Leptotene	Chromosome condensation commences. Axial elements are formed at the cores of the chromosomes. Telomeres bind to the nuclear membrane and also tend to congregate in a restricted part of the nucleus to form a chromosomal bouquet. Homologue searching is initiated.
Zygotene	Homology testing is undertaken using a recombination-like process. Synapsis is initiated between the axes of homologous chromosome segments to form the synaptonemal complex (SC).
Pachytene	Synapsis is at its maximum extent. Recombination intermediates, presumed to form during the homology testing process, mature into crossovers.
Diplotene	Synapsis begins to break down.
Diakinesis	Synapsis has completely disappeared and homologues are held together only at positions of meiotic recombination (chiasmata).
Metaphase I	A microtubular spindle is formed; chromosome pairs (bivalents) attach to and align on the spindle.
Anaphase I	Sister chromatid cohesion breaks down except at centromeres and homologous chromosomes segregate to opposite spindle poles to produce haploid nuclei.
Metaphase II	Chromosomes align on the spindle.
Anaphase II	Sister chromatid cohesion lapses at the centromeres, chromatids segregate to opposite spindle poles.

meiosis is prophase I when the chromosomes undergo two characteristic and important features of chromosome behavior, namely homologous chromosome pairing and recombination (4, 7).

Pre-Meiotic DNA Replication and Sister Chromatid Cohesion

The basic mechanisms of [▶DNA replication](#), for example the origin of replication sites used and the enzymes involved, appear to be similar in mitotic and premeiotic cells. Nevertheless, the time taken to complete replication is considerably longer in the premeiosis S phase. The reason for this has yet to be established but may be related to the need to modify chromatin organization to accommodate the unique aspects of chromosome behavior that occur in meiosis. In addition to replicating the genome, a vital structural re-organization of the chromatin occurs at premeiotic S phase. Following replication, a protein complex called [▶cohesin](#) is laid down between sister chromatids. In somatic cells, the cohesin complex is formed by 4 protein subunits called SMC (structural maintenance of chromosome) 1 α and 3, and SCC (sister chromatid cohesion) 1 and 3. Meiosis-specific variants have been found for 3 of these subunits, SMC1 β (SMC1 α), REC8

(SCC1) and STAG3 (SCC3). These variants replace some or all of the proteins present in somatic cells. This meiotic cohesin complex has important roles in meiotic chromosome pairing, recombination and in the correct segregation of chromosomes at the first meiotic division (2, 6). These roles are described more fully in the sections on chromosome pairing, recombination and segregation.

Homologous Chromosome Pairing

During leptotene, the chromosomes condense and form a continuous proteinaceous axis (Fig. 2). This is in part formed from the cohesin axis and also by the addition of particular meiotic proteins of the [▶synaptonemal complex](#) (SC), the meiosis-specific pairing structure (Fig. 3). To date, three SC proteins have been identified, namely SCP (synaptonemal complex protein) 1, 2 and 3. Two of these proteins, SCP2 and 3, associate with the cohesin axis. When the homologous partner is identified, then synapsis occurs at the axial interface (Fig. 2). A third SC protein, SCP1, stretches between the axes and is the binding protein of synapsis. SCP1 is a long filamentous protein with two coiled domains at the amino and carboxyl termini. The carboxyl end of the protein binds to the chromosomal

Meiosis and Meiotic Recombination. Figure 1 A schematic drawing of an idealised pair of chromosomes to illustrate chromosome pairing, recombination (chiasma formation) and chromosome and chromatid segregation. The characteristic features of each meiotic stage are described in Table 1.

axes, the amino terminal end to that of another SCP1 protein stretching out from the axis of the homologue (Fig. 3). Homologous chromosome synapsis is thus marked by the formation of a proteinaceous structure that, by electron microscopy, has a tripartite appearance comprising two ►lateral elements and a central region containing a ►central element. This synaptic structure, comprising the cohesin axes and the SC, is crucial for the control of the numbers and distributions of meiotic recombination events.

One of the unique features of meiosis is that pairs of homologous chromosomes actively seek out and

intimately associate with their partners during prophase I. This whole process falls within the general heading of pairing, but can be considered to include a number of distinct steps, homology searching and testing, alignment and synapsis.

Homologous chromosomes are usually located in separate regions (sometimes called domains or territories) of the nucleus. Consequently, homologous chromosomes need to undertake an active search for their partner in order to initiate pairing. The mechanism of this search has yet to be detailed, but there is clear evidence that chromosomes move around the nucleus

Meiosis and Meiotic Recombination. Figure 2 Human fetal oocytes at different stages of early prophase I. The cells have been stained simultaneously for the cohesin protein REC8 (green), the axial element (AE) protein SCP3 (red) and chromatin (blue). (a) Preleptotene: the cohesin protein is present throughout the nucleus, while the AE protein is largely confined to nucleoli (arrow). (b) Leptotene: the chromosomes have begun to condense and form linear fibrils composed of both cohesin and AE proteins. (c) Zygotene: homologous pairs of chromosomes have commenced synapsis; this is not complete, however (arrow). (d) Pachytene: the homologues are now fully associated along their axes to form linear synaptonemal complexes (SCs).

Meiosis and Meiotic Recombination. Figure 3 A cartoon illustrating the axial nature of synapsed chromosomes. Although not shown here, there is evidence that the bases of the chromatin loops extend into the central region of the synaptonemal complex. The bulk of the chromatin, however, lies outside the complex and apparently is not available for recombinational interaction with DNA from the non-sister-chromatids of the homologous partner.

during this process. One of the first identifiable events is the binding of telomeres to the nuclear membrane during leptotene (7). This is accompanied by condensation of the chromosomes into extended linear structures. In most organisms, the telomeres tend to congregate in a restricted region of the nuclear membrane in late leptotene to early zygotene (Fig. 4). This behavior is termed ‘bouquet’ formation and is believed to be part of the homology search process. Bouquet formation tends to be transitory.

Given that there are simultaneously many chromosomes in the nucleus attempting to pair, the question arises as to how the chromosomes distinguish their partners. The current consensus is that homology testing is achieved through a process involving recombination (see below). Where homology is present, then the pair of chromosomes associates (synapse) intimately and forms an SC.

The SC acts as the interface between homologous chromosomes during synapsis. It is important to realize that the bulk of the chromatin that comprises each chromosome is excluded from this synaptic interface. Most of the chromatin is present as long chromatin loops emanating from the chromosomal axis (Fig. 3). For the autosomes and the X chromosome pair in oocytes, synapsis occurs along the entire chromosomal axes. In the male, however, the X and Y chromosomes share homology only over short segments, a 2.6 Mb region at the ends of their short arms, and a 0.23 Mb region at the distal end of the long arm. Synapsis is therefore restricted between these two chromosomes.

Meiosis and Meiotic Recombination.

Figure 4 A leptotene stage, human fetal oocyte with fibrillar axial element formation (green). The centromeres are stained an intense green (arrow) and are located throughout the nucleus. In contrast, the telomeres (red, arrow) are concentrated peripherally in one part of the nucleus as a consequence of the chromosomes forming a bouquet.

Meiotic Recombination

Recombination and pairing/synapsis are intimately associated. The initial step in the pairing process is the formation of double strand breaks (DSBs). Recent

studies have shown that a DNA topoisomerase II-like enzyme, called SPO11, is central to the formation of DSBs. Organisms in which SPO11 is mutated, and therefore not functional, invariably show disrupted chromosome pairing. Once the DSB is formed, exonucleolytic enzymes digest one strand from the 5' end to leave a 3' overhang of single-strand DNA (Fig. 5). DNA repair proteins, such as RAD51 and DMC1, bind to this single-strand DNA and initiate strand invasion of double-stranded DNA, the initial step of homology testing and formation of meiotic crossovers (Fig. 5). In recent years, a number of proteins have been identified in mammalian cells that play a role in meiotic recombination (Table 2). One of the current challenges in meiotic research is trying to piece together the detail of the metabolic pathway of meiotic recombination.

It has long been supposed that the SC is the place at which **crossing-over** occurs between homologous chromosomes and that the SC also plays a crucial role in the control of numbers and distributions of crossovers. This supposition is based on the observation that where SC formation is abnormal, then there is a correlated effect on crossing-over. Recently it was shown that a DNA mismatch repair protein called MLH1 performed an essential role late in the process of meiotic recombination. This protein co-localizes with the SC (Fig. 6) as anticipated if this structure is the site of crossing-over.

After intimate synapsis between homologous chromosomes breaks down in diplotene, sister chromatid adhesion around the position of recombination maintains crossovers between homologous chromosomes. As the chromosomes condense, crossovers become visible cytogenetically as **chiasmata** (Fig. 7). Chiasmata hold the pair of homologues together through to metaphase I. Chiasmate pairs of homologous chromosomes are termed bivalents; if chiasma formation fails, the homologues separate and are present as **univalents**.

Chiasma numbers and distributions have been used to describe patterns of meiotic recombination in human spermatocytes. Various studies have shown that human males have on average about 50 chiasmata per spermatocyte and that these crossovers are biased in distribution towards the distal (telomeric) ends of chromosome arms.

Interestingly, human oocytes show a different pattern of recombination to spermatocytes; a significantly higher number of crossovers, more than 70 per cell on average, are formed and these tend to be more interstitially located than in the male (Figs. 6, 8). The mechanisms that produce such disparate distributions in the two sexes remain unclear.

One aspect of the control of crossover numbers has recently become somewhat clearer. Total SC lengths

Meiosis and Meiotic Recombination. Figure 5 An illustration of the double strand break (DSB) model for meiotic recombination. (a) A DSB is formed by SPO11 in combination with other proteins. (b) Exonucleolytic enzymes digest back (resect) the 5' ends of the DSBs to leave 3' overhangs. (c) Strand exchange proteins, such as RAD51 and DMC1, are recruited to the single strand overhangs. The single-strand DNA invades a duplex on the homologous, non-sister chromatid, displacing a DNA strand to form a D loop structure. (d) After both single strand ends have invaded, DNA synthesis initiates from the 3' ends to replace the digested base pairs. The resulting structure is called a double Holliday junction. (e) The Holliday junction is resolved into a crossover by cutting the Holliday structure in opposite orientations.

can vary between cells within an individual. It has been shown that the numbers of crossovers show a correlated variation. In other words, the length of the physical platform (the SC) available for recombination influences the numbers of crossovers. This effect is also clear when one compares the two sexes. The total length of SC in human oocytes is over 500 μm compared with 250–300 μm in the male and likewise the rate of recombination is higher in female meiosis. It is still unclear what produces this effect on axial chromosome lengths in the two sexes but there is a suspicion that sex-related differences in chromosome condensation are involved. Of course, this still leaves

Meiosis and Meiotic Recombination. Table 2 The timing of appearance and possible function of some recombination-associated proteins

Protein	Stages present	Role
SPO11 (sporulation)	leptotene – zygotene	Produces DSBs, essential for synapsis
RAD51	leptotene – pachytene	RecA homologue that binds to single-stranded DNA; may mediate single end invasion during recombination
DMC1 (disrupted in meiosis)	leptotene – pachytene	RecA homologue that binds to single-stranded DNA; colocalizes with RAD51
RPA (Replication protein A)	zygotene – pachytene	Binds to single-stranded DNA; possibly involved in early steps of recombination
BLM (Bloom syndrome mutated helicase)	leptotene – pachytene	Helicase, colocalizes with RPA
MLH1 (MutL-homologue)	zygotene – diplotene	Required for completion of crossing-over
MLH3	pachytene	Involved in DNA mismatch repair
MSH4/5 (MutS homologue)	zygotene – pachytene	Required for chromosome pairing, may interact with MLH1 to control crossing-over

unanswered the questions as to why such inter-sex variation in meiotic chromosome organization is present in the early part of meiosis and what may be the purpose of the different patterns of recombination in the two sexes.

Chromosome Segregation at Meiosis I

Although the SC begins to break down at the end of pachytene and is lost completely during diplotene, the cohesin axes appear to be maintained. Thus sister chromatids remain closely associated. This characteristic is essential for the maintenance of chiasmata between homologous chromosomes.

During diplotene, diakinesis and metaphase I, it is believed that a cohesin protein complex acts as a “glue” to bind together sister chromatids. It is not clear whether only the meiosis-specific cohesin proteins are involved or if other cohesin proteins, such as those present in somatic cells, also play some role. This will undoubtedly be clarified over the next few years. It is also unclear whether the cohesin proteins remain along the whole chromatid axis (as at early prophase I) or if binding is restricted to only some regions as occurs in mitotic metaphase chromosomes. What is clear, is that absence of meiotic cohesin proteins is incompatible with normal progression through meiosis and that affected germ cells generally die early in prophase I.

At metaphase I, a microtubular spindle forms; the bivalents attach to the microtubules *via* their

►kinetochores and move to the spindle equator. Unlike mitosis, the two kinetochores of each chromosome behave as a single unit and attach to microtubules from the same spindle pole. The kinetochores of each homologue, within a bivalent, orient to opposite spindle poles. When the bivalents are correctly oriented (and there appears to be a cell checkpoint that monitors this process) a signal pathway is activated that eventually results in the removal of the cohesin proteins from between sister chromatids, except at the kinetochores, and the homologous chromosomes segregate from each other (anaphase I). In somatic cells, breakdown of the cohesin complex is achieved through lysis of SCC1 by an enzyme called separase; it is presumed that the same process occurs in meiosis, although in this instance the target of lysis is REC8, the meiosis-specific version of SCC1. One of the principal differences between mitosis and meiosis is that at mitotic anaphase sister chromatids separate along their complete lengths, including ►centromeres, allowing chromatids to pass to opposite spindle poles. In meiosis, in contrast, cohesion breaks down along chromatid arms but remains in place at the centromeres. There is some evidence that the cohesin complex between chromatid arms may be constitutionally different from that in the centromere and that this differentiation may be fundamental to the protection from lysis of REC8 in the centromere at anaphase I of meiosis.

Meiosis and Meiotic Recombination. Figure 6
A pachytene stage spermatocyte and oocyte. The synaptonemal complexes (SCs) are stained red; in the male, centromeres are also stained (blue). The cells illustrate the localization of foci of the recombination protein, MLH1, to the SCs. The cells show the inter-sex variation in number of crossovers: in the male, there are 53 MLH1 foci, in the female, 78. Moreover, in the male, foci are often located close to chromosome ends (white arrows), while in the female, they are generally more centrally positioned (arrow). In the male, the position of the lightly staining X and Y chromosomes is indicated (green arrow).

Chromatid Segregation

At metaphase II, the two chromatids of each chromosome are held together only at their centromeres. These chromatids are now genetically dissimilar because of recombination, i.e. they are a mixture of sister and non-sister chromatids. At anaphase II, therefore, genetic segregation occurs to produce products that are genetically different. This is in contrast to mitosis where sister chromatids segregate to produce genetically identical daughter cells.

When the chromosomes are attached to the spindle, the cohesin at the centromeres is removed allowing the chromatids to segregate to opposite poles. Currently it is not clear if the cohesin complex is modified after meiosis I to make it responsive to lysis by separase or if

Meiosis and Meiotic Recombination. Figure 7
A single bivalent at pachytene and metaphase I. The photographs (top) show a pachytene synaptonemal complex with 2 MLH1 foci (arrows), and a metaphase I bivalent with 2 chiasmata. Below, is a cartoon to illustrate the formation of recombinant chromatids at metaphase I following crossing-over at pachytene.

Chromosome 21

Meiosis and Meiotic Recombination. Figure 8
A histogram displaying the positions of meiotic crossovers along chromosome 21 in male and female human meiosis. The male shows preferential location of crossovers towards the distal end of the long arm compared with a tendency for more central location in females.

a different mechanism of cohesin breakdown is employed in meiosis II.

Sex Differences in Germ Cell Development

The developmental profiles of oogenesis and spermatogenesis are very different. In most mammals, including humans, female meiosis is initiated during fetal development whereas in the male it begins

postnatally. In oocytes, the early stages of prophase I occur *in utero* with germ cells progressing to diplotene when they enter a cell division arrest phase that lasts until shortly before ovulation in the adult ovary.

Another important sex difference is that there are no self-replenishing oogonial stem cells in ovaries in obvious contrast to the testis that has spermatogonial stem cells. The lack of stem cells in the ovary has the important consequence that female mammals have a finite population of germ cells that is depleted during reproductive life. Female germ cells are also subject to considerable loss during development; late in gestation approximately 70% of oocytes die (a process termed atresia). It is thought that errors in meiotic chromosome pairing may be one of the factors that contribute to the likelihood of cells becoming atretic.

Clinical Relevance

The crucial importance of meiosis to gamete formation is emphasized by the consequences of errors in the process. Meiotic errors can have a variety of adverse outcomes; impaired fertility in the affected individual, generation of *de novo* gene and chromosome mutations, and production of aneuploid gametes.

There is evidence that the complex sequence of chromosome behavior in meiosis is subject to monitoring systems termed cell checkpoints (1, 5). Failure of chromosome pairing or recombination can trigger such checkpoints and cause affected cells to arrest in development. These checkpoints appear to be considerably more efficient in male than female meiosis, as adjudged by the fact that errors in pairing and recombination appear to be more likely to result in arrested cell development in the male. A number of studies have shown that errors of meiotic chromosome behavior are present in germ cells of a higher proportion of men with impaired fertility than in the general population. Notwithstanding this observation, meiosis appears to be more error-prone in human female than male meiosis. For example, one study of synaptonemal complexes in fetal oocytes recorded anomalies in over 30% of the cells. Although most of these cells are believed to be lost through atresia, there is a suspicion that a proportion may survive to contribute to the pool of oocytes in the adult ovary. Pairing errors have an adverse impact on chiasma formation; given the crucial role of chiasmata in chromosome segregation, these cells would be expected to have an increased risk of chromosome [▶nondisjunction](#) at anaphase I.

In human oocytes, the monitoring system at metaphase I for chromosome orientation appears either to be absent or somewhat inefficient. As a consequence, oocytes are able to progress into anaphase I with mal-oriented chromosomes resulting in a higher likelihood of the incorrect segregation of chromosomes (termed

chromosome non-disjunction) compared with spermatocytes. More than 90% of autosomal trisomies (i.e. conceptions with an abnormal chromosome number) are the result of chromosome nondisjunction in female meiosis (3). It is also worth noting that human oocytes also appear to be more likely than the equivalent male cells to have failure of crossing-over, resulting in unpaired univalent chromosomes at metaphase I. Once again, the reason(s) for this considerable sex disparity in meiotic chromosome behavior is unknown.

Meiotic Mapping

Definition

Meiotic mapping is a method of genetic mapping based on the segregation pattern in the progeny of genetic crosses.

▶Mutagenesis Approaches in Yeast

Meiotic Maturation

Definition

Meiotic maturation describes the final step of oogenesis, regulated by hormones. It includes nuclear

breakdown and separation of homologous chromosomes, and results in ovulation of an egg capable of being fertilized by sperm.

► [Mammalian Fertilization](#)

► [Meiosis and Meiotic Recombination](#)

Meiotic Mismatch

Definition

Meiotic mismatch refers to errors in DNA replication and comprises any non-complementary base pair in double stranded DNA. Mismatched DNA molecules are designated heteroduplexes. Their replication produces daughter molecules with different sequences at the site of unpaired bases.

MELAS

Definition

MELAS is the acronym for Mitochondrial Encephalomyopathy with Lactic Acidosis and Stroke-like episodes. MELAS is a rare, maternally-inherited mitochondrial disease, due to point-mutations in the mitochondrial tRNA^{Leu(UUR)} gene. The disease is characterized by stroke-like episodes and a mitochondrial myopathy. Organ systems included in the multi-systemic involvement are the central nervous system, skeletal muscle, eye, cardiac muscle, and more rarely the gastrointestinal system.

► [tRNA](#)

Melatonin

Definition

Melatonin is the trivial name for N-Acetyl-5-methoxytryptamin. That is a hormone which is produced by the pineal gland during the night and contributes to the regulation of seasonal rhythms. The suprachiasmatic nucleus (SCN) of the hypothalamus expresses melatonin receptors, and melatonin may have a direct action on SCN to also influence circadian rhythms.

Melting Temperature

Definition

Melting temperature (T_m) is operationally defined as the temperature at which half of a temperature-induced transition has occurred. It is not a thermodynamic quantity. The melting temperature (T_m), for instance, characterizes the stability of the DNA hybrid formed between an oligonucleotide and its complementary strand. T_m is critical for determining the optimal temperature at which to use an oligonucleotide as a primer in PCR applications.

Memory of Addiction

Definition

Memory of addiction means the neuroplastic changes that took place during drug-taking. Following repeated drug use, various brain structures store memories in various circuits. In the absence of reinforcement, the behavioral response will gradually diminish to finally be extinct. With regular use, tolerance develops and the abuser must use more drugs to achieve the same intensity or effect. Over time, physical dependence and addiction develop.

Synonyms

Mendelian hypertension; monogenic hypertension

Definition

The genetic defects causing Mendelian forms of hypertension are attributable to a defect in a single gene locus. The elucidation of Mendelian forms of hypertension is of great interest in identifying mechanisms that elevate blood pressure. All Mendelian forms of hypertension to date have been autosomal-dominant with a single exception, ►[apparent mineralocorticoid excess](#), which is autosomal-recessive. Complex genetic studies involving populations are underway to map genes that may influence blood pressure and to test associations with genetic variations of known genes important for blood pressure regulation.

Characteristics

The single strongest characteristic found to date in Mendelian hypertension is the role of mechanisms influencing volume homeostasis. All except one form have been so-called “salt-sensitive” forms of hypertension. In these forms, changes in dietary salt intake have a great influence on blood pressure. Thus, the influence of the ►[mutation](#) requires an environmental attribute, namely relatively generous salt intake. However, not all Mendelian forms of hypertension are salt-sensitive: In persons with ►[essential primary hypertension](#), about half are salt-sensitive while half are not.

Glucocorticoid-remediable Aldosteronism (GRA)

Patients with ►[glucocorticoid](#) remediable aldosteronism have an autosomal dominant hypertension and are usually suspected of having ►[primary aldosteronism](#) (►[aldosterone](#)). They have a volume expansion, a salt-sensitive form of hypertension, tend to ►[metabolic alkalosis](#) with ►[hypokalemia](#) and respond to both thiazide ►[diuretics](#) and spironolactone. The latter fact is a clinical clue that ►[mineralocorticoid](#) products may be involved. Their renin values are low while the aldosterone values are elevated. The patients also have 18-hydroxy- and 18-oxo-cortisol, steroids not normally found in urine in large amounts. Recognizing these abnormal products (an intermediate phenotype) led to solving the mystery. Replacement quantities of prednisone ameliorate the hypertension, cause the abnormal steroids to disappear and give the syndrome its name. The abnormal cortisol derivatives and the favorable effects of glucocorticoid treatment suggested that inner cortical zones, which express the gene for 17 β -hydroxylase (CYP17) and are ACTH-responsive, were the source of the excess mineralocorticoids. Two distinct gene products, 11 β -hydroxylase (CYP11B1) and aldosterone synthase (CYP11B2), perform the terminal steps in glucocorticoid and mineralocorticoid biosynthesis, respectively. ►[Linkage](#) analysis in a large ►[pedigree](#) localized the responsible gene to chromosome 8q, precisely at the site where the genes for 11

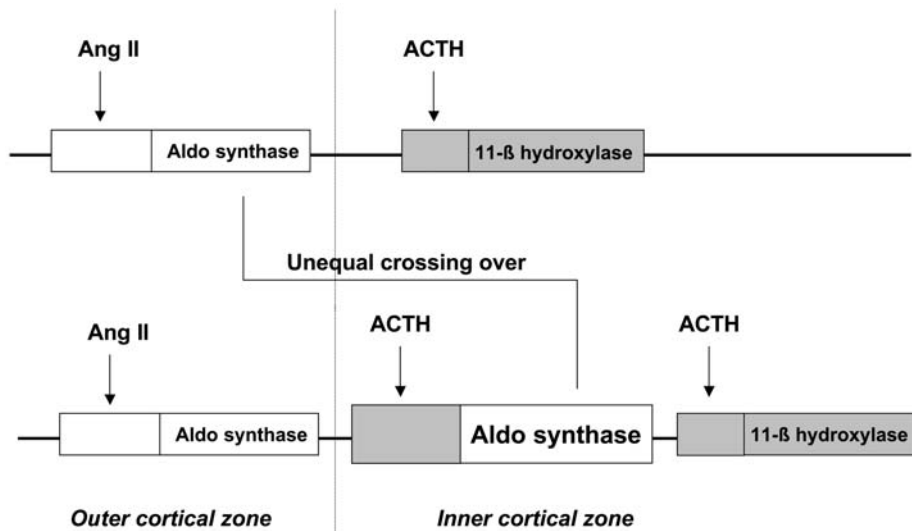

β -hydroxylase and aldosterone synthase also reside. In affected individuals, a chimeric gene consisting of the promoter-regulatory region of 11 β -hydroxylase and the structural portion of aldosterone synthase is located between CYP11B2 and CYP11B1. The chimeric gene results from a meiotic mismatch and unequal crossing over (Fig. 1). The protein product performs all reactions required for aldosterone production; however, the protein is ACTH rather than angiotensin (Ang) II-dependent. Ectopic expression of this protein in the inner cortical zones permits the formation of 18-hydroxy- and 18-oxo-cortisol, the biochemical hallmarks of GRA. Finally, suppressing steroidogenesis in the inner cortical zones with exogenous glucocorticoids alleviates the hypertension.

Liddle's Syndrome

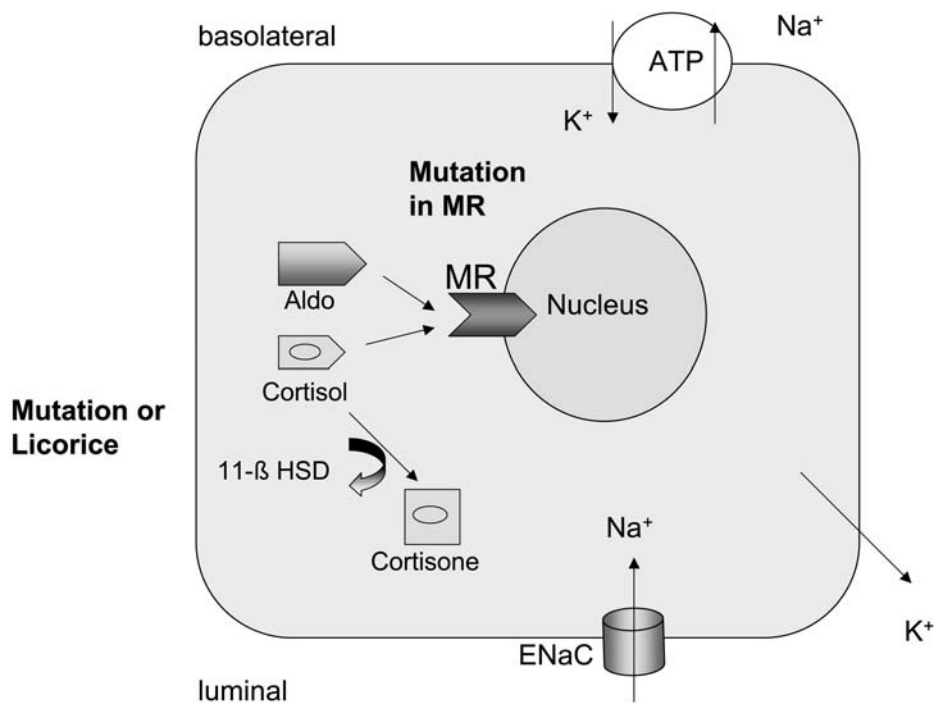

Liddle described patients with autosomal dominant Mendelian hypertension who also tended to metabolic alkalosis with hypokalemia. His patients had low renin and low aldosterone values; however, they did not respond to spironolactone, while thiazides and triamterene reduced the blood pressure. This observation convinced Liddle that they probably did not have a form of mineralocorticoid excess. Liddle speculated that they would show a distal tubular defect of enhanced sodium and chloride reabsorption. A renal transplant performed on a patient with ►[Liddle's syndrome](#) who developed renal failure cured the disease, providing strong evidence that the problem resided within the kidneys rather than in a humoral regulatory system. The responsible gene in a family with Liddle's syndrome was assigned to chromosome 16p. The gene encodes the β -subunit of the epithelial sodium channel (ENaC). The channel is amiloride and triamterene sensitive, explaining the efficacy of these drugs in the syndrome. The channel remains inappropriately permeable even in the face of high salt intake, thereby explaining the salt sensitive hypertension. The molecular mechanisms of Liddle's syndrome involve alteration or deletion in the cytoplasmic tails of the β - or γ -subunits. As a consequence, the channels are not internalized (clathrin-coated pits pathway) or degraded (Nedd4 pathway) and instead remain activated on the cell surface.

Apparent Mineralocorticoid Excess (AME)

Genetic AME resembles the syndrome observed in persons ingesting large amounts of licorice. Licorice gluttony and treatment with carbenoxolone both cause a volume expansion, low renin, low aldosterone, salt-sensitive form of hypertension, which may also feature metabolic alkalosis and hypokalemia. Interestingly, the hypertension responds to both thiazide and spironolactone, but no abnormal steroid products are present in the urine. Both licorice and carbenoxolone contain

Mendelian Forms of Human Hypertension and Mechanisms of Disease. Figure 1 A chimeric gene is formed by meiotic mismatch and unequal crossing over with the promoter region of the 11-β hydroxylase gene (dark box) and the coding region of the aldosterone synthase gene (white box). As a result, the aldosterone synthase gene is under control of ACTH in the inner cortical zone. Aldo, Aldosterone; Ang II, Angiotensin II.

Mendelian Forms of Human Hypertension and Mechanisms of Disease. Figure 2 Cortical collecting duct cell: The mineralocorticoid receptor (MR) has the same affinity for cortisol as for aldosterone (Aldo). The enzyme 11-β hydroxysteroid dehydrogenase (11-β HSD) “protects” the MR by metabolizing cortisol to cortisone, which has no affinity. A mutated or an inhibited enzyme results in an increased intracellular concentration of cortisol and an increased activation of the MR. Mutated MR can result in an altered configuration so that the MR is activated by sterols not containing a 21-hydroxyl group. Increased MR activity causes enhanced Na⁺ reabsorption (ENaC, Na-K-ATPase) and K⁺ excretion.

glycyrrhetic acid, which inhibits 11 β -hydroxysteroid dehydrogenase. The enzyme is responsible for converting cortisol to cortisone. In the distal renal tubule, this step is crucial for protecting the mineralocorticoid receptor, which has the same affinity for cortisol as for aldosterone. This step protects us all from developing AME. Inhibition of 11 β -hydroxysteroid dehydrogenase results in AME. Interestingly, AME may also occur as a rare, autosomal recessive form of hypertension. The 11 β -hydroxysteroid dehydrogenase gene, which has a renal-specific isoform, was a hot [▶candidate gene](#) for this condition. The clinical clues included volume dependent salt sensitive hypertension, tendency to hypokalemia and metabolic alkalosis, low renin and low aldosterone values, responsiveness to both thiazides and spironolactone despite absence of aldosterone or any abnormal mineralocorticoid products and resemblance to licorice gluttony. In 8 of 9 families, mutations in the renal-specific isoform gene for 11 β -hydroxysteroid dehydrogenase were found which indeed rendered the product incapable of converting cortisol to cortisone (2) (Fig. 2). Thus, the mineralocorticoid receptor is unprotected from cortisol in these patients and cortisol functions to occupy the mineralocorticoid receptor.

Mineralocorticoid Receptor

A new Mendelian form of hypertension caused by an activating mutation in the mineralocorticoid receptor was revealed by screening for mutations in the mineralocorticoid receptor in seven unrelated patients referred for possible monogenic hypertension. A mutation in heterozygous state at codon 810 in the mineralocorticoid receptor gene results in a leucine for serine substitution. This residue lies in the hormone-binding domain. The index case had severe hypertension, as did four relatives. Four other relatives had no hypertension. Affected persons all exhibited the leucine for serine substitutions, had low plasma renin activities and low aldosterone concentrations. Since the phenotype resembles Liddle's syndrome, the presence of ENaC mutations had to be ruled out. It was speculated that the mineralocorticoid receptor gene mutation is an activating mutation in the receptor. Interestingly, affected women exhibit worsening hypertension during pregnancy, suggesting that progesterone occupancy of the receptor results in activation rather than inhibition of aldosterone-like effects. Similarly, spironolactone makes the blood pressure elevation worse. The consequences of the mutation MR-S810L allow mineralocorticoid receptor activation by steroids lacking 21-hydroxyl groups (3). The L810 residue in helix 5 of the ligand-binding domain makes a new van der Waals interaction with A773 in helix 3. This interaction eliminates the requirement for the 21-hydroxyl group of aldosterone to interact with N770 in helix 3. The

Mendelian Forms of Human Hypertension and Mechanisms of Disease. Figure 3

Distal nephron: The thiazide-sensitive Na, Cl cotransporter is over-active in pseudohypoaldosteronism type 2. As a result, less Na⁺ is available for the ENaC and fewer K⁺ and H⁺ ions are excreted in the cortical collecting duct. Therefore the syndrome features volume expansion, hypertension, hyperkalemia and mild hyperchloremic metabolic acidosis. "With-no-lysine" (WNK) kinase 4 down-regulates the cotransporter. When the kinase is mutated, the cotransporter is hyperactive. WNK1 regulates WNK4 downward. Gain-of-function mutations in WNK1, would down-regulate WNK4, causing cotransporter hyperactivity.

modification explains why compounds that are normally antagonists now are agonists for the receptor.

