetha et al. 2011). Microscopic hematuria and/or proteinuria may persist for years despite a sustained remission (Magrey et al. 2009; Geetha et al. 2012).

Skin manifestations will eventually develop in 46 % of patients with GPA and may include palpable purpura, ulcers, vesicles, papules, and subcutaneous nodules. Nervous system involvement may occur and most typically manifests as mononeuritis multiplex in about 15 % of patients. Central nervous system involvement is rare

(8 % of patients) and can include strokes, cranial nerve palsies, and diabetes insipidus. Pericarditis is the most frequent cardiac manifestation (about 6 % of patients). Rarely, the cardiac muscles or vessels can be involved (<2 %). Rare cases of mass lesions have been reported in the kidneys, adrenal glands, parotid glands, pulmonary artery, breast, urethra, cervix, vagina, and spleen (Hoffman et al. 1992; Carrington and Liebow 1966).

There is a high risk of venous thrombosis in GPA. The estimated incidence is around 7 per 100 person-years. This is similar to the incidence observed in those with a history of thrombosis in the general population. Systemic lupus erythematosus (SLE) is another autoimmune condition with a high risk of thrombosis largely because of the association with antiphospholipid antibody syndrome. GPA is estimated to have seven times the risk of thrombosis as in SLE. The vast majority (80 %) of thrombotic events occur during periods of active disease. The pathogenesis behind this risk is incompletely understood. Risk factors, such as the presence of anti-β 2 glycoprotein antibodies, anticardiolipin antibodies, factor V Leiden mutation, prothrombin gene mutation, and methylenetetrahydrofolate reductase mutations, have not been consistently found in association with GPA (Sebastian et al. 2007; Merkel et al. 2005).

Diagnosis

GPA most commonly affects the upper airways, lungs, and kidneys. It should be suspected in patients presenting with pulmonary-renal syndromes. However, diverse manifestations have been described, and any organ can be involved. Earlier literature has referred to a subclass of patients as "limited" GPA, meaning absence of renal involvement (Carrington and Liebow 1966). However, the term "limited" was later redefined as lacking severe critical organ disease or life-threatening manifestations (Wegener's Granulomatosis Etanercept Trial (WGET) Research Group 2005). These terms are only accurate at the point in time that they are applied, as disease features often change over time. Positive ANCA antibodies, particularly those directed against PR3, are supportive of the diagnosis. However, up to 20 % of patients with GPA are ANCA negative.

Treatment

Over the last 30 years, the treatment strategies for patients with GPA have changed dramatically. Goals of treatment include achieving a sustained remission, prevention of relapses, and avoiding drug toxicity. Most patients can achieve remission. Glucocorticoids (GCs) remain the cornerstone of treatment. However, GCs alone are frequently ineffective at maintaining improvement and cannot be used in high doses indefinitely. A second immunosuppressive should always be used to anchor remission and allow for gradual GC tapering. The choice of the second agent is largely based on the severity of the manifestations. Severe disease is generally defined as manifestations that threaten critical organs or is life-threatening (i.e., diffuse alveolar hemorrhage, rapidly progressive glomerulonephritis, nervous system involvement, or gastrointestinal ischemia, etc.). For severe manifestations, pulse-dose glucocorticoids should be considered. Both cyclophosphamide (CYC) and rituximab (RTX) have been shown to be equivalent for induction of remission. CYC can be used in either monthly intravenous (IV) pulse doses (e.g., 0.5–1 mg/m^2) or a daily oral dose (e.g., 2 mg/kg/day). Hemorrhagic cystitis is a potential side effect from CYC but is extremely rare when use is restricted to 3–4 months for remission induction. Mesna should be given with IV CYC, and aggressive oral hydration should be part of CYC use regardless of route of administration. Blood counts should be performed regularly to monitor for hemocytopenias while using CYC. Because long-term use of CYC over more than 1 year is associated with increased risk of malignancies, especially transitional cell carcinoma of the bladder, cumulative CYC exposure should be limited to 3–6 months (Falk and Hoffman 2007; Fauci et al. 1983). RTX is given as multiple IV infusions (1,000 mg IV for 2 doses 2 weeks apart or

375 mg/m^2 body surface area weekly for 4 doses). Potential side effects include infusion reactions, late-onset neutropenia, or progressive multifocal leukoencephalopathy (Stone et al. 2010). For non-severe manifestations of GPA, methotrexate (MTX) can be used as an induction agent ($\geq$15 mg/week) (De Groot et al. 2005). A randomized controlled trial regarding the role of plasmapheresis in the treatment of glomerulonephritis and diffuse alveolar hemorrhage is ongoing.

After patients have achieved remission maintenance, additional immunosuppressive agents may be required to avoid relapses. Both MTX and azathioprine (AZA) are equally effective at sustaining remission (Jayne et al. 2003; Pagnoux et al. 2008). There remains a high relapse rate even while on maintenance medications. However, the majority of these relapses occur as the maintenance agent is being tapered or stopped (Villa-Forte et al. 2007). MTX is contraindicated in those patients with a creatinine greater than 2.0 mg/dl. Mycophenolate mofetil has been shown to be less effective at maintenance of remission compared with AZA (Hiemstra et al. 2010); however, it remains an option in those with intolerance or contraindications to MTX and AZA. Studies are ongoing regarding maintenance therapy after induction of remission with RTX. Other medications used in small series of patients include leflunomide and IV immunoglobulins. In the Wegener's Granulomatosis Etanercept (WGET) Trial, etanercept did not show efficacy when added to traditional treatment (CYC or MTX) (Wegener's Granulomatosis Etanercept Trial (WGET) Research Group 2005).

Local Therapy

Certain manifestations of GPA may require local therapy. Damage may occur to the nasal mucosa and paranasal sinus structures and include symptoms such as mucopurulent rhinorrhea, nasal crusting, epistaxis, facial pain, and anosmia. Daily nasal irrigation regimens including a lubricant or emollient in addition to a daily saline rinse can help reduce dryness and help remove crusts. Saddle nose deformities can occur in up to 24 % of patients. Surgical correction should be delayed until the patient has been in remission for a lengthy period of time. Prosthetic material is generally not recommended as it can increase the risk of infection, and active disease can threaten the vitality of the prosthesis.

The nasolacrimal duct can also be damaged and lead to epiphora or dacryocystitis. Surgical dacryocystorhinostomy during a period of remission can improve these symptoms.

Retro-orbital masses can lead to diplopia, proptosis, ocular movement limitations, and vision loss. Systemic therapy with glucocorticoids and CYC is often of modest (or no) benefit for orbital mass lesions; however, there are reports of improvement with RTX. The orbital mass often evolves into a pannus of fibrous tissue that can lead to an orbital contracture. This can produce enophthalmos, ocular movement limitations, and vision loss. Refractory disease may require surgical decompression.

Subglottic stenosis requires laryngoscopic and/or bronchoscopic evaluation to determine if the lesion is actively inflamed or has become a rind of scar tissue. Active subglottic inflammation can be resistant to systemic immunosuppressive agents in up to 80 % of patients. Local therapy includes intralesional glucocorticoids in combination with use of graduated dilators. Multiple topical applications of mitomycin C may be used to diminish fibrosis and restenosis. However, this intervention has not been studied in a randomized controlled fashion. Local laser therapy should be avoided as it can add to enhancement of scar tissue and high rates of restenosis. Refractory tracheobronchial disease may require repeated local dilatation, with intralesional depo-glucocorticoid injections (Hernandez-Rodriguez et al. 2010).

Prophylaxis

Prophylactic measures should be used to avoid treatment-related adverse events. *Pneumocystis jirovecii* pneumonia (PJP) has been reported to occur in 6 % of GPA patients who do not receive chemoprophylaxis. Trimethoprim-sulfamethoxazole (T/S) (160/800 mg given three times weekly or 80/400 mg given daily) will prevent most cases of PJP. Low-dose T/S

prophylaxis can safely be given to patients on MTX; however, full doses of these two folate antagonists should be avoided, as they can lead to bone marrow failure. Patients with contraindications or allergies to sulfa drugs can be given dapsone 100 mg daily or atovaquone 1,500 mg daily. Monthly inhaled pentamidine 300 mg can also be used but may not offer the same degree of protection. High-dose glucocorticoids can predispose patients to osteoporosis. Daily calcium and vitamin D supplements should be considered on all patients on glucocorticoids. In addition, bisphosphonates should be considered for osteoporosis prevention. Appropriate vaccinations should be considered in GPA patients and family members including the yearly influenza vaccine and the pneumococcal vaccine. Care should be taken to avoid live vaccines in patients using immunosuppressive medications. Daily folic acid or weekly folinic acid replacement can help prevent mucosal and hepatic side effects from MTX. Contraception should be emphasized in both male and female patients while being treated with potentially teratogenic medications. Depot leuprolide can reduce the rate of premature ovarian failure in female patients treated with CYC.

Conclusion

The pathogenesis of GPA is incompletely understood. It is categorized as an ANCA-associated vasculitis, emphasizing the importance of B cells and antibodies. While ANCA has a prominent role in GPA, it should be recognized that up to 20 % of patients with a convincing clinical phenotype for GPA are ANCA negative. Furthermore, ANCA levels correlate poorly with relapse and disease activity in large trials. Mononuclear cells that are of both Th1 and Th2 lineage are involved in a complex cross talk with B cells and neutrophils. The key to understanding the pathogenesis of GPA lies in discovering its etiology. That almost all GPA patients have evidence of airway disease with or without systemic symptoms at onset is suggestive of an infectious, airborne trigger. Increasing circumstantial evidence points to an infectious trigger in GPA.

Anaphylactoid purpura; Purpura rheumatica

Definition

Henoch-Schönlein Purpura (HSP) belongs to the group of diseases known as systemic or leukocytoclastic vasculitides. HSP is a multisystem disorder involving the skin, joints, gastrointestinal tract, and kidneys which mainly affects children. Its course is typically benign and self-limited though significant long-term complications may arise in a small percentage of patients.

The classic triad of symptoms in HSP includes non-thrombocytopenic palpable purpura, arthritis, and colicky abdominal pain. Renal involvement, if present, is often mild but rarely may progress to chronic renal failure. Involvement of other organ systems occurs less commonly.

Pathogenesis

HSP is an immunoglobulin A (IgA)-mediated immune vasculitis but the exact etiology remains unknown. As with most immune-mediated diseases, a combination of genetic, immunologic, and environmental factors is implicated (Saulsbury 1999). HSP is most often triggered by exposure to an exogenous antigen, typically an upper respiratory pathogen, immunization, or medication.