▶Pseudohypoaldosteronism Type II (PHA Type II)

PHA type II ([▶Gordon's syndrome](#)) is characterized by familial hypertension with hyperkalemia, slight hyperchloremic metabolic acidosis and otherwise normal renal function. Thiazide diuretics are highly effective in this syndrome, commensurate with salt sensitivity. Multilocus linkage analysis yielded a lod score of 8.1 for linkage to chromosomes 1q and 17p. Interestingly, the chromosome 17p locus overlaps with a syntenic interval in the rat that contains a blood pressure quantitative trait locus. Two genes cause pseudohypoaldosteronism type II (4). Both genes encode members of the WNK family of serine-threonine

Mendelian Forms of Human Hypertension and Mechanisms of Disease. Figure 4 Hand roentgenogram of a 6 year-old Turkish boy with autosomal dominant hypertension (blood pressure 150/90 mmHg) and brachydactyly type E is shown. The white arrow indicates the shortened metacarpal bones, which define this form of brachydactyly. The phalanges are also shortened. Additionally, cone shaped epiphyses are present (marked by arrowhead in the right panel).

kinases. Disease-causing mutations in WNK1 are large intronic deletions that increase WNK1 expression. The missense mutations in WNK4 cause loss of function. The mutations cluster in a short, highly conserved segment of the encoded protein. Both proteins are expressed in the distal nephron (kidney). WNK1 is cytoplasmic, while WNK4 localizes to tight junctions. The *Xenopus* oocyte system was used to show that WNK4 suppresses the thiazide-sensitive sodium chloride cotransporter (5). However, WNK4 does not interfere with cotransporter protein synthesis. Instead, the cotransporter is not incorporated into the cell membrane and cannot come to the surface. WNK1 expression, on the other hand, prevents the WNK4 suppression of the cotransporter. Thus, the WNK kinases serve as a sodium regulatory pathway in the distal nephron (Fig. 3). ▶ **Gain-of-function mutation** in WNK1 would result in highly active cotransporter function. Loss of function mutation in WNK4 would have the same effect.

Autosomal Dominant Hypertension with Brachydactyly

Affected family members with this syndrome featuring ▶ **brachydactyly** type E, have a dramatic increase in blood pressure with age and die before the age of 50 years from multiple strokes. The gene(s) responsible

were mapped to chromosome 12p (6). The hypertension can be easily distinguished from other Mendelian hypertensive syndromes described thus far. The patients are not salt-sensitive and have normal renin, angiotensin, aldosterone and catecholamine responses. By measuring plasma renin activity and plasma aldosterone supine and upright, other conditions can be conveniently excluded. The phenotyping efforts showed that the patients do not respond to any particular form of medication. Beta-blocker, calcium antagonists, alpha-blocker and ACE inhibitor all improve blood pressure without significant differences. A multi-drug therapy is required for the treatment of patients. The mechanism of the hypertension is unknown. However, an additional phenotype was discovered, which may provide a clue, namely anomalous vessels in the posterior fossa that may impinge upon the brain stem. Detailed autonomic testing revealed that the ability of the ▶ **baroreflex** to buffer changes in vascular tone was severely impaired (7). The hypertension could therefore be related to abnormal ▶ **baroreceptor reflex** function in these subjects.

Molecular Diagnostics

Glucocorticoid-remediable aldosteronism can be most easily identified from the clinical picture, response to minimal quantities of glucocorticoids (prednisone 5 mg

daily) or by Southern blot hybridization. Documenting the presence of mutations in the two subunits responsible can show Liddle's syndrome. Apparent mineralocorticoid excess also requires mutation screening of the responsible gene. Only a single mutation in the mineralocorticoid receptor gene has been found to date. Other loci for Gordon's syndrome have been found, but the genes have not yet been identified. Autosomal-dominant hypertension with brachydactyly has a typical type E brachydactyly phenotype. Since the gene(s) are not yet known, we have relied on linkage analysis, cosegregation of microsatellite markers, to obtain confirmatory evidence in additional families.

Mental Retardation

Definition

Mental retardation is defined by the US “Individuals with Disability Education Act” as “...significantly subaverage general intellectual functioning existing concurrently with deficits in adaptive behaviour and manifested during the developmental period that adversely affects a child's educational performance”.

►Fragile X Syndrome

Mesenchymal Stem Cells

Definition

Mesenchymal stem cells are adult stem cells that occur in various organs (bone marrow, skin, adipose tissue), and physiologically regenerate mesenchymal cell types including fibroblasts, muscle, bone, tendon, ligament adipose tissue.

►Stem Cells - Overview

Mesenchyme

Definition

Mesenchyme is the part of the embryonic ►mesoderm that consists of loosely packed, unspecialized cells of mesodermal and ectodermal origin, from which connective tissue, bone, cartilage, and the circulatory and lymphatic systems develop.

►Limb Development

►Lung

Mesoderm

Definition

Mesoderm is the middle embryonic germ layer, lying between the ectoderm and the endoderm, from which connective tissue, muscle, bone, and the urogenital and circulatory systems develop.

►Lung

Mesonephros

Definition

Mesonephros [derived from Greek terms *mesos* – middle; *nephros* – the kidneys] is the second excretory organ formed in the mammalian embryo, caudal to the pronephros. The pronephric ducts become mesonephric or Wolffian ducts in later development. The mesonephric duct portion persists in the adult male as sperm ducts.

►SRY – Sex Reversal

Messenger RNA

Definition

Messenger RNA (mRNA) refers to a ribonucleic acid that is transcribed from one strand of the DNA duplex, into a strand of mRNA by the action of DNA-dependent RNA Polymerase II, and serves as a template for protein synthesis. After transcription, the mRNA is processed, e.g. to excise introns, and then transported to the cytoplasm. There, the ORF (open reading frame) is translated into protein. Only 1–5% of the total cellular RNA is mRNA, the rest is ribosomal RNA, transfer RNA and functional RNA.

Definition

Genetic information flows from DNA to messenger RNA (mRNA) to protein (DNA→mRNA→protein).

The total amount of protein produced by a cell depends upon the efficiency of this information flow, that is (i) the rate of mRNA synthesis from the DNA template (transcription) and (ii) the rate of protein synthesis from the RNA template (translation). This chapter focuses on another critical variable that dictates the amount of protein produced – the stability of the mRNA template. While sometimes underappreciated, this level of regulation is extremely important since the half-lives of eukaryotic mRNAs can vary from a few minutes to more than a day. The decay rates of most mRNAs encoding housekeeping proteins are constant, whereas the half-lives of mRNAs encoding many cell type specific proteins change in response to specific extracellular and intracellular signals. This allows the amount of protein translated from these regulated mRNAs to vary in response to specific circumstances. The regulation of mRNA stability offers several advantages to a cell. First, rapid changes in mRNA stability can permit transient expression of proteins. This is essential in the case of cytokines and proto-oncoproteins, which have undesirable side effects (including developmental defects and lethality) when expressed for long periods. Second, regulation of mRNA stability works together with the regulation of the rate of mRNA synthesis to maximize the flexibility of gene expression. For example, an mRNA that is intrinsically unstable will reach its steady-state level after transcriptional induction more rapidly than will a stable mRNA. Conversely, the templates for many constitutively expressed proteins are stable mRNAs, presumably because this is energetically more favorable for the cell.

Because mRNA stability is a critical variable that determines the amount of protein ultimately produced, a multitude of factors control this event. Below we describe some of the regulatory elements and RNA-binding proteins that dictate both intrinsic and regulated mRNA stability.

Characteristics

Life of an mRNA

The generation of a translationally competent eukaryotic mRNA requires a series of events coordinated by ►RNA polymerase II (Pol II). A 7-methylguanosine-cap structure (►5' cap) is added in a three-step reaction to the 5' end of the mRNA as it emerges from Pol II (1). This reaction is mediated by a guanylyl transferase and a methyltransferase, both of which are bound to the carboxy-terminal domain (CTD) of Pol II. The 5' cap serves to protect mRNAs from decay by impeding 5'→3' exonucleases from processively degrading the 5' end of mRNAs (discussed below). After 5' capping, approximately 200 adenosine residues (a ►poly(A) tail) are added to the 3' end of the mRNA by

polyadenylation factors bound to the Pol II CTD, including poly(A) polymerase (1). Like the 5' cap, the 3' poly(A) tail protects the mRNA from decay. In addition, these 5' and 3' modifications are crucial for efficient mRNA splicing, nuclear export and translation.

After the mRNA 5' and 3' ends are modified, the mRNA is transported to the cytoplasm. In the cytoplasm, the mRNA is thought to form a circle. This circularization is accomplished by a tight interaction between the eukaryotic translation initiation factor 4F (►eIF-4F) and ►poly(A)-binding protein (PABP), which are bound to the 5' cap and the poly(A) tail, respectively. This closed circle conformation stabilizes the mRNA by sequestering the 5' and 3' ends within a multiprotein complex. In addition, this circular conformation may maximize protein production, as it is thought to allow ribosomes to circle around the mRNA many times to mediate multiple rounds of translation efficiently.

Alterations that break the stable mRNA circle lead to mRNA decay. A common means of breaking the mRNA circle is to remove the poly(A) tail. This ►deadenylation event releases PABP from the 3' end of the mRNA, thereby abolishing the interaction of the 5' and 3' ends of the mRNA. Opening of the mRNA circle exposes the mRNA to rapid attack by RNA cleavage enzymes that recognize the 5' and 3' ends of the linearized mRNA (►exonucleases). As discussed below, the speed of deadenylation is a major rate-limiting step dictating the rate of mRNA decay.

Deadenylation

Two deadenylation complexes have been identified in yeast. The first complex, PAN, contains two exonucleases, Pan2p and Pan3p (2). PAN is probably responsible for the initial trimming of the poly(A) tail that occurs in the nucleus. In addition, PAN contributes to complete mRNA deadenylation in the cytoplasm, which ultimately leads to decay of the mRNA body. The other yeast deadenylation complex consists of Ccr4p and Ccr4-associated factor 1 (Caf1p). Evidence suggests that these two proteins form a complex that mediates most of the mRNA deadenylation in the cytoplasm. While repression of either Ccr4p/Caf1p or PAN activity inhibits mRNA deadenylation, inhibition of both activities is required to prevent deadenylation completely. Therefore, these two complexes may have partially redundant functions.

Several deadenylases have been identified in mammalian cells. The best characterized one is ►poly(A) ribonuclease (PARN). So far, a direct homologue of PARN has not been found in yeast. Interestingly, PARN interacts not only with the poly(A) tail but also with the 5' cap. This suggests that binding of PARN with the 5' cap disrupts the interaction between the 5' cap and the

poly(A) tail, thereby opening up the RNA circle, which stimulates both the rate and processivity of deadenylation.

5'→3' Decay

In yeast, 5'→3' decay is the major pathway that degrades mRNA. For 5'→3' decay, the 5' cap must be removed from the mRNA by decapping protein 1 (Dcp1p) (2). However, Dcp1p can remove the 5' cap only after the mRNA has been deadenylated down to a single adenosine residue. Thus, deadenylation and decapping are coupled. After removal of the 5' cap, the mRNA body is degraded by the cytoplasmic 5'→3' exonuclease Xrn1p (Fig. 1). While most yeast mRNAs are degraded in the cytoplasm, for reasons that are presently unclear, some mRNAs are degraded in the nucleus by the nuclear 5'→3' exonuclease Xrn2p (Rat1p).

Mammalian cells also use the 5'→3' decay pathway to degrade some mRNAs, although *in vitro* studies suggest that it is not the major pathway used to degrade most mammalian mRNAs. Like yeast cells, mammalian cells have decapping enzymes (called ►DCP1 and ►DCP2 in humans) that remove the 5' cap from deadenylated mRNAs to make them susceptible to 5'→3' decay. 5'→3' decay is mediated by murine and human homologues of yeast Xrn1p and Xrn2p that have been identified (called ►XRN1 and ►XRN2 in humans).

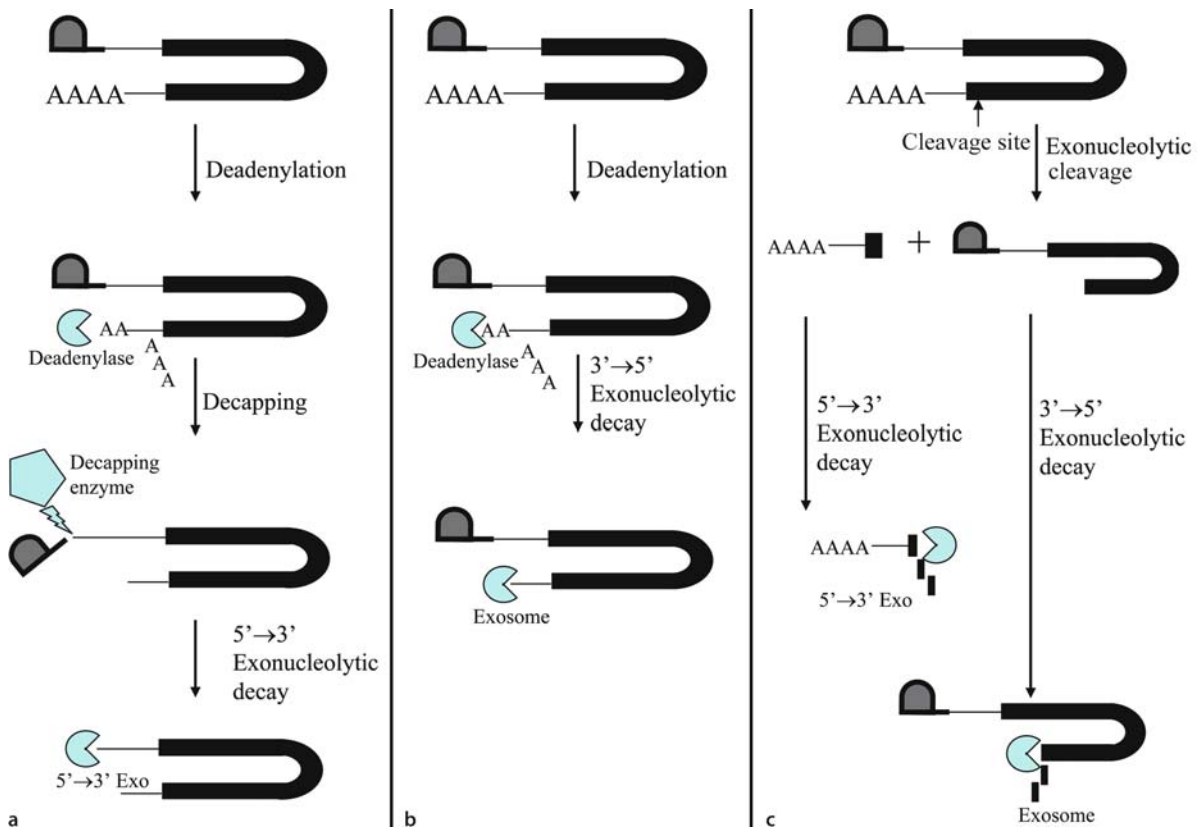

3'→5' Decay

A large ►exosome complex is responsible for 3'→5' decay (Fig. 1). The core exosome is a complex of 10 proteins, most of which are thought to be 3'→5' exoribonucleases. While 3'→5' exonucleolytic decay is the minor ►mRNA decay pathway in yeast, it appears to be the major mRNA decay pathway in mammalian cells (2).

Unlike 5'→3' mRNA decay, exosome-mediated mRNA decay can occur without decapping. However, in some cases decapping may be an obligate downstream consequence of exosome-mediated decay. This decapping is mediated by the scavenger decapping enzyme (►DcpS), which associates with exosome components to form a multi-enzyme degradation complex. The coupling of 3'→5' mRNA decay and decapping, the latter allowing for 5'→3' mRNA decay, provides an efficient and coordinated means of destroying mRNAs.

Endoribonucleolytic Decay

Some mRNAs are degraded by a pathway that is initiated by ►endoribonucleases, enzymes that cleave an mRNA at an internal site. These enzymes generate free 5' and 3' ends so that the mRNA is subject to rapid decay by the 5'→3' and 3'→5' exonucleases just

Messenger RNA Stability. Figure 1 mRNA decay pathways. (a) The 5'→3' exonucleolytic decay pathway. The mRNA is deadenylated, which is thought to open the mRNA circle, thereby exposing the 5' cap to hydrolysis by the decapping enzyme complex. Following decapping, the mRNA is degraded by 5'→3' exonucleases. (b) The 3'→5' exonucleolytic decay pathway. Following deadenylation, the mRNA is degraded by 3'→5' exonucleases present in the exosome. This pathway does not require decapping. (c) The endonucleolytic decay pathway. A site-specific endonuclease cleaves an mRNA at a specific site, which generates free ends that are recognized by 3'→5' and 5'→3' exonucleases, leading to rapid decay of the mRNA body.

described (2). Importantly, the initiation of this endoribonucleolytic decay pathway does not require either deadenylation or decapping (Fig. 1). Examples of mRNAs that are degraded by site-specific endoribonuclease activities are those encoding the growth-promoting proteins *c-myc* and transferrin receptor and the red blood cell protein β -globin. To date, the only mammalian transcript-specific endoribonuclease that has been purified is G3BP, which specifically cleaves between cytosine and adenine residues in the 3' untranslated region (UTR) of *c-myc* mRNA. Although little is known about how endoribonucleolytic decay is regulated, in theory it could be blocked when the cleavage sites are covered by sequence-specific RNA-binding proteins. Conversely, endonucleolytic decay could be reinitiated when the RNA-binding proteins are degraded or removed. Well-studied examples of regulated mRNA decay are described in the next section.

Regulated mRNA Decay mRNA-Stability Regulatory Proteins

The rates of decay of many mRNAs are altered to suit a new circumstance. For example, environmental cues such as stress, growth stimulation and metabolic changes alter the half-lives of many mRNAs. Common mRNA targets of this type of regulation are those encoding cytokines, proto-oncoproteins and growth factors. All of these need to be rapidly increased in levels when there is a need (e.g. to induce cell proliferation or to generate molecules to combat infection). This type of regulation also has the advantage that an mRNA can be quickly degraded when it is no longer needed. If this were not possible, the proteins encoded by these mRNAs could cause serious side effects, including malignancy and anti-host immune activity (i.e. autoimmune disease). One of the most intensely studied classes of elements that regulate mRNA stability is the **▶AU-rich elements**

(AREs). These important *cis* elements are present in the 3' UTRs of proto-oncogene, growth factor and cytokine mRNAs (3). AREs bind to a large group of regulatory proteins, some of which are shown in Table 1, that are collectively called ARE-binding proteins (AUBPs). When bound by their cognate elements, AUBPs alter the stability of the mRNA (Fig. 2). Some AUBPs destabilize their target mRNAs, others stabilize them and still others can either stabilize or destabilize mRNAs, depending on the circumstance. An example of a destabilizing AUBP is tristetraprolin (TTP), which decreases the stability of transcripts encoding the cytokines tumor necrosis factor- α and granulocyte-macrophage colony-stimulating factor. An example of an mRNA-stabilizing AUBP is HuR. Interestingly, HuR not only stabilizes ARE-containing mRNAs but can also promote their translation. AUBPs may also have other functions; for example, HuR may also participate in transporting some ARE-containing mRNA out of the nucleus, as HuR shuttles between the nucleus and the cytoplasm. Exactly how AUBPs regulate mRNA stability is currently under investigation. The AUBPs that promote mRNA decay may act by recruiting the exosome and/or enhancing deadenylation.

The stability of mRNAs can also be regulated by elements other than AREs. These elements can be in the 3' UTR (like AREs), the 5' UTR or the coding region. One of the better-characterized non-ARE elements is in the coding region of the proto-oncogene *c-fos* mRNA. This element, the major protein-coding determinant (mCRD), binds to a complex of at least five proteins, PABP, PABP-interacting protein, hnRNP D, UNR and NS1-associated protein 1 (Table 1) (4). Exactly how the mCRD complex destabilizes *c-fos* mRNA is not known but it must be at least 450-nt upstream of the poly(A) tail to function and it appears to act by promoting deadenylation. Because the mCRD complex contains PABP, one hypothesis is that the complex initially protects mRNAs from decay by sequestering the poly(A) tail from exonuclease attack. Then, after the first round of translation, the ribosome may either displace or reorganize the mCRD complex, thereby exposing the poly(A) tail to exonucleases, which ultimately causes the mRNA to be degraded by the enzymes described in earlier sections.

Nonsense-Mediated Decay (NMD)

Exposure to environmental chemicals and radiation causes DNA mutations, including nonsense mutations and frameshift mutations, both of which can generate ►premature termination codons (PTCs). PTCs also arise because of biosynthetic errors, including errors in transcription and mRNA splicing. Two types of genes that are particularly susceptible to acquiring PTCs are the T-cell receptor and immunoglobulin family genes.

These genes undergo programmed DNA rearrangements that frequently generate frameshifts and thus downstream PTCs (5). The truncated proteins produced from these and other PTC-bearing genes can have dominant-negative or deleterious gain-of-function effects on the cell. These undesirable consequences are prevented or reduced by ►nonsense-mediated decay (NMD), an evolutionarily conserved mechanism that recognizes mRNAs harboring PTCs and degrades them (5, 6).

Two signals are required to elicit NMD. The first signal is a stop codon in frame with the start ATG. In yeast, the second signal is a sequence element found in the 3' end of most *S. cerevisiae* mRNAs. In mammals, the second signal is typically a downstream spliceable intron (5, 6). This second signal serves to restrict the NMD response to mRNAs with premature, not normal, stop codons, as normal stop codons are usually in the 3' terminal exon and thus have no intron downstream. The downstream intron probably does not directly trigger NMD but rather creates a "mark" that is the direct signal eliciting NMD. This mark is a large complex of proteins called the exon junction complex (EJC) that is deposited approximately 20–25 nts upstream of every intron after RNA splicing (Fig. 2). The presence of an EJC after a stop codon triggers NMD, whereas EJCs before the stop codon do not, thereby restricting NMD to mRNAs with PTCs, not those with normal stop codons.

The EJC contains several proteins that have been shown to be essential for NMD, including UPF2 and the nuclear-cytoplasmic shuttling proteins UPF3 and UPF3X (Table 1). UPF2 serves as an adaptor protein that binds to UPF3 and UPF3X, as well as the DEAD-box RNA helicase UPF1 (SMG-2), which also shuttles between the nucleus and the cytoplasm. UPF3X also interacts with Y14, another shuttling EJC component essential for NMD. It remains to be determined how the EJC is assembled, including the order in which its individual components are recruited, as well as exactly how the EJC proteins trigger mRNA decay. Other proteins essential for NMD include SMG-1, -5, -6, and -7, which function in NMD by controlling the phosphorylation status of UPF1 (SMG-1 phosphorylates UPF1, while SMG-5, -6, and -7 promote UPF1's dephosphorylation).

Clinical Relevance

Alterations in mRNA stability can either prevent or promote disease. One example of the former is destabilization of aberrant transcripts harboring PTCs by the NMD pathway (8). NMD reduces the levels of mutant PTC-bearing transcripts encoding truncated proteins with dominant-negative or deleterious gain-of-function activities, thereby improving the phenotype of

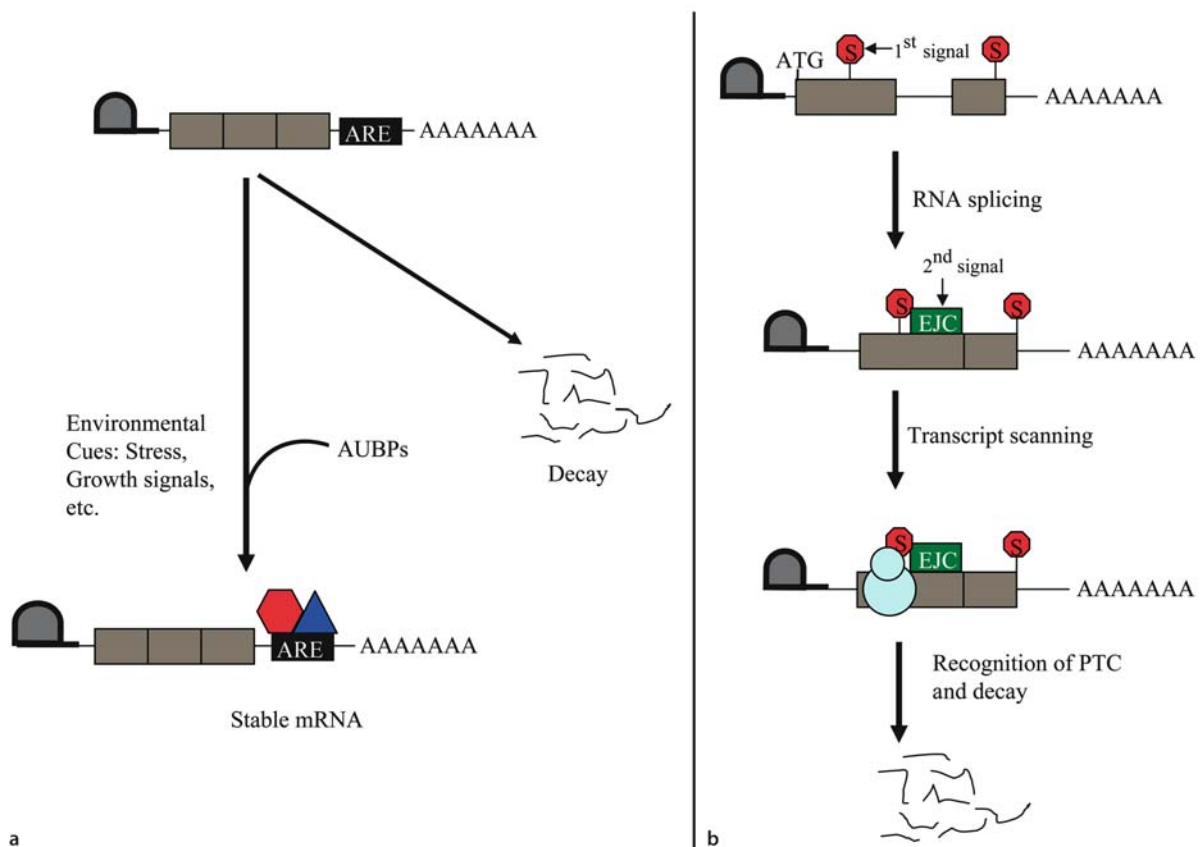

Messenger RNA Stability. Table 1 Factors that mediate or regulate mRNA Decay

Property	Factor	Family	Functions
General	PABP		binds poly(A) tail; promotes mRNA stabilization
	eIF-4F		trimer that binds the 5' cap
	Lsm	Sm-like	required for deadenylation-dependent decay
Nucleases	PARN	RNase D	deadenylase
	PAN (PAN2/3)	RNase D	deadenylase complex
	Caf1p	RNase D	forms complex with Ccr4p
	Ccr4p		deadenylase (catalytic subunit)
	XRN1	Exonuclease	5'→3' exonuclease, cytoplasmic
	XRN2 (RAT1)	Exonuclease	5'→3' exonuclease, nuclear
	Exosome		≥ 10-subunit 3'→5' exonuclease complex
	G3BP	Endonuclease	sequence-specific endonuclease
Decapping	DCP1/DCP2		dimeric complex that hydrolyzes the 5' cap
Regulated mRNA Stability	HuR	ELAV	ARE-binding protein, mRNA stabilizer
	AUF1	hnRNP (D)	ARE/mCRD-binding protein, stabilizer/destabilizer
	TTP	zinc finger	ARE-binding protein, mRNA destabilizer

	UPF3 (SMG4)	unknown	EJC protein, putative 2nd signal for NMD
	UPF3X (UPF3B)	unknown	EJC protein, putative 2nd signal for NMD
	SMG1	PI3-kinase	phosphorylates UPF1
	SMG5	TTP repeats	essential for SMG2 dephosphorylation, associates with PP2A phosphatase
	SMG6	TTP repeats	essential for SMG2 dephosphorylation
	SMG7	TTP repeats	essential for SMG2 dephosphorylation
	Y14	RNA binding	EJC protein that binds to Magoh
	Magoh		EJC protein
	Hrp1p	hnRNP-like	2nd signal that elicits NMD in yeast

many human genetic diseases (5, 6, 8). Disruption of the NMD pathway is embryonic lethal in mice, suggesting that mutations and biosynthetic errors that create dominant-negative or deleterious gain-of-function mutants may be relatively common. There are many cases of mRNA dysregulation that contribute to or cause disease (7). For example, the growth-promoting transcription factor c-myc is over-expressed as a result of mRNA stabilization in some

tumor cell types. This stabilization has been shown to be caused either by mutation of the *c-myc* 3' UTR or by amplification of the gene encoding CRD-BP, a KH-domain protein that binds to and stabilizes *c-myc* mRNA. Another nuclear growth-promoting factor that is over-expressed in tumors as a result of mRNA stabilization is cyclin G1. Rearrangements of the cyclin G1 gene in mantle cell lymphomas cause expression of truncated transcripts that lack AREs and are therefore

Regulated mRNA Decay

Messenger RNA Stability. Figure 2 Regulated mRNA decay. (a) mRNAs containing AU-rich elements (AREs) in their 3' untranslated region are unstable unless environmental cues such as stress, growth factors or antigenic insults cause these mRNAs to be stabilized. ARE-binding proteins (AUBPs) are responsible for regulating the stability of these mRNAs. Some AUBPs elicit mRNA stabilization (shown), while others trigger mRNA destabilization (not shown) (see Table 1). (b) Nonsense-mediated decay (NMD) is a putative RNA surveillance pathway that degrades mRNAs harboring a stop codon at a premature position (a nonsense codon). This RNA decay pathway is triggered when an mRNA contains a stop codon (first signal) followed by the EJC (second signal), a large complex of proteins deposited by the RNA splicing machinery just upstream of exon-exon junctions. Most normal mRNAs only contain a stop codon in the final exon, and thus there is no second signal, rendering these mRNAs impervious to NMD.

stabilized. Secreted factors that stimulate cell growth are also sometimes over-expressed in tumors as result of mRNA stabilization. Examples of this type of dysregulation include transcripts encoding the cytokines IL-1, IL-3, IL-6, GM-CSF and M-CSF. Cytokine mRNA stabilization not only contributes to tumor formation but can also cause inflammation. This has been demonstrated in a transgenic mouse model in which TNF α mRNA stabilization (as a result of removal of the AREs from the 3' UTR) causes chronic inflammatory arthritis and bowel disorders mimicking naturally occurring human conditions. A human disease sometimes associated with

mRNA destabilization, rather than stabilization, is α -thalassemia, a red-blood cell disorder. Naturally occurring mutations in the normal α -globin stop codon cause read-through of ribosomes into the 3' UTR, which dislodges specific RNA-stabilization factors, thereby causing α -globin mRNA destabilization. Dysregulation of mRNA stability is also associated with many other human diseases, including Alzheimer's disease. However, while many of these examples are intriguing, in most cases it remains to be determined whether such alterations in mRNA stability are merely markers of disease or whether they actually cause the disease.

Metabolic Alkalosis

Definition

Metabolic alkalosis refers to disturbance(s) in the acid/basic equilibrium indicated by an increased pH-value above 7.44. It is characterized by an increase of bicarbonate ions, loss of H⁺-Ions (exchange of H⁺ for Na⁺ in the renal tubuli), hypokalemia, endocrine imbalances (hyperaldosteronism), and treatment with corticoids.

Synonyms

Metabolome Profiling; Metabolite Profiling

Definition

Metabolomics is defined as the science of comprehensive monitoring of the metabolic complement in biological systems. In this sense, metabolomics adds the fourth Rosetta stone to the previously developed systems wide approaches towards global analysis of biological processes, such as genomics, transcriptomics and proteomics. Metabolomics encompasses cellular and secreted metabolites of organisms and includes [▶xenobiotic substances](#), when internalised or subject to biochemical conversion. The chemical nature of metabolites comprises low molecular weight gases, volatile compounds, inorganic and organic ions, highly polar to lipophilic substances and biopolymers, except DNA, RNA and proteins. Multi-parallel metabolomic studies will be instrumental in understanding gene function at the metabolic level and will allow insight into the function of the multitude of primary and secondary metabolites. Moreover, metabolome profiles will contribute to unravelling the mode of action of drugs and increase our knowledge about diseases.

Characteristics

Metabolomics is a young field of analytical science in dynamic development. Currently no single technology platform that would allow the multi-parallel analysis of the complete metabolome is conceivable (1). This is in contrast to genome, transcriptome and proteome profiling technologies, which monitor molecules of highly similar chemical properties, such as DNA, RNA and proteins, respectively. Major obstacles in metabolome analyses are the high diversity of substance properties a metabolome analysis has to accommodate and the vast range of metabolite concentrations. These may range from highly abundant, dominating compounds to equally important trace compounds, which may carry biological signals.

Thus the field of metabolomics may be best discussed starting from technology platforms, which are recruited for comprehensive metabolite analysis, through experimental set-up and designs, to major areas of application and appropriate bioinformatics tools for data mining.

Technology Platforms

Technology platforms in metabolomic analysis utilise universal properties of chemical compounds, such as the mass of molecules and molecular fragments, nuclear magnetic resonance, chromatographic interaction and spectrophotometric properties. No single technology will provide sufficient insight into the metabolome. Instead combinations of technologies will be developed, which have a minimum overlap of

assessed metabolites and which are adjusted to the expected composition of the biological sample under investigation. Four aspects of analytical technologies need to be taken into consideration, the [▶sensitivity](#) and [▶dynamic range](#) of quantitative analysis, the [▶selectivity](#) of detection, the speed of analysis and the potential to unravel the chemical identity of metabolites. In general, so-called hyphenated analytical technologies exhibit the highest potential for use in effective metabolomic studies (1, 2). Hyphenated technologies link compound separation technology such as liquid chromatography ([▶HPLC](#)), gas chromatography (GC), or capillary electrophoresis (CE) to highly specific means of detection, such as optical, spectroscopic detectors using infrared (IR), near infrared (NIR) and ultraviolet (UV) wavelength ranges, surface enhanced Raman spectroscopy (SERS) or induced fluorescent detection (LIF), nuclear magnetic resonance ([▶NMR](#)) or [▶mass spectrometry](#) (MS).

Non-Hyphenated Separation Technologies

GC, LC, and CE have longstanding applications in quantitative chemical analysis and are routinely coupled to single wavelength channel detectors. Single channel detector devices are mostly non-selective, i.e. flame ionisation detection (FID) or single wavelength UV detection. For this reason substance identity has to be established by highly specific, laborious and time-consuming pre-purification or chemical derivatisation steps. Extensive pre-processing is in fundamental conflict with the comprehensiveness required in metabolomic analysis. However, such analyses have the potential to provide highly exact quantitative metabolite information about single compounds or a small number of compounds of the same compound class. Multi-dimensional chromatographic methods, like two-dimensional thin layer chromatography (2D-TLC) or two-dimensional gas chromatography (GC-GC), which both exploit differential separation principles in consecutive steps, appear promising.

Non-Hyphenated Detection Technologies

NMR, MS, or spectrophotometric analysis were first applied to highly purified chemical compounds and used for structural elucidation of novel chemical compounds and metabolites. The development of 2D-NMR, multi-dimensional MS (MS^n), and Fourier transform (FT) spectroscopic applications, i.e. Fourier transform infrared spectroscopy FTIR, allows the application of these methods with a minimum of pre-purification required. Thus 2D-NMR, MS^n , and FTIR are under intense scrutiny for direct applications in metabolomic studies. This set-up of metabolome analysis promises high sample throughput due to the high speed of analysis, but is limited by three

fundamental aspects. Firstly, MS does not provide information about the identity or presence of structural isomers. MSⁿ and MS coupled to highly reproducible molecular fragmentation, such as electron impact ionisation (EI), improves this deficiency but ultimately fails at the level of stereoisomers and epimers. Nevertheless, MS allows extremely high selectivity at the level of mass resolution. Technologies range from mass unit resolution provided by bench-top GC-MS systems to the unsurpassed mass resolution and mass accuracy of Fourier transform ion cyclotron mass spectrometry (FT-ICR-MS) (2). Secondly, NMR and 2D-NMR provide exact insight into the conformation of molecules and even allow non-invasive application to living organisms or cell cultures. However, NMR spectra of complex mixtures are difficult to deconvolute into sets of signals that belong to a single metabolite. Signals of trace compounds are often obscured by predominant metabolites. Thirdly, resolution of spectroscopic properties is usually relatively poor. Thus changes in respective spectra, UV, NIR, FTIR or SERS, from complex samples are usually difficult, if not impossible, to relate to changes in specific metabolites.

Hyphenated Technologies

Hyphenated technologies allow one to counterbalance deficiencies introduced by limitations of the chosen separation or detection technologies. Thus hyphenated methods, e.g. HPLC-NMR, HPLC-UV with photodiode array detection (PAD), HPLC-MS, GC-MS, CE-MS, HPLC-LIF or CE-LIF, currently dominate metabolomic technology. Approximate sensitivities of several methods were estimated (1) at 10⁻⁶ mol (NMR), 10⁻⁹ mol (HPLC-UV), 10⁻¹² mol (GC-MS), 10⁻¹⁵ mol (LC-MS) and 10⁻²³ mol (CE-LIF). In general, analytical technologies appear to gain sensitivity at the expense of selectivity. Technologies aimed at highly concentrated compounds allow generic sample preparation, whereas analysis of trace compounds requires more targeted sample preparation and enrichment from higher amounts of sample. Four technologies will be shortly described.

NMR

NMR is least sensitive of the current metabolomic methods, but the only non-destructive technology available for *in-situ* monitoring. In non-hyphenated applications, high automation and sample throughput can be obtained. Hyphenation to HPLC greatly increases NMR potential by successive analysis of HPLC peaks in stop-flow experiments. Gain in sensitivity is at the expense of greatly increased time required for each sample. The focus of HPLC-NMR is the structural elucidation of non-identified metabolites. Especially effective systems in structural elucidation interface HPLC-NMR with MSⁿ.

HPLC-MS

HPLC-MS is one of the most wide spread technologies. HPLC systems aimed at separation of lipophilic as well as hydrophilic compounds are available. However, the separation properties of HPLC result in broad peaks, a high number of co-eluting compounds and comparatively long times of analysis per sample. In addition, the means of ionisation, for example electrospray ionisation (ESI) are subject to severe ion suppression. This effect suppresses signals of co-eluting and easy to ionise compounds. Suppression in ESI leads to artefacts, such as highly variable measurements or even complete loss of signal. The strength of HPLC-MS is the broad scope of metabolites that can be monitored without need of chemical derivatisation and the availability of a range of different MS detectors. Ion trap ESI-MS allows generation of fragmentation pathways for substance elucidation, triple-quadrupole detectors or quadrupole-time of flight detectors are applied in multi-parallel quantitative analysis. Finally, Fourier transform ion cyclotron mass detectors (FT-ICR-MS) combine high mass resolution with accuracy and optional in-source fragmentation for quantitative and structural analysis, unfortunately at very high cost.

GC-MS

GC-MS is the first relatively low cost but high-throughput technology routinely applied in diagnostic metabolite profiling and plant metabolomic studies. GC provides high separation efficiency, which allows ideal separation of complex biological mixtures. However, GC requires samples to be volatile, a requirement which can readily be accommodated by chemical derivatisation. A toolbox of generic as well as highly specific derivatisation schemes is available from the long history of quantitative GC analysis. Hyphenation to electron impact ionisation MS allows highly reproducible mass spectral fragmentation without the occurrence of suppression effects. Quadrupole GC-MS systems are widespread in quantitative analysis; hyphenation to ion trap MS systems allows structural elucidation and analysis of trace compounds. Novel time of flight (TOF) mass analysers allow rapid detection, enhanced automation and increased sample throughput in fast GC-TOF-MS applications (3).

Experimental Design

Two major approaches have become evident in recent metabolomic studies (4).

► Metabolite Fingerprinting

Fingerprinting approaches in metabolomics – the term metabonomics is more frequently used in this context – are aimed at high throughput classification and description of biological samples. Analysis of the changes in detector readings is sufficient for the fingerprinting of

samples. Unravelling the underlying changes in metabolite composition is either optional or performed off-line after isolation of those detector readings that are discriminatory for the types of samples and conditions under investigation. Fingerprints are often performed with minimal sample preparation, direct infusion and analytical systems with fast duty cycles. Applications may be mainly in FTIR, NIR, SERS and NMR.

Metabolite Profiling

In contrast, metabolite profiling requires *a priori* knowledge about metabolite identity. Ideally, known metabolites are monitored by multi-parallel quantification. Quantification may be absolute or – as routinely performed in gene expression profiling – relative to a pre-defined control sample. This multi-targeted quantitative approach may be extended to those components of biological samples that are yet to be chemically identified, but can be reproducibly and unambiguously recognised. Means of reproducible recognition are combinations of molecular features, such as molecular mass, mass spectral fragmentation, chromatographic retention, specific shifts in NMR and optical spectra. Consequently, metabolic profiling is mostly performed with hyphenated technologies, for example HPLC-MS and GC-MS. In these cases separation of isomers by chromatographic interaction ideally complements high resolution mass detection of molecules and identification by mass spectral fragmentation.

Applications and Bioinformatics Tools

Metabolomic studies, even though currently restricted to relatively small portions of the metabolic complement of microbial organisms, plants, animals and humans (see clinical relevance), are applied in descriptive as well as in functional analysis. Descriptive approaches aim at microbial, plant and animal characterization by analysis of the so-called ►**metabolite phenotype** of samples. The focus of interest is the metabolic diversity in different organs under biotic and abiotic stress conditions, as well as changes in response to nutrient availability or upon genetic modification (2, 5). Applied bioinformatics and statistical tools, which support sample description and classification, are hierarchical. K-means cluster analysis, multivariate principal component analysis, self-organizing maps and probability testing (this overview allows the presentation of only a small selection of the multitude of reported bioinformatics applications) are some of the tools used. Metabolomics contributes to functional genomics approaches and is used for comparatively low cost screening of systematic gene silencing or over-expression projects, which can only be performed if supported by customized metabolic databases and access to public genomic and metabolomic databases (1, 2). Analysis of drug and pesticide modes of action

leads to attempts to assign function to metabolites and xenobiotics. These novel multi-parallel approaches are made possible only by metabolite profiling. Changes of metabolite concentrations may now be understood at systems level in interaction with other metabolites or measurements of protein and mRNA levels. Studies start to attempt metabolic and regulatory pathway reconstruction, metabolic modelling using flux studies, metabolite network analysis and large-scale co-response analysis, e.g. the simultaneous change of metabolite, protein or transcript concentrations (1, 2, 6).

Clinical Relevance

Metabolite profiling was first suggested and applied in the field of clinical chemistry, before metabolomics was discovered for the field of functional genomics. Body fluids, especially blood plasma and urine are subjected to chemical screening *via* metabolite profiling technologies. The aim of these studies is to discover novel biomarkers and indicative metabolite patterns for tumour diagnosis and monitoring of reproductive and other human diseases (2). Metabolomic approaches are currently revisited, because metabolite profiling may represent relatively low cost alternatives to proteomic and transcriptomic clinical analysis. In addition recently improved data mining tools, for example automated mass spectral deconvolution and identification software for GC-MS profiles of complex biological samples facilitate metabolome analyses (1, 2, 3). Increased numbers of novel metabolic markers and patterns will improve diagnosis of human diseases, help monitoring of drug treatment and aid therapy. Pharmacokinetic studies, which currently predominantly utilise radioactive tracing of applied drugs, may be complemented by metabolomic analysis for the detection of unexpected side effects in endogenous human metabolism. Drug development may benefit from discovery and characterisation of early pre-clinical and clinical safety markers and markers for clinical efficacy.

Metaphase Plate

Definition

Metaphase plate refers to the plane midway between two spindle poles to which chromosomes align in

► [metaphase](#) cells.

► [Mitotic Spindle](#)

Metastable Disulfide Species

Definition

Metastable disulfide species comprise of a subset of disulfide-protected species, in which both the disulfide bonds and thiol groups are protected, inhibiting all disulfide bond reactions (oxidation, reduction, and reshuffling). Thus, a local or global unfolding step must precede disulfide bond reactions in such metastable species. Two kinds of metastable species exist: disulfide-secure and disulfide-insecure.

► [Protein Disulfide Bonds](#)

Metastasis

Definition

Metastasis describes the ability of tumor cells to leave their site of origin and migrate to other locations in the body, where a new colony is established.

Methylation of Proteins

MARK T. BEDFORD

The University of Texas M.D. Anderson Cancer Center, Science Park – Research Division, Smithville, MO, USA
mtbedford@mdanderson.org

Definition

Proteins can be methylated on the side-chain nitrogens of arginine and lysine residues or on carboxy-termini. Protein methylation is a way of subtly changing the primary sequence of a peptide so that it can encode more information. This process of covalently altering a protein after its synthesis is called posttranslational modification. Apart from methylation, proteins can be posttranslationally modified by phosphorylation, acetylation, ubiquitination, sulfation and hydroxylation. Most of these modifications are on the whole reversible; arginine and lysine methylation is relatively stable.

Characteristics

Protein methyltransferases utilize the methyl donor – *S*-adenosyl-L-methionine (AdoMet) – as a cofactor. Lysine and arginine residues are the primary acceptors of methyl groups within the body of a protein. A smaller group of proteins are methylated at their C-terminal ends, either in the absence of additional modification or after processing.

Arginine Methylation

Arginine methylation is a very common posttranslational modification, that occurs predominantly in the nucleus and the main pool of proteins that are modified

Methylation of Proteins. Figure 1 Chemical structure of the methylated forms of arginine. Arginine residues within different sequence motifs and different substrates are methylated by different protein methyltransferases (PMT). The Type I enzymes catalyze the formation of asymmetric $\text{N}^{\text{G}},\text{N}^{\text{G}}$ -dimethylarginine residues and the Type II enzyme catalyzes the formation of symmetric $\text{N}^{\text{G}},\text{N}^{\text{G}}$ -dimethylarginine residues. N^{G} -monomethylarginine is an intermediate that is generated by both enzyme types.

in such a way are those proteins with RNA binding properties (1). In addition, enzymes that facilitate histone acetylation ([▶CBP/p300](#)) and histones themselves are also arginine methylated – thus implicating this modification in [▶transcriptional regulation](#). The methylation of arginine residues is catalyzed by at least two different classes of protein arginine methyltransferase (PRMT) enzymes (Fig. 1). The Type I enzymes catalyze the formation of asymmetric $\text{N}^{\text{G}},\text{N}^{\text{G}}$ -dimethylarginine (aDMA) residues and the Type II enzyme catalyzes the formation of symmetric $\text{N}^{\text{G}},\text{N}^{\text{G}}$ -dimethylarginine (sDMA) residues. Both enzyme types generate N^{G} -monomethylarginine (MMA) intermediates. In mammals, five Type I enzymes (PRMT1, 3, 4, 6 & 8) and a single Type II enzyme (PRMT5) have been described. Regions of proteins that are methylated are often, but not always, glycine and arginine-rich and are referred to as [▶GAR motifs](#). The direct biological consequences of arginine methylation are at the level of protein-protein interactions. More broadly, arginine methylation has been implicated in a variety of cellular processes, including protein trafficking, signal transduction and transcriptional regulation (1).

Lysine Methylation

Histones are proteins that create a hub around which DNA is wrapped to form [▶chromatin](#). The N-terminal tails of the core histones are exposed, and are targets for posttranslational modification and protein recognition that regulate gene expression. The pattern of modifications on the histone tails is referred to as the “[▶histone code](#)” and different combinations of posttranslational modifications (methylation, acetylation and phosphorylation) are recognized by distinct proteins. Lysine methylation plays a central part in the “histone code”. Most lysine methyltransferases contain an evolutionarily conserved [▶SET domain](#) (named after three *Drosophila* proteins that harbor this domain, Su(var), Enhancer-of-zeste and Trithorax). SET domains possess AdoMet-dependent methyltransferase activity, but are structurally distinct from other AdoMet binding proteins (2). Lysine residues can accept up to three methyl groups forming mono-, di-, and trimethylated derivatives (Fig. 2). Different SET domain-containing proteins possess distinct substrate specificities. For example, SET1, SET7 and MLL methylate lysine 4 (K4) of histone H3, whereas Suv39h1, ESET and G9a

specifically methylate lysine 9 (K9) of histone H3. Methylation at K4 and K9 are mutually exclusive and the consequences of site-specific methylation are diametrically opposed. Methylation at K4 correlates with an active state of transcription whereas methylation at K9 is strongly associated with transcriptional repression and [▶heterochromatin](#). Additional lysine residues on histone H3 (K27 and K36) and histone H4 (K20) are also significant sites of methylation by specific SET domain-containing enzymes. Although the histones are the prime target of lysine methyltransferases, other cellular proteins carry *N*-methyllysine residues including elongation factor 1A and the calcium sensing protein calmodulin.

Prenylcysteine Methylation

Eukaryotic proteins with C-termini that end in a CAAX motif are often subjected to a series of posttranslational modifications. This CAAX-tail processing takes place in three steps. First, a prenyl lipid anchor is attached to the cysteine through a thioether linkage. Then endoproteolysis occurs to remove the last three amino acids (-AAX) of the protein to expose the prenylcysteine α -COOH group. Finally, the exposed prenylcysteine group is methylated. The targeted disruption of the methyltransferase for mouse CAAX proteins, isoprenylcysteine carboxyl methyltransferase (ICMT), resulted in mid-gestation lethality (3), thus emphasizing the importance of this modification. The biological function of prenylcysteine methylation is to facilitate the targeting of CAAX proteins to membrane surfaces within cells. Prenylcysteine can be demethylated and this reverse reaction is catalyzed by isoprenylcysteine carboxyl methyltransferases (ICME). CAAX box containing proteins that are prenylcysteine methylated include Ras, GTP-binding proteins, nuclear lamins and certain protein kinases. Many of these proteins participate in cell signaling, and they utilize prenylcysteine methylation to concentrate them in two dimensions on the cytosolic surface of the plasma membrane where they are functional. It has been hypothesized that [▶small molecule inhibitors](#) of ICMT will retard the growth of tumors caused by activated Ras by restricting its

cellular localization to the cytosol and effectively incapacitating the oncogene, but such drugs have yet to be developed.

Protein Phosphatase 2A Methylation

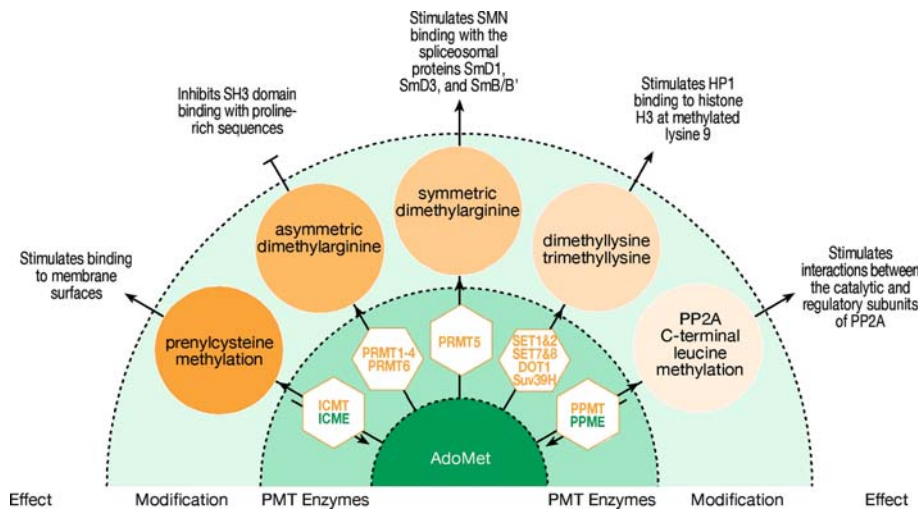

In eukaryotic cells, phosphatases catalyze the removal of phosphate groups from tyrosine, serine and threonine phosphoproteins. The catalytic subunit of the major serine/threonine phosphatases, PP2A, is covalently modified by the reversible methylation of its C-terminus to form a leucine carboxy methyl ester. Unlike CAAX motif methylation, no C-terminal processing is required to facilitate methylation. This C-terminal methylation event regulates the recruitment of regulatory proteins into PP2A complexes through the stimulation of protein-protein interactions, thus indirectly regulating the activity of the PP2A complex (4). Methylation is catalyzed by a unique protein phosphatase methyltransferase (PPMT). The methyl group is removed by a specific protein phosphatase methyltransferase (PPME). These two opposed enzymes make PP2A methylation a dynamic process that fluctuates during the [▶cell cycle](#) and in response to stimuli like cAMP.

L-Isoaspartyl Methylation

As proteins age within a cell they undergo spontaneous damage, including the formation of isoaspartyl peptide bonds. The accumulation of isoaspartyl within proteins is deleterious to the cell as it causes protein instability, loss of biological activity and stimulation of autoimmune responses. A methyltransferase dependent pathway exists for the conversion of L-isoaspartyl back to L-aspartyl. The spontaneous time/age-dependent degradation of L-aspartyl residue results in the formation of a succinimidyl intermediate. This intermediate is spontaneously hydrolyzed either back to L-aspartyl or, in a more favorable reaction, to abnormal L-isoaspartyl. To prevent the accumulation of L-isoaspartyl, this residue is methylated by the protein L-isoaspartyl *O*-methyltransferase (PIMT), which catalyzes the formation of a methyl ester, which in turn is converted back to a succinimidyl intermediate (5). Loss

Methylation of Proteins. Figure 2 Chemical structure of the methylated forms of lysine. Lysine residues within different sequence motifs and different substrates are methylated by different SET domain containing protein methyltransferases (PMT). Lysine residues can be mono-, di-, and trimethylated.

Methylation of Proteins. Figure 3 Graphic depiction of the broad spectrum of biological effects caused by protein methylation.

and gain of function mutations have unmasked the biological importance of PIMT in age-related processes. Mice lacking this enzyme die young as a result of fatal epilepsy, whereas flies engineered to over-express PIMT exhibit an increase in life span of over 30%.

Functional Importance of Protein Methylation

Regulation of Protein-Protein Interactions

A common theme with methylated proteins, as is also the case with phosphorylated proteins, is the role this modification plays in the regulation of protein-protein interactions (Fig. 3). The arginine methylation of proteins can either inhibit or promote protein-protein interactions depending on the type of methylation. The asymmetric dimethylation of arginine residues in close proximity to proline-rich motifs can inhibit the binding to ►SH3 domains (6). The opposite effect is seen with interactions between the survival of motor neurons protein (SMN) and the snRNP proteins SmD1, SmD3 and SmB/B', where binding is promoted by symmetric dimethylation of arginine residues in the snRNP proteins (7).

A well-characterized example of a methylation dependent protein-protein interaction is related to the selective methylation of lysine 9, by Suv39h1 on the N-terminal tail of the histone H3 (2). Di- and trimethylation of this lysine residue facilitates the binding of heterochromatin protein HP1. Because HP1 and Suv39h1 interact, it is thought the binding of HP1 to histone H3 is maintained and even allowed to spread along the chromatin. The HP1 protein harbors a ►Chromo domain that is responsible for the methyl-dependent interaction between HP1 and lysine 9 of histone H3. It is likely that additional Chromo domain

containing proteins will bind the same site as HP1, as well as to other lysine methylated positions on histones H3 and H4.

C-terminal methylation has also been implicated in the regulation of protein-protein interactions. The methylation of the protein phosphatases 2A (PP2A) catalytic subunit enhances the binding of the regulatory B subunit and facilitates PP2A holoenzyme assembly (4). Although the posttranslational addition of methyl groups to amino acids does not alter the charge of the modified residue, it does add one to three fairly bulky groups that are used for structural recognition by protein domains and protein folds.

Clinical Relevance

Myelination

Human myelin basic protein (MBP) is symmetrically dimethylated at arginine 107. The methylation of MBP is involved in the maintenance of myelination—the process that insulates axons—carried out by the plasma membrane of a Schwann cell. Arginine methylation augments the interaction between MBP and myelin lipids. A shortage of vitamin B₁₂ causes a decrease in AdoMet levels and an ensuing reduction in methylated MBP, which in turn results in demyelination. Thus, the arginine methylation of MBP is central for the formation and maintenance of compact myelin.

Spinal Muscular Atrophy

Mutations in the survival of motor neurons (SMN) protein cause the neuromuscular disease—spinal muscular atrophy. SMN is involved with the assembly of RNA-protein complexes called small nuclear ribonucleoproteins (snRNPs). snRNPs play a key role in the ►splicing of nuclear pre-mRNA in eukaryotes.

Methylation of Proteins. Figure 4 The activated methyl cycle. The numbers represent enzymes: 1 – methionine adenosyltransferases, 2–AdoMet-dependent methyltransferase, 3–AdoHcy hydrolase, 4–betaine homocysteine methyltransferase, 5–methionine synthase. With elevated homocysteine levels the orange pathway becomes more active.

SMN binds the spliceosomal core proteins SmD1, SmD3 and SmB/B', and this binding is contingent on the symmetric methylation of arginine residues in the C-terminal regions of these splicing factors. Whether protein methylation levels play a role in spinal muscular atrophy has yet to be determined.

Regulation of Nitric Oxide Synthases

Nitric oxide (NO), which is synthesized by nitric oxide synthase (NOS), plays multiple roles in the cardiovascular system. L-arginine is the substrate for endothelial NO generation. The arginine analogues, N^G -monomethylarginine (MMA) and asymmetric N^G, N^G -dimethylarginine (aDMA), but not symmetric N^G, N^G -dimethylarginine (sDMA) (Fig. 1), inhibit the activity of NOS. Proteolysis of methylated proteins provides the cellular source of free methylarginine residues. This methylarginine pool size is controlled by at least two dimethylarginine dimethylaminohydrolase (DDAH) enzymes, which specifically hydrolyze MMA and aDMA but not sDMA. The NOS inhibitory properties of free methylarginine are thus under tight enzymatic control.

Cancer

Arginine and lysine methylation play a central role in the regulation of transcription. The arginine methyltransferases, PRMT1 and PRMT4 are transcriptional coactivators of nuclear steroid receptors (►nuclear hormone receptors) and as such are involved in hormone

responsive tumor progression. With regard to lysine methylation and SET domain containing proteins, the best link to cancer has been established by translocations at the *MLL1* locus. The *MLL1* protein contains a SET domain, and ►chromosomal translocations involving the *MLL1* gene occur in about 80% of infant leukemias. Another SET domain containing protein, *RIZ1*, has been implicated in a broad spectrum of human cancers. The *RIZ* gene maps to the distal short arm of chromosome 1, a region that is often rearranged in cancers. On a molecular level, frameshift and missense mutations of *RIZ1* have been found in human tumors, and reduced *RIZ1* expression is associated with many types of cancer. The many associations between protein methylation and cancer are consistent with these enzymes playing important regulatory roles in the cell.

Hyperhomocysteinemia

Hyperhomocysteinemia is caused by disturbances of the methyl cycle (Fig. 4), which is responsible for the conversion of homocysteine into methionine and then the generation of the methyl donor—S-adenosyl-L-methionine (AdoMet). Methylation reactions that use AdoMet as a co-factor produce a methylated product (proteins, DNA, RNA, lipids, polysaccharides or small molecules) and S-adenosyl homocysteine (AdoHcy). AdoHcy is then broken down by AdoHcy hydrolase into adenosine and homocysteine. If the remethylation of homocysteine is blocked, then accumulated homocysteine will drive AdoHcy hydrolase to synthesize

AdoHcy in an energetically favorable reverse reaction (Fig. 4, highlighted in orange). AdoHcy is a potent product inhibitor of cellular methyltransferases and its elevated levels result in hypomethylation of a broad spectrum of substrates. Epidemiological and clinical studies have identified hyperhomocysteinemia as a risk factor for heart disease, neurodegenerative diseases (like Alzheimer's disease) and neural tube defects. Elevated levels of homocysteine can be caused either by enzyme perturbations at the genetic level or by vitamin deficiency.

Microarray Data Analysis

ALVIS BRAZMA

European Bioinformatics Institute, European Molecular Biology Laboratory Outstation-Hinxton, Cambridge, UK
brazma@ebi.ac.uk

Definition

Understanding and utilizing massive amounts of data generated by microarray experiments require the use of a variety of nontrivial data analysis methods. Microarray data can help in understanding gene function and regulation, in finding the differences between normal and diseased states of a living system and in understanding the disease mechanisms. The choice of a particular data analysis method depends on the type of microarray used and on the goals of experiment, such as studies of gene expression, protein-DNA binding locations, genome rearrangements or single nucleotide polymorphisms.

Characteristics

There are two relatively well-defined parts in microarray data analysis. The first part, the raw data analysis, transforms the digital images generated by microarray hybridisation scans into measurements such as gene expression levels. The second, the higher-level analysis, aims at finding new insights into the biological processes studied in the respective experiments by analysing these measurement data. The first part mostly depends on the particular microarray platform used in the experiment, while the second depends on the goal of the experiment. To describe microarray data analysis methods first we need to consider how data is generated.

Data Generation

► **Microarrays** are a common name for a variety of technologies; here we will concentrate exclusively on ► **DNA microarrays**. These are used to measure the absolute or relative abundance of DNA or RNA molecules of different nucleotide sequences in a mixture (sample) of such molecules. There can be tens of thousands of features (spots) on such an array, each containing a large number of identical or related DNA molecules of lengths from about twenty to hundreds of nucleotides. After hybridising the sample to the array, by the rules of preferential binding each molecule in the sample will tend to bind to the spot on the array containing DNA of complementary sequence. If the molecules in the sample are labelled for detection, e.g. by fluorescent dyes, then the abundance of the molecules bound to a particular spot can be assessed by measuring the fluorescence intensity at the particular location on the array. Consequently, if we know the DNA sequences on the array, we can estimate the abundance of different molecules in the sample, which in turn can be used for measuring gene expression levels.

In practice the relationship between the fluorescence intensity, which we can measure directly and the abundance of a given DNA molecule is not straightforward.

Many technology specific features have to be taken into account in data analysis to transform the first value into the second. To improve the measurement accuracy, instead of measuring the molecule abundance directly, microarrays are often used for comparison of two samples, or of a sample to a control (for instance a sample from a diseased tissue can be compared to a normal one). In this case the sample and the control molecules are usually labelled with different fluorescence dyes, for example a red dye (Cy5) for the DNA from the sample and a green dye (Cy3) for the control. By measuring both intensities for each spot and calculating the intensity ratio, we can tell whether a particular molecule is abundant in the sample or in the control. This approach is known as ► **two channel microarrays**.

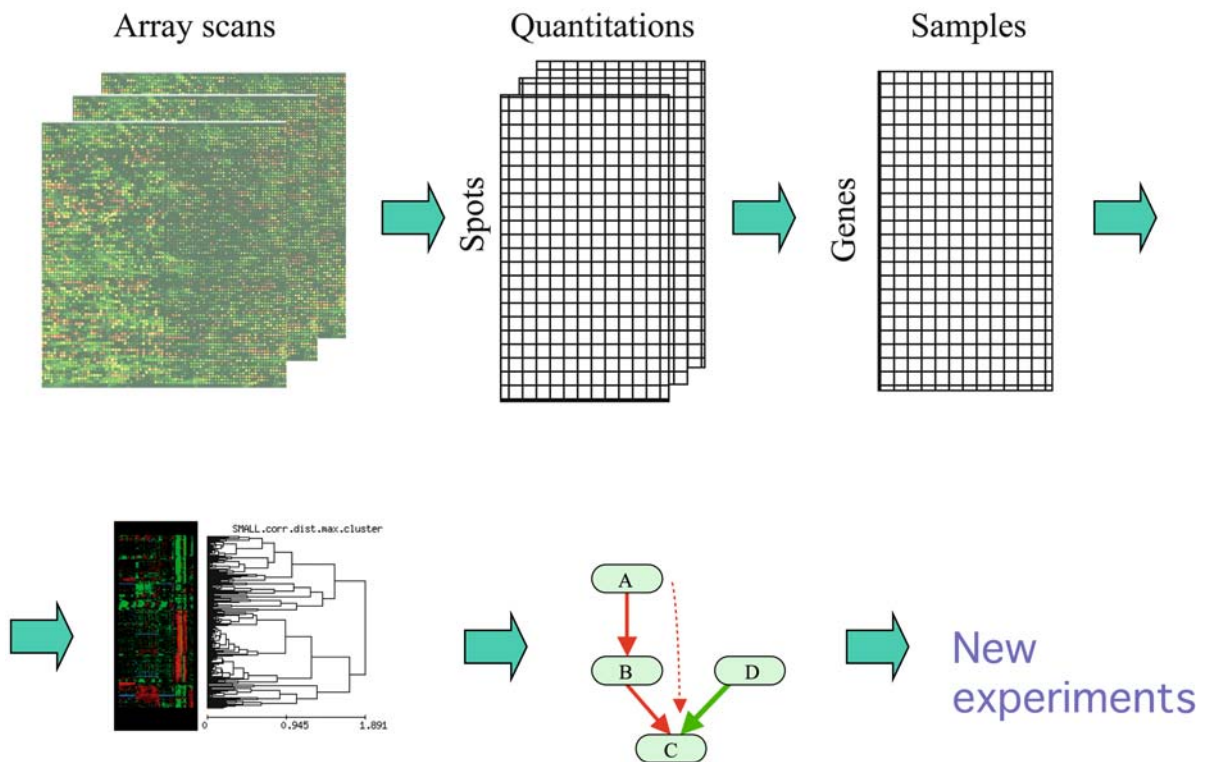

Alternatively each DNA sequence to be measured can be represented on the array by a set of different fragments, some of which may contain ► **mismatch nucleotides**. Comparing the intensities for perfect and mismatch sequence spots, the abundance of particular DNA molecules can be assessed. The popular Affymetrix GeneChip(technology exploits this principle. The exact methods of raw data analysis will obviously depend on the particular technology type.

Microarray data generation results in a digital image obtained by scanning the hybridized arrays. In fact, a microarray experiment will usually consist of a series of hybridizations, producing a series of images. For instance, if the goal of the study is to compare the gene expression in different cell types, the experiment will produce a set of images, one (or several) for each cell type. This set of images will be the starting point for data analysis (Fig. 1).

For simplicity, from now on we will assume that we are dealing with data from two channel microarrays used in gene expression studies, unless stated otherwise.

Raw Data Analysis – from Hybridisation Images to Gene Expression Data Matrix

First we have to transform each image into a numeric representation, which we call the spot quantitation matrix. In this matrix, each row represents a spot (feature) on the array, while each column represents a particular quantitation type, such as the mean of the pixel intensities in a spot, the median, the standard deviation or the mean (median) intensity of the pixels in the local background, as well as various spot quality indicators. This transformation step is performed by ► **image analysis** software, which identifies and delineates each spot on the array and extracts from each spot a set of quantitations (values). Various free and commercial microarray image analysis software packages exist; most of them produce from about 10–20 different values per spot.

Microarray Data Analysis. Figure 1 The starting point for microarray data analysis is a set of images from microarray scans. The first step is to transform each image into a spot quantitation matrix, where each row corresponds to one spot on the array, while each column contains different spot characteristics. The next step is to summarize these matrices in a gene expression matrix, where each row represents a gene, each column represents a particular experimental condition and each position in the matrix characterizes the expression level of a particular gene under particular experimental conditions. This completes raw data analysis. The analysis steps are rather variable, depending on the particular goals of the experiment, but typically they involve the reduction of the dimensionality of the data, e.g., by hierarchical clustering and trying to understand the biological mechanisms underlying the system under study. This may lead to new hypotheses, which can be verified in new experiments.