IgA plays a central role in the development of HSP. Normally, IgA is found in mucosal fluids and serum and exists at 2 subtypes: IgA1 and IgA2. Mucosal IgA is 60 % IgA2 and mainly polymeric, whereas serum IgA is mainly IgA1 and monomeric. In HSP, immune complexes contain polymeric IgA1 which is capable of activating the alternate complement pathway. During the course of the illness, total serum hemolytic complement (CH_{50}) and properdin levels may be depressed, while levels of C3d, a C3 breakdown product, may be elevated. Immune complex deposition incites release of inflammatory mediators, with infiltration of polymorphonuclear leukocytes and monocytes. The end result is tissue injury mediated by alternative complement pathway activation and membrane attack complex formation. Some authors have proposed

that abnormal glycosylation of the IgA leads to deposition in the renal mesangium and subsequent development of HSP. An abnormal form of the IgA1 known as Gal-d IgA1 has been identified and found to be higher in HSP nephritis compared with HSP without nephritis and normal controls (Lau et al. 2007). IgA autoantibodies, including rheumatoid factor and antineutrophil cytoplasmic antibodies (ANCA), also may be found in serum of patients with HSP, though their role in pathogenesis of disease is unclear (Boulis et al. 2010).

Histology is consistent with an immune complex-mediated leukocytoclastic vasculitis. Small blood vessels demonstrate necrosis associated with a perivascular infiltrate composed of neutrophils and mononuclear cells. Immunofluorescence and electron microscopy of fresh lesions may detect deposits of IgA, C3, and fibrin (Davin 2011). Renal biopsies typically show an endocapillary proliferative glomerulonephritis involving endothelial and mesangial cells. Proliferation of extracapillary cells and fibrin deposition in Bowman's capsule may also occur, resulting in variable degrees of crescent formation.

Epidemiology

HSP is the most common form of childhood vasculitis, with an incidence of 10 to 20 per 100,000 children less than age 17 years and a peak age of onset between 4 and 6 years (Gardner-Medwin et al. 2002). Most patients are between the ages of 3 and 10 years, boys are affected 1.5–2 times as frequently as girls, and HSP is most prevalent during the fall, winter, and spring, periods of time coinciding with higher rates of infection. These associations provide support for an infectious trigger. Indeed, about 50 % of patients with HSP have a preceding upper respiratory tract infection, most commonly with Streptococcus. Other reported triggers for HSP include Staphylococcus aureus, Haemophilus influenzae, influenza, parainfluenza, Epstein-Barr virus, adenovirus, parvovirus, mycoplasma, vaccinations, drugs, and insect bites (Levy et al. 1976). Interestingly, in adults, HSP seems to be more common in the summer, which suggests a different etiopathogenesis.

The incidence of HSP is also affected by a patient's background genetic makeup. For example, the rate of HSP is as high as 5 % in patients with a mutation of the gene associated with familial Mediterranean fever (known as the "FEMV" gene) (Bayram et al. 2011) and in those with certain complement deficiencies.

Clinical Manifestations

The classic presentation is that of a previously well child developing palpable purpura, arthritis or arthralgia, and colicky abdominal pain. Occasionally, these may be preceded by malaise or a low-grade fever. These symptoms may develop in rapid succession or sequentially over a period of days to weeks. **Rash** is the initial feature in about 75 % of affected children. It is present in almost all children with the disease, though this is at least partially due to the fact that the diagnosis is exceedingly difficult without evidence of palpable purpura.

The typical rash is a deep purple or dark red, non-blanching papular exanthem that is painless and non-pruritic (Fig. 1). It often begins as urticarial wheals or erythematous papules that eventually evolve to form the characteristic purpura or ecchymoses. Patients also may develop petechiae. Occasionally, areas of skin may demonstrate bullous or hemorrhagic lesions, or areas that look like deep bruises. The purpura generally resolves over the course of a week, fading to yellow or purple brown as the heme pigment is phagocytosed and enzymatically converted to bilirubin and then hemosiderin. Successive crops of rash may appear over time, giving the rash a polymorphous appearance. Episodes of rash recur in approximately one third of patients, usually within weeks, but at times up to a year after disease onset. Successive recurrences tend to become progressively milder, and the rash does not scar.

The rash of HSP is generally distributed symmetrically. In younger, non-ambulatory children, gravity-dependent areas such as the

Vasculitis: Henoch-Schönlein Purpura, Fig. 1 Typical dependent purpuric rash of Henoch-Schönlein purpura (Courtesy of Arturo Borzutzky, M.D.)

face, trunk, and upper extremities predominate, while pressure-dependent areas such as extensor surfaces of the legs and buttocks are more commonly affected in older patients. This pattern may reflect deposition of large IgA immune complexes which then activate the alternate complement pathway, disrupting vascular integrity and leading to the rash. Other signs of dermatologic involvement include localized subcutaneous edema which may be slightly tender. This typically affects the scalp, forehead, periorbital areas, or the dorsal aspects of the hands and feet.

Joint involvement is the second most common manifestation of HSP. **Arthralgias** or **arthritis** occurs in 50–90 % of all affected children and is the presenting symptom in about one in six patients (Trapani et al. 2005). Arthritis is nondestructive with no permanent sequelae. There is often prominent periarticular swelling and tenderness, but usually without joint effusion, erythema, or warmth. Typically, one to three joints are affected, the knees and ankles being the most common. Elbows, wrists, and hands may be affected as well. Small joint involvement is rare, though edema of the hands and feet may be confused with interphalangeal joint synovitis. Regardless of the number of joints involved, they tend to be very uncomfortable, and patients may have considerable pain and limitation of motion as a result.

The third cardinal manifestation of HSP is gastrointestinal involvement, most often **colicky abdominal pain** (50–75 % of patients). Abdominal symptoms usually occur within a week of the rash but may present up to 4 weeks later. When abdominal pain precedes the rash, it may be difficult to distinguish from appendicitis.

Abdominal pain is caused by submucosal hemorrhage and edema of the gastrointestinal (GI) tract, analogous to superficial manifestations of HSP visible in the integument. It is often self-limited but may be severe enough to prevent adequate oral intake. The pain typically waxes and wanes, with exacerbations causing affected children to curl up or cry, followed by a pain-free interval minutes later. Any acute change in the nature or intensity of the pain should prompt urgent evaluation for complications such as intussusception, bowel infarction, or perforation.

Intussusception is the most common gastrointestinal complication of HSP, occurring in 1–5 % of patients. The lead point of the intussusception is hemorrhage and edema in a portion of the gut. Such lesions are ileoileal in up to 60 % of cases, in contrast to the typical ileocolic intussusception accompanying mesenteric adenitis or nonspecific viral infections in young children (Choong and Beasley 1998). When intussusception is suspected, ultrasonography should be the

initial screening test. Contrast enemas, on the other hand, are unable to detect the ileoileal intussusception seen in HSP because the contrast does not reach the ileum.

Gastrointestinal bleeding may manifest as melena, heme-positive stools, or hematemesis. Massive gastrointestinal hemorrhage is rare. Vomiting and paralytic ileus may be seen. Rarer gastrointestinal manifestations include acute pancreatitis, cholecystitis, hydrops of the gall bladder, or protein-losing enteropathy (Feldt and Stickler 1962).

Renal involvement represents the fourth classical feature of HSP, seen in 20–54 % of children (Brogan and Bagga 2011). Renal involvement is often asymptomatic – detected only on urinalysis – and usually occurs within the first 6 weeks of disease (Stewart et al. 1988). The overwhelming majority of patients develop some evidence of nephritis during the first 6 months of the illness, with children most commonly demonstrating microscopic hematuria with or without mild proteinuria. The risk of progression to chronic renal failure in such cases is less than 5 %. The risk rises to 19 % if the child has both nephritic and nephrotic features (Narchi 2005). While older patients have approximately the same overall incidence of renal involvement, the likelihood of progression to renal failure is significantly higher – up to 30 % in adults. Renal biopsies show histological features similar to IgA nephropathy, including crescent formation in the most severe cases.

Although the skin, joints, GI tract, and kidneys are most commonly involved in HSP, as a systemic vasculitis it may affect virtually any organ system. In one study, pulmonary involvement was detected by measurement of pulmonary diffusion capacity in 97 % of children with HSP (Chaussain et al. 1992), though subsequent attempts to confirm these findings were unsuccessful. Interstitial pneumonia and diffuse alveolar hemorrhage have been described, mostly in adults and adolescents, but for the most part pulmonary involvement is asymptomatic.

Clinically relevant neurologic involvement is rare and mostly affects patients with significant renal disease. Seizures, focal neurologic deficits, ataxia, mental status changes, headaches, and peripheral neuropathies have all been described (Garzoni et al. 2009). Such central nervous system dysfunction may results from a variety of causes, including severe hypertension, electrolyte aberrations due to GI and renal involvement, or stroke and intracranial hemorrhage. Only in the latter cases are symptoms persistent.

Other rarer findings in HSP may include scrotal swelling and tenderness, usually from epididymo-orchitis in 5 % (Brogan and Bagga 2011) and hypocomplementemia from vascular deposition of activated immune complexes.

Diagnosis and Evaluation

The diagnosis of HSP is a clinical one, often made after the appearance of the typical rash, with associated articular or gastrointestinal involvement in a child. There is no specific laboratory test for HSP. Rather, investigations serve the purpose of assessing the extent of organ involvement or excluding alternative diagnoses. Routine blood tests typically yield nonspecific abnormalities. A complete blood count may reveal a raised white blood cell and platelet count. A mild anemia may reflect occult gastrointestinal hemorrhage or anemia associated with inflammation. Acute phase reactants may be somewhat increased, with the degree of elevation often related to the triggering antigen. Thus, HSP related to a streptococcal infection is typically associated with higher inflammatory markers than one precipitated by a viral illness. Coagulation studies to exclude bleeding diatheses are not strictly necessary if the clinical picture is typical, though they may be part of the process of excluding sepsis. In uncomplicated HSP, the prothrombin and partial thromboplastin times should be normal. Serum IgA is elevated in 50–70 % of patients with HSP (Trygstad and Stiehm 1971). Such a finding is not typically seen in other causes of purpura, abdominal pain, hematuria, or arthritis, so an elevated IgA level may support the diagnosis of HSP. Serum complement levels are normal in about 90 % of patients, while autoantibodies

are usually absent and should not be routinely interrogated unless the diagnosis of HSP is in question.

Urinalysis for cells, casts, and proteinuria should be carried out at diagnosis in all patients. All adults should have a serum creatinine measured at presentation as they are at increased risk for significant renal disease, whereas in children, this is not necessary if the child is normotensive and urinalysis is bland. Evidence of renal involvement usually follows other manifestations of HSP, so testing should be continued for at least 6 months after the acute presentation.

In ambiguous cases in which the presentation is atypical or incomplete, biopsy of an affected organ (preferably a skin lesion that is less than 24 h old) may be helpful, demonstrating a leukocytoclastic vasculitis with IgA deposits in the postcapillary venules. Similar findings are found in mesangial vessels if the kidney is biopsied. As HSP is significantly less prevalent in adults, biopsies may be more crucial for confirmation of the diagnosis in older patients, particularly to distinguish the condition from other vasculitides. A renal biopsy is indicated in the presence of significant proteinuria, renal impairment, or persistent evidence of glomerulonephritis (hematuria, especially with dysmorphic red blood cells or red blood cell casts, and/or hypertension). Histology is useful for delineating extent and severity of nephritis and hence determining treatment. The risk of developing end stage renal disease increases with the percentage of glomeruli with crescents.

When abdominal symptoms are present and persistent, imaging should be carried out to look for complications such as intussusception, ileus, ischemia, or bowel perforation. Plain radiographs may show dilated loops of bowel from obstruction or ileus. Abdominal ultrasonography is the imaging of choice for suspected intussusception. The classic finding of a "target/bull's eye/doughnut sign" on transverse section (appearance of alternating layers of hyper- and hypoechoic lesions) results from one portion of bowel invaginating into another. Ultrasound may also reveal bowel wall thickening, abnormal peristalsis, or hematomas. Imaging is indicated as well in boys with HSP who develop scrotal pain. Doppler flow studies will help distinguish testicular torsion, in which blood flow is decreased or absent, from the epididymo-orchitis of HSP, characterized by perfusion that is normal or increased as a result of inflammation.

Differential Diagnosis

The diagnosis of HSP is usually straightforward, particularly in children, unless the presentation is incomplete or atypical, or dermatologic features are initially absent. Nonetheless, other causes of palpable purpura must be excluded before a patient with presumed HSP can be confirmed to have a benign condition. The differential diagnosis of cutaneous manifestations of HSP, particularly petechiae and purpura, includes septicemia, idiopathic thrombocytopenic purpura, hemolytic-uremic syndrome, leukemia, and coagulopathies (e.g., hemophilia). They are not always clinically distinguishable from HSP but may be suggested by the presence of abnormal platelet counts and coagulation studies.

When purpura is accompanied by normal platelet counts and coagulation studies, considerations mainly include other vasculitides, including those associated with connective tissue disorders such as systemic lupus erythematosus (SLE). Most common of the primary vasculitides is hypersensitivity (or allergic) vasculitis, an inflammatory condition of small vessels primarily seen in adults following drug exposure or infection. The patient typically presents with fever, urticaria, lymphadenopathy, arthralgias, elevated ESR, and depressed serum complement. Histology shows a leukocytoclastic vasculitis without IgA deposition in vessel walls. Vasculitis associated with antineutrophil cytoplasmic antibodies (ANCA), such as Churg-Strauss syndrome (CSS) and granulomatosis with polyangiitis (Wegener's) (GPA), is quite rare but delays in diagnosis may lead to development of irreversible renal or pulmonary failure. Children younger than 2 years of age may develop an immune complex-mediated vasculitis known as acute hemorrhagic edema of infancy (AHEI).

Vasculitis: Henoch-Schönlein Purpura, Fig. 2 Large non-blanching macules typical of acute hemorrhagic edema of infancy (AHEI)

This is likely a forme fruste of HSP that develops in younger patients unable to mount an IgA response to foreign antigens (Saraclar et al. 1990). The rash of AHEI resembles that of HSP though the purpuric lesions are often larger than the typical rash of HSP (Fig. 2). It is usually associated with fever and generalized edema, but renal involvement is typically absent.

Etiologic considerations in patients presenting with renal disease are quite broad and beyond the scope of this entry. Histopathologically, the glomerulonephritis of HSP is most similar to, and in fact may be indistinguishable from, that seen in patients with IgA nephropathy or Berger's disease.

Management

HSP is for the most part benign and self-limited, with therapy focused on providing symptomatic relief and supportive care. Hospitalization may be necessary for patients who are unable to maintain adequate oral hydration and have severe abdominal or joint pain, significant gastrointestinal bleeding, altered mental status, renal insufficiency, hypertension, or significant nephritis or nephrotic syndrome.

Joint pain tends to respond to acetaminophen, with severe symptoms improving after nonsteroidal anti-inflammatory drugs (NSAIDs), e.g., naproxen 10–20 mg/kg/day (maximum 1,500 mg, 1,000 mg if used beyond a week) in two divided doses. There is no contraindication to this in the setting of normal renal function and/or urinalysis and in particular no evidence that NSAIDs increase the risk of gastrointestinal hemorrhage in HSP. Nevertheless, they should be used with caution, while maintaining adequate hydration, to minimize potential adverse effects. Abdominal pain also may be ameliorated by acetaminophen and/or NSAIDs. Patients with physical findings suggestive of peritonitis or obstruction should undergo urgent evaluation, often by a surgeon for concerns of bowel infarction, perforation, or intussusception. Physical examination alone is often inadequate to diagnose intestinal vasculitis.

Corticosteroids may be helpful in cases characterized by more significant discomfort. These medications have not been shown to shorten the duration of abdominal involvement or reduce the risk of intussusception (Weiss et al. 2007). However, they may be indicated in patients who have not responded to NSAIDs and whose abdominal pain is severe enough to

prevent adequate oral intake or whose joint involvement interferes with ambulation and activities of daily living. Steroids should not be given until abdominal complications such as intussusception or perforation are definitively excluded, as they may mask signs of peritonitis. It is also important to stress the fact that steroids do not alter the pathophysiology of the disease, but only mitigate associated inflammation. Thus, after starting prednisone or methylprednisolone at a dose of 1–2 mg/kg/day, in two divided doses, steroids should be tapered gradually, by no more than 25 % per week. Tapering more rapidly than the speed with which pathologic immune complexes are cleared from the circulation may increase the risk of symptom recurrence. Additionally, bowel edema may compromise absorption of medications, including steroids, and so parenteral administration may be required until acute intestinal involvement improves. Preemptive use of steroids has not been consistently shown to prevent development of long-term sequelae or alter the prognosis of HSP, so such use of steroids is generally not recommended.

More potent immunosuppression with agents such as cyclophosphamide, azathioprine, or mycophenolate mofetil may be necessary in children with biopsy-proven crescenteric glomerulonephritis or organ- and/or life-threatening complications such as pulmonary hemorrhage or central nervous system vasculitis. Reports of success with these medications are limited to case series. Guidelines for their use are not available and treatment courses are typically complex and prolonged. Thus, involvement of specialists experienced in the use of potent immunosuppressive medications for the treatment of severe inflammatory diseases is essential in such cases.

Prognosis

The prognosis of HSP in children is generally excellent. Apart from renal disease, the mean duration of symptoms is 3–4 weeks. Approximately one third of children have at least one recurrence (Saulsbury 2002), usually within 4 months of the initial episode, although recurrences may occur up to 2 years later. Recurrences are more likely in those who have a more severe course of HSP, though subsequent episodes tend to be successively milder and of shorter duration.

Renal involvement determines the long-term prognosis of HSP and may cause late morbidity and mortality. The risk of progressive renal disease is highest in adults, with severity of renal involvement highest in patients with nephritic range proteinuria, elevated serum creatinine, hypertension, and severe histologic findings. Generally, chronic kidney disease is reported in 1–5 % of children with HSP, with the higher estimates likely affected by ascertainment bias in case series from tertiary referral centers.

Monitoring

Generally, patients with HSP should have urinalysis and blood pressure monitoring weekly to biweekly for the first 2 months after presentation. Somewhat less frequent follow-up should continue for up to a year thereafter. If blood pressure and urine sediment remain normal, ongoing monitoring may be limited to measurement of blood pressure and urinalysis during annual physical examinations. Serum creatinine should be followed more closely in any patient with persistent or significant urinary abnormalities or hypertension, often in conjunction with a nephrologist. Pregnant women with a history of HSP should be monitored closely, as they have a higher risk of hypertension and proteinuria (Ronkainen et al. 2002). Neither a strong family history of HSP nor a previous episode of HSP seems to confer an increased risk of developing HSP. Similarly, repeated development of apparently unrelated episodes of HSP is rare; such patients may recover following removal of indwelling hardware or other antigenic triggers. If no trigger can be identified, colchicine or intravenous immunoglobulin may ameliorate exacerbations.

Mucocutaneous lymph node syndrome

Definition

Kawasaki Disease (KD) is a childhood vasculitis affecting small- and medium-sized blood vessels and manifesting classically as fever, bilateral conjunctivitis, erythema of the lips and oral mucosa, cervical lymphadenopathy, rash, and extremity changes.

Introduction

Kawasaki Disease (KD) is the second most common childhood vasculitis and the leading cause of acquired heart disease among children in the

developed world (Burns and Glodé 2004). It is an acute, self-limited febrile illness of unknown cause, characterized by fever and signs of mucocutaneous inflammation. Fifteen to 25 % of untreated children develop coronary artery abnormalities, placing them at risk of developing ischemic heart disease or sudden death later in life (Kato et al. 1996). Therapy in the acute phase is aimed at reducing inflammation using intravenous immunoglobulin (IVIG), thereby minimizing the risk of coronary artery aneurysms and other late sequelae.

Diagnostic Criteria

Epidemiologic criteria for the diagnosis of KD remain largely unchanged since the initial description of the condition by Dr. Tomisaku Kawasaki in 1967 (Ayusawa et al. 2005):

Fever that persists for at least 5 days plus at least four of the following:

1. Bilateral nonsuppurative conjunctival injection
2. Changes of the lips and oral cavity
3. Cervical lymphadenopathy
4. Polymorphous exanthema
5. Changes in the peripheral extremities (such as erythema, swelling, or desquamation) or perineal area (an erythematous eruption)

Patients with at least 5 days of fever but less than four principal criteria can be diagnosed with KD on the basis of coronary artery abnormalities as seen on 2D echocardiography or angiography. The diagnosis may also be made in patients with just 4 days of fever possessing at least four of the principal criteria if the fever is alleviated by administration of IVIG.

As with all conditions diagnosed on the basis of clinical manifestations, sensitivity and specificity of the KD criteria are imperfect. Children who manifest five or six clinical criteria may have other conditions, including drug reactions, systemic onset juvenile idiopathic arthritis, or viral syndromes. One study of patients referred for possible KD found that the standard clinical diagnostic criteria for KD were fulfilled by 18 of 39 patients (46 %) who were later diagnosed with something else (Burns et al. 1991). Of greater concern is the fact that children may have an incomplete or atypical form of KD and remain at risk for developing coronary artery aneurysms despite not fulfilling diagnostic criteria. At least 10 % of those who develop coronary artery aneurysms never meet criteria for KD (Sundel 2002). This is actually not surprising in view of the fact that Dr. Kawasaki published his description of KD before cardiac involvement was recognized. To correct these deficiencies in the classical diagnostic criteria, an expert panel developed an algorithm which takes into account a child's risk of developing coronary artery changes based on laboratory and epidemiologic factors in addition to clinical findings (Newburger et al. 2004). Treating children using this algorithm, even though they may not meet epidemiologic criteria for the diagnosis of KD, results in a significantly decreased risk of coronary artery involvement (Yellen et al. 2010).