The spot quantitation matrix is the starting point for the next data transformation step, which has to summarize the set of spot quantitation matrices into one [gene expression data matrix](#). Note that a gene can be represented by several features on the array, containing the same or different sequences, while the same experimental condition can be studied on several arrays. In the gene expression matrix, each row represents a gene (as opposed to a feature on the array), each column represents a particular experimental condition and each position contains one or more quantities characterizing the abundance of the particular gene product. For two channel technologies the ratio or a logarithm of the ratio of such abundances are often used. Ideally we would also like to have one or more additional quantities, characterizing the estimated error level or the reliability of the particular data point. To transform fluorescence intensity measurements into related nucleotide abundances, we have to remove systematic noise originating from a variety of sources.

Different arrays may have different amounts of DNA on different spots; moreover the arrays may have imperfections introducing a noise component dependent on the location on the array. The behavior of different dyes may be different in altering the nucleotide hybridization kinetics, in the response to scanning and in other factors. The transformations that correct for the systematic noise and derive the abundance measurements are known as [data normalisation](#) (1).

The data normalisation methods can be based either on external controls (specific control features spotted on the array in combination with control molecules added to the sample) or on making various assumptions about the measurement data itself. One of the most popular assumptions used is the equality of the total amount of nucleic acids hybridised in all the samples. Such assumptions may or may not be reasonable for the particular experiment and one has to be careful in applying them. Among the most popular normalisation

methods is the locally weighted linear regression Lowess. Variance stabilising normalisation methods are now gaining popularity and have the advantage of being based on a general well-defined model. External control based normalisation is necessary in some cases, particularly if we do not know how the total amount of nucleic acid changes in the sample.

In addition to normalisation, there are different transformations we may wish to apply to the data either before, during or after the normalisation. For instance, we may wish to retain only the ratios that are obtained from spots with a fluorescence signal higher than a given threshold. Such filtering may result in missing data points, which we may need to impute from other related measurements. Sometimes we may want to discretize the measurements from continuous values into discrete ones, such as 'expressed', 'not expressed', 'up-regulated', 'down-regulated' or 'marginal'. Various nontrivial statistical methods have been developed to make such discretization meaningful.

There are a number of free and commercial software tools available for raw data analysis. We mention only a few here, since these tools are rapidly developing and new ones are becoming available. At this time, one of the most popular free image analysis software packages is ScanAlyze from Stanford University and MIDAS from TIGR. Bioconductor is an open source software library, which is popular for data normalization.

Higher Level Analysis – Extracting Biological Meaning from Data

The gene expression matrices contain information about gene expression levels under different conditions. We can use such a matrix to look for groups of genes that have similar expression profiles, i.e. that are expressed under similar experimental conditions in a similar way, and then predict the function of unknown genes in the group from the known ones. If a comparison between diseased and healthy states is the goal of the experiment, we can look for the genes that are differentially expressed in these two conditions, map this information onto the known metabolic or signalling pathways and try to derive new hypotheses about the disease mechanisms.

The size of the gene expression matrices is usually too large for a human researcher to study genes individually (for instance, for a human microarray there can be over 25,000 rows in the matrix – a row per gene). Therefore automated data analysis methods have to be used first. These methods can be roughly classified into two categories – supervised and [unsupervised analysis](#) methods (2).

The goal of unsupervised data analysis is to effectively reduce the dimensionality of gene expression data matrix to a manageable size. For instance hierarchical or other [clustering](#) methods are used to group genes

of similar expression profiles. Coupled with visualizing the gene expression matrices in colour coded expression intensity maps (3), these methods provide a powerful tool for reducing thousands of profiles into several clusters characterizing the patterns of behavior (Fig. 2). To apply clustering methods, first we need to define a measure of similarity or distance between expression profiles. Each expression profile can be treated as a vector in a multidimensional space, therefore distance measures developed for vectors, such as Euclidian or correlation distance, can be used. Alternative unsupervised analysis methods are the principal component and correspondence analyses. Specialized methods, such as auto-correlation or Fourier analysis, can be applied to time-series data.

After reducing thousands of profiles into a few clusters of genes exhibiting 'interesting' expression behavior, a human investigator can study these genes in the context of prior knowledge to draw conclusions about the underlying biological processes and propose new, experimentally testable hypotheses. Automated software tools can help in finding clusters of genes sharing the same gene annotation or in analyzing their regulatory regions by looking for shared sequence patterns. Such approaches have been successful, for instance in identifying transcription factor binding sites in yeast.

Supervised data analysis methods exploit our prior knowledge about the genes or experimental conditions right from the beginning. For instance, if we are given a set of gene expression measurements for diseased and healthy samples, we can look for expression values in the matrix that allow the prediction of the 'disease' or 'normal' state of a new sample by its expression profile. This can be used in diagnostics, but moreover, if the predictors can be described by simple rules, these can also help us in understanding the biological mechanisms of the disease. For instance, if we observe that a small subset of genes are highly expressed in the disease state and poorly expressed in the normal state or *vice versa*, these can be hypothesized to be involved in the mechanisms of the particular disease. This approach has been successfully used, for instance, in cancer [classification](#).

There are a number of different techniques used in supervised gene expression data analysis, including linear regression or linear discriminant analysis, nearest neighbourhood analysis, support vector machines, neural networks and decision trees. In principle any [supervised analysis](#) or machine learning techniques can be applied. However it has to be noted, that in gene expression analysis the number of objects that we want to classify (samples) is typically much smaller than the number of parameters that can be used in classification (genes). This situation is driving the development of new data analysis methods.

Microarray Data Analysis. Figure 2 Hierarchical clustering. A gene expression data matrix has been clustered by a hierarchical clustering method, joining genes and groups of genes of similar expression profiles. The 'dendrogram' (hierarchical tree) on the right side of the image shows the order of joining. The left side of the image shows a so-called 'heat map' of the clustered gene expression data matrix, by visualizing the positive values in red and the negative values in green with the brightness representing the intensity of these values.

Automated methods can go beyond simple clustering or classification approaches. For instance the problem of reverse engineering of gene regulation networks has recently become popular. One can build Bayesian networks 'explaining' the gene expression matrices, or networks describing the changes in gene expression measured under different perturbations (such as gene knockouts), or one can use microarrays to study the transcription factor binding locations (microarray based chromatin immunoprecipitation experiments) and build networks of transcription factor interactions (4). Though it is unlikely that reverse engineering of gene regulation networks is possible purely from microarray data, nevertheless these attempts are

providing valuable insights into different properties of gene regulation networks (5).

There exist a large number of commercial and free software tools implementing various analysis methods. Some of the most popular free software tools are Cluster, TreeView and XCluster from Stanford, TIGR MultiExperiment Viewer from TIGR and Expression Profiler from the EBI.

Data Meta-Analysis and Microarray Databases

Microarray experiments are relatively expensive, but on the other hand they generate data that can continue producing new knowledge long after the experiments have been completed. Large, systematic, high quality

datasets are proving to be a valuable resource for the research community, similarly to genome sequence data. ► **Meta-analysis** of such datasets combining them with other relevant datasets and using new analysis methods may bring new insights, which go beyond the scope of the original studies. For instance, the comparison of the expression profiles of homologous genes across a range of organisms can help in predicting the orthologous genes, or comparing similar processes, such as the cell-cycle in different organisms. Gene expression data analysis, supervised or unsupervised, can help a biologist only if in addition to the gene expression data, information about the genes and experimental conditions reflected in the matrix are also provided. For instance, if the goal of the experiment is to study the cell-cycle, we will need to know at which time-points the measurements have been taken and how the cells have been synchronized and grown. We will also need to use the prior knowledge about the genes, such as what are the functions of the known genes, and what are the orthologs of these genes in other organisms. This means that the gene expression data matrix has to be well annotated if it is to be of use to the researchers.

The Microarray Gene Expression Data (MGED) Society has developed a standard for annotating microarray experiments known as the Minimum Information About a Microarray Experiment (► **MIAME**) (6). This has been adopted by most of the major scientific journals as a requirement for publication, and public databases have been recently established, accepting data annotated according to the MIAME standard. ArrayExpress (► <http://www.ebi.ac.uk/arrayexpress>) is such a public repository at the European Bioinformatics Institute. A researcher can ask the database for all the experiments of a given type for a given organism and retrieve the relevant data, which then can be combined with the researcher's own data, or used for designing new experiments. With amounts of microarray data growing, quality improving and new analysis methods being developed, such databases are becoming an essential resource for functional genomics research.

Microarray Technology

Synonyms

Biochip Technology; Gene Chip Technology; DNA Chip-Technology

Definition

Microarray technology describes an analytical procedure that is based on the orderly arrangement of multiple, micron-sized spots of biomolecule probes (i.e. nucleic acids with known sequences such as oligonucleotides, cDNA or genomic DNA) on a carrier (e.g. a glass slide), hybridized with a complex, labelled nucleic acid target in order to identify gene mutations or the expression level (abundance) of genes (RNA). The underlying principle of the procedure is nucleobase-pairing. A single array may represent parts of a genome or the entire set of genes of a given organism/cell. The most common gene expression microarrays fall into two categories: Affymetrix Genechips (a proprietary commercial array using 25 base oligonucleotides probe sets), and spotted DNA microarrays in which long cDNA probes or oligos are deposited and bound to a substrate, usually a coated glass microscope slide.

Synonyms

Colorectal cancer (CRC) is one of the most prevalent cancers in Western Europe and North America. At least 50% of the Western population develops a colorectal adenoma by the age of 70 and in about 1 in 10 of these individuals progression to malignancy ensues (Fig. 1) (1). The prognosis in advanced cases is poor, as more than one-third of the patients will die from progressive disease within five years. Currently, only a small fraction of the patients respond to treatment and its effectiveness is best in early stages of the disease.

The left panel shows normal colonic crypts in transverse section. Epithelial cells are aligned along the basement membrane. The center panel shows the dysplastic morphology typical of an adenoma, a benign lesion. Note the increased nuclear/cytoplasmic ratio, lack of uniform architecture, and many nuclei that are no longer lined up along the basement membrane. The

right panel shows a carcinoma, a malignant lesion that invades the basement membrane and infiltrates the subserosal layer. Cancer cells that migrate to distant locations, in many cases the liver, give rise to metastases. CRC was one of the first major epithelial cancers in which genetic alterations were described to occur in a systematic fashion during disease progression (2). The molecular mechanisms have been under intensive study for the last two decades. Normal cell growth depends on a balanced expression of growth-promoting and growth-suppressing genes. If growth-promoting genes are activated to a state of hyperfunction, either by mutation or quantity, they are termed “oncogenes”, which exert a positive effect on cell growth. One common example is *K-ras*, which is activated in CRC and many other tumors. Growth-suppressing genes are defined as “tumor suppressors” and are commonly lost following Knudson’s “two-hit” hypothesis (loss of one allele and inactivation of the other allele by mutation or promoter methylation). The best-characterized tumor suppressors inactivated in CRC are ► *APC* (*adenomatous polyposis coli*), which is involved in tumor initiation, and *Smad4/DPC4* (*deleted in pancreatic cancer locus 4*) and *p53*, which are involved in tumor progression to the late adenoma and carcinoma stages, respectively. Additionally, abrogation of mismatch repair systems contributes to some colorectal cancers (1). Nevertheless, exactly how those genetic alterations bring about the development and progression of colorectal adenomas to carcinomas remains to be resolved. To complicate the picture, accumulation of other genetic and epigenetic changes can occur, including loss of heterozygosity, gene inactivation, methylation, loss of imprinting and/or gene amplifications, all of which may alter gene expression. Therefore, genome-wide monitoring of gene expression is of great importance to disclose the numerous and diverse events associated with colorectal carcinogenesis.

This is where ► **gene expression analysis using DNA microarrays** comes into play, by making it possible to quantify the expression levels of thousands of genes in a tissue sample in one experiment. Messenger RNAs (mRNAs) are extracted from a biological sample, converted into DNA, labeled with fluorescent dyes, and then washed over a glass slide bearing a grid spotted with DNA sequences from tens of thousands of genes. The labeled sequences bind to spots representing the genes from which the mRNAs were transcribed. By analyzing the location and intensity of the fluorescent signals, one can determine the level of activity for each gene. The expression levels of all genes tested within a sample constitute its ► **gene expression profile**, which is then compared with other tumor or normal tissue expression profiles. In some cases, it is possible to analyze two samples on the same chip by using different colored dyes (3).

Microarrays in Colorectal Cancer. Figure 1 Adenoma-carcinoma sequence in colorectal tumorigenesis.

Definition

An important goal of expression profiling is the molecular [classification](#) of tumors into homogeneous groups that can predict their clinical behavior. The identification of genes whose expression is altered in colorectal cancer compared to normal colon epithelium is of tremendous importance because it may allow a better understanding of pathways that regulate colorectal carcinogenesis and yield new diagnostic biomarkers or targets for therapy.

Characteristics

Gene Expression Analysis in Colon Cancer

Several DNA microarray gene expression studies were undertaken with the aims of differentiating benign from malignant colorectal tumors and learning how the progression from normal tissue through adenoma and adenocarcinoma is mirrored in changes in gene expression (4, 5, 6). In these studies, typically around 20 tumors with paired normal colon were subjected to microarray analysis using high-density oligonucleotide microarrays (4, 5, 6) or complementary DNA microarrays (5). Generally, around 2% of the genes detected on the microarrays differ between tumor and normal colorectal tissue. Many of these changed genes were already known to be abnormally expressed in neoplastic tissue in general, or colon cancer in particular, but a large number had no previously characterized function. The comparison of gene expression data across tumor and normal samples from different studies revealed a large variability, probably representing a combination of assay heterogeneity, true biological difference and different percentages of tumor cells in microdissected samples (Fig. 2) (5) versus bulk tissue (4, 5, 6). The genes presented here showed tumor-specific expression changes in at least two microarray gene expression studies or were confirmed by independent methods (Table 1).

Unsupervised two-way hierarchical clustering performed by Levine et al. successfully distinguished adenocarcinoma from adenoma and normal tissue, generating a tree that appropriately represented the clinical relationship between the three tissue types (Fig. 3) (6). This supports the concept that genome-wide

Microarrays in Colorectal Cancer. Figure 2 Laser-capture microdissection of colon tumors. Tumors are complex tissues containing other cell types such as stroma cells and infiltrating immune cells (top panel). To enrich for tumor cells, they may be microdissected from briefly fixed and stained frozen sections using laser-capture technology. Usually, 5-10,000 cells are collected for RNA isolation (bottom panel). The RNA is subjected to two rounds of linear amplification to yield enough material for microarray hybridization.

expression profiling may permit a molecular classification of adenomas and carcinomas. Indeed, Nakamura and coworkers established a scoring system to separate

Summary of confirmed changes in gene expression identified in three microarray studies analyzing primary tumors (4-6) and one studying metastatic cell lines (7). Genes included in the list were found in at least two studies, were validated by an independent analysis method, or in the literature. Functional annotation for biological process was performed using the SOURCE web search (9).

adenomas from carcinomas based on the expression levels of 50 discriminating genes. Application of this scoring system for evaluating five additional colorectal tumors correctly predicted their histological features (5).

However, many of the expression changes noted in the cancers were presaged by those in premalignant adenomas (4, 5, 6), which is not surprising since adenomas are considered the pathological and genetic precursors to adenocarcinoma of the colon (1). Examples of genes that are upregulated in both adenoma and adenocarcinoma are *EBNA-2 co-activator (100kD)*, *transforming growth factor beta-induced gene product (TGFB1)*, *CDC28 protein kinase regulatory subunit 2 (CKS2)*, *chemokine (C-X-C motif) ligand 1 (CXCL1/melanoma growth stimulating activity, alpha)*, *transcription factor IIIA (GTF3A)* and *matrix metalloproteinase 7 (MMP7/matrilysin)*. These genes may play a role at a relatively early stage of carcinogenesis. *MMP7* is detected in over 80% of adenomas and is not expressed in most normal epithelial cells. This metalloproteinase mRNA may be regulated by beta-catenin (also over-expressed in adenoma and CRC) and is an emerging target for cancer therapy (6). Adenomas also displayed attenuated expression of several genes identified as down-regulated in the carcinomas, including the colonic epithelial cell product *guanylin (GUCA2A)*, colon mucosa-associated *solute carrier family 26, member 3*

(*SLC26A3*) and *tetranectin (TNA)*. Several genes showed intermediate expression between adenoma and carcinoma, including the down-regulated genes *ATP synthase 5A1 (ATP5A1)*, *alcohol dehydrogenase 1 C (ADH1C)* and *phosphoenolpyruvate carboxykinase 1 (PCK1)* and the up-regulated genes *MMP7* and *CXCL1*.

Orntoft and coworkers studied different clinical stages and found that 70% of the alterations in gene expression occurred during the transition from normal to early-stage Dukes' A tumors (4). Far fewer genes are changing their level of expression during the progression through the different Dukes' stages. This indicates that the basic properties of tumor cells are acquired in the early tumor stages and that only minor changes, perhaps those involving the stromal components are needed later on. From a therapeutic point of view, this is important because the same targets seem to be present at most Dukes' stages (4). Some of the selected candidate genes can be regarded as progression markers that change in at least two consecutive stages, or Dukes' classifiers that show major change in one stage only (4). Examples of such progression markers are *phosphoenolpyruvate carboxykinase (PCK1)* and *interleukin 8 (IL8)*.

The majority of CRC related deaths are secondary to liver ►metastasis. One of the challenges to effective treatment lies in understanding the complex biology of metastasis in CRC, thus allowing for new therapeutic and genetic intervention. Quackenbush and coworkers

Microarrays in Colorectal Cancer. Figure 3 Hierarchical clustering differentiates colorectal adenomas, adenocarcinomas and normal samples. Expression levels of approximately 1800 genes in 18 carcinomas, 4 adenomas and 22 matched normal samples were combined into a single matrix. Both genes and samples were analyzed for similarity using two-way hierarchical clustering. Each color in the resulting visual map represents the expression level of the associated gene in that tissue sample, with a continuum of expression levels from dark green (lowest) to bright red (highest). Missing values are coded as silver. The carcinomas and their benign precursors, the adenomas, are placed on an entirely different trunk of the tree from the paired normal samples. Strikingly, the adenomas and carcinomas are also separated from each other, occupying different branches of the same trunk. Adapted from: Notterman *et al.*, 2001, *Cancer Research* 61, 3124–3130.

(7) compared gene expression profiles in two cell line models for human CRC metastasis. They identified genes that appeared to be differentially expressed in all highly metastatic cell lines relative to their reference. Included in the set are those previously known to possess altered patterns of expression in (colon) cancer as well as a large number with previously uncharacterized functions. Two

newly identified transcripts were shown to be differentially expressed in paired tumor and normal tissue samples, demonstrating the utility of cell line analysis as a model for understanding metastasis. The transcript *KIAA0746* was identified as a potential metastasis marker that showed increased expression correlated to progressing tumor stage.

Biological Processes Involved in Colorectal Carcinogenesis

Tumor Metabolism

Numerically, the most prominent group of genes that change expression during colon cancer progression encode proteins related to cell metabolism, in particular energy metabolism, nucleotide and nucleic acid metabolism (including gene products involved in mRNA transcription and processing) and protein synthesis and modification (4, 5, 6, 7). Examples of up-regulated genes involved in RNA/protein processing are ribosomes, general transcription factors, translation elongation/initiation factors, and chaperones. Several mRNAs encoding glycolytic enzymes are increased. Nuclear-encoded mitochondrial proteins showed a distinct behavior because the genes encoding these were all down-regulated in at least one of the tumor stages (4). The above data shows that an accelerated metabolism is a common feature of adenomas and carcinomas. Rather than a primary transforming event, the changes in metabolism may be a secondary effect of proliferation rate. Even so, they represent a neoplastic signature that can be used for classification.

Cell Growth and Tumorigenesis

The epithelium of the colon is renewed continuously by proliferating stem cells that are located at the bases of the colonic crypts. Their progeny migrate up the crypt, stop dividing and differentiate into mature cells. When the differentiating cells reach the top of the crypt, they undergo apoptosis and are shed into the lumen. Dysregulation of genes involved in these processes can tip the balance to hyperplasia and cancer. Cell-cycle progression is driven by positive and negative regulators that ultimately direct the fate of a cell either to form two daughter cells or to enter into the resting state. Deregulated cellular proliferation, arising from abnormal expression of genes that control cell cycle checkpoints such as *cell division cycle 25B* (*CDC25B*), and *CDC28 protein kinase regulatory subunit 2* (*CKS2*), plays a crucial role in tumorigenesis. Cell-cycle pathways are critical for the initial steps of tumorigenesis, and were found to be continuously involved in late stages of cancer progression and metastasis (4, 5, 6, 7). Among the deregulated genes are several associated with cell death, which may imply that broad repression of programmed cell death pathways is a crucial step in colorectal tumorigenesis (5).

Tumor Invasion

For a CRC tumor to become invasive, it must pass through the muscularis mucosa and infiltrate into the subserosal layer in which terminal lymphatics reside. Subsequently, genes that are involved in cell motility, breaking the barriers of cellular adhesion and remodeling

of the extracellular matrix play important roles in tumor invasiveness (4, 5, 6, 7). The cytoskeleton is the basic machinery that makes cells motile, a characteristic property of invasive cells. The structural cytoskeleton genes *actin beta* (*ACTB*), *tubulin alpha* (*K-ALPHA-1*), and *tubulin beta* (*TUBB*), and *gelsolin* (*GSN*), which is involved in actin filament polymerization, are up-regulated in CRC. Among the down-regulated genes encoding structural components were several keratins, which are intermediate filament proteins responsible for the structural integrity of epithelial cells. Cell adhesion molecules up-regulated in adenomas and carcinomas include *transforming growth factor beta-induced* (*TGFB1*), which is a negative regulator of cell-matrix adhesion, and *cadherin 3* (*CDH3*). Among the down-regulated genes involved in cell adhesion are the carcinoembryonic antigen-related cell adhesion molecules *CEACAM1* and *CEACAM7*, *galectin 4* (*LGALS4*) and *TNA*. TNA, a stromal component of tumors and a participant in proteolytic processes through its binding to plasminogen, is regarded as a tumor suppressor; a low plasma TNA level is related to a shortened survival (4). The microarray studies also indicate the involvement of several matrix metalloproteinases (MMP) in CRC; *Stromelysin 3* (*MMP11*), *interstitial collagenase* (*MMP1*) and *MMP7* were significantly more highly expressed in colonic neoplasia than in normal tissue. Proteins of the MMP family are involved in the breakdown of extracellular matrix in normal physiological processes, such as embryonic development and tissue remodeling, as well as in disease processes, such as arthritis and metastasis.

Hypoxia-induced Gene Expression

Neovascularization and increased glycolysis, two universal characteristics of solid tumors, represent adaptations to a hypoxic microenvironment that are correlated with tumor invasion, metastasis and lethality. In CRC expression studies, up-regulation of glycolytic enzymes, including *glyceraldehyde-3-phosphate dehydrogenase* (*GAPD*), *enolase 1* (*ENO1*) and *lactate dehydrogenases A* (*LDHA*) and *B* (*LDHB*), was found. Conversely, gene products involved in oxygen-dependent mitochondrial energy metabolism were down-regulated. A number of genes discriminating carcinoma from adenoma were relevant to hypoxia. Conceivably, carcinoma cells may be more exposed to starved and hypoxic conditions, where carbohydrate/oxygen homeostasis is impaired, than are adenoma cells (5). Although these metabolic changes are not the fundamental defects that cause cancer, they might confer a common advantage on CRC and many different types of cancers, which allows the cells to survive and invade. The only angiogenesis-inducing factor found up-regulated in CRC microarray studies

is *IL8*. This angiogenic cytokine was also shown to be produced by tumor cells in a CRC cell line-based study (6).

Validation of Microarray Expression Data

Expression changes found in microarray studies are usually verified by comparison with other gene expression studies using similar samples. The possibilities of doing this *in silico* are still expanding, with gene expression information available in several web-based gene annotation tools (8, 9). Also, microarray results can be compared to databases (10) containing several hundreds of tissues that have been analyzed by cDNA sequencing or ►serial analysis of gene expression (SAGE), a tag-sequencing method for measuring absolute gene expression levels. Experimental approaches to validate microarray results at the single gene level in additional tumor samples include quantitative ►RT-PCR and ►Northern blot analysis. Immunohistochemistry using antibodies directed against tumor-specific gene products gives additional information about protein expression in individual cell types.

Although the precise magnitude of expression change is not always recapitulated, the direction and order of magnitude of change predicted by the array is generally confirmed (4, 5, 6, 7). The good correspondence between the different microarray studies and traditional mRNA and protein expression data in colorectal cancer indicates the validity of the large number of new alterations that were found in the large-scale studies.

Clinical Relevance

As described above, DNA microarray studies have made significant contributions to the identification of genes that are differentially expressed during the development and progression of colorectal cancer. The characterization of these genes may give fundamental insights in the molecular processes involved in tumorigenesis in the colon. Although it is tempting to interpret changes in tumor-related pathways as important for tumorigenesis itself, the direct involvement of these changes in the initiation and progression of colon cancer has to be demonstrated. Correlation with disease mutations or interference in biological model systems may provide supporting evidence. However, both causative and secondary molecular alterations in CRC may serve as diagnostic biomarkers and new targets for therapy.

Because the clinical behavior of tumors cannot be accounted for completely by morphology, it is the hope of medicine that a molecular taxonomy based on specific expression profiles will provide a more accurate prognosis and prediction of response to therapy. Studies on other cancer types have shown

that the expression of a group of 20–70 selected genes defines a pattern with prognostic importance (reviewed in 3). As a first step to ensure that this is also possible in CRC, the global gene expression studies summarized here recapitulate the present classifications based on histology (4, 5, 6, 7). Future studies including tumors with clinical follow-up information should identify expression signatures that discriminate patients in various risk groups. This will allow a better-tailored treatment that may involve an aggressive therapy for the high-risk group and a limited operative procedure avoiding morbidity and disability in an early, low-risk subtype of a previously uniform tumor entity. Very promising in this respect are two studies in breast cancer and medulloblastomas that showed that gene expression features present in primary tumors at the time of presentation predict the course of the disease. This implies that properties such as the tendency to metastasize or treatment response might be diagnosed from analysis of the primary tumor and used as the basis of clinical decision-making (3).

Microarrays will continue to be used in research to find molecular portraits of clinical significance, but may not be practical for routine clinical diagnostics. The limited number of genes that define a signature facilitates the use of other techniques such as real-time quantitative PCR, which conserves samples and is faster, easier and less expensive than DNA microarrays.

Microarrays in Pancreatic Cancer

MALTE BUCHHOLZ, THOMAS M. GRESS

Department of Internal Medicine I, University of Ulm,
Ulm, Germany

malte.buchholz@medizin.uni-ulm.de

thomas.gress@medizin.uni-ulm.de

Definition

Pancreatic cancer is the fifth leading cause of cancer related deaths in industrialized countries. With a 5-year survival rate of less than 5% and a median survival of less than 6 months, pancreatic cancer carries the most dismal prognosis of all solid tumors. Due to the lack of early specific symptoms, the disease is usually only detected at very advanced stages. In addition, pancreatic tumors tend to be aggressively invasive and are largely insensitive to chemotherapy and/or radiotherapy, leaving surgical resection as the only curative treatment option. Although considerable progress has been made in recent years in elucidating the molecular basis of ►**tumorigenesis** in the pancreas and a number of disease-associated genes have been identified, the biology of pancreatic tumors and especially the chain of early molecular events leading up to tumor formation remain poorly understood. The use of microarray technology, including comparative genomic analyses (►**Matrix-CGH**) for the identification of chromosomal imbalances, single nucleotide polymorphism (►**SNP**) analyses for the detection of mutations and genetic polymorphisms and gene expression profiling for the simultaneous assessment of ►**transcript** levels of up to several tens of thousands of genes in a single experiment, is rapidly adding to our understanding of pancreatic cancer genetics, laying the basis for the development of new diagnostic tests as well as new curative treatment modalities.

Characteristics

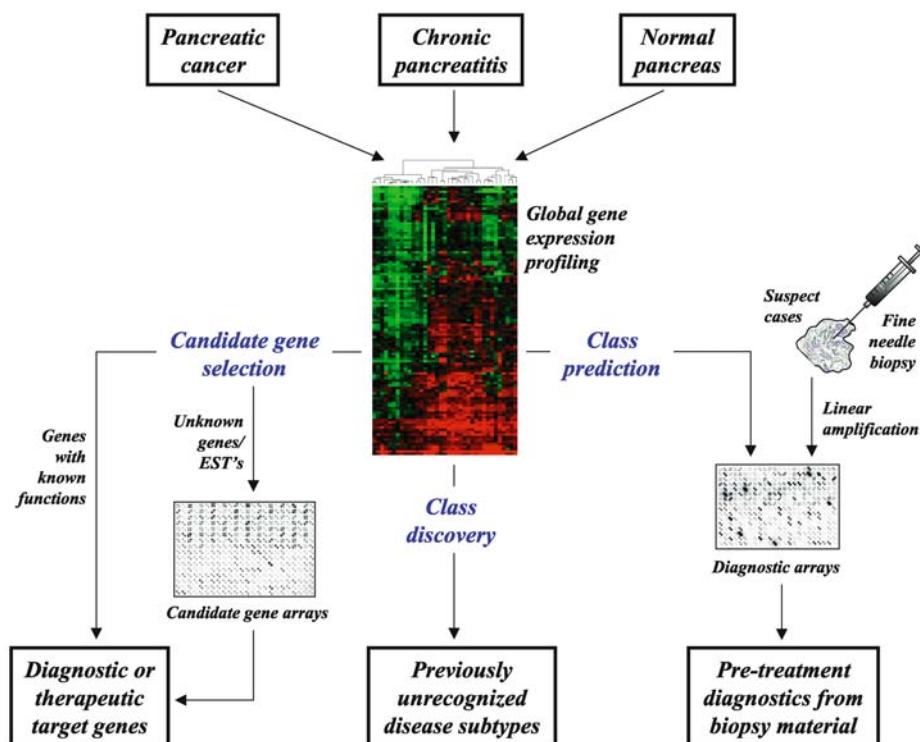

More than 90% of pancreatic tumors can be histologically defined as ductal adenocarcinomas, while all other types of pancreatic neoplasms (acinar-cell carcinomas, endocrine tumors, serous cystadenomas, carcinomas of the Papilla Vateri) are very rare. The term “pancreatic cancer” therefore exclusively refers to ductal adenocarcinomas throughout this article.

Pancreatic cancer is particularly difficult to diagnose accurately, both because of the lack of early symptoms and the fact that malignant tumors in the pancreas are often hard to differentiate from benign tumors arising in the context of a ►**chronic pancreatitis**. Inflammatory as well as malignant tumors are typically associated with

the production of massive amounts of ►**extracellular matrix** (ECM) components within the tumor, seriously compromising cytological analyses of biopsy samples. Up to 95% of the volume of a malignant pancreatic tumor can be made up of ECM deposits, a situation commonly referred to as the desmoplastic reaction of pancreatic cancer.

The ►**etiology** of pancreatic cancer remains poorly defined. The risk of developing this disease clearly increases with age, while the influence of environmental factors is still a matter of debate. An estimated 10% of pancreatic cancers are due to an inherited predisposition, but unlike other familial cancer syndromes, familial pancreatic cancer has a low ►**pene- trance** (<10%) and the age of onset is comparable to that observed in ►**sporadic cases**. In recent years, a number of genetic lesions have been identified that are linked to familial pancreatic cancer. Among them are ►**germline mutations** in the CDKN2A (which encodes two tumor suppressors – INK4A and ARF), BRCA2, LKB1 and MLH1 genes (for an overview, see 1). ►**Somatic mutations** in some of these genes are also implicated in the development of sporadic pancreatic cancer (see below). Another inherited syndrome predisposing for pancreatic cancer is hereditary pancreatitis (HP), a chronic inflammatory condition of the pancreas, which is most often caused by mutations in the cationic trypsinogen gene (PRSS1). Interestingly, longstanding sporadic chronic pancreatitis (spCP), which can arise from a number of different causes, is an established pancreatic cancer risk factor as well. It is not known if the different risks associated with HP and spCP are due to the length of the illness or some other factor.

Sporadic cases of pancreatic cancer have been demonstrated to be frequently associated with somatic mutations in the KRAS, CDKN2A, TP53, BRCA2 and SMAD4/DPC4 genes. However, since early stages of the disease are rarely detected, information about the sequence of mutational events and their contribution to the evolution of pancreatic cancer is scarce. Likewise, it is still unknown what cell type(s) pancreatic cancer arises from. Pancreatic adenocarcinoma cells resemble pancreatic duct cells in shape, ►**antigen expression** and formation of tubular structures. However, the focal expression of non-ductal lineage markers, including endocrine factors and pancreatic enzymes, and observations from animal model systems suggest that there are several routes to pancreatic adenocarcinoma, involving putative pancreatic stem cells and ►**trans- differentiation** of ►**endocrine** and ►**exocrine cells**. The use of microarray technology is expected to substantially improve our understanding of the biological principles of pancreatic cancer development. Especially the analysis of so-called pancreatic intraepithelial

Microarrays in Pancreatic Cancer. Figure 1 Application of microarray technology in pancreatic cancer diagnostics.

neoplasias (PanIN), which are thought to represent the precursor lesions of pancreatic cancer, will yield valuable information about the early steps in pancreatic cancer development and progression.