To summarize the algorithm:

1. Infants 6 months or younger who have had at least 7 days of fever and evidence of systemic inflammation without a clear explanation should have an echocardiogram performed.
2. Children who have the requisite 5 days of fever but only two or three clinical criteria should have laboratory investigations performed. If CRP is equal to or more than 3.0 mg/dL and/or ESR is equal to or greater than 40 mm/h, and they have at least three supplemental criteria (albumin $\leq$3.0 g/dL, anemia for age, elevation of alanine aminotransferase, platelets after 7 days $\geq$450,000/mm^3, white blood cell count $\geq$15,000/mm^3, and urine $\geq$10 white blood cells/high-power field), they should be treated and have an echocardiogram. Children who have less than three supplemental criteria may be treated for KD if the echocardiogram reveals findings suggestive of KD.

Pathogenesis

The etiology of KD is unknown but numerous epidemiologic features point to an unusual inflammatory response to one or more ubiquitous infectious pathogens in genetically predisposed individuals (Burgner and Harnden 2005).

Features in support of this mechanism include the preponderance of KD in children between 1 and 5 years of age (very young infants are presumably protected by passive maternal antibody transfer, while adults have already experienced asymptomatic infection) and its predominantly winter and springtime seasonality, coinciding with peaks in contagious disease incidence. In addition, KD demonstrates "epidemics," such as five- to tenfold spikes in incidence in Japan during the 1980s and 1990s. These spread centrifugally from incident communities, though cases of person-to-person transmission remained unusual, presumably because the prevalent infection only triggered KD in a small number of susceptible individuals. Nevertheless, extensive investigations using culture and serologic techniques as well as nucleic acid primers and deep sequencing have failed to identify consistent evidence of specific pathogenic trigger(s). This has led others to postulate alternative mechanisms for the development of KD, such as immune activation due to a superantigen, particularly considering the clinical and immunological similarities between KD and staphylococcal or streptococcal toxin-mediated illnesses (Matsubara et al. 2006). All such hypotheses remain merely theories, awaiting definitive confirmation.

At the cellular and molecular level, KD appears to be a T cell-mediated disease. Limited examination of autopsy specimens has shown infiltration of the coronary arterial wall by CD8+ T cells (Brown et al. 2001). During the acute illness, proinflammatory T effector memory cells are present in peripheral blood, while cessation of inflammation is associated with expansion of the regulatory T cell population (Franco et al. 2010). The pathways ultimately leading to vascular inflammation and damage are also incompletely elucidated, but it appears that endothelial cell activation and infiltration by CD68 monocyte/macrophages and oligoclonal IgA plasma cells leads to cytokine and matrix metalloproteinase-mediated arterial wall disruption.

The genetic basis of susceptibility is similarly uncertain. In some studies, certain polymorphisms of HLA have been linked to disease susceptibility and formation of coronary artery aneurysms. Genome-wide association studies have identified preferential expression in children with KD of five genes (LNX1, CAMK2D, ZFHX3, CSMD1, and TCP1) which are functionally related to inflammation, apoptosis, and cardiovascular pathology (Burgner et al. 2009), as well as ITPKC, which acts as a negative regulator of T cell activation (Onouchi et al. 2008). Additional studies have suggested an association of KD with a variety of other genes, including transforming growth factor-β and the Fc fragment of IgG low-affinity IIa receptor (FcϒR2A), among others. However, none of these associations accounts for more than a few percent of the incidence of KD. Further work, now ongoing, is needed to clarify the role of genetics in the development of KD.

Epidemiology

Kawasaki disease accounts for 23 % of all childhood vasculitides, making it the most common childhood vasculitis after Henoch-Schonlein purpura (Bowyer and Roettcher 1996). Ninety percent of cases occur in children younger than age 5 years, and boys are approximately 60 % more susceptible than girls. Distribution is worldwide with an Asian preponderance. Thus, the annual incidence of KD in the United Kingdom is 8 per 100,000 children under 5 years of age, and 20 per 100,000 children under 5 in the United States (Holman 2010). The rates in Taiwan and Japan are more than five times higher (Huang et al. 2009).

Clinical Manifestations

KD is a triphasic disease with an initial acute febrile phase lasting up to 14 days, a subacute phase of 2–4 weeks and a convalescent phase that can last months to years.

The *acute febrile phase* is characterized by persistent and high fever that is minimally responsive to antipyretics. The fever lasts an average of 12 days without treatment but may continue for weeks (Newburger et al. 2004). The remaining five cardinal features of KD tend to occur

sequentially, though the order in which they develop may vary from case to case.

Conjunctivitis affects 85 % of children and is generally bilateral, limbal sparing, nonsuppurative, and painless. Other ocular manifestations include anterior uveitis, keratitis, papilledema, vitreous opacities, and subconjunctival hemorrhages, often with accompanying photophobia.

Oral mucosal changes are seen in 90 % of affected children including red, dry, or cracked lips which may bleed, a "strawberry tongue," and diffuse injection of the oropharyngeal mucosa. Oral ulcers and pharyngeal exudates are rarely seen.

Cervical lymphadenopathy is the least common finding among the diagnostic criteria, affecting just 25 % of children with KD. When present, there tends to be a single enlarged lymph node limited to the anterior chain measuring more than 1.5 cm in diameter. The enlarged node is usually firm, non-fluctuant, and non-tender, without significant overlying erythema. An ill-defined cervical mass may prompt imaging with ultrasound or CT scan; this may demonstrate multiple enlarged nodes without suppuration, giving the appearance of a "bunch of grapes."

A *rash* is seen in 70–90 % of patients with KD and may take on many appearances. Most commonly it is macular, targetoid or morbilliform, and non-pruritic. Occasionally, it may appear urticarial, erythrodermic, or, rarely, pustular. Usually, the rash is extensive and involves the trunk and limbs, though in 2/3 of cases it begins in the perineal region where it eventually desquamates. Children who have had prior Bacille Calmette-Guerin (BCG) vaccination may have prominent erythema and induration of the BCG scar.

Extremity changes during the first week of KD take the form of erythema of the palms and soles and/or swelling of the dorsum of the hands and feet. During the third or fourth week, periungual desquamation – actual sheets of sloughed epidermis – is common.

Other clinical findings, while not included among the diagnostic criteria, may help distinguish KD from other febrile exanthems of childhood. The most noteworthy manifestations include irritability, anorexia, tachycardia out of proportion to the fever, arthralgias/arthritis (involving large joints during the acute phase of the illness, moving later to the small acral joints), diarrhea, vomiting, abdominal pain, cough, S3 gallop, muffled heart sounds, and rhinorrhea.

The *subacute phase* of KD generally begins towards the end of the second week of illness. It is characterized primarily by periungual desquamation of the fingers and toes, with possible extension to the palms and soles. Otherwise, children treated with IVIG are usually asymptomatic. Arthritis may persist into or develop during this period. Most of the coronary artery dilation and aneurysms that develop are detectable by this stage. Laboratory testing generally shows normalization of the CRP and white blood cell count, development of a reactive lymphocytosis, but an ESR that remains elevated for up to 6 weeks.

The *convalescent phase* is another period usually devoid of symptoms. By this time, normalization of inflammatory markers in the blood should be largely complete. One or two months after the onset of the fever, Beau's lines may appear. These are deep transverse grooves across the nails reflecting a nonspecific response to significant inflammation.

A more severe form of KD, with sustained hypotension or clinical signs of poor perfusion, has been described as Kawasaki shock syndrome. This variant is associated with more severe laboratory markers of inflammation, greater risk of coronary artery abnormalities, mitral regurgitation, and prolonged myocardial dysfunction. These patients may be resistant to immunoglobulin therapy and require additional anti-inflammatory treatment (Kanegaye et al. 2009).

Diagnosis and Evaluation

The diagnosis of KD is a clinical one, with no definitive diagnostic test available. Diagnosis is based on evidence of systemic and mucocutaneous inflammation, reflecting the diffuse medium and small vessel vasculitis underlying the disorder. As noted above, diagnostic criteria were supplemented in 2004 by an algorithm to facilitate identification and treatment of children failing to meet classical diagnostic criteria but who

are nonetheless at risk for developing coronary artery aneurysms (Newburger et al. 2004). Incomplete KD should be considered in all children with unexplained fever for over 5 days associated with two or three of the principal clinical features. Incomplete KD is more common in young infants, for whom the risk of developing coronary artery aneurysms is substantial. Laboratory findings are non-diagnostic but may heighten or reduce the suspicion in ambiguous cases. Children under 6 months of age with persistent fever for 7 days and evidence of inflammation should have an echocardiogram to screen for atypical KD even in the absence of clinical criteria. Supportive evidence includes perivascular brightness, ectasia, and lack of tapering of the coronary arteries. These findings may represent coronary arteritis before the formation of aneurysms, which are rarely apparent before day 10 of illness. Decreased left ventricular contractility, mild valvular regurgitation (most commonly mitral regurgitation), and pericardial effusion also may be seen.

Laboratory studies were not included in the diagnostic criteria for classic KD but they may support the diagnosis. The most consistent finding is evidence of systemic inflammation, as evidenced by elevated acute phase reactants. C-reactive protein (CRP) and neutrophilic leukocytosis are most characteristic. The erythrocyte sedimentation rate (ESR) is generally elevated as well, though in severe cases of KD complicated by a consumptive coagulopathy, the ESR may be normal or low. Thrombocytosis develops in most cases as well, though platelet counts generally do not rise above normal until the second week of illness. During the convalescent phase platelet counts may reach 1,000,000/mm^3.

Other laboratory findings may include a normocytic, normochromic anemia, sterile pyuria due to urethritis (and hence not evident on urine samples obtained via suprapubic aspiration or catheterization), and abnormal liver functions tests (due to intrahepatic congestion or obstructive jaundice from hydrops of the gall bladder). Hyponatremia, if present, is associated with an increased risk of coronary artery aneurysms. Other bodily fluids may reveal inflammation as well, including a mononuclear pleocytosis with depressed glucose and elevated protein levels in the cerebrospinal fluid, and joint fluid with up to 100,000 neutrophils per mm^3. Uveitis on slit lamp examination may provide further evidence for the diagnosis, since inflammation of the anterior chamber is seen more often in KD than in mimics of KD.

Differential Diagnosis

The clinical features of KD overlap with a variety of other childhood illnesses. These KD mimics include the following:

- Viral exanthems such as adenovirus, measles, enterovirus, echovirus, and EBV
- Less common infections such as Rocky Mountain Spotted Fever and leptospirosis
- Toxin-mediated illnesses including Staphylococcal scalded skin syndrome, toxic shock syndrome, and scarlet fever
- Drug reactions, particularly Steven-Johnson Syndrome
- Inflammatory conditions, most importantly systemic onset juvenile idiopathic arthritis and polyarteritis nodosa
- Hypersensitivity reactions, e.g., mercury toxicity

An additional challenge is the fact that up to 40 % of children with the diagnosis of KD simultaneously have evidence of a bacterial or viral infection. Documentation of such infections does not preclude the diagnosis of KD, though it may complicate evaluation of the patient. On the other hand, certain clinical features are preferentially seen in KD mimics compared to KD itself. Thus, a child is less likely to have KD if he has an exudative conjunctivitis, exudative pharyngitis, discreet intraoral lesions, bullous or vesicular rash, or generalized lymphadenopathy (Burns et al. 1991).

Management

The aims of therapy are to reduce inflammation and prevent development of coronary artery abnormalities. The American Heart Association describes standard of care as a single infusion of

intravenous immunoglobulin (IVIG 2 g/kg) and high-dose *aspirin* (80–100 mg/kg, maximum 4 g/day) within the first 10 days of illness. This therapy has been shown to reduce the incidence of coronary artery aneurysms from over 20 % to less than 5 % (Newburger et al. 1991). Once fever has been absent for 48 h, the aspirin dose may be reduced to 3–5 mg/kg daily until normalization of inflammatory markers or resolution of coronary aneurysms, if present. IVIG has the additional beneficial effect of normalizing serum lipoprotein profiles which otherwise may remain abnormal for years (Newburger et al. 2004).

IVIG is recommended before 10 days of disease but is also warranted after that time period in patients with clinical and laboratory evidence of ongoing inflammation and vasculitis. The benefits of IVIG in patients with established coronary artery aneurysms are more ambiguous, though the excellent tolerability of IVIG therapy favors its use whenever there is even a small chance that the patient will benefit.

Although numerous explanations of the efficacy of IVIG in KD have been proposed, the actual mechanism(s) remains uncertain (Kaveri 2012). IVIG contains a range of antibodies to microbial antigens and superantigens, cytokines, cytokine receptors, and endothelial antigens. Given early in the course of disease, IVIG ameliorates cytokine release, and prevents endothelial damage. Explanations of these effects include inhibition of monocyte/macrophage cytokine synthesis (especially TNF alpha and IL-1), blockade of cytotoxic reactions, and inhibition of complement activation. Meta-analyses suggest that aspirin does not add to the cardioprotective effects of IVIG, but it continues to form part of the recommended therapeutic regimen for KD because all significant studies of the effects of IVIG in KD included treatment with aspirin as well. Nonetheless, adverse effects of aspirin must be borne in mind, including raised liver enzymes and transient hearing loss. Gastrointestinal side effects are a theoretical risk but they are less common in children than adults. Reye Syndrome remains a concern and hence the drug should be discontinued if there is exposure to or signs of influenza or varicella infection.

Treatment of Refractory Disease

Approximately 10–15 % of patients fail to respond to initial treatment with IVIG. Failure is defined as persistence or recurrence of fever within 36 h from the end of the IVIG infusion. Fever prior to 36 h may be secondary to infusion reactions, but beyond this time systemic inflammation is likely due to KD. As such, it suggests ongoing vasculitis and is associated with an increased risk of coronary artery aneurysms. Current American Heart Association (AHA) guidelines recommend a second dose of IVIG in children who do not recover fully after initial treatment. If two or more doses of IVIG are ineffective in treating the fever and other signs of inflammation, pulse methylprednisolone (30 mg/kg daily for 1–3 doses) or infliximab (5 mg/kg) should be considered. Case reports have suggested that other agents, such as cyclosporine, ulinastatin, and cyclophosphamide, may also be beneficial in children with refractory KD. Additionally, when coronary artery aneurysms develop, antiplatelet therapy in the form of low-dose aspirin, and at times systemic anticoagulation with heparin or warfarin, may be needed to forestall arterial thromboses. Should ischemic symptoms or evidence of obstruction occur, additional antiplatelet or anticoagulant therapy and/or revascularization with thrombolytics or coronary angioplasty may be indicated. Such interventions should be left to tertiary care centers with considerable experience in treating complicated KD.

Vaccinations

Patients should not receive any vaccinations within 9–11 months of IVIG, with the exception of those who are exposed to an outbreak of any vaccine-preventable disease(s). Children above 6 months of age on chronic aspirin therapy should receive influenza and varicella immunization to minimize the risk of Reye Syndrome (American Academy of Pediatrics 2012).

Complications

Complications in KD primarily involve the cardiovascular system and are a consequence of

coronary artery thrombosis in inflamed aneurysmal vessels. In the acute phase, heart failure may occur, usually from myocardial inflammation rather than ischemia. IVIG often results in rapid clinical improvement. After the first week, new myocardial dysfunction is usually a result of ischemia or infarction. Electrocardiogram and echocardiography may be necessary to distinguish between inflammation and ischemia. Myocardial ischemia may also cause arrhythmias and this is usually the cause of the rare deaths seen in KD. Peripheral artery disease may result in ischemia or gangrene of the involved limb (Newburger et al. 2004).

Prognosis

The prognosis of KD is generally good in patients who receive IVIG (and appropriate salvage therapy if persistently febrile) during the acute phase of illness. Outcomes are primarily dependent on the presence or absence of coronary artery involvement and attendant risk for myocardial ischemia. The majority of patients recover without long-term cardiovascular sequelae. The reported mortality rate is 0.1–0.3 %, with death usually resulting from coronary artery thrombosis, myocardial infarction, or aneurysmal rupture. Mortality rates based on data from the Japanese registry of over 6,000 patients demonstrate an increased rate within the first 2 months of disease, which drops to population risk after the acute phase (Kato et al. 1996).

Morbidity is more difficult to measure. Children without cardiovascular abnormalities up to 8 weeks after onset of disease appear to be asymptomatic 10–21 years later but their longer-term atherosclerotic risk remains unknown. Coronary artery dilatation of <8 mm generally regresses over time and most smaller aneurysms (<6 mm in diameter) fully resolve by echocardiogram (Fukushige et al. 1996). About 20 % of patients who develop coronary artery aneurysms during the acute stage of the disease will develop stenosis. Patients with giant (8 mm or more) coronary artery aneurysms are at a long-term risk of developing aneurysm thrombosis or coronary artery stenosis and myocardial infarction even years after the acute illness (Kato et al. 1996).

Recurrence rates according to Japanese surveys have been recorded at 2 % of patients or 6.9 per 1,000 person-years, usually in younger children who had cardiac sequelae during the first episode, and within 12 months of the initial KD. The risk of cardiac sequelae is increased in patients with recurrent KD.

Follow-Up

Children with KD should be followed indefinitely regardless of echocardiographic findings. Although the long-term risk of developing coronary artery disease after acute KD is not known, late findings such as impaired endothelial function and carotid intimal thickening suggest that long-term vigilance is warranted (Newburger et al. 2004). The AHA and AAP have published guidelines for subsequent therapy, physical activity, and follow-up visits based on the risk for myocardial infarction (Newburger et al. 2004).

Viral Myocarditis

Pam Lincez and Marc S. Horwitz
Department of Microbiology and Immunology, University of British Columbia, Vancouver, BC, Canada

Synonyms

Virus-mediated cardiomyopathy

Definition

In 1995, the World Health Organization assigned the following definition to inflammatory cardiomyopathy: "Inflammatory cardiomyopathy is defined by myocarditis in association with cardiac dysfunction. Myocarditis is an inflammatory disease of the myocardium and is diagnosed by established histological/immunological, and immunohistological criteria. Idiopathic, autoimmune, and infectious forms of inflammatory cardiomyopathy are recognized." Viral myocarditis sits in the latter portion of the WHO definition for inflammatory cardiomyopathy: an infectious form of the disease induced by a viral or combination of viral infections in the heart and leading to inflammation of the heart muscles. Virus-mediated cardiomyopathy includes direct virus-mediated damage to cardiomyocytes and associated secondary immune responses that ensue such as inflammation and autoimmunity.

Disease Incidence and Pathology

Assigning appropriate clinical symptoms to characterize viral myocarditis is difficult as the disorder presents a myriad of clinical forms ranging from nonspecific systemic symptoms to dilated cardiomyopathy to complete heart failure. The Dallas criteria were first established in 1984 to provide clinicians a set of pathological guidelines to follow with endomyocardial biopsies and for the diagnosis of myocarditis (Marchant et al. 2011). Diagnosis by endomyocardial biopsy allows an assessment of any viral presence and the extent of inflammation in the myocardium (Esfandiarei and McManus 2008; Yajima and Knowlton 2009).

Though the criteria were considered the gold standard for almost two decades, they didn't allow for identifying viral genomes in the heart. Evidence has accumulated in the past decade of many viruses linked to myocarditis, spurring the need for the Dallas criteria to be revisited. Following skeptical clinical trials using solely the Dallas criteria, diagnosis of myocarditis was supplemented with newly developed detection technologies such as polymerase chain reaction (PCR) to detect the presence of viral genomes, immunohistochemical staining for upregulated cardiac myocyte markers intercellular adhesion molecule (ICAM) and major histocompatibility complex class II (HLA-DR), and immunoserological testing for anticardiac myocyte antibodies. In situ hybridization and electron microscopy have also successfully identified viruses in myocarditis patients (Esfandiarei and McManus 2008; Yajima and Knowlton 2009).

Following viral infection, myocarditis patients may endure a phase of autoimmunity with viral and myosin epitope cross-reactivity. Depending on the severity of injury caused by both cellular and humoral autoimmunity, disease may progress to dilated cardiomyopathy (DCM). The potential onset of an autoimmune chronic disease demonstrates the importance of both host and viral genetics in the pathogenesis of viral myocarditis (Marín-García 2011).

Viruses Linked to Human Disease

A range of cardiotropic viruses have been linked to myocarditis using endomyocardial biopsy samples from patients with acute or dilated cardiomyopathy. Human cardiotropic viruses linked to myocarditis include adenoviruses, enteroviruses, parvovirus B19 (PVB19), human herpesvirus 6 (HHV6), cytomegalovirus, Epstein-Barr virus (EBV), influenza virus, hepatitis C virus (HCV), herpes simplex virus (HSV), and human immunodeficiency virus (HIV), where their genomes have been recovered using PCR and in situ hybridization techniques (Laurent 2011).

PVB19 and HHV6 have both been detected in patients with idiopathic DCM. Although the true etiology of viral myocarditis has yet to be established, the literature strongly implicated PVB19 as one of the most frequently detected cardiotropic viruses. Interestingly, PVB19 infects endothelial cells and avoids cardiac myocytes (Bock et al. 2010). PVB19 genomes dominate in isolated diastolic dysfunction unexplained cases. PVB19 likely contributes to endothelial dysfunction, increased inflammation, and the progression to diastolic dysfunction. In a recent follow-up study of 50 patients previously diagnosed with severe acute myocarditis, nested PCR detected mostly PVB19 genomes and, to a lesser extent, HHV6 in patients that had developed heart failure with a normal ejection fraction (HFNEF) in the long term (Eurlings and Heymans 2011). Clinical studies from Germany have also reported the extensive presence of PVB19 in myocarditis patients compared with other cardiotropic viruses. Still, it is important to acknowledge that PVB19 genomes have also been isolated from patients without myocarditis (Yajima 2011).