Clinical Relevance

Gene expression profiling using different types of DNA arrays is the most advanced and most widely used application of microarray technology in cancer research to date. The use of expression profiling in cancer diagnostics and therapy can broadly be divided into three general categories, candidate gene selection, class prediction and class discovery. While the first aims at identifying individual genes which may serve as new diagnostic or therapeutic targets, the latter two applications comprise the analysis of complex gene expression patterns to assign clinical samples to known disease entities or to define new disease subtypes which were previously not recognizable using classical diagnostic procedures (Fig. 1).

Candidate Gene Selection

From a data analysis point of view, this category is the most straightforward application of microarray technology. ▶**Expression profiles** of cancer tissues are compared with profiles of non-cancerous tissues from

the same organ using simple statistical tests to identify genes that are predominantly or exclusively expressed in the malignant state. However, exploitation of the results is complicated by the fact that several hundreds of genes may change their expression levels upon malignant ▶**transformation** of a normal cell. This also holds true for pancreatic cancer, where more than 360 differentially expressed genes were detected by our own group in the first ever expression profiling analysis of a solid tumor (2) and more genes have been added to the list since. While well-described genes can be screened for known characteristics enabling the development of new diagnostic tests or new treatment modalities, unknown genes or ▶**ESTs** have to be characterized in additional series of *in vitro* and/or *in vivo* experiments to select the most promising candidates. To this end, the genes are assembled on specialized candidate gene arrays and screened in serial experiments using model systems modulating important characteristics of tumor cells (invasive and metastatic potential, escape from growth control, resistance to chemotherapeutic agents, escape from programmed cell death etc.) for their involvement in crucial steps in tumorigenesis. Applying this strategy to pancreatic cancer, we were for example able to identify a novel RNA-binding protein (KOC) which in the

healthy organism is exclusively expressed in embryonic tissues, but is aberrantly re-expressed in pancreatic cancer as well as a number of other malignant diseases (3). PCR-based diagnostic assays for the presence of this gene product detect malignant cells in biopsy samples with 91% specificity and 97% sensitivity, thereby greatly enhancing the accuracy of 'traditional' cytological diagnostics.

An example of a novel therapeutic target selected on the basis of known characteristics is the tight junction protein claudin-4, which we found to be ectopically expressed by pancreatic cancer cells in many patient samples. This protein is normally located on the surface of intestinal epithelial cells and has previously been demonstrated to serve as the receptor of the *Clostridium perfringens* enterotoxin (CPE), the causative agent of many food poisonings. CPE exerts an acute cytotoxic effect on claudin-4 expressing cells by disrupting the cell membrane and destroying ion gradients, while cells not expressing claudin-4 remain completely unaffected. Since the protein is absent from all healthy pancreatic cells, CPE can be locally administered to selectively kill claudin-4 expressing cancer cells, as has been successfully demonstrated in animal experiments using subcutaneously implanted pancreatic tumors in immunodeficient nude mice (4).

Class Prediction and Class Discovery

A principally different approach to using expression profiling for diagnostic purposes is to try to identify complex patterns within gene expression profiles that are associated with the presence or absence of known diseases or disease subtypes (class prediction) or that will even allow definition of previously unrecognized disease subtypes associated with a characteristic prognosis, response to therapy, risk of relapse etc (class discovery). The analysis of the large amounts of data that are generated in the expression profiling experiments and their combination with clinical patient data to extract relevant expression patterns represents a challenging task that can only be met with the help of advanced computer sciences. Pattern recognition and data classification algorithms are being adapted and augmented for this purpose, but generally accepted standards are not yet emerging. Computational analysis of microarray data is an active area of research in bioinformatics and will undoubtedly see much advance in the near future.

A way to reduce the complexity (and the costs) of microarray analyses in diagnostics is to build specialized arrays with limited numbers of selected genes that have a high probability of yielding useful information. In order to improve the so far unsatisfactory accuracy of pre-operative pancreatic cancer diagnostics, we have developed such a specialized "diagnostic cDNA array" based on results of our own large scale expression

profiling analyses (see above) as well as public gene expression databases (►<http://www.ncbi.nlm.nih.gov/SAGE/>, ►http://www.ncbi.nlm.nih.gov/UniGene/info_ddd.shtml) and reports from the literature. The "diagnostic array" is composed of 487 features (corresponding to ca. 300 genes, some of which are represented by more than one cDNA clone) "spotted" in duplicate on nylon membranes. Since nylon membrane arrays are hybridized with radioactively labeled samples, this system offers a greater sensitivity and a broader ►dynamic range than glass slide microarrays, which are hybridized with fluorescently labeled samples. The feasibility of using this array to differentiate between pancreatic cancer and chronic pancreatitis was tested using surgically resected patient material. Since the biopsy samples which are available for pre-operative diagnostics in the clinical setting only yield very little mRNA material for analysis, linear amplification procedures as described for example by Eberwine et al. (5) have to be employed which allow the production of additional copies of every transcript from the sample prior to the labeling step without altering the relative abundance of each mRNA species in the original preparation. In the case of pancreatic fine needle biopsy samples, the situation is further complicated by the fact that the pancreas is the primary site of ►RNase production in the gastrointestinal tract, so that additional measures have to be taken to isolate and linearly amplify intact mRNA successfully from these samples. Using protocols developed in our lab, it is possible to obtain relevant expression profiles from as few as 500 cells from pancreatic tissues, a number which is far exceeded even in fine needle biopsy samples. In a preliminary series of experiments, we were able to demonstrate that our diagnostic array differentiates between benign and malignant processes in the pancreas with >90% accuracy using both surgically resected material and clinical fine needle biopsy samples.

In addition to this class prediction type of use of the diagnostic array, we expect to extend the analysis of the array data in a class discovery type of scenario to correlate characteristic expression patterns to clinical parameters such as tumor stage, prognosis, risk of relapse, response to therapy etc. The definition of distinct subtypes of pancreatic cancer based on characteristic expression patterns will provide much more detailed information about each individual tumor that can be used to select the most promising treatment option, setting the stage for therapy schemes custom tailored to the individual patient.

Definition

Microarrays consist of glass microscope slides (initially they were also made on membranes) with tiny, covalently attached spots of DNA (1.28 cm² can carry up to 500,000 DNA spots!). Each spot is called a “probe set” or “feature” and contains millions of identical single- or double-stranded DNA molecules from a specific plant gene. Hybridisation of the array with labelled cDNAs made from a population of mRNAs gives a “snapshot” picture of the plant transcriptome at the instant of tissue sampling. Thus, genome-wide alterations in gene expression between different states, e.g. leaves in the dark *versus* leaves in the light, can be catalogued in one experiment. If the identity of the genes making up the spots is known or suspected, the results of a microarray experiment can give an insight into the complexities and interrelationships of the gene expression associated with the response under investigation. This is an important first step into integrating the ►systems biology approach to close the gap in our understanding of how genotype “becomes” phenotype.

Characteristics

Whole genome studies became feasible in the late 1990s as completely sequenced genomes from several different organisms became available. Techniques were developed to study several thousand gene fragments,

called expressed sequence tags (or ►ESTs) and, in a few cases, even all of the genes of an organism in single experiments. Microarrays were among the first tools to be used in this way. Initially, the target gene sequences were spotted on to the support by hand but manual application was far too laborious and imprecise to yield reliably reproducible results. Therefore, robots were developed which could spot fractions of a microliter onto membranes or glass slides at very precise intervals. Another improvement has been the synthesis of the DNA strands directly on surface-modified glass slides.

Initially, PCR amplified double-stranded DNAs, made from plasmids containing inserts of variable length were used to prepare arrays. However, the different sizes of the DNA molecules resulted in different signal strengths due not only to transcript abundance in the probe DNA population but also to different hybridisation kinetics. The results from array experiments have been continually made more accurate and reliable by standardising the length of the target DNA sequence of each feature. Thus, today, homogenous single-stranded oligomers of 25, 60 or 80 nucleotides are used, bringing one of the two molecular species involved in hybridization to standard behaviour. Unfortunately, size differences in the complex cDNA probe cannot be controlled.

The application of DNA microarray technology to plant genomics in recent years has largely been with the model dicotyledonous plant *Arabidopsis thaliana*, which was the first plant whose entire genome was sequenced. Since *Arabidopsis* has “only” approximately 25,000 genes, DNA molecules designed to match specifically each of these genes can be arrayed on a single glass slide similar to the ones used in light microscopy. Since the position of each feature and its corresponding gene sequence on the microarray is known, it is possible to specifically detect the intensity of hybridisation signals from each spot and compare it to a reference array in a fully automated way. Thus, there are commercially available arrays in which all of the approx. 25,000 genes of the model plant *Arabidopsis* are represented. Whole genome arrays for plants of agricultural importance, e.g. rice and barley, are in production. For plants, in which the entire genome is not (yet) sequenced, there is no alternative but to resort to large EST-DNA arrays.

At the other end of the scale, arrays of a limited number of genes whose expression is associated with a particular stimulus can be prepared and serve to give a “fingerprint” or “signature” for a plant in a particular state. For example, about 150 key genes respond to the volatile signals released in plants by wounding. Reymond et al. (3) prepared an array with these genes and compared the wounding signature with that produced by aphid feeding and came to the conclusion

that aphids were able to minimise the expression of a subset of defence genes.

How Does an Array Experiment Work?

Microarray experiments aim at revealing the molecular events underlying dynamic processes. If you are interested in comparing plants in state A with plants in state B (let's say plants exposed to pathogens compared to control plants not exposed), you need to extract RNA from both plant populations. This RNA will be enzymatically converted to cDNA. In the conversion step labelled nucleotides are also incorporated into the cDNA molecules (this can be radioactive label or, in microarray-experiments, more commonly fluorescent label). The labelled cDNA from plant population A will then be hybridised to one array, while the labelled cDNA from plant population B will be hybridised to a duplicate array. The absolute (fluorescent or radioactive) signals from each spot on the array will then be analysed and compared between arrays A and B. This identifies genes that are up- or down-regulated by the different conditions used.

In this way, numerous studies have been carried out to date. The different conditions analysed reflect the current interest in different topics in plant development and responses to various stimuli.

At the time of writing, searching PubMed for "Arabidopsis" and "microarray" returns 87 hits of which at least 41 are relevant, i.e. they report microarray results. Obviously, all aspects of plant biology are covered by this flood of studies, including the development from seed to the mature, flowering plant and changes in transcription during a day/night cycle. Different abiotic stress conditions like hypoxia, ozone, heat, cold, salt, osmotic challenge, high light and de- or re-hydration have been studied with microarrays, as well as the response of plants to biotic stress using pathogens such as viruses, bacteria and fungi and pests such as nematodes and aphids. Similarly, plant nutrition/primary metabolism is a frequently studied topic, investigations being reported with plants grown under low nitrate, phosphate or iron conditions. Moreover, responses to hormone treatments were monitored with microarrays after exposing plants to auxin, abscissic acid or brassinosteroid (Table 1).

What Is the Purpose of Microarray Experiments?

Up- or down-regulation of genes points to a potential role of those genes in the process under analysis. For example, if a gene is differentially regulated in the population of plants that was exposed to the pathogen, this might reflect this gene having something to do with defence.

A danger in microarray studies is that they can lead to the production of long lists of up- or down-regulated

genes, without any real integration into a framework of biological relevance. Refinements to facilitate this step will be the next challenge for using microarray data in functional genomics. Attempts to utilise microarray data at this functional level have been made. Thus, Maleck et al. (2) showed in 2000 that a combination of cluster-analysed microarray data and data from genome sequencing projects identified potential regulatory elements in promoters of genes showing a similar expression pattern in the microarray. They used the *PR1* gene, known as a marker for systemic acquired resistance in plants, and grouped 45 ESTs from approximately 31 different genes showing a similar expression pattern into a *PR1* cluster. They identified within the 26 available 1.1 kb sequences upstream of the predicted translation start sites (ATG) a pentameric sequence, called the W box, which is present in all these 26 promoters and highly over-represented as compared to promoters of genes found in non-*PR1* clusters.

In another study, Scheideler et al. (4) were able to verify biochemical data gained over several years of research in plant pathophysiology in many labs with a microarray. They analysed in detail a set of 51 genes from a 13,000 EST microarray for up- or down-regulated genes encoding enzymes involved in primary or secondary metabolism at four time points after plants were exposed to an avirulent pathogen. They showed that changes in gene expression for genes encoding enzymes involved in primary metabolism were much less dramatic than changes in expression of genes encoding enzymes involved in pathways typically associated with pathogen defence, like the shikimate pathway or secondary phenolic metabolism starting from phenylalanine.

Moreover, arrays may help in the elucidation of a problem particularly pertinent in plants i.e. assigning a specific function to a given member of a multi-gene family or, on a larger scale, gene super families. For example, in *Arabidopsis* there are around 300 members of the supergene family encoding cytochrome P450 haem-thiolate proteins. What do they do? Why are there so many? One might get a first clue by looking at organ or tissue specific expression. This can be analysed by generating a "candidate" array containing only the genes under investigation (Table 1).

Another way to make use of array technology is the comparison of the transcriptome of a mutant with that of the wild type. This is particularly useful for mutants with a lesion in a regulatory gene. Understanding which downstream genes are misregulated in a given mutant under a specific condition can point to a potential function of that regulatory gene, which had otherwise been obscured by a non-penetrant phenotype. A further innovative use of micro array

Microarrays in Rheumatoid Diseases

THOMAS HÄUPL

Department of Rheumatology, Charité, Humboldt-University, Berlin, Germany
thomas.haeupl@charite.de

Definition

The Greek word “rheuma” or “rheumatism” has the meaning of “flow”. It relates to the ancient concept of the four “humors” flowing through the body and thought to be unbalanced in painful afflictions, resulting in swelling with fluids in tissue and joints.

Today, our understanding of rheumatic diseases is very different, leaving only the association of rheumatism with pain, which “flows” in the musculoskeletal system from joint to joint. Although rheumatic diseases comprise several hundred different entities of chronic disease, mostly recognized by their clinical phenotype, etiologic and pathophysiological knowledge is still limited. There are rheumatic diseases with systemic inflammation, degenerative joint and vertebral diseases, soft tissue diseases and metabolic diseases associated with musculoskeletal pain. The inflammatory rheumatic diseases with their main representatives listed in Table 1 present with a prevalence of about 5%. Disabilities early in life and life-threatening complications are of high socio-economic relevance.

Rheumatoid arthritis with about 1% prevalence is the most important representative.

In rheumatic diseases, gene expression screening is expected to improve pathophysiological understanding and therapeutic target identification. Furthermore, serologic autoreactivities provide important parameters for disease identification and classification. Based on familial predisposition, the search for markers of inheritance has also become increasingly relevant. Therefore, multiparameter analyses in rheumatic diseases comprise not only arrays for mRNA but also for protein and SNP analyses (►Microarrays).

Phenotypic clinical signs dominate in defining rheumatic diseases (Fig. 1). Only a few molecular parameters are currently established for routine application and qualify for diagnostic and classification purposes. These include autoantibodies like rheumatoid factor (RF), anti-citrullinated peptide antibodies and antinuclear antibodies (ANA) as well as unspecific markers of inflammation like C-reactive protein, erythrocyte sedimentation rate or differential blood count. For some of these diseases, such markers and targets are summarized in Table 2. Beyond these, many molecular parameters including cytokines, intracellular signaling molecules and transcription factors, markers of matrix destruction or genetic markers especially of the ►HLA locus have been investigated. However, insufficient disease specificity as well as variability between individual patients when collected as single parameters have discouraged usage for routine diagnostic purposes. These diagnostic limitations also apply to the most recent therapeutic targets, tumor necrosis factor alpha (TNF- α) and interleukin-1 (IL-1). Nevertheless, several of these parameters may reflect the heterogeneity of rheumatic diseases in stage, activity and possibly not yet characterized sub-entities, which seem to be recognized only by molecular means using multiparameter analysis with microarrays.

Characteristics

Samples for Microarray Analysis

The main expectations in microarray analyses are to gain an overview of the different pathological processes and to identify new or predominant pathways. Although genome wide screens have become available, interpretation of data is limited by the development of bioinformatics tools that sort the differentially expressed genes into meaningful data. For example, tissue analysis in synovitis may provide insight into the leading pathological processes of organ specific manifestations. However, variability of cellular composition due to infiltration in these complex samples will confuse the molecular interpretation. Analysis of purified cell types in contrast may provide insight into cell type associated pathologic profiles and gene regulation but

may introduce artefacts during separation. Both approaches, complex samples and purified cell types, have advantages and disadvantages and will provide different and complementary information.

Tissue Pathology

► **Rheumatoid Arthritis** (RA) is a good example to demonstrate the characteristics of tissue pathologies in

rheumatic diseases. Although classified as a systemic inflammatory disease, synovitis and joint destruction represent the central pathology in this disease (Fig. 2). The typical histological finding is infiltration of synovial pannus tissue into joint cartilage and subchondral bone, resulting in progressive destruction of the articulating surfaces. The synovial lining, normally only one or two cell layers that separate joint space from stromal tissue, is transformed in RA into a tremendously enlarged lining layer with macrophage accumulation and fibroblast proliferation. The sublining tissue displays extensive neovascularisation, formation of lymphocyte aggregates and stromal activation (1). Performing microarray analyses, these changes need to be attributed to their molecular equivalent to identify underlying pathomechanisms. Furthermore, it is difficult to identify in the large number of differentially expressed genes those regulated by disease specific molecular processes and separate others that only accumulate by infiltration of immune cells.

Gene Expression Profiling of Tissues and Tissue Cells

Based on a customized array with 96 pre-selected genes, Heller et al. demonstrated applicability of array technology for synovial tissue analysis to detect genes involved in joint destruction (MMPs stromelysin 1, collagenase 1, gelatinase A and human matrix metallo-elastase, TIMP 1 and 3) and inflammatory processes (IL-6, VCAM, MCP-1, MIF and RANTES) (2). More detailed analyses of synovial tissues from RA and osteoarthritis (OA) patients were performed on a 24,000 cDNA spotted array platform (3). These studies suggest a sub-classification into at least two different molecularly defined groups of RA, one with signatures of high inflammation, B- and T-cell activation (immunoglobulins, lck, STAT1, SDF1, HLA class II, IFI30 etc.) and the other with low inflammation but processes of tissue remodeling including expression of different types of collagen (II, XI) and activation of signaling pathways known from embryonic morphogenesis (Wnt5a). These results reflect the heterogeneity described in established histological scoring and grading of RA based on cellular composition and structural changes (1). Our own data on synovial tissues, established on a different technology platform,

Microarrays in Rheumatoid Diseases. Table 2 Molecular Markers and targets

Disease type/group	autoantibodies	genetic markers	therapeutic targets
RA	RF, anti-citrulline	HLA-DR4	TNF- α , IL-1, CD20
SpA	none characteristic	HLA-B27	TNF- α
SLE	ANA (anti-dsDNA, -Ro, -La, -Sm, etc.)	HLA-DR2	CD20
vasculitis	ANCA	variable	TNF
myositis	Jo-1, PM-Scl, Mi-2	HLA-DR3	miscellaneous

**Microarrays in Rheumatoid Diseases. Figure 2** Characteristics of synovial tissue inflammation in rheumatoid arthritis.

confirm many of these findings (4). A similar tissue-based analysis of periprosthetic membranes from prosthetic loosening in RA and OA patients also revealed up-regulation of various inflammatory genes (5). To enable association of differential gene expression with characteristic histomorphological structures or cell types, array analysis of laser micro-dissected synovial tissues with RNA from as few as 600 cells was shown to be feasible (6).

Alternatively, studies on purified and cultivated synovial fibroblasts are well established and several characteristics are sustained for many culture passages, reflecting an imprinted phenotype of molecular changes. Thus, Pierer et al. investigated profiles of synoviocytes on a functional basis by stimulation *via* toll-like receptor 2. With focus on chemokines, preferential activation of GCP-2, RANTES, MCP-2, IL8 and GRO2 was identified. Induction of MCP-2, RANTES and GCP-2 were dependent on NF- κ B.

Monocyte migration was influenced by RANTES and MCP-2, T-cell migration only by RANTES. Expression of GCP-2 and MCP-2 was identified not only in synovial tissue but also in synovial fluid, confirming the relevance of these results.

Gene Expression Profiling of Peripheral Blood Cells

Peripheral blood contains a mixture of different leukocytes, which may reflect systemic inflammatory processes. In a search for common and differentiating expression profiles in autoimmune diseases, Maas et al. investigated peripheral blood mononuclear cells (PBMC) from patients with rheumatoid arthritis, ▶systemic lupus erythematosus (SLE), type I diabetes and ▶multiple sclerosis. Comparing microarray expression profiles of these autoimmune diseases with profiles of healthy donors and their response to influenza vaccination, they characterized genes discriminating between normal immune and autoimmune responses.

However, no patterns were found to distinguish between the different autoimmune diseases. Candidate genes of autoimmunity were involved in apoptosis, cell-cycle progression, cell differentiation and cell migration but were not typical immune related genes. The algorithm that characterized patients with autoimmune diseases also identified healthy relatives of these patients, suggesting that the selection of genes may reflect a genetic trait rather than the disease process.

Analyses of PBMC in SLE revealed activation of interferon dependent pathways by comparing the findings with profiles induced by IFN- α in PBMC from healthy donors *in vitro* (7, 8). However, in one of these studies differential expression of granulopoietic genes was identified as well and turned out to originate from cells of the myeloid lineage. These cells co-separated, obviously upon disease associated changes, only in SLE. These findings again demonstrate the difficulties and risks of misinterpretation when microarray analyses are performed on complex cellular mixtures of unknown composition.

PBMC were also investigated in spondylo-arthropathies, rheumatoid arthritis and psoriatic arthritis on a 588-gene commercial array platform (9). Identified candidate genes included a myeloid nuclear differentiation antigen (MND1), two members of the S100 family of proteins (calgranulin A and B), JAK3 and MAP-kinase p38, TNF receptors, the chemokine receptors CCR1 and CXCR4 and IL-1 β and IL-8. As SDF-1, the ligand of CXCR4, was found to be increased in the synovial fluids of arthritides, the authors suggested an important role of this chemotactic axis in SpA and RA.

Genomic Markers of Disease

Investigations of genetic mutations are currently advancing into screening technologies for as many as possible identified [▶single nucleotide polymorphisms](#) (SNPs) in the human genome. In the past, some rheumatic diseases were found to be associated with certain HLA haplotypes. Focused investigations as well as genome wide approaches now suggest a growing number of polymorphisms as potential markers for rheumatic diseases. Such recently suggested polymorphisms in RA are in regulatory sequences or coding sequences of PADI4 (10), SLC22A4 (11) and others. However, it may be deduced from the heterogeneity of the clinical phenotype and the fact that new pathogens identified in the last decades, such as *Borrelia burgdorferi*, may contribute to the multitude of arthritic conditions that rheumatic diseases may not be explained by a monogenetic trait or one polygenetic pattern. Therefore, multiparameter analyses will also develop for genetic screenings in rheumatic diseases.

Microarrays used for expression profiling may contribute to the identification of genetic markers. Interesting bioinformatic technologies were applied to expression candidates that were common to two genetically different murine arthritis models. Using a spatial autocorrelation function, a statistical technique in astrophysics, critical clusterings of selected genes in these two different genetic backgrounds were identified. These may contain relevant polymorphisms and are therefore possible hot spots for further investigation.

Microarrays and Autoreactivity

The role of B-cells and their products, antibodies, has been the first focus in RA research. It was initiated by the identification of RF *via* its complex formation by Waaler and Rose. RF is found in about 70% of all RA patients and is directed against the constant region of immunoglobulins. Formation of complexes and activation of complement in the joint significantly promote inflammation by constant recruitment of inflammatory cells. Furthermore, B-cells also contribute by their function as antigen presenting cells and their co-stimulatory capacities. As a consequence, B-cell depleting therapies by anti-CD20 targeting have been started and may provide new tools in the treatment strategies for RA (12). Serologic autoreactivity screening also has important practical consequences in connective tissue diseases like SLE for identification and classification of the disease. As current autoimmune screens already demand for many different autoantigens, protein microarrays were developed for application in eight different rheumatic diseases (13). Using the multiple spotting technique, combined spotting of antibodies on top of the immobilized antigen revealed extremely high sensitivity and specificity (14). These qualities of microarray based autoreactivity screening may support the development of criteria for sub-classification of rheumatic diseases. Furthermore, these microarrays may provide parameters of disease activity by quantification of selected seroreactivities.

Clinical Relevance

RA, which has the highest socioeconomic impact, serves as an example for other rheumatoid diseases. Within a decade after onset, this disease leads to work disability defined as a total cessation of employment in more than 50% of patients. Total costs of this disease are at least 2–3 \times higher than direct health care costs. These are consequences of the unknown etiology and the lack of appropriate treatment.

Current clinical classification criteria have not been able to predict responsiveness to defined therapy regimens. Different models of molecular pathology have been suggested in the past based on candidate

driven research, but none is unequivocal or has provided sufficient exclusiveness to improve classification. A common molecular diagnostic tool beyond screening for rheumatoid factor or anti-citrullinated peptide antibodies is not available. On the other hand, a predominantly TNF driven pathophysiology obviously occurs only in a subgroup of RA patients, suggesting that subgroups may be defined by molecular means. Microarray analyses as published up to now seem to confirm this assumption. Considering this complexity, it cannot be expected that a single gene or factor will molecularly describe the multiple characteristics of rheumatic diseases.

Diagnostic improvement is needed for many decisions in clinical care for these patients. The identification of the disease at the very early stage when treatment can be most effective to prevent joint destruction is important. Identification of subgroups may reveal different pathomechanisms and define criteria for therapeutic stratification, especially for the evolving targeted therapies with biologicals. Therapeutic effectiveness is difficult to estimate by solely clinical criteria, since these will not allow differentiation between insufficiency of dosage or failure because of targeting the wrong pathway(s). Finally, infections may complicate the disease but present clinically similarly to a flare of the rheumatic disease.

All these difficulties demonstrate the importance of new molecular screening technologies. Microarrays as we know them today will certainly have high impact on the development of these diagnostic tools. However, rapid technological progress in this field may find cost effective ways of integrating not only the currently dominating gene expression and autoreactivity screens but also protein detection and modification.

Synonyms

Chromosomal microdeletion syndromes; Contiguous gene syndromes

Definition

Progress in diagnostic methods allows the identification of the etiology of increasing numbers of clinical syndromes showing that microdeletions or occasionally microduplications are the specific type of causative mutations. The cytogenetic term microdeletion can be misleading, in particular to molecular geneticists, who consider microdeletions as extremely large at the molecular level. Other expressions such as “cryptic”

or “submicroscopic” deletion are no better, as molecular cytogeneticists regard chromosomal microdeletions neither as cryptic nor as submicroscopic. The term “microdeletion” should be avoided in favor of chromosomal microdeletion or simply deletion.

Chromosomal microdeletions represent deletions below the cytogenetic detection limit. The smallest unit in cytogenetics is the chromosomal subband or band which, given the length of the haploid human genome (~3,000,000,000 base pairs) and the number of bands resolved by standard karyotyping (450–550), spans around 6 Mb of genomic DNA in length. However, these 6 Mb cannot be simply equated with the cytogenetic detection limit, which strongly depends on the resolved number of bands, chromosomal location and banding pattern of the area in question. Microdeletions typically span in the order of 2–6 Mb of genomic DNA. The “subtle” rearrangements at the cytogenetic detection limit cover around 4–12 Mb. Strictly speaking, there are no exact borders between the cryptic, near-cryptic and subtle chromosome rearrangements and any rigid classification is artificial.

Characteristics

In 1956 a new syndrome of severe neonatal hypotonia, hypogenitalism, small hands and feet, obesity, short stature and mild mental retardation in the older child was delineated, and named ► [Prader-Willi syndrome](#). In the 1980s it was found that a subset of Prader-Willi patients have deletions at chromosome 15q11-q13 visible only by high-resolution methods. The 15q11-q13 deletion was found to be a constitutional deletion, removing 3–4 Mb of genomic DNA from the paternal chromosome 15q11-q13, due to the presence of ► [low copy repeats](#) in this area. With the advent of molecular cytogenetic techniques using fluorescence labeled DNA probes on metaphase chromosomes (fluorescent *in situ* hybridization, FISH) in the 1990s, several familiar and less well known phenotypes were discovered to be microdeletion syndromes, and became accessible for laboratory diagnosis. Microdeletions have been found in numerous genes and virtually all human chromosomes. At least 50 different microdeletions (Table 1) recur and generate more or less recognizable microdeletion syndromes (Figs. 1, 2, 3, Fig. 4c, d, e, f, g) that may be diagnosed by the medical specialist (clinical dysmorphologist). There is no distinct line that can be drawn between the microdeletion syndromes and the private syndromes (Fig. 4a, b) that are occasionally diagnosed in unique patients showing exceptional clinical signs.

Chromosomal microdeletions are one of the multitude of mutational mechanisms causing Mendelian disorders in man. Mutations such as single nucleotide substitutions are well known in human medicine, but

Microdeletion Syndromes. Figure 1 Phenotypes in Wolf-Hirschhorn syndrome; (a–b) 1 year old boy – note severe failure to thrive, anisochromia of iris and hypertelorism; (c–d) 14 year old girl with Pitt-Rogers-Danks syndrome (mild Wolf-Hirschhorn variant).

chromosomal microdeletions removing a string of neighboring genes out of a chromosome or a number of exons out of a large gene such as *DMD* (►Duchenne muscular dystrophy) represent a less known concept. Chromosomal areas harboring microdeletions at a high frequency include 7q11.23, 15q11-q13, 17p11.2-p12 and 22q11 (Fig. 3a). These areas are also prone to the formation of other constitutional cytogenetic microarrangements such as inversion 7q11.2, supernumerary marker chromosomes 15 or 22 and duplication 17p11.2-p12.

The genetic content of the different chromosomal microdeletions varies greatly but can be determined if the size and location of the deletion have been defined. The number of genes included in a microdeletion can be roughly estimated based on the number of genes and the total length of the haploid human genome. Genes are spaced at an average distance of 100,000 base pairs within the human nuclear genome. Therefore, a typical microdeletion such as the common 22q11 deletion, which spans around 3 Mb, removes approximately 30 genes. The precise content of a deletion can be computed using human genome browsers (Ensembl: ►<http://www.ensembl.org>, UCSC Genome Browser: ►<http://genome.ucsc.edu>) that display known and predicted genes in molecularly defined areas.

Nearly all microdeletion syndromes show genetic heterogeneity, for example by different mechanisms

of mutation (e.g. Prader-Willi syndrome; microdeletion, ►uniparental disomy, imprinting center mutation or chromosomal translocation) or by mutations on different chromosomes (e.g. ►DiGeorge syndrome due to mutation at 22q11 or at chromosome 10p14).

Moreover, deletions and duplications in the same area may cause different phenotypes (clinical heterogeneity). Deletion of the *PMP22* gene at 17p12 causes HNPP, whereas the 17p11.2-p12 duplication including *PMP22* leads to the more severe ►Charcot-Marie-Tooth disease (Table 1). Due to the heterogeneous origin, the specification of the cause is necessary for genetic evaluation of reproduction risks in affected families. The clinical work-up should include parents of those affected being checked for chromosomal rearrangements and cytogenetic mosaicism, even if they appear healthy.

The incidence of many well-known microdeletion syndromes is high, ranging from 1:4,000 to 1:30,000 in the general population. The constant and relatively high rate of microdeletions results from the common etiological mechanism that includes unequal crossing over during meiosis.

Rearrangements at the chromosome ends, such as the 4p16 deletion causing ►Wolf-Hirschhorn syndrome (Fig. 1), the 7q36 deletion causing ►holoprosencephaly and related defects, or other subtelomeric deletions are known to arise in a subset of cases secondary to a balanced familial translocation. More recently, low copy repeats (LCRs) were identified as a major cause of microdeletions during meiosis, in particular, interstitial microdeletions. By definition LCRs are large rare DNA motifs at specific chromosomal sites and have been reported to cause the constitutional micro-rearrangements at chromosomes 7q11.23, 15q11-q13, 17p11.2 and 22q11. LCRs have been associated with different types of rearrangements showing constant molecular breakpoints such as deletions, duplications, inversions, supernumerary marker chromosomes and translocations. The presence of defined LCRs and molecular breakpoints also explains why certain microdeletions typically show constant chromosomal breakpoints and why these microdeletions sometimes coincide with a different micro-rearrangement present in one parent. For example, the 7q11.23 deletion (Williams syndrome) has been associated with micro-inversion on one homologue 7q in a parent.

Due to the diploid nature of the human genome, a microdeletion typically results in heterozygous deletion (monosomy), with a normal allele of the deleted gene remaining present on the intact homologous chromosome. Yet a few microdeletions occur at imprinted chromosomal areas and therefore cause genetic nullisomy, e.g. ►Prader-Willi syndrome represents nullisomy of the paternal chromosome 15q12 and Angelman

Microdeletion Syndromes. Table 1 Chromosomal microdeletion syndromes

Syndrome or disorder	OMIM	Molecular region	Chromosomal region
Monosomy 1p36 syndrome	607872	–	1p36.3

Gonadal dysgenesis, XY female type; Swyer syndrome; sex-determining region Y; SRY	480000	SRY	Yp11.31

syndrome is due to nullisomy of the maternal chromosome 15q12. These syndromes can be caused by microdeletion or alternatively, in a subset of cases, by uniparental disomy, or by defective imprinting.