From a large-scale US study with myocarditis patients, a recurrent presence of adenoviruses and enteroviruses was detected using PCR on endomyocardial biopsy samples. Cytomegalovirus genomes were also identified though much less frequently than adenovirus genomes, which were predominant in both child and adult patients (Bowles et al. 2003; Yajima 2011). With human cytomegalovirus (HCMV), only mRNA for the

early viral enzymatic proteins can be detected in cardiomyocytes and fibroblasts since the herpesvirus likely establishes a latency phase, making the detection of mRNA for the late structural proteins difficult. The latency and reactivation mechanisms of herpesviruses like HCMV in heart tissue and their roles in myocarditis and the onset of chronic heart disease have yet to be understood.

Some groups suggest enteroviruses such as the Coxsackie group B serotypes (CVB) as the most likely agents responsible for myocarditis (Chapman and Kim 2008). Enteroviral RNA has been detected in both myocarditic and DCM patients though there is a range in percentages reported from various studies. The variability in reporting numbers is due to variability in detection techniques (Chapman and Kim 2008). Importantly, CVB serotype 3 provides stages of disease progression in mice models that mimic those seen in human myocarditis and DCM patients, urging the support and widespread use of this virus in animal model studies (Richer et al. 2007; Chapman and Kim 2008; Lincez et al. 2011).

The reduction in endocardial fibroelastosis cases following the instillment of the mumps vaccine suggested a potential role for the mumps virus in myocarditis-related pathogenesis. Human immunodeficiency virus (HIV) has also been linked to myocarditis. It has been suggested that cardiomyocytes become damaged and undergo apoptosis when HIV infection of immune cells induces pro-apoptotic ligands and signaling and the production of nitrous oxide. Respiratory tract viruses such as influenza A and Epstein-Barr have also been detected and associated with myocarditis cases. The pathogenic contribution of each virus individually or as a collective remains to be determined and will require the contribution of successful clinical and animal model studies using sufficiently large cohorts. Detection of viral genomes in the myocardium does not necessarily implicate the virus' pathogenicity or involvement in the disease. Recovered genomes or virus particles may be coincidental bystanders or secondary infection participants (Marín-García 2011).

Despite the range of viruses associated with human myocarditis, Coxsackievirus B3 is most commonly used in animal models to induce disease and to study the accompanying cellular and molecular mechanisms.

Experimental Models

CB3-Induced Myocarditis

Though rats, guinea pigs, and rabbits have been used to study virus-induced myocarditis, mice present as the most widely used and effective animal model system for studying the disease. Murine models allow for the separation of mechanisms underlying autoimmune myocarditis and viral myocarditis. Similar genetics with humans, cost-effective care, the availability of transgenic models, and susceptibility to a range of cardiotropic viruses are all advantages that allow mice to supersede other animal models for studying viral myocarditis (Lincez et al. 2011).

The cellular and molecular mechanisms underlying viral myocarditis are typically studied in animal models using Coxsackievirus B3 (CB3) though the entry mechanisms for other cardiotropic viruses such as encephalomyocarditis virus (EMCV) have been demonstrated. Though other virus-induced myocarditis models exist, the CB3 model is advantageous against other viruses. The virus strain, CB3, that induces myocarditis is conserved for human and mice. In fact, CB3 does not have a limited tropism for species. Also, CB3-induced myocarditis models can be divided into two separate models for studying either viral damage or viral-induced autoimmunity (Fairweather and Rose 2004).

Cardiotropic virus selection for either endothelial or myocyte cells in the myocardium has been observed for a range of viruses using an array of detection methods including, but not limited to, electron microscopy, in situ hybridization, immunohistochemistry, and PCR joint with laser capture microdissection. The mammalian viral receptor Coxsackie-adenoviral receptor (CAR) has been identified as the point of entry for CB3, EMCV, and other myocyte-targeting viruses. In fact, CAR-deficient mice infected with CB3 do not develop myocarditis. CB3 can also bind to and use decay accelerating factor (DAF) as

a receptor for endocytosis. After undergoing receptor-mediated endocytosis, the viruses release their genomes inside the myocyte where translation and replication to produce new productive virus progeny can ensue. CB3's RNA genome has a positive polarity, allowing it to be directly translated into a polyprotein upon release into the host cell. CB3's replication affects a vast distribution of host proteins and cellular pathways including death pathways that may contribute to the ultimate demise of infected cells in the myocardium (Marchant et al. 2011). Viral persistence is observed for a long course in murine models. Over this course, pathologies similar to those observed with human myocarditis such as necrosis, fibrosis, and calcification of the myocardium are observed in mice and have shown to lead to cardiac dilation similar to the development of DCM in humans.

The immunopathological phases observed with CB3-induced myocarditis in murine models include acute, subacute, and chronic phases. During the subacute or viremic phase, viral infection leads to myocyte lysis and the release of viral and cellular antigens that activate innate immunity responders such as macrophages and stimulates the production of cytokines IL-1 and IL-2 and the TNFs and IFNs (Lincez et al. 2011). This phase can last up to 4 days before merging into a subacute phase where NK cells are activated to release perforin and cytotoxic T cells, and B lymphocytes also activate and induce the production of neutralizing and antimyosin antibodies. The subacute phase ultimately leads to viral clearance up to day 14 postinfection. The last phase observed in CB3-induced myocarditis is the chronic stage of disease, where virus has been able to escape the initial immune defenses and persists in the myocardium (Chapman and Kim 2008; Yajima and Knowlton 2009; Lincez et al. 2011).

Experimental Autoimmune Myocarditis

As previously discussed, mice are critical experimental models for studying virus-induced myocarditis. To discern pathologic and physiological changes between acute infection and the autoimmune phase of disease, an experimental autoimmune myocarditis (EAM)-induced model was created. The EAM model pairs an inducer of myocarditis, an immunogen, and alike virus-induced myocarditis and mimics the chronic disease phase characteristically observed in susceptible mice challenged with virus like CB3. During EAM, stages of disease severity are tracked and given a score based on the level of inflammatory infiltrates observed at the peak of inflammation. Classic inducers of myocarditis in the EAM model include cardiac myosin with complete Freund's adjuvant and the pertussis toxin. An alternative to cardiac myosin is a myocardiogenic peptide derived from the alpha cardiac heavy chain that is emulsified in complete Freund's adjuvant. This peptide induces disease and peak inflammation in the heart by day 21 postinjection. A combination of self-antigen such as cardiac myosin and adjuvants injected in mice will induce the generation of cardiac myosin-specific autoantibodies and mimic the pathology observed in the hearts of mice challenged with CB3 at 3-week postinfection (Lincez et al. 2011). Another inducer used in EAM models is cardiac troponin I. Following injection in mice, troponin I causes an intense autoimmune response consisting of both humoral and cellular responses. Myocardial inflammation and fibrosis are observed with troponin I EAM models as demonstrated with programmed cell death-1 receptor deficient mice injected with troponin I that produce high-titered autoantibodies and develop cardiomyopathy. Interestingly, troponin I EAM models exude a genetic and sex bias in susceptibility to myocardial inflammation compared with other EAM models. The key components for studying myocarditis with an EAM model are the use of a defined immunogen from the same species as the one used as the model and to use genetically defined inbred susceptible strains for proper analysis of the cellular and molecular mechanisms driving autoimmune disease and resulting pathology in the heart. The choice of susceptible mice for EAM studies is critical as the host's complex genetics can influence the severity and resolution of an infection or challenge with immunogen and whether the host will succumb to an adverse autoimmune incidence or not. Cardiac myosin challenge will only induce disease in genetically

susceptible mice as demonstrated by Poffenberger et al. (Lincez et al. 2011).

Antigen-specific peripheral tolerance induction can be used in EAM models to determine underlying mechanisms of autoimmunity. Myosin-specific tolerization and tissue homogenates are both used as tools to prevent EAM and to study potential myocarditis-associated autoimmunity therapeutic intervention. In an effort to determine whether the induction of peripheral tolerance from a self-antigen could be used to prevent autoimmunity typically observed with CB3-induced myocarditis, Horwitz et al. used nonobese diabetic (NOD) mice in an EAM model. Tolerization to cardiac myosin with a covalently coupled antigen approach before CB3 infection did not prevent autoimmune disease onset and demonstrated the ineffectiveness of targeting a single heart antigen for the prevention of viral-mediated autoimmune myocarditis (Richer and Horwitz 2009; Nussinovitch and Shoenfeld 2011). The application of an EAM model helped reveal the possibility of other cardiac antigens and not solely cardiac myosin as the autoantigen responsible for the onset of autoimmunity in viral-mediated myocarditis.

EAM is a critical tool for studying the cellular and molecular mechanisms underlying viral myocarditis and associated autoimmunity. Though the EAM model is rather artificial, it has implicated many key immune players contributing to disease pathogenesis and autoimmune mechanisms in vivo in the absence of an infective agent.

Immunomodulation

Yajima et al. discuss four separate phases from the perspective of the virus that define viral myocarditis: the preinfection phase where susceptibility factors and prevention from the onset of disease should be considered, phase 1 encompassing the time from initial virus infection in the myocardium through viral replication and lasting until viral replication ends, phase 2 when viral replication is undetectable though viral genomes persist, and phase 3 when viral genomes are undetected and patients are treated for ailing chronic heart conditions such as DCM (Yajima and Knowlton 2009). During Yajima et al.'s proposed phase 1 and following viral entry into cardiomyocytes or endothelial cells, many key immune players contribute to the elimination of virus and the initiation of inflammatory and possible autoimmune responses. If the innate response is incapable in controlling and eliminating viral replication, chronic disease in the myocardium can materialize and lead to the onset of debilitating conditions like DCM and heart failure. The key innate immune players include the toll-like receptors (TLRs), the double-stranded viral RNA sensors retinoic acid-inducible protein I (RIG-I) and melanoma differentiation-associated gene 5 (MDA-5), Janus kinase (JAK) and signal transducers and activators of transcription (STAT) signaling, and cytokines such as the interferons (IFN)-α/β, γ, interleukin IL-6, IL-1β, IL-4, tumor necrosis factor (TNF)-α, and transforming growth factor (TGF)-β (Lincez et al. 2011; Marín-García 2011).

Viruses harboring double-stranded RNA are sensed by TLR-3, MDA-5, and RIG-I. Activation of these viral sensors and associated signaling pathways is suggested to induce type I IFN responses. TLR3 knockout mice are impaired in controlling CB3-mediated myocarditis. Mice deficient in the viral sensor have enhanced disease and reduced IFN production and other key modulators of inflammation such as IL-1β and IL-12 following CB3 infection. TLR2, TLR4, and TLR8 are other pathogen recognition receptors implicated in viral myocarditis pathogenesis. TLR2 and TLR8 can be activated by cardiac myosin epitopes to induce an inflammatory state in the myocardium, and mice deficient in TLR4 reduces viral pathogenesis and the production of IL-1β and IL-18. Knocking out myeloid differentiation primary response gene (MyD88) in mice also protects mice from enhanced disease progression in both CB3-induced and EAM models (Hofmann et al. 2011; Lincez et al. 2011; Marín-García 2011).