Some 50 microdeletion syndromes (Table 1) have been delineated. A few syndromes such as the Wolf-Hirschhorn (Fig. 1), Prader-Willi, and ►**Smith-Magenis syndromes** (Fig. 2) demonstrate a fairly constant phenotypic appearance, but many others display considerable phenotypic variation between affected individuals, with the 22q11 deletion syndrome (Fig. 3) at the extremely variable end of the spectrum. Variability in the extent and severity of features is observed within the family as well as inter-familially. In particular, the 22q11 deletion syndrome has been reported with normal stature, normal appearance and normal intelligence (Fig. 3l, m).

The clinical signs of a microdeletion syndrome are defined by the hemizygous deletion of a string of genes on the recombinant chromosome. Between different chromosomes, a general correlation between the size of the microdeletion and the phenotypic manifestation does not exist. The phenotypic variability reflects the fact that the microdeletion syndromes are distinguished from each other by the clinical signs and symptoms that arise mainly from the deletion of genes with dominant effects within the deletion interval (monogenic traits), and to a lesser extent by other genes.

The paucity of the genes with dominant effects in the human genome (~1,000) can help to explain some of the peculiar characteristics of the microdeletion syndromes. Relatively few microdeletion syndromes (Williams-Beuren syndrome, proximal 11p deletion syndrome) represent true contiguous gene syndromes, in which the haploinsufficiency of two or more

neighboring ‘dominant’ genes contributes significantly to the patient’s phenotype. In other microdeletion syndromes the phenotype largely reflects the haploinsufficiency of a single ‘dominant gene’ (*SHH* gene causing holoprosencephaly and related defects in the monosomy 7q36 syndrome, *UBE3A* causing neurological defects in Angelman syndrome, *TBX1* causing pharyngeal pouch defects in 22q11 deletion syndrome). In some syndromes there is a minor contribution from another ‘dominant’ gene in a subset of cases.

A considerable number of microdeletions do not generate specific traits at all but only unspecific clinical signs and symptoms representing polygenic traits; this has been referred to as the chromosomal phenotype. To facilitate the diagnosis of subtle chromosomal imbalances in individual patients with an unspecific phenotype (Fig. 4a, b, c), clinical checklists have been established (2, 4). These checklists characteristically include four key points; 1) developmental delay, 2) abnormal (compromised) growth, 3) congenital anomalies (compromised development of complex body parts such the face, heart or reproductive organs) and 4) the chromosomal pedigree. Premature birth it is another unspecific sign frequently occurring with chromosome aberrations and could also be integrated into such checklists.

The developmental retardation (brain and neurological dysfunction) in the chromosomal phenotype is polygenic in origin and highly variable including prenatal disorders and severe hypotonia in the newborn and, at the mild end of the spectrum, only mildly abnormal behavioral phenotypes, impaired learning or even normal development. Correspondingly, the compromised growth and development may already be recognizable by prenatal ultrasound (intrauterine

Microdeletion Syndromes. Figure 2 Phenotypes of two unrelated male individuals, aged 14 and 20 years, with Smith-Magenis syndrome – note broad forehead, flat midface, refraction disorder and short neck.

Microdeletion Syndromes. Figure 3 Partial metaphase by FISH – note deletion at 22q11.2 (left homolog of chromosome 22) and normal control signals at both chromosome 22q13.3 homologues; b-m: Phenotypes of four unrelated children and mother and daughter with Di George syndrome at different ages – note hypertelorism, full cheeks, bulbous nose, small mouth and dysplastic ears.

growth retardation), may appear later in life (short stature, microcephaly), or may not even become apparent at all (normal stature included). Moreover, characteristic short stature and microcephaly in the chromosomal phenotype can be camouflaged in certain situations. The 22q13.3 deletion has been reported with tall stature and macrocephaly in some individuals and with normal (Fig. 4c) or short stature in others, predicting a growth regulating gene within the deletion interval, as yet unknown, but in the hemizygous state results in overgrowth in some individuals and in normal or compromised growth in others. The genetic background such as familial tall stature or familial macrocephaly can also camouflage the chromosomal phenotype of short stature or microcephaly in some patients. Congenital anomalies such as unspecific craniofacial dysmorphism (abnormal ear shape/structure, small chin, etc.) and unspecific heart defects are other common signs non-randomly associated with

chromosome aberrations, indicating disturbed embryonic and fetal development.

The chromosomal pedigree (recurrent miscarriage, stillbirth, affected relatives, and non-Mendelian transmission) is predominantly found with the terminal deletion syndromes (examples 4p- or Wolf-Hirschhorn syndrome (Fig. 1), 5p- or [Cri-du-chat syndrome](#), 17p- or [Miller-Dieker syndrome](#)), because these can arise from a subtle or cryptic balanced translocation in one of the parents. Interstitial microdeletions may also occur secondarily to familial chromosome rearrangements in rare cases (Williams syndrome, proximal 11p deletion syndrome).

Microdeletions result in the loss of a number of neighboring genes, causing the impaired function (by haploinsufficiency) of a subset of the proteins that are encoded by these genes and thereby generating the corresponding phenotype in the patient (contiguous gene syndromes). The molecular cytogenetic techniques

Microdeletion Syndromes. Figure 4 Phenotypes of children with sub-microscopic or subtle deletions at the ends of the chromosomes. (top) Three unrelated boys – note mild unspecific facial dysmorphism and absence of seminal features; (middle, bottom) Two unrelated male infants with subtle terminal deletion at 13q – note unspecific facial dysmorphism and characteristic ano-genital malformations.

(FISH, fluorescent *in situ* hybridization) made possible the visualization of single genes, and even parts of genes, on metaphase chromosomes and in non-dividing cells (interphase nuclei). The detection of chromosomal microdeletions is a standard procedure in clinical medicine today. Standard FISH tests have become available for most well-known microdeletion syndromes, but many disorders (Table 1) still require “home-made” or research FISH tests. Microdeletion syndromes are increasingly defined by the ‘dominant’ genes causing the major clinical signs. BAC/PAC clones

representing these causal genes are ideal DNA probes in the diagnostic FISH tests.

Subtelomeric microdeletions have been identified as the cause of 5% of severe idiopathic mental retardation (Fig. 4, top part) and the population incidence of all subtelomeric deletions combined is apparently at higher than 1 in 4,000 newborns. Nearly 50% of subtelomeric microdeletions are inherited from one parent, who then is a carrier of a balanced translocation or another cryptic rearrangement. These couples have a high recurrence risk (up to 50%).

Unfortunately, the test for detecting deletions or duplications at the telomeres, the subtelomere screen, is laborious and demanding, and therefore subtelomeric rearrangements are certainly underdiagnosed. Several working groups presently attempt solving this problem by use of microarrays (“DNA chips”) typically representing 6,000 and more BAC/PAC clones.

Cellular and Molecular Regulation

The molecular basis of the microdeletion syndromes is becoming increasingly elucidated. The disease-associated ‘dominant’ genes (Table 1) within the deletion interval give rise to the specific clinical signs making up the phenotype and gestalt of the syndrome. Most human genes are not dosage-sensitive to the deletion of one of the two alleles. For these genes, the lack of function of the allele on the deleted homologue of the chromosome is compensated by the other allele, which is present on the normal non-deleted homologous chromosome. Therefore, it is mainly the small subset of autosomal ‘dominant’ genes within the deletion interval that causes the phenotype of the individuals with a microdeletion. For example, the malformations in the common large 22q11 deletion are thought to be caused by only one gene (*TBX1*) out of the ~30 deleted genes. In addition, other genes within the deletion interval may contribute to multifactorial traits such as intelligence or behavior (1). Compromised intelligence is a frequent sign in chromosomal microdeletion syndromes, with the individual IQ outcome ranging from normal to mental retardation depending on many factors. As a rule, the smaller the deletion or duplication of a given chromosomal region, the better mental outcome can be expected. For example, there is evidence that individuals with a 1p36 deletion of 2.2 Mb and less in size are much less retarded than patients with a 1p36 deletion encompassing 3.6 Mb and more; and patients with Angelman syndrome caused by uniparental disomy (imprinting defect) often can speak several words whereas Angelman patients with the typical 15q11-q13 deletion (haploinsufficiency of additional genes) are typically completely a verbal. A small subset of individuals with a chromosomal microdeletion syndrome may present exceptional clinical signs, usually of a recessive disorder. Such cases can be explained by the high frequency of disease-causing recessive alleles in the population.

Clinical Relevance

Molecular cytogenetic testing (►FISH) has bridged the gap between cytogenetic diagnosis (typically detecting congenital disorders caused by genomic imbalance involving more than 6 Mb of genomic DNA, or 60 genes) and molecular diagnosis (typically detecting disorders caused by a molecular defect within a single

gene), leading to the growing recognition of the chromosomal microdeletions as a significant cause of human congenital disorders. The most frequent microdeletion, the 22q11 deletion (Fig. 3a), occurs at 1 in 4,000 newborns and was found to be second most frequent autosomal aneusomy in humans after trisomy 21 (incidence 1 in 700 newborns).

Microdeletion or subtelomere screening (using different DNA probes that are specific to each of the human chromosome ends) may be extremely valuable in patients with congenital anomalies and/or developmental delay (4), and has also been utilized in hematologic malignancies, in recurrent miscarriages, for prenatal detection, and for preimplantation diagnosis, given that it is allowed in the given country. Chromosomal microdeletions make up for a significant proportion of congenital disease. Congenital disorders in man occur in 3–4% of live births in the general population; mild mental retardation (MR) occurs at 1–2% and severe MR at about 0.5% of adults. Microdeletions, including those that do not cause a recognizable syndrome but can be detected by the FISH subtelomere screen or DNA microarray techniques, occur at an estimated total incidence of more than 1 in 1,000, or >0.1% of newborns. Taken together they account for around 3% of all inborn human disorders in man, for 3–5% of mild MR and for 5–10% of severe idiopathic MR.

Prenatal prevention is feasible after gestational week 11 by chorion villus biopsy, and by amniocentesis.

Clinical Features

In the last decade the number of newly recognized chromosomal microdeletion syndromes has greatly increased (Table 1). Characteristics common for this group of disorders include

1. frequently a characteristic craniofacial phenotype or recognizable face (Figs. 1, 2, 3), growth retardation (often with prenatal onset) (Fig. 1), congenital heart defects, developmental delay and mental retardation (all patients shown, except Fig. 3l, m).
2. Many microdeletion syndromes (DiGeorge, Williams, Prader-Willi, Angelman, and Smith-Magenis syndromes) have defined chromosomal breakpoint areas, and the seminal clinical features result from the deletion of a few dominant gene(s). Thus, in many cases, the phenotypic variability between patients with a given syndrome does not reflect differences in size of the microdeletions, but most likely is due to unknown (environmental or genetic) factors.
3. New mutations are the common etiology; only 1–10% of chromosomal microdeletions are inherited due to the identical deletion, or a balanced translocation, point mutation in imprinting centers or gonadal mosaicism in one parent.

4. Recurrence risk is generally low (new mutations) but may be as high as 50% in cases of an inherited mutation and spontaneous abortions can occur.

Microfilaments

Definition

Microfilaments are thin actin filaments comprising of part of the cytoskeleton that function in structure and movement of eukaryotic cells.

- Actin Cytoskeleton
- Cell Polarity
- Cytoskeleton

Microfluidics

Definition

Microfluidics denotes manipulating and understanding transport of small volumes of fluid (μL – nL).

- Proteomics in Microfluidic Systems

Microglia

Definition

Microglia are a neuroglial subtype of mesodermal origin. They are the resident macrophage population of

the CNS, and are considered to be its major immunocompetent elements. Microglia are activated by any type of brain pathology. Their activation results in conversion to so-called brain macrophages. Activated microglia secrete proinflammatory cytokines and chemokines, which can migrate to the lesion site and start to phagocytose.

MicroRNA

V. NARRY KIM

School of Biological Sciences and Institute of Molecular Biology and Genetics, Seoul National University, Seoul, Korea
narrykim@snu.ac.kr

Synonyms

The first two ► *microRNAs*, *lin-4* RNA and *let-7* RNA, were collectively named small temporal RNAs

(stRNAs), because of their temporal expression patterns and their roles in temporal regulation (5). After the discovery of hundreds of small RNAs in 2001, members of this non-coding RNA family were renamed as microRNAs (miRNAs) (1).

Definition

MicroRNAs (miRNAs) are defined as single-stranded RNAs of ~22 nt in length (range 19~25 nt) generated from endogenous transcripts that can form local hairpin structures (1, 2) (Fig. 1). MiRNAs act as guide molecules in gene silencing, by base pairing with the target mRNAs leading to translational repression and/or mRNA cleavage. The target gene locus is distinct from the miRNA gene locus itself.

Most miRNAs were found by the cDNA cloning method but a significant number of miRNAs are also being discovered by computational prediction. To identify and distinguish miRNAs from siRNAs or fragments of other RNAs, a combination of the following criteria are used (1): (A) detection of a distinct ~22 nt RNA by Northern blotting, (B) identification of the ~22 nt sequence in a library of cDNAs made from size-fractionated RNA, (C) presence of the ~22 nt sequence in one stem of a potential hairpin precursor structure, (D) phylogenetic conservation of the ~22 nt sequence and (E) accumulation of precursor when Dicer function is reduced. Usually evidence for (A+D) is sufficient. An RNA sequence meeting the criteria (A+C) or (B+D) is also regarded as miRNA.

MiRNAs are named with the “miR” prefix and a sequential number. Identical mature sequences from distinct precursors get names like miR-16-1 and miR-16-2, while highly related ones get names like miR-15a and miR-15b. When two miRNAs are cloned from opposite strands of one precursor, the more abundant one used to be assigned a name like miR-142 and the other one has an added asterisk as in miR-142*. When the relative abundance is not known, they were named miR-142-s (from the 5' strand) and miR-142-as (from the 3' strand). The current convention, however, is that miRNAs from the 5' strand are named miR-142-5p while those from the 3' strand are referred to as miR-142-3p, regardless of their relative abundance. The nomenclature follows the conventions of the organism so that miR-1 is in *C. elegans* and *Drosophila* and MIR39 in plants. The genes encoding the miRNAs are named with italics and capitalization like *mir-1* in *C. elegans* and *Drosophila* and *MIR39* in plants. The Rfam database of RNA families provides a searchable database for published miRNAs and assigns the miRNA gene names before publication (►<http://www.sanger.ac.uk/Software/Rfam/mirna>).

Characteristics

The Gene

Hundreds of small RNA genes have been found in animals, plants and viruses (2, 6). Many miRNAs are conserved across species, indicating that they have evolutionarily conserved roles in gene regulation (Fig. 1A). Most of the miRNA genes are found in intergenic regions or in antisense orientation to annotated genes, suggesting that they constitute independent transcription units. MiRNAs that are located in the boundary of annotated genes are mostly found in intronic regions. These miRNAs are likely to be transcribed as a part of the hosting gene.

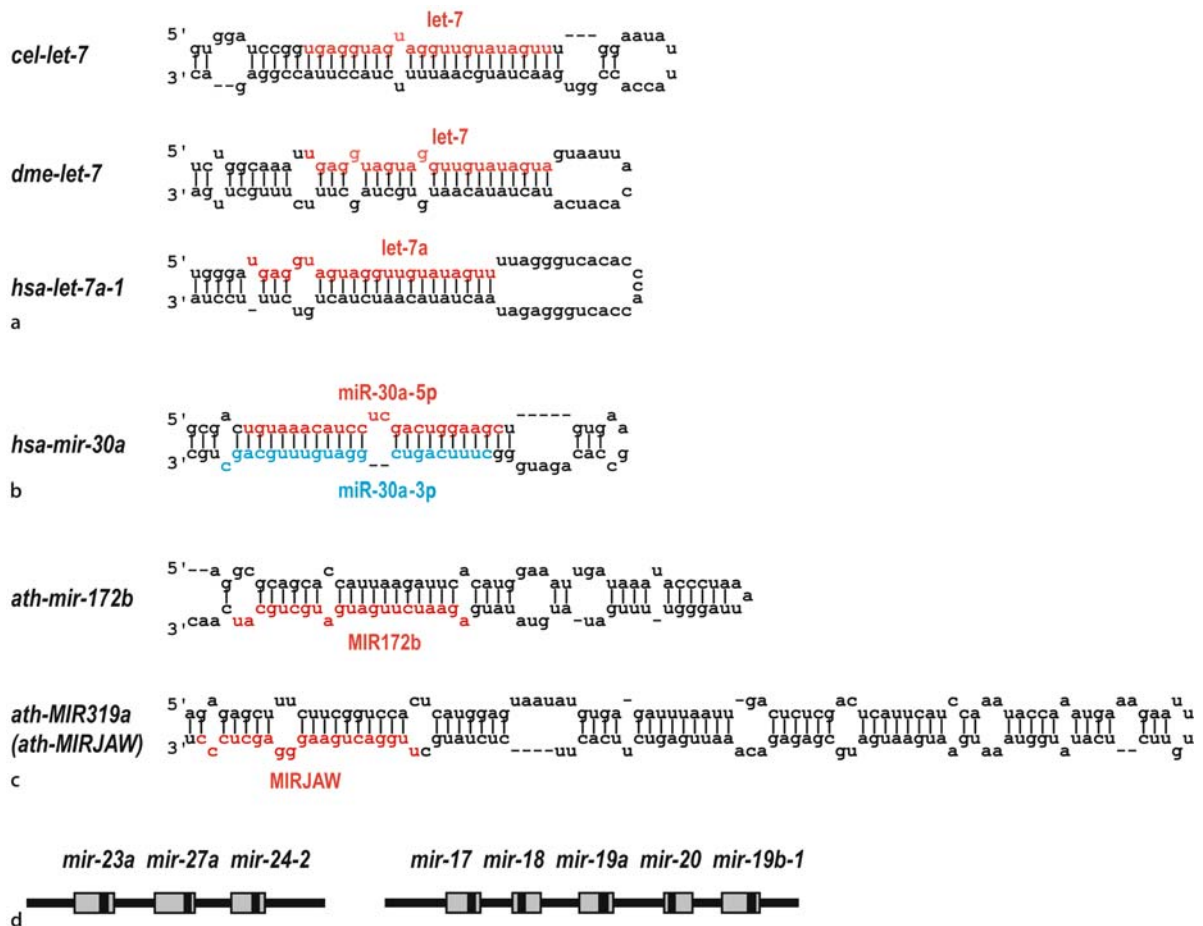

More than half of miRNA genes are in close vicinity to each other, forming operon-like gene clusters (Fig. 1D). They are expressed as polycistronic transcripts containing multiple hairpins. Because the miRNAs in a given cluster are transcribed together and often related to each other, this operon-like gene organization may provide a coordinated control over functionally related protein-coding genes.

The gene structure and the transcription mechanism of miRNA genes are still largely unknown. Detailed analysis of the gene structure (especially the promoter elements) and the transcription machinery will be important to elucidate the regulation mechanism of miRNA biogenesis.

Biogenesis

MiRNA genes are transcribed by RNA polymerase II (pol II) to generate primary transcripts (►*pri-miRNAs*) that are much longer than the 60~70 nt stem-loop (Fig. 2). Pri-miRNAs are first trimmed to release the hairpin intermediate (►*pre-miRNA*). This cleavage is executed by the RNase III type enzyme Drosha in the nucleus (4). Pre-miRNA then gets exported to the cytoplasm by exportin-5 (Exp5), which is a member of the Ran-dependent nuclear transport receptor family. Upon arrival in the cytoplasm, pre-miRNAs are subjected to the second processing by Dicer, the cytoplasmic RNase III type protein. Pre-miRNA is cleaved into the short-lived miRNA duplex, whose one strand is degraded by an unknown nuclease while the other strand remains as a mature miRNA.

MiRNA maturation appears to be well coordinated. Exportin 5 recognizes its cargo by specifically interacting with the short 3' overhang and the dsRNA (stem) structure, which are the characteristic features common in the products of Drosha-mediated processing. Dicer has a preference towards a terminus of dsRNA containing short 3' overhang so that it cleaves at ~22 nt away from the terminus of the pre-miRNA stem. Thus Drosha is responsible for producing optimal substrates for the downstream events, thereby pre-determining the

MicroRNA. Figure 1 Examples of miRNAs. Predicted stem-loops are shown here with the mature miRNA sequence (red or blue) and the flanking sequence. (a) *let-7* RNA genes in *C. elegans* (*cel-let-7*), *D. melanogaster* (*dme-let-7*) and human (*hsa-let-7a-1*) are highly conserved. The human genome has at least nine *let-7* subfamily genes while nematode worm and fruit fly have one each. (b) The human *mir-30a* gene expresses a pair of miRNAs from both arms, the more abundant miR-30a (red) and the less abundant miR-30a* (blue). (c) Examples of miRNAs from *Arabidopsis thaliana*, MIR172b and MIRJAW. (d) Examples of miRNA genes that are organized as clusters. Grey and black boxes indicate the regions corresponding to 60–70-nt precursors and mature miRNAs, respectively.

sequence of the mature miRNA and facilitating biogenesis.

Many miRNAs accumulate differentially in a spatially and/or temporally regulated manner. MiRNA gene regulation is likely to take place mainly at the transcriptional level like other genes, although some miRNAs may also be under post-transcriptional control such as in processing and export.

MiRNA biogenesis in plants is different from that in animals in many respects (2). MiRNA stem-loops in plants are highly variable in length and structure. The precursors of 60–70 nt are not found in plants. DCL1 (Dicer-like 1), HEN1 (a putative dsRNA methylase) and HYL1 (dsRNA RNA-binding protein) are required for miRNA accumulation. Plants have several Dicer homologues while no Drosha homologue has been

found. HASTY is a plant homologue of Exp5, and plays an important role in miRNA biogenesis.

Function

It is becoming clear that miRNAs have key roles in diverse regulatory pathways (2). The paradigm for the function of miRNAs has been provided by *lin-4* and *let-7* RNA. They act as post-transcriptional repressors of their target genes when bound to their specific sites in the 3' untranslated region (3'UTR) of the target mRNA. The level of target mRNA does not change, indicating that the inhibition occurs at the level of translation.

Out of hundreds of miRNAs, only a handful of miRNAs are known for their biological functions. For instance, *bantam* RNA from *Drosophila* suppresses

MicroRNA. Figure 2 Model for miRNA biogenesis and action mechanism. MiRNA genes are transcribed by RNA polymerase II to generate the primary transcripts, referred to as pri-miRNAs. The initiation step (cropping) by Drosha results in pre-miRNAs of ~70-nt, which are exported by Exp5. Upon export, Dicer participates in the second step (dicing) to produce miRNA duplexes. The duplex is separated and one strand is usually selected as mature miRNA while the other strand is degraded. Final products act as guide molecules in translational control or cleavage of certain mRNAs, depending on the degree of complementarity between the miRNA and the target mRNA. The question marks indicate unidentified biogenesis factors.

apoptosis and stimulates cell proliferation by inhibiting translation of *hid* mRNA. Being expressed in a temporal and tissue-specific manner, *bantam* RNA regulates tissue formation during development. Another nematode miRNA, *lsey-6* RNA, was recently identified in a gene screening for left/right asymmetry of neuronal chemoreceptor expression. *Lsey-6* RNA targets *cog-1* transcription factor. In mammals, miR-181 is involved in the control of hematopoiesis through

as yet unknown target(s). More recently, miR-196 miRNAs were shown to repress the expression of the *HOXB8* gene, which is a transcription factor important in developmental regulation. MiR-196 RNAs are the first examples of animal miRNAs that cause target mRNA cleavage rather than translational repression. Plant miRNAs generally show higher degrees of complementarity to the target mRNAs, resulting in target cleavage. For instance, MIRJAW binds and

guides the cleavage of TCP4 mRNA, which encodes a transcription factor regulating leaf development and embryonic patterning.

Interestingly, most of the known targets of plant miRNAs are transcription factors, particularly those involved in developmental regulation or cell differentiation. Functions of the targets of animal miRNAs seem to be more diverse than those of plant miRNAs. MiRNAs and their targets seem to constitute remarkably complex regulatory networks, since a single miRNA can bind to and regulate many different mRNA targets and, conversely, several different miRNAs can cooperatively control a single mRNA target.

Action Mechanism

The fate of the target mRNA when bound to miRNA – translational inhibition or mRNA cleavage – seemingly depends on the degree of complementarity between the miRNA and the target mRNA (Fig. 2). In either case, the highest complementarity (near perfect match) is found at positions 2–8 nt relative to the 5' end of miRNA. Base pairing at this position appears to be important for target recognition. For translational inhibition, multiple binding of miRNAs on a single mRNA induces a synergistic effect.

MiRNA is strongly associated with the Argonaute family protein and is a part of a ribonucleoprotein complex termed **miRNP** (also called miRISC). Argonaute family proteins are highly basic proteins of ~100 kD that contain two common domains, PAZ and PIWI domains. The PAZ domain, consisting of ~130 amino acids, is usually located at the center of the protein and interacts with the 3' overhang of dsRNA. The C-terminal PIWI domain containing ~300 amino acids is important for its interaction with Dicer. Although Argonaute proteins play a central role in various aspects of small RNA pathways, their biochemical functions are still unclear. The miRNP in humans also contains other proteins such as Gemin3 (a putative helicase), Gemin4, and **FMR1/FMRP** (the fragile X mental retardation protein).

The mechanism of translational repression remains elusive because polysome profiling on the target mRNA indicates that ribosomes still proceed on the mRNA as if they are being normally translated. The detailed mechanism of mRNA cleavage has been unravelled by the recent discovery of the nuclease that executes the cleavage of mRNA. The nuclease in humans is hAgo2, one of the Argonaute family proteins, whose PIWI domain serves as the catalytic domain.

Related Molecules and Pathways

There are other types of small RNAs that share common structural features with miRNA, the size (19~27 nt) and the end structure (the 5' phosphate

group and the 3' hydroxyl group). RNase III proteins play central roles in the generation of the small RNA family. Dicer homologues can be found in *S. pombe*, *C. elegans*, *Drosophila*, mammals and plants, suggesting that small RNA-mediated regulation is evolutionarily ancient and may have critical biological roles. Small RNAs regulate remarkably diverse pathways, including **RNA interference** (RNAi), heterochromatin formation and chromosome rearrangement.

RNAi refers to sequence-specific gene silencing induced by double-stranded RNA (dsRNA) (7). The small RNA acting in RNAi is called **small interfering RNA** (siRNA), which is defined as small RNA of ~22 nt generated from long dsRNAs of exogenous or endogenous origin. Dicer cleaves dsRNA to short (~22 nt) RNA duplexes that contain a 2 nt overhang at each 3' end. Each strand contains a 5' phosphate group and a 3' hydroxyl group. siRNA is incorporated into a nuclease complex called **RISC** (RNA-induced silencing complex, also called siRISC). The initial RISC containing a siRNA duplex is inactive until it is transformed into an active form, which involves loss of one strand of the duplex. The activated RISC then targets and cleaves mRNA that is complementary to the siRNA. Biochemical studies using *Drosophila* S2 cell extracts and human HeLa cell extracts revealed the presence of argonaute family proteins in the RISC. Argonaute-2 (AGO2) and eIF2c2 (hAGO2) were found in *Drosophila* and human, respectively. Depletion of the eIF2C proteins by RNAi showed that they are required for RNAi. Intriguingly, human let-7 was found to be a component of a RISC and can catalyze target cleavage if the mRNA has perfect complementarity to let-7. Thus, RISC and miRNP may simply be different names for the same complex, although they might represent distinct complexes with slightly different compositions and functions. At least in *Drosophila*, some of the protein factors are distinct in the two pathways. Dicer-1 is responsible for miRNA accumulation whereas Dicer-2 functions in siRNA production.

One of the most popular RNAi techniques is to express short hairpin RNA (shRNA) from which active siRNA is generated by Dicer (Fig. 2). ShRNAs are transcribed from an RNA polymerase III-dependent promoter such as the U6 snRNA gene promoter that allows termination at a stretch of four Us. Because the structure of shRNA resembles that of pre-miRNA, shRNA is exported and processed by miRNA maturation machinery. Therefore shRNAs can be regarded as artificial pre-miRNAs.

Endogenous siRNAs found in *S. pombe* are derived from centromeric repeat transcripts and direct heterochromatin formation in this region. The centromeric RNAs were found as part of a ribonucleoprotein complex called **RITS** (RNA-induced initiation of transcriptional gene silencing) that also contains Ago1,

the only argonaute homologue in fission yeast, together with Chp1 (a chromodomain-containing protein) and Tas3p. Mutations of these protein genes result in the loss of the heterochromatin state at the centromeric repeats. A similar mechanism seems to exist in *Drosophila*, where Aubergine and Piwi (Argonaute proteins) are required for heterochromatin formation.

Clinical Relevance

Some miRNAs have been implicated in tumorigenesis (3). Human miR-15a and miR-16-1 are located in the intronic region of a non-coding RNA gene named LEU2. This region at chromosome 13q14 is frequently deleted and/or the expression is down-regulated in the majority (~68%) of B cell chronic lymphocytic leukemia (B-CLL) cases. Some miRNA genes are located near breakpoint regions in cancer, including miR-142 whose promoter is thought to be placed upstream of the MYC gene leading to MYC over-expression. There may also be miRNAs acting as proto-oncogenes. For instance, miR-155 is part of a non-coding RNA gene, BIC, originally found as a target for retroviral insertion-induced B cell lymphomas in chicken. Human BIC RNA, which is a precursor of miR-155, is highly expressed in pediatric Burkitt lymphoma and in Reed-Sternberg cells of Hodgkin lymphoma. Identification of the molecular targets for these miRNAs will be necessary to provide direct links between miRNA genes and cancer.

FMR1 (also named FMRP) whose loss of function in human causes fragile X mental retardation syndrome was found associated with miRNA and Argonaute proteins in *Drosophila* and human (5), implying that the miRNA pathway may be involved in fragile X syndrome.

Microsatellite/Microsatellite Marker

Definition

Microsatellites are DNA sequences, typically shorter than 1000 bp, which are composed of tandemly repeated units 1–10 bp long (also 1–6 bp or 1–13 bp ranges are used). Microsatellites are also known as short tandem repeats (STR) or simple sequence repeats (SSRs). These repeat sequences occur frequently and randomly across the human genome. Microsatellites are highly polymorphic and make ideal markers for linkage analysis.

Microtubule

Definition

Microtubule refers to a hollow tube of 25 nm diameter formed by 13 protofilaments. Each protofilament consists of polymerised α and β tubulin heterodimers. Microtubules are polarized and have a plus and a minus end. They form a structural network within the cytoplasm of eukaryotic cells, build up cilia and flagella, and are involved in intracellular transport and migration.

Definition

► Microvilli are finger-shaped ► plasma membrane protrusions that are found at the surface of a large variety of cell types but are most numerous and elaborated on simple epithelial, for example intestinal mucosa and the ► epithelium of the kidney proximal tubule. In contrast to other plasma membrane extensions, microvilli are not attached to the extra-cellular matrix but cover free cell surfaces that are, in many cases, facing a lumen where exchange occurs. These protrusions were termed microvilli by analogy with the intestinal villi because they increase, as do those, the absorptive surface of the gut. Microvilli of cells of the placental syncytiotrophoblast contribute to the bi-directional foeto-maternal exchanges. However, the function of microvilli is not restricted to absorption. Microvilli of the apical surface of hepatocytes participate in secretion. ► Stereocilia are surface projections present on the surface of the hair cells of the sensory neuroepithelium of the ► inner ear that participate in the transformation of a mechanical stimulation into an electrical auditory signal. Similarly, the photoreceptor cells of the eye also bear modified microvilli on their apical surface. Microvilli covering the surface of circulating ► immune cells, such as leucocytes, mediate adhesion to the endothelium, a key step in the activation of migration of immune cells to the sites of inflammation. Microvilli-like structures are also induced by pathogens and are linked to their propagation cycle within the infected organism.

Characteristics

Common and Function-Specific Features of Microvilli

Microvilli contribute to very diverse biological functions, yet they are all constructed following the same principle. The organisation of a prototype microvillus was established on the basis of the information gained from ultrastructural and biochemical analysis of the relatively stable microvilli of ► absorptive intestinal cells (1). The plasma membrane is supported by a

Microvilli. Figure 1 Schematic representation of a prototype microvillus. The major cytoskeleton components are indicated.

bundle of a variable number of cross-linked proteinaceous filaments, made of **actin**, a 43 kD monomeric protein (Fig. 1). Actin has an intrinsic asymmetry and self-assembles into a polar filament with a fast- and a slow-growing end, also termed the plus- and minus-ends. The fast growing ends of microvillar actin filaments are oriented towards the tip of the microvillus and addition of monomers at this end is required for membrane extension. In some cases, the cross-linked actin filaments exhibit a hexagonal, paracrystalline organisation, the structural constraint of which dictates the binding of other proteins. Linker proteins tethering the F-actin core bundle to the inner face of the plasma membrane increase the stiffness of the microvillus and play an important role in the maintenance of its structural and functional integrity and in the integration of signals. The microvillar plasma membrane is a specialised domain containing lipid rafts that are lipid-based sorting platforms for proteins involved in **endocytosis**, **signalling** and cell adhesion.

Comparison of different types of microvilli reveals that, in addition to the proteins involved in specific, cell type-dependent functions, they also contain a common repertoire of proteins. Highly conserved throughout evolution, these proteins frequently control the assembly of microvilli or are required for their structural integrity. Three representative types of microvilli with distinct biological functions will be considered here to illustrate the common and specific features of these structures: 1) microvilli of absorptive epithelial cells of the gut, 2) stereocilia of the inner ear hair cells and 3) microvilli of immune cells.

Molecular Interactions

Microvilli permanently covering the apical surface (**Apical Membrane**) of polarised absorptive epithelial cells or the stereocilia of the sensory neuroepithelium of the inner ear are the basic units of two highly specialised structures (Fig. 2, Table 1).

The well-characterised microvilli of the absorptive epithelial cells of the small intestine are densely packed and all of similar size (1–2 μm), forming a stable structure named the “**brush border**” that is specialised for nutrient up-take (2). The actin filament core bundle comprises 15–20 actin filaments plunging into a cap of dense material present at the tip of the microvillus. The major cytoskeletal components of the brush border microvilli are the actin filament bundling proteins **villin**, fimbrin and espin. These proteins harbour two closely spaced F-actin binding sites endowing them with the capacity to cross-link actin filaments into a tight, unipolar bundle. The non-conventional brush border myosin I, a Ca^{2+} -calmodulin-complexed actin-based ATPase **motor protein**, and ezrin, an **ERM (ezrin radixin moesin)** family member, link the actin core bundle to the plasma membrane. Ezrin and other family members bind to F-actin as well as to membrane proteins including adhesion and signalling molecules. Fodrin, a tetrameric actin cross-linking protein, anchors the actin core bundle “roots” to a dense meshwork of filaments, named the terminal web, further stabilising the microvillus. Related to its function in absorption, the plasma membrane of intestinal microvilli contains proteins involved in sugar transport and enzymes implicated in the degradation of nutrients like dipeptidyl peptidase IV or in ion transport. Intestinal microvilli also contain signalling molecules, including Ca^{2+} -buffering proteins like calmodulin, enzymes involved in phosphoinositide metabolism, serine/threonine or tyrosine protein kinases and **small GTPases** like ras. The microvillar plasma membrane is enriched in cholesterol-glycosphingolipid-containing microdomains, the “lipid rafts” that have been assigned a role in membrane trafficking. Playing an important role in the biology of brush border microvilli, these microdomains contain proteins involved in nutrient up-take, including ion channels, enzymes, immunoglobulin receptors and signalling molecules.

Stereocilia found at the apical surface of hair cells are modified microvilli that are arranged in ranks of increasing height (up to 120 μm) and connected to each other with extracellular linkages. Linked stereocilia, 30–300 in number, form a functional unit, the hair cell bundle, that is a primary detector of sound vibrations. Despite their distinct biological roles, intestinal microvilli and stereocilia share common structural and biochemical features. The stereociliary membrane is supported by a hexagonal, unipolar, actin

Microvilli. Figure 2 Transmission electron microscopy images of the intestinal cell brush border. (a) The apical surface of polarised epithelial cells of the small intestine exhibit finger-like plasma membrane extensions, the microvilli, forming the brush border. (b) Higher magnification of the brush border visualising the microvillar actin cytoskeleton. (c) Transverse sections of the microvilli. Bar, 1 μm (a) and 0.2 μm (b and c).

filament bundle with which the actin filament bundling proteins fimbrin and espin are associated. Radixin, an ERM protein, is detected at the base of the stereociliary bundle. The rootlets of the core bundle are tethered *via* the cross-linking proteins fodrin and alpha-actinin to a dense meshwork of filaments, named the cuticular plate. Comparison of brush border microvilli and stereocilia also reveals differences. Unlike brush border microvilli, stereocilia contain several hundreds of actin filaments and exhibit a staircase organisation, implying a specific control mechanism of actin filament length. The inter-stereocilia proteinaceous linkages play an important role in mechanotransduction. Mechanically gated channels that are part of the molecular mechanotransduction machinery are located at the tip of short and on the sides of long stereocilia, at interconnection sites. When stereocilia deflect during sound stimulation, the elastic linkages stretch, thereby opening the

transduction channels. In keeping with their function, stereocilia harbour a specific set of proteins, including adhesion molecules like cadherin 23 and proteins controlling stereocilium length or adjusting the position of the linkages. ► **Unconventional myosins** may contribute to these regulatory mechanisms by controlling membrane traffic and membrane protein distribution. Among these, myosins VI, VIIa and XVa are the best studied because of their implication in ► **genetic hearing diseases** (3). They distribute with the cuticular plaque (e.g. myosin VI), along the stereociliary core bundles (e.g. I beta, VIIa) or are restricted to the tip (myosin XVa), suggesting that they have distinct functions in hair cell assembly and maintenance.

Unlike microvilli of the brush border and stereocilia, those covering the entire surface of immune cells are non-permanent structures whose formation depends on the activation state of the cell. The microvilli of

lymphocytes and leucocytes mediate contact with the endothelium under flow, also named rolling adhesion, the first event of a cascade leading to their emigration from circulation to tissue in response to inflammation (4). Microvilli also mediate homotypic and heterotypic interactions of lymphocytes. Although less information is available on the structural and biochemical properties of these transient structures when compared to brush border microvilli or to stereocilia, they contain, as do those, a polarised actin bundle that is linked *via* the ERM family member moesin to the plasma membrane. The plasma membrane of immune cells' microvilli is a domain specialised in adhesion and signalling. Segregation of specific adhesion molecules to microvilli or planar membrane areas is thought to depend on lipid rafts. In addition, the repertoire of adhesion molecules of the microvillar membrane is defined by cell type specific regulation of gene expression. While selectin type adhesion molecules are present at the tip of leucocyte microvilli, $\alpha 4 \beta 7$ (CD 49d) ►integrins mediate lymphocyte attachment under flow.

Regulatory Mechanisms

Assembly Mechanisms of Microvilli

The assembly of all microvilli is regulated in time and space by a specific set of associated proteins. However, the time course of the assembly process varies considerably when comparing different types of microvilli. For example, while microvilli of epithelial cells form progressively during embryonic development and undergo terminal differentiation in adults, activation of the immune response requires rapid growth of microvilli on the surface of circulating blood cells. Nevertheless, in both cases the important steps of the cascade of events leading to the morphogenesis of microvilli include

1. temporally and spatially regulated nucleation of a rudimentary actin ►cytoskeleton at the inner face of the plasma membrane,
2. elongation of actin filaments and assembly of the microvillar actin core bundle,
3. regulation of the length and width of microvilli
4. spatial restriction of plasma membrane proteins and lipids.

Although signals triggering the assembly of microvilli are diverse and depend on the cellular background, common molecular mechanisms underlie microvillar morphogenesis. Indirect evidence indicates that Rho GTPase family members, molecular switches regulating actin assembly and disassembly through effector proteins, may control the assembly of the microvillar cytoskeleton. In the same way, WASp (►Wiskott Aldrich syndrome protein), a cdc42 and rac GTPase effector protein, is a plasma membrane-cytoskeleton

linker. Initially identified as the gene causing the Wiskott Aldrich syndrome, a rare ►genetic X-linked disease associated with immune cell disorders, WASp appeared to be required for the morphogenesis of microvilli of immune cells (5). WASp deficient lymphocytes exhibit fewer and shorter microvilli when compared with normal cells. Upon inactivation of intramolecular autoinhibition of ►WASp by cdc42 or rac, this scaffolding protein localises to the plasma membrane and recruits the Arp2/3 complex (actin related protein). Made up of seven subunits, this complex binds to the sides of actin filaments and initiates the assembly of a new filament with a free barbed end from which it will grow, yielding a branched filament network. Whether WASp initiates the assembly of the microvillar cytoskeleton is still a matter of debate. In support of such a mechanism, WASp was shown to be required for the temporally correct assembly of rhabdomeres, microvilli-like structures of the insect eye. However, WASp deficient lymphocytes are not totally devoid of surface projections, suggesting that other WASp family members, like WAVE, or alternatively another so far unknown nucleating protein initiate the assembly of the microvillar actin cytoskeleton. Evidence has been given that ERM family members may also contribute significantly to microvillar morphogenesis. Activation of the EGF receptor results in tyrosine phosphorylation of ezrin and concomitant growth of microvilli in epithelial cells. Phosphorylation and PIP2 binding release the intramolecular autoinhibition of ERM proteins, exposing their plasma membrane and actin binding sites. Inhibition of the expression or function of ERM family members severely impairs the formation of cell surface projections. Consistent with a function in microvillar regulation, inactivation of ERM actin-membrane linkers by dephosphorylation precedes microvillar breakdown in immune cells. In addition to the stabilisation of actin filaments, ERM proteins may also control the spatial distribution of plasma membrane proteins. Bundling proteins arrange the elongating actin filaments into a unidirectional array that grow from their free, membrane-oriented ends, generating the force required for plasma membrane protrusion. Bundling proteins may not only align actin filaments into unipolar arrays, but also control elongation. Indeed, forced expression of the bundling proteins villin, fimbrin or espin causes the growth of microvilli. Several, non-exclusive mechanisms may account for this activity. Binding of bundling proteins to the sides of actin filaments may interfere with Arp2/3-dependent nucleation of a dendritic network and contribute to its conversion into a parallel array of actin filaments, as shown for fascin, a filopodia-associated bundling protein. Alternatively, they may control the length of

microvilli by regulating the turnover of actin in the microvillar core bundle, as suggested in a recent study with espin. In addition, non-conventional myosins may control the length of microvilli by regulating membrane traffic. However, the precise mechanism of action of these motor proteins remains to be elucidated. Recently, activation of the serine/threonine kinase LKB1, a human homologue of the *C. elegans* Par-4 polarity proteins, by the adaptor protein STRAD was shown to induce the polarisation of single intestinal epithelial cells and the assembly of a brush-border like structure (6). In the future, the identification of the downstream effectors of LKB1 will contribute to unravelling the assembly mechanism of brush border microvilli.

Dynamics of Microvilli and Remodelling

Mature microvilli are not static but dynamic structures, capable of shrinking or growing in response to specific stimuli. This is most obvious for immune cell microvilli that assemble or disassemble depending on the activation state. However, permanent microvilli of the intestinal brush border or of stereocilia are also dynamic structures. Intestinal microvilli shorten in physiological situations like fasting or in pathological situations, such as infections of intestinal cells by viral or bacterial pathogens. Similarly, exaggerated bending can damage terminally differentiated stereocilia so that they need to be repaired. Actin incorporates at the tip of mature microvilli, showing that their actin cytoskeleton is continuously renewed. Thus, the above-described mechanisms of molecular regulation are not only for microvillar assembly but also contribute to the maintenance of their integrity, their renewal or remodelling. This duality is illustrated by villin, a multifunctional, Ca^{+2} -regulated actin-binding protein that bundles actin filaments in the absence of Ca^{+2} and depolymerises actin filaments in a Ca^{2+} -dependent manner. Consistent with its *in vitro* properties, villin might have a role in both the assembly and breakdown of microvilli in epithelial cells.

Disorders of Microvilli and Pathology

Although exhibiting very different clinical features, microvilli-associated pathologies are frequently caused by mutations in genes encoding cytoskeleton components or adhesion molecules. The close relationship between the actin cytoskeleton, cell signalling and communication is illustrated by the X-linked Wiskott-Aldrich syndrome, a rare recessive disorder caused by mutations in the *WAS* gene yielding severe defects in platelets and immune cells (5). The ►[scaffolding protein](#) WASp not only regulates actin polymerisation in microvilli but also controls T-cell receptor complex formation. As a consequence, T-lymphocytes of WAS

patients exhibit abnormal short microvilli, impaired interaction with B-cells and poor response to protein antigens. Hearing impairment is frequently caused by mutations in genes encoding unconventional myosins (3) and actin-associated proteins like espin that regulate stereociliary length and shape. For example, myosin VIIA seems to play a role in the formation of the linkages connecting neighbouring stereocilia (USH-ER1B syndrome). Myosin VIIA was shown to interact with verzinin, a protein of cadherin-catenin ►[adherens junctions](#) and with signalling molecules. Notably, mutations in the myosin VIIA gene also lead to blindness, demonstrating the close structural and functional relationship of these microvilli-like structures. Recently, mutations in the whirlin gene were shown to cause human autosomal recessive deafness (DFNB31). This ►[PDZ domain](#) protein might organize a group of proteins into a functional complex required for stereociliary elongation. In addition, mutations in cell-cell contact molecules, like cadherin 23, also impair hair cell function by causing spraying of stereocilia in hair cell bundles. Pathologies linked to microvilli dysfunction are also found in endoderm-derived cells like hepatocytes and enterocytes. ►[Biliary atresia](#), a clinical disorder resulting in progressive liver cholestasis, correlates with the disorganisation of bile canalicular microvilli and the absence of the actin bundling protein villin (7).

MIDAS

Definition

MIDAS stands for Metal Ion-Dependent Adhesion Site. It is formed by an array of key residues in some integrin head domains which coordinate a divalent cation during ligand binding.

► [Integrin Signalling](#)

MIF

Definition

This term has been used in several different ways:

- a) ► <http://www.copewithcytokines.de/cope.cgi> Mesoderm inducing factor: factors inducing the formation of the mesoderm of amphibian embryos. These are members of the TGF- β , FGF, and Wnt families of proteins.
- b) Macrophage migration inhibitory factor is a proinflammatory cytokine that was originally defined on the basis of inhibition of emigration of mononuclear cells from capillaries. MIF has been associated with various types of adenocarcinoma.
- c) Müllerian-duct inhibiting factor refers to a factor that suppresses the further development and maintenance of the Müllerian-ducts in embryos.

Migration

Definition

Migration corresponds to the movement of cells on a certain substrate, in response to a certain chemotactic or chemokinetic signal. During migration, cell surface receptors are continuously recycled from the rear to the leading edge of the cell as result of dynamic cytoskeleton rearrangements.

Milk-Alkali Syndrome

Definition

Milk-alkali syndrome refers to a chronic disorder that is characterized by deposition of calcium in many sites, especially in the kidney. It is induced by ingestion of large quantities of calcium and alkali, formerly used to treat peptic ulcers.

► [Hyper- and Hypoparathyroidism](#)

Miller-Dieker Syndrome

Definition

Miller-Dieker syndrome (MDS) is a contiguous gene syndrome (1:20,000 newborns) that is caused by loss of one allele of PFAH1B1 (platelet activating factor acetylhydrolase, isoform Ib alpha subunit), and neighboring genes at chromosome 17p13.3. Features include lissencephaly and a very mild facial dysmorphism. PFAH1B1 point mutations result in a similar clinical outcome (isolated lissencephaly sequence) but without the facial dysmorphism of MDS.

► [Microdeletion Syndromes](#)

Miller Planes

Definition

Planes parallel to the faces of the unit cells and all other diagonal planes formed using the vertices of combinations of unit cells. These sets of equally spaced parallel planes correspond to the Miller indices of the individual diffracted spots. The planes parallel to the faces of the unit cell correspond to the basic Miller indices (100), (010) and (001); higher indices correspond to the more narrowly spaced diagonal planes. In general, the Miller indices (h,k,l) indicate the number of planes crossing the a, b and c axes of the unit cell, respectively. The reflection F(h,k,l) can be measured when the orientation of the Miller planes relative to the incoming X-ray beam fulfills Bragg's law.

- OMIM

MIN/MSI

Definition

Mutations in genes that repair damaged DNA cause genomic regions called microsatellites to get longer or shorter, a phenomenon that is called microsatellite instability (MIN, also termed MSI). Microsatellites usually consist of repeated mono, di-, or trinucleotide sequences, which are prone to errors during DNA replication. MSI occurs in some but not all sporadic tumors, and can lead to frameshift mutations of genes when present in the coding sequence.

Mitochondria – Biogenesis and Structural Organization

ANDREAS S. REICHERT, WALTER NEUPERT
Department of Physiological Chemistry, Ludwig-Maximilians-University Munich, Munich, Germany
andreas.reichert@med.uni-muenchen.de
neupert@med.uni-muenchen.de

Definition

► **Mitochondria** are cellular compartments of eukaryotes that are enclosed by two membranes. They are often called the powerhouses of the cell because of their central role in energy transduction. Fundamental metabolic processes such as oxidative phosphorylation, iron-sulfur cluster biogenesis, beta-oxidation of fatty acids, the citric acid cycle, part of the urea cycle and heme synthesis take place in this organelle. Mitochondria further play important roles in apoptosis, ageing, signal transduction and cancer.

They are bounded by two membranes, the outer membrane and the inner membrane. The aqueous compartment enclosed by the inner membrane is called the ► **matrix** and the space between the two membranes is called the ► **intermembrane space**. The inner membrane can be further divided into the ► **inner boundary membrane** and the ► **cristae** membrane. The former is in continuous and close apposition to the outer membrane; together with the outer membrane it forms a kind of envelope of the mitochondria. Stable and dynamic ► **contact sites** between these two

membranes are necessary for a number of central mitochondrial functions, such as the channeling of metabolites, coordinated fusion and fission of mitochondria and protein transport into mitochondria (1). Cristae are invaginations of the inner boundary membrane that protrude into the matrix space. They harbor the complexes required for respiration and ATP synthesis. Cristae are connected to the inner boundary membrane by so-called ►**cristae junctions** (2). Rather than being wide openings, as often shown in biochemistry textbooks, cristae junctions are narrow tubular structures of varying length, which potentially act as diffusion barriers between the inner boundary and the cristae membrane.

Characteristics

Biogenesis of Mitochondria

Mitochondria contain their own genome (mtDNA), which, however, encodes only 8–13 proteins (yeast and human, respectively). The majority of mtDNA encoded proteins are components of oxidative phosphorylation, in particular of respiratory complexes I, III and IV, and of the F_1F_0 -ATP synthase. Approximately 99% of all mitochondrial proteins are encoded in the nuclear genome. Consequently, most of the proteins are imported into mitochondria after being synthesized in the cytosol (3). The mitochondrial proteomes of various species and organs including the human heart, rice, baker's yeast and the inner membrane of mouse liver mitochondria have been analyzed. In yeast 750 proteins were identified, of which a large proportion (25%) is involved in the maintenance and expression of the mitochondrial genome (4). Thus, nearly 200 proteins are involved in the synthesis of only eight mitochondrial proteins. The function of another 200 proteins is still unknown. Mitochondria contain translocases responsible for import and sorting of preproteins into the different mitochondrial subcompartments. Translocases control the specificity of the sorting processes and facilitate the vectorial movement of polypeptides across and into mitochondrial membranes.

Morphology of Mitochondria

The macroscopic appearance of mitochondria in cells as observed by fluorescence microscopy depends on the organism and the cell type as well as the metabolic state. Mitochondria exhibit a great variety of shapes, ranging from spherical or threadlike organelles to branched tubular networks (5). The reticular tubular network of mitochondria observed in different cells from yeast to human is highly dynamic and requires a balance of constantly occurring fusion and fission processes (reviewed in 6). This dynamic nature of mitochondrial morphology is essential for the inheritance of mitochondrial DNA and for spermatogenesis. Furthermore,

fragmentation of mitochondria is required for cells to undergo apoptosis. In apoptotic cells, release of cytochrome c from the intermembrane space is further accompanied by remodeling of the cristae membrane. Moreover, complementation of mutations in mitochondrial DNA within cells depends on the capability of mitochondria to fuse with each other. Thus, fusion of mitochondria seems to be important as a defense mechanism against oxidative damage and ageing (6). Taken together, the biogenesis as well as the dynamic nature of the structural organization of mitochondria is crucial for maintaining their functionality within the cell.

Molecular Interactions

Protein Import into Mitochondria

Correct targeting of preproteins requires the presence of signal sequences. A typical mitochondrial targeting sequence is a positively charged stretch of about 15–80 amino acid residues located at the N-terminus which is able to form an amphipathic helix. Internal sorting signals also exist such as those found in members of the mitochondrial solute carrier family. The ►**TOM complex** (translocase of the outer membrane) recognizes preproteins on the cytosolic side of the outer membrane of mitochondria and mediates their transfer into the intermembrane space or into the outer membrane. A recently discovered complex in this membrane, the ►**TOB complex**, is essential for the integration of β -barrel proteins into the outer membrane after they have passed the TOM complex. The inner membrane contains three known translocases: the TIM23, the TIM22, and the ►**OXA1 complex**. The ►**TIM23 complex** transports preproteins containing typical N-terminal mitochondrial targeting sequences into the matrix or into the inner membrane. The ►**TIM22 complex** facilitates the import of hydrophobic inner membrane proteins that contain internal signal sequences such as members of the solute carrier family. Other proteins are first imported into the matrix *via* the TIM23 complex before they are exported and inserted into the inner membrane by the OXA1 complex. The latter complex also mediates the insertion of mitochondrially-encoded proteins. The mitochondrial translocases act in a coordinated fashion. This cooperation is instrumental in correct sorting and maintenance of mitochondrial identity and thereby in the functionality of this highly complex organelle.

Fusion and Fission of Mitochondria

Many of the molecular mechanisms underlying fusion and fission of mitochondria were initially understood from studies in baker's yeast. For example, deletion of Mgm1 leads to extensive fragmentation of mitochondria, loss of mitochondrial DNA and abolishment of mitochondrial fusion. Mgm1 is an intermembrane

space localized dynamin-like protein. Dynamins are large GTPases, which are normally known as key players in vesicle formation during endocytosis. Mgm1 was proposed to be involved in modulating the cristae membrane morphology and to be essential for the fusion of mitochondria (6). Fusion requires at least two more proteins in yeast, Fzo1 and Ugo1. Both are outer membrane proteins and were shown to interact with Mgm1. Thus, Mgm1, Fzo1 and Ugo1 are likely to be part of dynamic contact sites in mitochondria that mediate fusion processes between mitochondria. Fission of mitochondria depends on the dynamin-related GTPase Dnm1. This protein is mostly localized in the cytosol but part of it assembles into a ring-like complex on the cytosolic side of mitochondria in order to facilitate the division of mitochondria. This division apparatus contains two other proteins, Fis1/Mdv2 and Mdv1/Fis2/Gag3, which are equally important for mitochondrial fission. However, the molecular details of how fusion and fission of a double-membrane enclosed organelle occurs are still far from being understood, as are the mechanisms of the regulation of these processes.

Regulatory Mechanisms

Energy Dependency of Mitochondrial Biogenesis and Dynamics

Oxidative phosphorylation is usually the major source of ATP in mammalian cells. The glycolytic pathway, however, is the predominant origin of ATP in cancer cells. Baker's yeast is able to switch between these two pathways depending on the type of carbon source present and is therefore a highly suitable model organism for studying the energetic requirements of mitochondrial biogenesis. Import of proteins into or across the inner membrane as well as mitochondrial fusion and fission are energy dependent. Dissipation of the membrane potential of the inner membrane using uncoupling chemical compounds such as CCCP impairs import of preproteins into the matrix or into the inner membrane. In addition to a membrane potential, import of preproteins into the matrix using the TIM23 complex requires the presence of matrix ATP. This results from the ATP-dependency of the 70 kD mitochondrial heat shock protein (mtHsp70) which is an essential component of the import motor. However, in the case of preproteins using the TIM22 or the OXA1 translocase, the presence of a membrane potential is sufficient to complete translocation into the inner membrane. Insertion of proteins into the outer membrane depends on cytosolic ATP but not on a membrane potential nor on matrix ATP. Fusion of mitochondria is also a process that depends on the membrane potential; however, the underlying molecular mechanism is unknown.

Both, fusion and fission of mitochondria are processes that require the action of a dynamin-like GTPase,

Mgm1 and Dnm1, respectively. Therefore it is likely that at least one energy dependent step in both processes is the hydrolysis of GTP. Fragmentation of mitochondria and loss of mitochondrial DNA upon deleting *Mgm1*, *Fzo1*, or *Ugo1* can be prevented by blocking mitochondrial fission, e.g. by deletion of *Dnm1*. When fission is blocked, but fusion still going on, mitochondria adopt a characteristic net-like structure. Fusion and fission of mitochondria therefore are independent processes, which under normal conditions are balanced in order to maintain a tubular reticular structure. How this balance is regulated within cells is one of the major unresolved questions concerning mitochondrial dynamics.

Mitochondrial Diseases Caused by Nuclear Mutations

Not surprisingly, mitochondrial dysfunctions play an important role in the pathogenesis of a variety of diseases (reviewed in 7). They are caused either by alterations in the mitochondrial or the nuclear DNA and mostly manifest as a reduced respiratory function accompanied by reduced ATP synthesis. Defects in the biogenesis and the structural organization of mitochondria are also associated with diseases in humans. The molecular mechanisms related to two such disorders are briefly summarized.

Mohr-Tranebjaerg syndrome

The Mohr-Tranebjaerg syndrome is the only known mitochondrial disorder associated with a defect in the mitochondrial import machinery (reviewed in 8). It is a rare neurodegenerative disorder caused by mutations in the X-linked gene coding for the deafness-dystonia peptide (DDP1/TIMM8a). DDP1 is localized in the intermembrane space of mitochondria and, together with TIM13, facilitates the import of preproteins into the inner membrane. In general, this process depends on the presence of a membrane potential across the inner membrane. The corresponding Tim8/Tim13 complex from yeast was shown to be required for import of preproteins into the inner membrane, in particular under bioenergetically unfavorable conditions leading to a reduced membrane potential. One substrate that requires Tim8/Tim13 under these conditions is Tim23, which itself is an essential component of the TIM23 complex. Mutations in DDP1 are likely to exert pleiotropic effects on the import of the vast majority of mitochondrial matrix and inner membrane proteins. The exact molecular pathomechanisms leading to the Mohr-Tranebjaerg syndrome, however, are unknown.

Optic atrophy type I

Optic atrophy type I (OPA1) is the most prevalent hereditary optic neuropathy, occurring with a frequency of 1:12000 to 1:50000. OPA1 is an autosomal-dominant

inherited disease with onset in the first two decades of life. It is characterized by progressive loss of visual acuity, development of cecocentral scotoma, color vision disturbances, and bilateral optic atrophy. Several mutations in the nuclear encoded gene *opal* on chromosome 3q28-29 are linked to *OPAL* in different families. *Opal* is homologous to *Mgm1* from baker's yeast, which was shown to be essential for mitochondrial morphology (see above). Down-regulation of *Opal* by small interfering RNA in cell culture results in alterations of cristae morphology. In addition, this leads to release of cytochrome *c* from the intermembrane space and promotes apoptosis. Nevertheless, it is not understood at all how mutations in *opal* lead to degeneration of the optic nerve and it will be interesting to see to what degree mitochondrially induced apoptotic pathways are involved in the pathogenesis of optic atrophies.

Complex V = ATP synthase

Definition

According to the endosymbiont hypothesis, mitochondria evolved from bacteria that were incorporated into protoeukaryotic cells more than a billion years ago. Those bacteria carried the capacity to generate cellular energy efficiently through aerobic metabolism, the oxidation of substrates to generate energy in the form of adenosine triphosphate (ATP). The pathway responsible for aerobic energy metabolism is composed of five enzymes complexes; four ►respiratory chain enzymes (complexes I-IV) generate a proton gradient across the inner mitochondrial membrane and complex V uses the proton gradient to generate ATP by ►oxidative phosphorylation (Fig. 1). In addition to their biochemical functions, the bacteria brought their own DNA, much of which has been incorporated during evolution into nuclear DNA. Nevertheless, mitochondria retained a small portion of their own genome. Consequently, mitochondria are the products of two genomes, one in the nucleus and the other within the organelle.

Characteristics

The ►mitochondrial genome is a small, 16,569 base-pair, circular DNA molecule (Fig. 2), efficiently packed with no introns and very few non-coding segments (1, 2). The genome contains 37 genes encoding: 22 transfer RNAs (tRNAs), two ribosomal RNAs (rRNAs)

Mitochondrial Genome. Figure 1 Schematic representation of the mitochondrial respiratory chain and oxidative phosphorylation enzyme complexes. Nuclear DNA encoded subunits are depicted as gray ovals and mitochondrial DNA encoded subunits are shown as colored ovals.

and 13 polypeptides required for respiratory chain function and oxidative phosphorylation. A mitochondrion has about five copies of mitochondrial DNA and each cell harbors hundreds of mitochondria; therefore, each cell contains hundreds to thousands of copies of mitochondrial DNA.

The two strands of the mitochondrial DNA differ in composition; one strand, disproportionately rich in guanine and thymine residues, is heavier in alkaline cesium chloride gradients and is therefore called the “heavy” or H-strand. Naturally, the other strand is identified as the “light” or L-strand.

Of the 13 polypeptides encoded in the mitochondrial genome, seven are subunits of complex I of the mitochondrial respiratory chain, one is a subunit of complex III, three are subunits of complex IV and two are subunits of complex V (Figs. 1, 2). In addition, about 70 structural polypeptides encoded in the nuclear DNA are required for mitochondrial respiratory chain activity. Only complex II is encoded entirely by nuclear DNA. In addition, 22 tRNA and 2 rRNA molecules encoded in the mitochondrial genome are required for mitochondrial protein synthesis.

Transcription of the Mitochondrial Genome

Unlike genes in nuclear DNA that are transcribed individually into RNA, the mitochondrial genes are transcribed as two large 16 kilobase polycistronic precursor molecules. The light strand and heavy strand promoters (LSP and HSP respectively) for transcription are located close to each other in the D-loop, a non-coding segment of the genome (Fig. 2). The

polycistronic transcripts are processed into individual messenger RNAs (mRNA) as well as tRNAs and rRNAs. Most of the mRNAs are separated by tRNAs that serve as “punctuation” signals for processing of the polycistronic transcripts into single gene RNA transcripts (Fig. 2).

Translation of the Mitochondrial Genome

Within mitochondria, mRNAs are translated into proteins. Four of the mitochondrial codons (three nucleotide segments that encode either an amino acid or a termination signal) differ from the 64 “universal” triplets. For example, AUA encodes methionine in the mitochondrial genome but encodes isoleucine in nuclear DNA.

Replication of the Mitochondrial Genome

During evolution, transfer of mitochondrial genes into the nuclear genome has made the mitochondrial genome a “slave” of the nucleus because all the factors required for replication and repair of mitochondrial DNA are encoded in nuclear DNA.

The mechanism of mammalian mitochondrial DNA replication is a controversial subject. According to the strand-asymmetric model, replication of mitochondrial DNA originates at two sites, the origins of heavy-strand synthesis (O_H) and light-strand synthesis (O_L) (Fig. 3) (7). In this model, mtDNA replication begins with binding of mitochondrial transcription factors and mitochondrial RNA polymerase and initiation of RNA synthesis at the LSP. This light strand transcript may generate a polycistronic RNA molecule as

Mitochondrial Genome. Figure 2 The mitochondrial genome. Structural gene abbreviations: A, ATP synthase; COX, cytochrome c oxidase; Cyt *b*, cytochrome *b*; ND, NADH dehydrogenase; 12S and 16S, ribosomal RNA genes; 1-letter code, transfer RNA genes. Control regions: HSP, heavy-strand promoter; LSP, light strand promoter; O_H , origin of heavy-strand replication and O_L , origin of light-strand replication.

previously described or may produce a short RNA primer for polymerase γ to initiate DNA synthesis at O_H . Replication of the heavy strand proceeds about two-thirds of the way around the mitochondrial genomic circle and exposes O_L , which serves as the initiation site for light strand replication. In contrast, the strand-synchronous model for mitochondrial DNA replication asserts that H-strand synthesis is initiated at O_H and is closely coupled with synthesis of the L-strand (Fig. 3) (5).

Mitochondria maintain nucleotide pools that are distinct from those of the rest of the cell and rely more heavily on nucleotide salvage pathways than nuclei, which depend on *de novo* synthesis.

Repair of the Mitochondrial Genome

Because mitochondria generate large quantities of reactive oxygen species (ROS) that can damage DNA, lipids and proteins, the organelles have effective mechanisms to repair ROS-damaged DNA. In contrast,

mitochondria seem to lack repair systems for other forms of abnormal DNA. For example, mitochondria are unable to remove ultraviolet-induced pyrimidine dimers. The differences in repair mechanisms and exposure to mutagenic factors may contribute to the ten-fold higher mutation rate of the mitochondrial genome compared to that of nuclear DNA.

Mitochondrial Inheritance

Human mitochondria and mitochondrial DNA are maternally inherited; a mother transmits her DNA to all of her children. This non-Mendelian inheritance pattern may be in part due to the overwhelming number of mitochondrial genomes, about 100,000, in each oocyte compared to about 100 copies of mitochondrial DNA in each sperm. In addition, there is evidence that after entry into oocytes, sperm mitochondria are lost early in embryogenesis. The mechanism of the selective elimination of sperm mitochondria is not fully understood. Nevertheless, there is a single well-documented

Mitochondrial Genome. Figure 3 Replication of the mitochondrial genome (modified from (7)). See text for detail.

man who developed a mutation in paternally derived mitochondrial DNA (6). It is not certain whether this patient represents a unique medical curiosity or is part of a more generalized phenomenon.

Segregation and Heteroplasmy

As previously noted, each cell contains a large population of hundreds to thousands of copies of the mitochondrial genome, which is strikingly different from the situation in nuclear DNA, where somatic cells have only two copies of each autosome. In most individuals, the mitochondrial genomes are identical (homoplasmy); however, mitochondrial DNA

polymorphisms can be present in variable proportions, a situation known as **heteroplasmy**. Consequently, in an individual with a heteroplasmic mitochondrial DNA polymorphism, the composition of mitochondrial DNA can vary from tissue to tissue or even from cell to cell within a tissue.

In oocytes, although there are about 100,000 copies of the mitochondrial genome, there is a bottleneck of a relatively small number of segregating units, perhaps as few as 5–50 that determine the mitochondrial genomic population of the embryo. Furthermore, the distribution of the polymorphic mitochondrial DNA may be skewed in different tissues.

Clinical Relevance

Mitochondria are vital organelles required for energy production and can affect virtually any organ. Brain and skeletal muscle are particularly vulnerable to mitochondrial defects because of their high energy requirements. Due to their dual genetic origin, mitochondrial disorders can be caused by mutations in mitochondrial or nuclear DNA. More than 150 point mutations and hundreds of deletions of mitochondrial DNA have been associated with human diseases (3). Because of the unique features of mitochondrial DNA, these mutations show unusual clinical characteristics. For example, most disorders of mitochondrial DNA are maternally inherited. Because of heteroplasmy and skewed segregation of pathogenic mitochondrial DNA mutations, phenotypic variability is common even within families harboring an identical mitochondrial DNA mutation.