Antigen-presenting cells (APCs) also play a critical role in disease progression. APCs influence lymphocyte responses. With two signals, antigen-loaded MHC and T cell receptor engagement and costimulatory signals CD40

and B7, APCs activate T cells and regulate helper T cell responses, peripheral tolerance, and regulatory T cells responses. Macrophages and dendritic cells (DCs), specialized APCs, produce cytokines and chemokines once activated, influencing the surrounding immunoenvironment and immune responses that affect disease pathogenesis. DCs in CB3 infected mice are defective in cytokine and chemokine production, impairing their ability to maintain peripheral tolerance and controlling the onset of autoimmune myocarditis. Macrophages and the immunomodulator TGF-β are critical in maintaining a balance between antiviral responses and avoidance of autoimmunity in CB3-induced myocarditis. It is also interesting to note the difference in macrophage phenotype for male and female mice in a CB3-induced myocarditis model. Male mice are typically most susceptible and demonstrate severe disease with CB3 infection compared to females. It has been suggested that this may be the influence of protective myocardial infiltrating macrophages observed in female mice. A gender bias in the cytokine signature infiltrating the myocardium has also been demonstrated with virus-induced myocarditis. Cytokines and chemokines that influence disease pathogenesis in EAM and virus-induced models include IL-2, IL-4, IL-6, IL-10, IL-12, IL-17, IL-23, TGF-β, IFNs, CCL2, and CXCL10 (Lincez et al. 2011).

Therapeutic Approaches, Challenges, and Future Directions

Generally, myocarditis treatment focuses on treating symptoms of heart dysfunction. If initial treatments fail and disease progresses to DCM, the remaining rescue treatment is heart transplantation. Unfortunately, in an effort to target viruses likely contributing to disease pathogenesis, broad-spectrum antivirals have been tested in trials with children and adults with little to none success. However, patients that have undergone endomyocardial biopsies with confirmation of enteroviral infection have been treated with IFNs-α/β and show significant clinical improvements including a reduction in inflammation and virus persistence in the heart.

Since there is a range in possible etiological agents responsible for viral myocarditis, it is difficult to design specific therapeutic interventions (Schultheiss et al. 2011). Nonetheless, the use of animal models and tools, such as the EAM and transgenic models, has identified key host and viral components that may present as successful therapeutic targets. The CB3 proteases 2A and 3C have been identified as contributors to the direct destruction of cardiac myocytes via activation of the caspase-8-mediated pathway. Inhibitors targeting these viral proteases may present as effective anti-CB3 and myocarditis therapeutic agents. Antiviral approaches are however risky, and the susceptibility to viral evasion and development of resistance must be considered. Another challenge in targeting viruses linked to myocarditis is the lack of understanding in the molecular mechanisms that influence reactivation of latent viruses such as PVB19 and the activation of immune pathways that instigate the reemergence of viral replication and the onset of chronic disease in the myocardium.

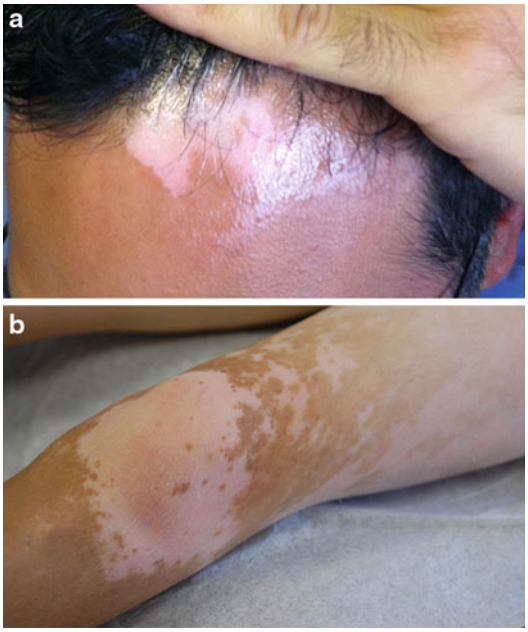
Definition

Vitiligo connotes a group of acquired disorders that result from loss of melanocytes, the pigment-producing cells of the body (Fig. 1a). Melanocytes are located primarily in the skin, hair, and eyes and to a lesser extent in the mucosal tissues, ears, heart, lungs, and adipose tissue. Melanocytes of the skin, hair, and mucosa are the targets in vitiligo, although in rare instances, melanocytes in the eyes and ears are also destroyed. The most common sites for vitiligo lesions are periorificial areas such as around the eyes, mouth, and genitalia and overlying joints. Lesions can progress, stabilize, or repigment. Repigmentation can occur after years of inactivity. Vitiligo affects both males and females at the same rate with 1–2 % of people afflicted worldwide, although in some areas, rates can reach 8 %. Disease onset can occur at any age but generally occurs in the first two decades of life.

Vitiligo has a significant impact on the physical and mental health of affected individuals, as well as on their quality of life. Lack of pigmentation compromises photoprotection of the skin, which is then more susceptible to solar damage. Melanocytes in the eyes are occasionally lost causing photophobia and night blindness. However, the most severe impact of vitiligo is on psychological well-being. Vitiligo frequently affects visible areas such as the face and hands causing additional distress, particularly among individuals with darker skin pigmentation (Nordlund 1992).

Diagnosis of vitiligo is generally based on clinical features including history, presence of depigmentation (rather than hypopigmentation), distribution, as well as (if present) evidence of repigmentation. The use of a Wood's lamp may be helpful when examining light-skinned individuals. Unlike disorders of melanocyte migration like piebaldism and Waardenburg syndrome where patches devoid of melanocytes are typically present from birth, lesions of vitiligo are generally acquired and progress over time. The location of lesions is also different.

Various forms of vitiligo, defined by the distribution of lesions, have been identified. Generalized vitiligo, also known as vitiligo vulgaris,



Vitiligo, Fig. 1 (**a**) Depigmented scalp lesion. (**b**) Depigmentation of the knee with evidence of follicular melanocyte repigmentation (Source: S. J. Orlow MD PhD)

is the most common form with widely distributed and symmetric progressive lesions. By contrast, segmental vitiligo presents with unilateral depigmented patches that are quasi-dermatomal. Segmental vitiligo has an early onset and a more limited and predictable course than generalized vitiligo. It does not generally progress beyond the single body segment affected. In contradistinction to segmental vitiligo, generalized vitiligo is associated with an increased incidence of certain other autoimmune disorders, including rheumatoid arthritis and diabetes (Alikhan et al. 2011). The focus of this entry is on generalized vitiligo, which is referred to as vitiligo hereafter.

Etiology of Vitiligo

Vitiligo is a multifactorial, polygenic disorder, and the precise molecular mechanisms underlying disease etiology are poorly understood. Depigmented lesions are devoid of melanocytes; however, precisely how melanocyte loss occurs remains to be elucidated. Susceptibility to vitiligo is genetically determined. Affected individuals may have a family history of vitiligo, while genetic association studies have been performed that identified disease susceptibility genes. Concordance among siblings is 6 % (Alkhateeb et al. 2003), although the majority of cases are sporadic. It is believed that environmental exposure to a trigger then determines if a susceptible individual will actually develop the disease.

In many cases, the trigger event is not known, hence the classification of most cases as idiopathic vitiligo. In some cases, vitiligo is known to occur due to exposure to a chemotoxin, resulting in contact vitiligo. When exposure occurs in the workplace, it is classified as occupational vitiligo. Despite the varying nature of the triggers, the same mechanisms are thought to underlie disease onset and progression, with no other discerning features separating the various forms. Thus, a number of recent studies aimed at elucidating the pathobiology of vitiligo have used contact vitiligo as a model.

Oxidative stress is thought to be a key factor in the early stages of vitiligo, prior to the onset of autoimmune disease. Studies have demonstrated increased markers of oxidative stress in serum and lesional skin from individuals with vitiligo, including increased expression of antioxidants such as superoxide dismutase and catalase. Genetic association studies in some population groups have shown linkage between antioxidant response genes and increased risk of developing vitiligo.

A neuronal component to vitiligo etiology has also been suspected. Melanocytes share neural crest origins with nerves, while lesions of vitiligo are sometimes more common at nerve endings. It has been suggested that neuromediators are released leading to melanocyte death (Le Poole et al. 1993).

While there is typically no overt inflammation at lesion sites (e.g., redness is lacking), there is an increase of proinflammatory cytokines in perilesional skin. Thus, it has been suggested that "microinflammation" precedes autoimmunity in vitiligo (Taieb 2012). Further evidence of inflammation is the presence of infiltrating CD4+ and CD8+ T cells at the periphery of lesions.

Although melanocytes are the target in vitiligo, the disease may be a reflection of keratinocyte dysfunction. Keratinocytes produces growth factors and hormonal signals that elicit survival responses in the melanocyte, for example, exposure to ultraviolet light (UV) results in the production of α-melanocyte-stimulating hormone, a ligand for the melanocortin-1 receptor (MC1R) on the surface of the melanocyte. MC1R activation promotes melanin synthesis but also stimulates pro-survival pathways such as DNA repair functions (Kadekaro et al. 2003).

Cell adhesion dysregulation is also thought to contribute to loss of melanocytes in vitiligo. A recent study showed an association between discoidin domain receptor 1 (DDR1) and vitiligo susceptibility. DDR1 is a collage-activated transmembrane tyrosine kinase receptor that facilitates E-cadherin adhesion to collagen type IV (Silva de Castro et al. 2010).

It is possible that several factors combine to trigger vitiligo. It has been proposed that a trigger event causes melanocyte stress, most likely in the form of oxidative stress. Melanocytes of individuals susceptible to developing vitiligo are unable to effectively mount an antioxidant response causing cell damage that leads to apoptosis and/or increased antigen presentation. A subsequent autoimmune response then perpetuates melanocyte death resulting in the progressive appearance and broadening of depigmented patches.

Generalized Vitiligo Is an Autoimmune Disorder

While the initial steps may involve oxidative damage, by the time of presentation, vitiligo appears to be primarily an autoimmune disorder. Melanocytes in lesional areas are presumed to be targeted for immune destruction. Antibodies against a number of melanocyte-specific proteins have been identified in sera from patients with vitiligo. Furthermore, individuals with vitiligo sometimes present with other autoimmune disorders that affect melanocytes (halo nevi), the skin (psoriasis), and other organs including Addison's disease, adult-onset type 1 diabetes mellitus, rheumatoid arthritis, Graves' disease, and systemic lupus erythematosus.

The most significant progress in understanding the immune component in vitiligo progression stems from genetic association studies that have identified key genes that contribute to increased susceptibility to vitiligo (Jin et al. 2012; Spritz 2012). Some of these genes play a role in immunity, while others encode melanocyte proteins that serve as antigens and elicit the autoimmune response (Table 1). Interestingly, some genes that are associated with increased risk of melanoma are associated with a lower risk of vitiligo. It has been suggested that these genes contribute to the ability of cells to evade immune detection in melanoma, while causing melanocytes to be targeted more easily by the autoimmunity in vitiligo. A prime example of this may be the association of a variant of the melanocyte-specific protein tyrosinase.

Tyrosinase is an enzyme that is critical for the biosynthesis of melanin. It undergoes extensive posttranslation modification to ensure functionality. A polymorphism at amino acid 402, among Caucasians, encodes for either glutamine (402Q) or more commonly arginine (R402). The 402Q variant is hypoglycosylated and is not readily processed for antigen presentation, thus decreasing the risk of vitiligo but increasing melanoma risk (Spritz 2012). A number of antibodies targeting melanocyte-specific proteins have been identified in addition to tyrosinase, including tyrosinase-related proteins 1 and 2, Pmel17, and MC1R.

It should be noted that there are some differences in the genes associated with vitiligo in different population groups; thus, a cohesive overall picture of vitiligo pathobiology is likely to consist of multiple pathways that contribute to varying degrees in disease onset and progression.

Immune Response in Vitiligo

Inflammatory cells are present in perilesional skin, and T cells harvested from perilesional areas can target melanocytes (van den Boorn et al. 2009). Although CD8+ and CD4+ T cells

Vitiligo, Table 1 A subset of genes associated with increased risk of vitiligo and other autoimmune disorders or with vitiligo alone

Gene class	Gene	Associated disorders
Plasma cell differentiation	BACH2 basic leucine zipper transcription factor 2	GD
Member of C1qTNF family may be involved in innate immunity	C1QTNF6 C1q and tumor necrosis factor-related protein 6	T1D, RA
Apoptosis	CASP7 apoptosis-related cysteine peptidase 7	
B-cell differentiation and maturation	CCR6 chemokine (C-C motif) receptor 6	IBD, RA, GD
Cell-cell and cell-matrix interactions	CD44	T2D
T-cell proliferation and cytokine production	CD80	Juvenile idiopathic arthritis
Immunoreceptor signaling	CLNK cytokine-dependent hematopoietic cell linker	ALS
T-cell regulation	CTLA-4 cytotoxic T-lymphocyte-associated protein 4	T1D, GD, IBD
MHC class II	HLA-DQA1 major histocompatibility complex, class II, DQ alpha 1	Multiple including GD and arthritis juvenile rheumatoid
MHC class II	HLA-DRB1 major histocompatibility complex, class II, DR beta 1	RA, IDD, AID, SLE
B-cell differentiation	FOXP1 forkhead box P1	
T-cell regulation	FOXP3 forkhead box P3	? T1D
Induction of apoptosis by cytotoxic T cells	GZMB granzyme B (granzyme 2, cytotoxic T-lymphocyte-associated serine esterase 1)	Stevens-Johnson syndrome
	HCG9 HLA complex group 9 (non-protein coding)	
MHC class I	HLA-A, major histocompatibility complex, class I, *A*	AH
MHC class I	HLA-G, major histocompatibility complex, class I, *G*	RA, T1D, SLE
MHC class I	HLA-J, major histocompatibility complex, class I, *J* (pseudogene)	
Innate immunity	IFIH1, interferon induced with helicase C domain 1	(Melanoma)
	IKZF4, IKAROS family zinc finger 4 (Eos)	AA
Immune modulation	IL2RA, interleukin 2 receptor alpha	RA
Cell adhesion	LPP, LIM domain containing preferred translocation partner in lipoma	CD, RA
Melanocyte function	MC1R, melanocortin 1 receptor (alpha melanocyte-stimulating hormone receptor)	(Melanoma)
Apoptosis/inflammation	NLRP1, NLR family, pyrin domain containing 1	Multiple disorders including autoimmune diabetes, rheumatoid arthritis, and psoriasis
Melanocyte function	OCA2, oculocutaneous albinism II	(Melanoma)
T-cell receptor signaling	PTPN22, protein tyrosine phosphatase, non-receptor type 22 (lymphoid)	GD, HT, RA, SLE
Apoptosis related	RERE, arginine-glutamic acid dipeptide (RE) repeats	(Linked to antioxidant regulator Nrf2)

(*continued*)

Vitiligo, Table 1 (continued)

Gene class	Gene	Associated disorders
T-cell receptor activation	SH2B3, SH2B adaptor protein 3	IDD, CD
Negatively regulates T-cell receptor signaling	SLA, Src-like adaptor	(Melanoma?)
Innate immunity	TICAM1, toll-like receptor adaptor molecule 1	(Melanoma)
Release of T-cell-attracting chemokines	TSLP	
Melanocyte function	TYR, tyrosinase	(Melanoma)
Regulates T-cell receptor signaling	UBASH3A, ubiquitin associated and SH3 domain containing A	T1D
Differentiation of plasma cells/stress response	XBP1, X-box binding protein 1	CRD

Compiled from data provided at http://www.genecards.org/ (Spritz 2012) and (Jin et al. 2012)
Abbreviations: *AA* Alopecia areata, *ALS* Amyotrophic lateral sclerosis, *AH* Autoimmune hepatitis, *AID* Autoimmune diabetes, *CD* Celiac disease, *CRD* Crohn's disease, *GD* Graves disease, *HT* Hashimoto's thyroiditis, *IBD* Inflammatory bowel disease, *IDD* Insulin-dependent diabetes, *RA* Rheumatoid arthritis, *SLE* Systemic lupus erythematosus, *T1D* Type 1 diabetes

are both present, there is a greater presence of CD8+ cells. CD8+ cells have been implicated in other autoimmune disorders such as diabetes. CD4+ cells are thought to facilitate the expansion of CD8+ cells prior to migration to the skin. CD8+ cells are activated when CTLA-4, encoded by a gene that is also associated with risk of developing vitiligo, is knocked out, but only if CD4+ cells are present. A recently developed mouse model for vitiligo involved the transplant of CD8+ T cells that target melanocytes in mice engineered to support interfollicular melanocytes. Depigmentation required additional treatment with interferon-γ (Harris et al. 2012). In a chicken model of vitiligo, interferon-γ expression was increased as melanocyte loss began (Shi and Erf 2012). In addition to interferon-γ, other cytokines that may facilitate an autoimmune response are also elevated, including interleukin 6 (IL-6) and IL-17. Increased IL-6 and IL-17 expression may account for the increase in Th17 cells at the periphery of active lesions. Langerhans cells are also present and may facilitate the activation of the Th17 cells (Wang et al. 2011).

While CD4+/CD8+ cell numbers increase, there is a concomitant reduction in the number of regulatory T cells (Tregs), which may also contribute to vitiligo pathogenesis. Tregs are immunosuppressants and reduced the risk of developing autoimmunity against "self" proteins. Foxp3, a marker for Tregs, has been shown to be associated with vitiligo (Spritz 2012), while expression of the skin homing chemokine CCL22 is reduced in perilesional skin (Klarquist et al. 2010). Thus, multiple mechanisms may contribute to the reduced presence of Tregs.

Linking Events That Trigger Vitiligo with Autoimmunity

While oxidative stress plays a role in triggering vitiligo and autoimmunity plays a role in disease progression, the link between these events is not well understood. It was recently demonstrated that chemical agents that trigger vitiligo, such as phenolics, induce oxidative stress that disrupts the protein folding machinery of the endoplasmic reticulum (ER). The redox balance of the ER is carefully regulated given that protein folding, disulfide bond formation, and recycling of folding chaperones require oxidation-reduction reactions. In perilesional skin and melanocyte from individuals with vitiligo, the ER is dilated suggested that homeostasis is indeed induced. ER dysregulation leads to the activation of a stress response known as the unfolded protein

response (UPR). UPR activation following exposure to phenolics results in activation of the UPR and subsequent expression of cytokines IL-6 and IL-8 (Toosi et al. 2012) that may lead to recruitment of immune components to the skin. In combination with the processing and presentation of melanocyte antigens, this recruitment may lead to autoimmunity in susceptible individuals.

Treatment Strategies for Vitiligo

There are few predictors of disease progression. While some individuals experience extensive pigment loss that eventually affects the entire body, others experience episodic changes in lesion size and number. Depigmentation continues long after exposure to the triggering agent, while spontaneous repigmentation can occur by migration of melanocytes from perilesional skin or unaffected hair follicles into areas of epidermal melanocyte loss. Current treatments include:

- Corticosteroids, which are thought to act through modulation of the immune system. They are frequently the first line of treatment and can be used in adjuvant therapy. Although typically used as topical agents, systemic corticosteroids are sometimes employed when spread is rapid.
- Topical calcineurin inhibitors such as tacrolimus which inhibit certain T-cell functions and reduce cutaneous inflammation, but lack some of the side effects of corticosteroids, have also been shown to be effective.
- Phototherapy is often utilized. Ultraviolet B (UVB) especially narrowband UVB (311 nm) is the most widely utilized form. Psoralen in combination with UVA (PUVA) is also effective but has fallen out of favor due to the increased risk of skin cancer (especially nonmelanoma skin cancer) and persistent photosensitivity. Excimer laser therapy (essentially a targeted UVB treatment) has been gaining popularity, with demonstrable improvement in 95 % of patients in some studies.
- Surgical treatment is considered an option in the treatment of recalcitrant vitiligo. Options include suction blister grafting, punch grafting, or grafting of melanocyte suspensions. Surgical options increase the risk of scarring and patchy repigmentation.
- Depigmentation therapy is useful in patients with extensive lesions where there is no longer hope of repigmentation. Monobenzyl ether of hydroquinone (a phenolic that can itself provoke vitiligo) is approved for this purpose; however, depigmentation is not always complete.

Numerous additional therapies have been suggested or tested for efficacy in vitiligo. Certain plant-derived substances such as *Ginkgo biloba* and *Polypodium leucotomos* extract have shown early promise in augmenting the effectiveness of UVB treatment when administered orally. No therapy is effective in all patients and long-term success rates are variable. Furthermore, many are accompanied by potential side effects including skin atrophy, hyperpigmentation, and scarring (Whitton et al. 2010).

There is no current protocol for evaluating which patients would benefit from a particular treatment or which patients are refractory to particular treatments. It is however clear that in order for agents that work by promoting melanocyte migration into depigmented areas to be effective, the hairs in these areas must remain pigmented so that there is a reservoir of follicular melanocytes. The success of a therapy is often heralded by formation of pigmented circles around hair follicles within the lesion as melanocytes migrate up and out of the follicles (Fig. 1b).

Recent suggestions for therapeutics include inhibitors of tumor necrosis factor-α (TNF-α) since studies have shown increased levels of TNF-α in perilesional skin. An additional therapeutic target may be IL-17A, which has also been shown to be elevated in perilesional skin (Wang et al. 2011).

Development of therapies has been hampered by the lack of clarity with regard to the pathobiology of vitiligo. With greater lucidity on the precise immune mechanisms that result in persistent melanocyte loss, it may be possible to develop more targeted therapies. It should however be noted that genetic association studies

suggest that melanocyte targeting by the immune system perpetuates melanocyte loss but is also crucial for immune surveillance that prevents melanoma.