Autosomal diseases of the mitochondria are being identified with increasing frequency. A group of Mendelian disorders with secondary quantitative or qualitative defects in mitochondrial DNA is being defined at the molecular level.

The potential role of mitochondrial DNA in aging has generated much interest and even greater controversy. According to the mitochondrial theory of aging, ROS derived from mitochondria may cause somatic mutation of mitochondrial DNA that, in turn, leads to more ROS production and a vicious cycle of additional deleterious alterations in the mitochondrial genome (4). For further information about specific mitochondrial disorders, readers are referred to the article on mitochondrial disorders in this Encyclopedic Reference of Genomics and Proteomics in Molecular Medicine.

Mitochondrial Membrane

Definition

There are two membranes for mitochondria that are small organelles found within eukaryotic cells. The outer membrane is semi-permeable, allowing small molecules like orotate to penetrate. The inner membrane is selectively permeable, and contains the electron transport chain required for respiration and reaction 4 of the pyrimidine pathway.

nils-goran.larsson@labmed.ki.se

Synonyms

Mitochondrial disease; Oxidative phosphorylation disease

Definition

Mitochondrial myopathies are diseases of varying severity caused by a dysfunction of the mitochondrial respiratory chain. They are often accompanied by symptoms in other tissues, particularly those with a high energy demand such as brain, liver, kidney and heart muscle. Tissues that are ► [post-mitotic](#), meaning that most of their cells do not divide any more, are often affected in mitochondrial disease. The terms mitochondrial disease, mitochondrial cytopathy, mitochondrial myopathy, mitochondrial encephalomyopathy and oxidative phosphorylation disease all refer to a heterogeneous group of diseases caused by defective function of the respiratory chain. The symptoms are extremely variable and onset of disease may be from early infancy to late adulthood.

The mitochondrial network is located in the ► [cytoplasm](#) of the cell and contains the respiratory chain. The respiratory chain consists of five enzyme complexes that generate the common form of energy currency, ► [ATP](#), required for a large array of metabolic processes in the cell. The respiratory chain is dependent on two

separate genomes to function, the nuclear DNA and the mitochondrial DNA, ►**mtDNA**. The mtDNA contains 37 genes, encoding 13 proteins and 24 RNAs needed for mitochondrial protein synthesis. A typical human cell contains 1,000–10,000 mtDNA molecules. Mitochondrial myopathies are caused by a variety of genetic defects in the mtDNA or nucleus.

Characteristics

Rolf Luft described the first patient with mitochondrial dysfunction more than forty years ago, even before mtDNA was discovered (1). The clinical manifestations of mitochondrial myopathies can be of varying severity and symptoms include muscle weakness, exercise induced cramps and ►**myalgia**. Other frequent symptoms are ptosis and ►**progressive external ophthalmoplegia** (PEO). Ptosis is when the muscles surrounding the eyes are weak and the patient has droopy eyelids. PEO is weakness of the muscles that control eye movement. The severity of PEO can vary from mild to complete paralysis. Less common skeletal muscle symptoms are episodic weakness with ►**rhabdomyolysis** and ►**myoglobinuria** (2).

The primary morphological hallmark of mitochondrial myopathies is the occurrence of ragged red fibers, RRF. These are muscle fiber segments that have an abnormal accumulation of mitochondria. The term RRF refers to the irregular shape of the mitochondrial accumulations and the finding that these accumulations can be stained red with a specific chemical stain (modified Gomori trichrome).

Respiratory chain deficiency caused by nuclear mutations usually affects all cells in a tissue in a uniform way, whereas mutations of the mtDNA result in a characteristic mosaic pattern of enzyme deficiency. The explanation for this pattern is that patients harboring mutations of mtDNA often have a mixture of normal and mutated mtDNA.

The levels of mutated mtDNA often vary widely between different organs in the patient and even between different cells of the same organ. A certain minimal number of mutated mtDNA molecules, a threshold level, is needed to produce a respiratory chain deficiency. This threshold level is different for different mutations and also varies depending on the affected tissue. The occurrence of two or more different kinds of mtDNA in a single cell is called heteroplasmy.

The distribution of mutated mtDNA is an important determinant of symptoms in patients carrying heteroplasmic mtDNA mutations. One particularly striking example is children with an infantile anemia and pancreas insufficiency disorder (Pearson syndrome) caused by widespread distribution of high levels of deleted mtDNA. This syndrome is often lethal but some infants recover; however they always develop a

severe neuromuscular syndrome (Kearns-Sayre syndrome) years later. The likely explanation for this complete change of symptoms with time is that clones of rapidly dividing bone-marrow cells with high levels of deleted mtDNA may be lost due to selection, thus allowing a recovery from anemia. However, deleted mtDNA will accumulate with time in non-dividing tissues such as muscle and nerve cells and this will lead to later onset of the neuromuscular syndrome (3).

Nuclear mutations causing respiratory chain deficiency may also have varying clinical phenotypes. Patients with ►**autosomal recessive** depletion of mtDNA usually die in infancy with severe myopathy. Patients with autosomal dominant or recessive PEO and multiple mtDNA deletions often have a milder disease with adult onset of symptoms.

In spite of recent advances in the understanding of the pathogenesis of mitochondrial diseases, there is no efficient treatment. There are some pharmacological treatments but there is no consensus on the efficacy of these drugs. Some progress has been made using small nucleic acids that selectively inhibit the replication of mutated mtDNA, hindering it from reaching threshold levels within the muscle fiber. Also, there has been some success with a strategy where affected muscle fibers are selectively killed. In this way dysfunctional muscle cells are removed and new, functional muscle can take their places. The optimal cure would be gene therapy, introducing the missing gene(s) into the mitochondria or, in the case of a nuclear mutation, the nucleus.

Genetics

There are three main categories of genetic defects causing mitochondrial myopathy:

1. Known mtDNA mutations; point mutations and deletions
2. Known nuclear mutations
3. Unknown mutations

In addition to these genetic categories, there can also be an accumulation of sporadic mutations in aging muscle. This can then lead to a late-onset mitochondrial myopathy affecting elderly individuals.

Known mtDNA Mutations: mtDNA Point Mutations

Mitochondrial DNA is maternally inherited. This means that the mtDNA from an individual comes from the mother. During the production of the egg, there is a phenomenon called the mtDNA “bottleneck”. This is thought to be when only a few mtDNA molecules are transferred from the precursor germ cell and then replicated up to the 100,000 copies of mtDNA in the mature egg cell (3). The “bottleneck” explains how a mother who has no or only mild symptoms can have

severely affected children. The random shift of mutation load between generations also means that it is difficult to predict the probability of having an affected child.

Today there are over 100 point mutations of mtDNA that are known to cause mitochondrial dysfunction. Point mutations leading to mitochondrial myopathies are often in a ▶**tRNA** gene, but disease-causing mutations in protein-coding genes have also been found (4). A tRNA mutation often leads to an impairment of mitochondrial translation and therefore a loss of several mitochondrial encoded respiratory chain subunits.

Examples:

- a mutation in *tRNA*^{Lys} causes myoclonic epilepsy with ragged red fibers (MERRF)
- a mutation in *tRNA*^{Leu} causes mitochondrial myopathy, encephalopathy, lactic acidosis and stroke-like episodes (MELAS)
- a mutation in *tRNA*^{Leu} causes progressive external ophthalmoplegia (PEO)

Known mtDNA Mutations: mtDNA Deletions

Single large deletions of the mitochondrial DNA are usually sporadically occurring. There is no obvious explanation as to why mtDNA deletions are rarely transmitted from the mother whereas mtDNA point mutations are frequently transmitted. Single large mtDNA deletions are thus usually sporadic and often not maternally transmitted, i.e. they happen by chance. There are several known nuclear mutations that cause multiple mtDNA deletions. However, in these cases it is the predisposition to develop mtDNA deletions that is inherited, not the deletions themselves.

Large deletions in mtDNA that cause diseases always remove at least one tRNA gene, leading to impaired translation of mitochondrial proteins and respiratory chain dysfunction.

Examples:

- chronic progressive external ophthalmoplegia (CPEO)
- Kearns-Sayre syndrome

Known Nuclear Mutations

Around 85 of the protein subunits in the respiratory chain as well as all proteins needed for the maintenance of the mtDNA are encoded by the nucleus. A wide range of proteins involved in other aspects of mitochondrial function such as transport across the mitochondrial membranes or protein assembly are also nucleus-encoded. The number of identified mutations in nuclear genes known to cause mitochondrial disease has increased dramatically over the last few years, and so far more than 20 have been documented (3).

When a nuclear mutation is the cause of mitochondrial myopathy, it will be inherited in a ▶**Mendelian** fashion. There are different kinds of mitochondrial myopathies and most of them are inherited in an ▶**autosomal dominant** way. Nevertheless, diseases with autosomal recessive or ▶**X-linked inheritance** are also known.

The clinical manifestations of a nuclear mutation affecting mitochondrial function can be very severe if a crucial enzyme activity is totally abolished. On the other hand, symptoms may be less severe if there is only a partial decrease of function or the mutation affects a redundant protein.

Examples:

- a mutation in *adenosine nucleotide transferase 1* (▶**ANTI**) causes autosomal dominant progressive external ophthalmoplegia (adPEO)
- a mutation in *thymidine phosphorylase* (▶**TP**) causes mitochondrial neurogastrointestinal encephalomyopathy (MNGIE)
- mutations in *DNA polymerase gamma* (▶**POLG**) cause autosomal recessive or dominant progressive external ophthalmoplegia (arPEO/adPEO)
- a mutation in mitochondrial *thymidine kinase* (TK2) causes autosomal recessive mtDNA depletion and severe infantile myopathy

Unknown Mutations

There are many cases with clinically established mitochondrial disease where no causative mutations have been found. In fact, this group of patients is the largest. In these cases, it is prudent to believe that the cause is a nuclear mutation that has not been identified yet. The mitochondrial genome is rather small, only 16,569 base pairs, and is easily sequenced for mutations. The nuclear genome, on the other hand, is too large and contains too many polymorphisms to be routinely sequenced. Success in finding nuclear mutations causing mitochondrial myopathies largely depends on the presence of families where one can observe if a candidate mutation is inherited together with the disease.

Clinical Relevance

When mitochondrial disease is suspected, there are many ways to test whether this is indeed the case. Laboratory diagnosis of mitochondrial disorders often includes a combination of biochemical, morphological and genetic methods to diagnose respiratory chain dysfunction (2). The most widespread diagnostic method for mitochondrial myopathy is to look for the occurrence of ragged red fibers, RRF. These fibers can be visualized by the modified Gomori trichrome technique, which stains the irregular accumulations of mitochondria red (Fig. 1). When mtDNA is mutated,

Mitochondrial Myopathy. Figure 1 Ragged red fibers (RRFs), one of the hallmarks of mitochondrial disease, stained with the modified Gomori trichrome stain. A cross-section of a skeletal muscle specimen shows the individual muscle fibers as rounded structures. Normal muscle fibers are stained evenly blue, whereas RRFs show an accumulation of mitochondria around the edges, stained red. *Picture by Anders Oldfors, Gothenburg University.*

mitochondrial translation is often impaired. When this is the case, mitochondrially encoded respiratory chain enzymes will disappear. Another way to visualize mitochondrial deficient RRFs is to stain for the enzyme activities of succinate dehydrogenase (SDH) and cytochrome c oxidase (COX), the so-called COX/SDH stain. COX is a respiratory chain enzyme with critical components encoded by mtDNA, whereas SDH is entirely nuclear encoded. This means, that if the mtDNA is compromised there will be plenty of SDH activity but no COX activity. With this double staining method respiratory chain deficient muscle fibers will appear blue whereas normal fibers will appear brown. The activities of other respiratory chain enzymes can also be detected by enzyme histochemistry, although it is less common.

It is possible to measure the function of the different respiratory chain complexes directly on isolated mitochondria. In this case, one adds chemical substrates that enter the respiratory chain at different levels and monitors the oxygen consumption. If a particular enzyme complex is not working properly, the addition of that enzyme's substrate will not result in elevated oxygen consumption. It is also possible to measure the mitochondrial ATP production rate or the activities of the individual respiratory chain enzyme complexes.

In the case of mitochondrial myopathies, the mitochondria are often more abundant and display an abnormal morphology, with crystalline structures in the [▶matrix](#) and a general disorganized appearance. [▶Electron microscopy](#) is well suited to detect these abnormalities.

One can also use this method to detect the accumulation of mitochondria in dysfunctional muscle fibers and to calculate the percentage of the total cell volume occupied by mitochondria.

Molecular genetics methods are used to detect specific mtDNA and nuclear mutations. Point mutations in the mtDNA are easy to diagnose with the polymerase chain reaction, [▶PCR](#) or by sequencing candidate regions. [▶Southern blot](#) or [▶long PCR](#) analysis is used to detect mtDNA deletions and rearrangements. These analyses are sometimes performed on a sample of the patient's blood. There is one large pitfall with this approach, analyses of mtDNA mutations in blood are unreliable. Some classes of mtDNA mutations are absent in blood, even though they are present in high levels in skeletal muscle. If the cause of the disease is a nuclear mutation, one can with PCR analysis and sequencing easily test if one of the genes known to cause mitochondrial myopathies is mutated. However, a large number of nuclear mutations causing disease are still unknown and cannot be detected by this approach.

Mitochondrial Permeability Transition Pore

Definition

The mitochondrial permeability transition pore (MTP) is a high conductance channel consisting of the adenine nucleotide translocator (ANT) in the mitochondrial inner membrane, the matrix protein Cyp22, as well as apoptosis-regulatory proteins from the Bax/Bcl-2 family which is involved in mitochondrial membrane permeabilization. Transient openings of the MTP play an important role in the pathways leading to cell death.

Mitogen-Activated Protein Kinases

Mitogen-activated protein kinases (MAPKs) are an evolutionarily conserved family of serine/threonine protein kinases, involved in the regulation of a variety of cellular processes including proliferation, differentiation and apoptosis. MAPKs become activated by dual phosphorylation on threonine and tyrosine residues. The MAPK family includes the stress activated protein kinases (SAPKs), the Extracellular signal Regulated Kinases (ERKs) and p38-related kinases. MAPKs of all subgroups are activated by dual specificity kinases, the MAP kinases kinases (also designated as MEKs), which in turn are regulated by MAP kinase kinase kinases (also designated as MEKKs). Thus, defined groups of a MAPK, a MAPKK and a MAPKKK can act in a cascade as a functional unit. According to the identity of the MAPK involved, one discriminates between the ►JNK cascade, the p38 ►MAP kinase and the ►ERK cascade. The MAPK signalling modules can be triggered by a variety of stimuli including ligands of the TNF family.

Mitosis

Definition

Mitosis is the process of cell and nuclear division in somatic cells, which results in the production of two daughter cells from a single parent cell. The daughter cells are identical to one another and to the original parent cell (mitotic recombination).

Mitotic Figure

Definition

Mitotic figure is a term that is used by pathologists. Cells in mitosis are discriminated by visible chromosomes (like dark-stained threads) and the absence of a nuclear membrane. The number of mitotic figures is sometimes used to distinguish a benign from a malignant tumor.

Definition

Mitotic recombination (MR) results from somatic crossing over between homologous sequences during mitosis. MR is a term used inconsistently among geneticists, molecular biologists and biochemists. Herein, MR will be used to describe both exchange of genetic material between sister chromatids (SCEs) – which is an effective, common repair mechanism usually without genetic or phenotypic consequence – and exchange between homologous chromosomes. The latter process manifests either as so-called gene conversion (GC) in which a relatively short length of chromosome becomes identical to its homologue or as ‘mitotic recombination proper’ (which we shall term ‘mitotic crossing-over’, MXO) in which the entire distal chromosome arm becomes identical to its homologue. GC and MXO are rare compared with meiotic crossing-over because homologues do not normally pair at mitosis. GC and MXO lead to homozygosity in a daughter cell for markers distal to the crossover site for a variable length along the chromosome arm, up to and including the telomere. MXO is distinct from mitotic non-disjunction, in which a whole chromosome is lost or gained, but the definition of MR may include mitotic gene conversion, in which a relatively short, interstitial chromosome segment becomes identical to its homologue.

In its strict sense, MR may also be used to describe recombination between non-homologous chromosomes in mitosis, leading to translocation and associated rearrangements; I shall not, however, focus on non-homologous recombination below. Finally, I shall regard non-homologous end joining (NHEJ) repair in mitosis as distinct from MR.

Characteristics

History

Some of the first clues as to the existence of MR came from observations by Stern in *Drosophila* (7). He found that a few flies showed patches on their body, which could be best explained by somatic reduction to homozygosity of chromosomal segments between some location on the chromosome arm and that arm's telomere. MR appeared to occur largely at random in different tissues at different stages of development, thus producing flies with varying phenotypes. In principle, given enough heterozygous phenotypic markers, an MR map could be built up by identifying phenotypes that were revealed together when MR occurred. MR has since been shown to occur in a variety of organisms from *Aspergillus* to humans. In humans, MR by MXO or GC can sometimes be visualised as chiasmata in mitosis and these are distributed non-randomly, with hotspots hypothesised to correspond to gene-rich regions. MR crossovers can also, however, occur in heterochromatin.

The Normal Role of MR in DNA Repair

Mitotic recombination is envisaged to occur as the result of DNA repair processes. Specifically, MR is probably one of several possible outcomes of DSB (double strand break) repair. DSBs classically occur as a result of ionising radiation, but other genotoxic agents can cause them and 'spontaneous' DSBs can occur at stalled replication forks, perhaps at sites of existing single strand breaks. Non-homologous end joining is believed to repair most DSBs, but homologous recombinational mechanisms appear important in certain cells and at certain stages of the cell-cycle (S and G2). Figure 1 shows the model proposed whereby DSB repair leads to MR (5). In this model, DSB repair occurs as a result of invasion of one strand of the broken DNA molecule into the double helix of its homologue. Unless alternative repair mechanisms (such as synthesis-dependent strand annealing or break-induced replication) occur, repair proceeds through new DNA synthesis complementary to the unbroken strands. In this model, it is hypothesised that the form of the resolution of the resulting Holliday junctions determines whether or not a crossover occurs. In most cases, MR will occur in the form of SCE. If, however, homologous chromosomes happen to be in close physical alignment during mitosis, the crossover

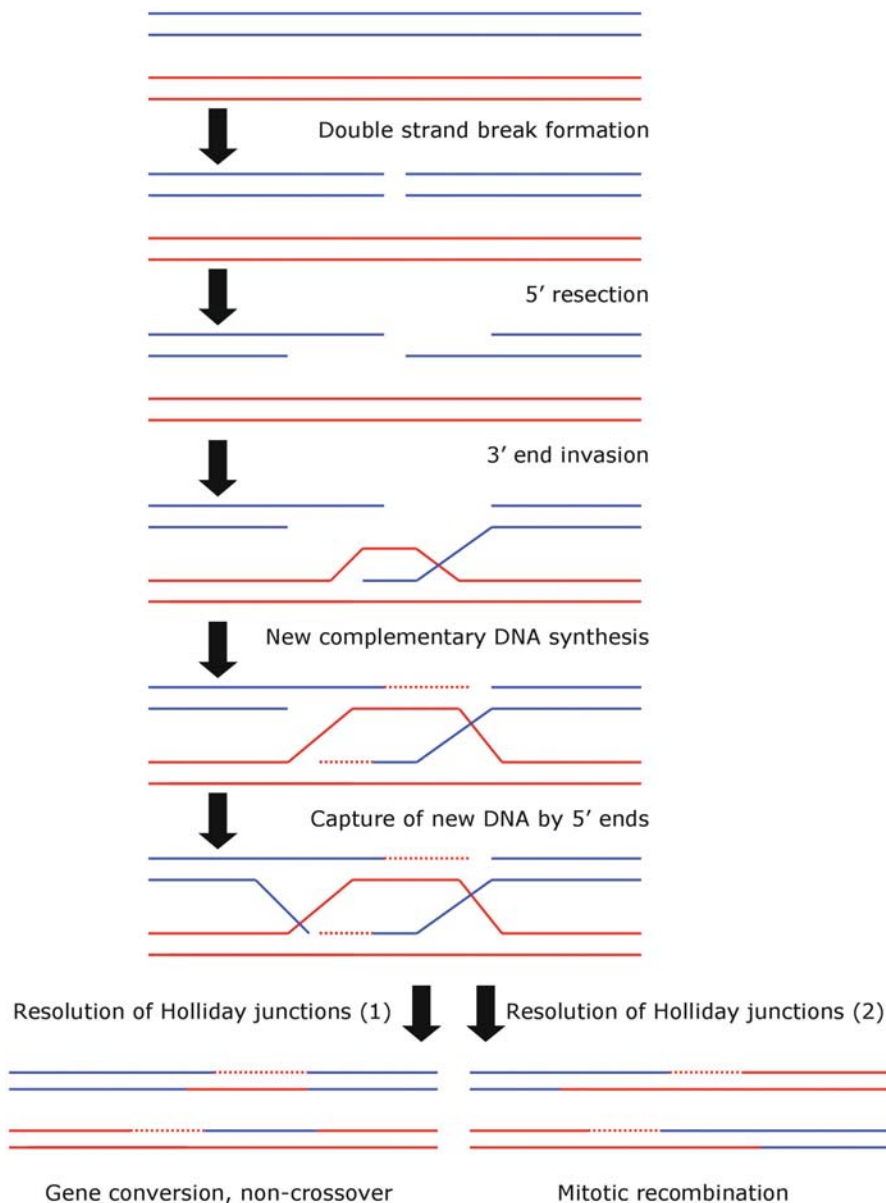

can occur between non-sister chromatids and GC or MXO results. It can readily be seen both that MXO is not the usual result of DSB repair and that MXO involves a small region of GC close to the DSB. If non-homologous chromosomes participate in MR – for example if orthologues or repeated sequences act as 'illegitimate' templates for repair – reciprocal or unbalanced translocations may result.

Molecules Involved in MR

The molecules involved in DSB repair and MR remain largely unknown in mammalian cells. Prado et al. (5) have reviewed the genes that are known to be important in yeast, which include *RAD51*, *RAD52* and components of the mismatch repair machinery. Mammalian homologues of *RAD51* and *RAD52* include *RAD51B/C/D*, *RAD54*, *RAD54B*, *RAD50*, *MRE11*, *XRCC2* and *XRCC3*. The mechanism of DSB repair by SCE or other forms of MR in higher organisms is not well characterised. It is suggested that ATM and NBS1, complexed with MRE11 and RAD50 may be involved in the initial signalling to the repair machinery that a DSB has occurred. RAD52 and other proteins may recognise the DNA ends and a single-strand region with a 3' overhang is generated by exonuclease digestion. RAD51 may polymerise onto the single stranded DNA with the help of RPA and RAD52, and the resulting nucleoprotein filament in some way searches for a homologous DNA duplex. RAD52 and RAD54 may then help with single strand invasion of the intact duplex. DNA polymerases re-synthesise DNA complementary to the intact strands, before strand ligation and resolution by unknown enzymes. Mouse *Rad54*^{-/-} cells show decreased SCE and *Xrcc2*^{-/-} and *Xrcc3*^{-/-} hamster cells show reduced levels of homologous recombination. Interestingly, RAD51 interacts with the breast cancer protein BRCA1, although – perhaps paradoxically for tumour promotion – *BRCA1*^{-/-} cells have been reported to show reduced homologous recombination (reviewed in 8). It has been suggested that one role of BRCA1 is to promote homologous recombination repair when DSB damage occurs in S- or G2-phase.

Diseases Resulting from Deficient MR

Humans with two mutant copies of the ► **Bloom syndrome** gene (*BLM*) have genetic instability, which is characterised by an increased frequency of SCEs (OMIM 210900). An ancestral mutation accounts for over-representation of the disease in Ashkenazi Jews. Bloom syndrome patients have proportionate pre- and post-natal growth deficiency, are sun-sensitive, suffer from telangiectasia and have hypo- and hyper-pigmented skin; patients also have an increased risk of a wide variety of malignancies, including both solid tumours and haematological malignancies. Men with Bloom

Mitotic Recombination. Figure 1

syndrome are sterile; women have reduced fertility and a shortened reproductive span. *BLM* encodes a DNA helicase that is homologous to RecQ in *E. coli*. The *Blm* 'knockout' mouse has been found to develop several types of tumour as a result of raised GC and *Blm*^{-/-} cells show raised frequencies of chiasma formation, homologous recombination (including SCE) and loss of heterozygosity (see below). Breaks, gaps and complex chromosomal rearrangements are also seen relatively often. The BLM protein promotes branch migration of Holliday junctions and may help to re-start stalled replication forks. Recently, BLM has been shown directly to suppress recombination.

Individuals with Werner syndrome (OMIM 277700), a recessively inherited condition of premature ageing, have scleroderma-like skin changes, cataract, subcutaneous calcification, premature arteriosclerosis, diabetes mellitus and a wizened facies. There is also an increased risk of sarcoma. Werner cells have normal SCE and appear to acquire chromosomal changes through increased non-homologous MR and consequent translocations/deletions. Like *BLM*, the Werner syndrome gene (*WRN*) is a RecQ homologue. BLM and WRN may interact (8), although the specific role of WRN is unknown. Rothmund-Thomson syndrome (OMIM 268400) is, in some cases, caused by mutations

in another helicase, *RECQL4*; this condition is characterised by hereditary dermatosis (comprising atrophy, pigmentation and telangiectasia) and is frequently also associated with juvenile cataract, saddle nose, congenital bone defects, disturbances of hair growth and hypogonadism. Sarcomas, largely arising from bone and soft tissue, are relatively common in Rothmund-Thomson syndrome.

Other molecules with putative roles in mammalian MR include the ataxia telangiectasia protein (ATM), Nijmegen breakage syndrome protein (NBS1), RAD50, BRCA2 (which interacts with RAD51) and MRE11. ATM may control many aspects of DSB repair. Recessively inherited germline *ATM* mutations cause a phenotype of chromosome breakage associated with cerebellar ataxia, telangiectases, immune defects and a predisposition to malignancy (OMIM 208900). *NBS1* (OMIM 251260) mutations produce a similar recessively inherited syndrome of microcephaly, growth retardation, immunodeficiency and predisposition to cancer. *BRCA1* and *BRCA2* mutations, by contrast, cause dominantly inherited, early-onset breast and ovarian cancer in which the genes act as classical tumour suppressors (OMIM 113705, OMIM 600185), although double *BRCA2* mutants have a phenotype of Fanconi anaemia (OMIM 227650), another recessive chromosomal breakage syndrome.

Factors Predisposing to MR in 'Normal' Individuals

The frequency of MR is increased by any factor which increases DNA damage that can be repaired by a mechanism in which homologous recombination occurs. DSBs are, for example, more prevalent in individuals exposed to X-rays or a variety of chemical carcinogens (9) or after oxidative damage.

There is also evidence that the frequency of MR varies in the normal population (2), although it is not known whether this occurs as a result of increased rates of DNA damage, a specific tendency to repair damage by homologous recombination or some other factor, such as an increased tendency for homologues to pair at mitosis. Holt et al. (2) estimated MR to occur at a rate of $\sim 1 \times 10^{-6}$ per locus per cell division in culture. Females showed higher MR levels than males, and rates increased with age. Variation in MR might therefore contribute to diseases such as cancer that depend on somatic mutations.

Shao et al. (6) showed that MR was decreased in crosses of distantly related strains of mice, whereas meiotic recombination was little affected. Similar effects have been found for the *Apc*^{Min} mutant mouse, which develops intestinal polyps when the wild type *Apc* allele is lost by MXO or GC; the frequency of allelic loss generally decreases when mouse strains are crossed and hence the number of polyps is reduced

commensurately (1). MR by MXO or GC therefore appears to depend greatly on the availability of closely homologous sequences, perhaps because this affects the probability of homologue pairing at mitosis.

How is MR Detected and Measured?

In mammalian cells, MR can be detected indirectly by observing reduction to homozygosity of polymorphic markers along a chromosome arm from the recombination site towards the telomere, together with the exclusion of alternative mechanisms, notably large deletions. Such a task is, in general, impractical as a means of screening for a rare event in large numbers of somatic cell clones (although for expansions of single clones, such as tumours or cases of UPD, it is feasible). Somatic cell clones that may have undergone MR are therefore generally identified initially in culture using a selectable marker which is heterozygous in the germline and for which homozygosity can be detected. Shao et al., for example, analysed cultured fibroblasts from *Aprt* +/- mice and selected for cells that had lost the wild type allele using 2,6-diaminopurine. Polymorphic markers showed about 80% of such losses to occur by MR. The estimated median frequency of cells with *Aprt* MR was 1.2×10^{-6} . MR breakpoints were not distributed randomly along the chromosome, although the reasons underlying breakpoint clustering were not clear. In a similar analysis in cultured human lymphocytes, Turner et al. found that oxidative damage by H₂O₂ predisposed to MR at the HLA locus. Other studies have, in general, found similar results and are reviewed by Wijnhoven et al. (9).

MR as a Mutagenic (or Sub-Optimal Repair) Process

In addition to inherited defects that may increase the rate of MR, 'spontaneous' GC or MXO (that is, at a normal frequency) may also contribute to disease processes as a side effect. In such a case, of course, it might well have been better for SCE to have occurred, or even for DSB repair to have failed and apoptosis to have been triggered. If GC or MXO happens to occur early in human development, it is one of several mechanisms whereby uniparental isodisomy may occur. Here, part or all of a chromosome is derived from a single parent. Various pathologies – or none – may occur, resulting either from unmasking of deleterious recessive alleles or from failure of controlled genetic imprinting. In the latter case, MXO has been implicated in mosaic forms of Beckwith-Wiedemann syndrome (UPD11p15.5) and in Prader-Willi and Angelman syndromes (UPD15q11-q13). The involvement of MR in the generation of UPD raises the question as to whether MXO, in particular, is a true mechanism of DNA repair, or a side effect of the preferred repair process, SCE.

MR and Tumorigenesis

Arguably, the most important occurrence of MR in humans is as a cause of loss of heterozygosity (LOH) in tumorigenesis. LOH is generally envisaged as the 'second hit' which knocks out a tumour suppressor gene (4). There is plentiful evidence to show that tumour suppressor genes often acquire a 'second hit' by LOH, but very few data to show the mechanism involved (MXO, GC, whole chromosome loss (with or without reduplication) or deletion (interstitial or terminal)). The reason for this lack of knowledge is that the underlying cause of LOH can only be determined by both knowing the pattern of apparent homozygosity (generally using polymorphic markers) and successfully making the distinction between true homozygosity and hemizyosity (using an *in situ* method such as FISH, or dosage quantitation, for example using real-time PCR or array-comparative genomic hybridisation). The type of 'second hit' is undoubtedly influenced by two factors, first the rate of occurrence of each mutation (small-scale change, large deletion, whole-chromosome loss, GC and MXO) and second the selective consequences of each change (which cannot readily be predicted and may depend on local sequence variation). Of the studies which have undertaken a comprehensive analysis of the mechanisms of LOH, there is good evidence that LOH at *RB1* in retinoblastoma almost always occurs by MXO, that MXO usually accounts for LOH at *NF1* in neurofibromatosis, but that MXO and GC are common at *APC* in human colorectal tumours. These examples are all probably early events in the pathogenesis of these tumour types. In contrast, there is evidence that many examples of LOH in malignant tumours result from chromosomal scale losses and gains, usually on a background of an aneuploid/polyploid karyotype. It is a moot point as to whether or not any human tumours gain an advantage by acquiring an increased tendency to MR as they do others forms of genetic instability, such as those resulting from silencing of DNA mismatch repair. It is notable that sporadic tumours very rarely harbour mutations in any of the known genes associated with MR, although this does not exclude other forms of aberrant expression or mutations in other, unknown genes in the same pathways.

Clinical Relevance

The role of mitotic recombination in the somatic inactivation of tumour suppressor genes and in generating parental isodisomy (UPD) has been described above. Genetic testing for mitotic recombination in clinical practice is generally related to the detection of isodisomy and is therefore indirect. Isodisomy analysis chiefly involves three diseases, Beckwith-Wiedemann, Prader-Willi and Angelman

syndromes. Other syndromes that are infrequently tested for isodisomy include transient neonatal diabetes (UPD6q), cystic fibrosis (UPD7q), Silver-Russell syndrome (UPD7p) and problems associated with UPD. Isodisomy testing generally uses multiple highly polymorphic markers within the region of the disease loci, searching for absence of heterozygosity. Distinguishing isodisomy from deletion therefore usually relies on a failure to demonstrate the latter using methods such as FISH. Isodisomy resulting from mitotic recombination is usually not distinguished from other mechanisms such as chromosomal loss and rescue.

Testing for mitotic recombination – or, more generally, for allelic loss – in cancers is rarely performed routinely in clinical practice. The value of testing for somatic genetic changes in tumours, for indicating outcome and response to therapy, is likely to become better recognised and routine in the coming years.

Conclusions

Mitotic recombination generally takes one of two forms; SCE, which is very difficult to detect and has no functional consequence or GC or MXO, which may have important effects on human disease. MR is used by the cell to repair DNA damage, in particular DSBs. SCE is perhaps best viewed as an efficient form of repair, generally likely to preserve genetic integrity, whereas GC or MXO are prone to exposing deleterious recessive mutations or, in some situations, causing defective imprinting. The existence of human diseases such as Bloom and Werner syndromes shows that excessive MR is pathogenic; whether the disease phenotype results primarily from increased MXO/GC rather than SCE is not known. Arguably, however, the most important "role" of MR in a pathological situation is as a cause of LOH in tumorigenesis. It appears that MXO and GC are not uncommon as the 'second hit' at tumour suppressor loci, but comprehensive studies are relatively rare and there is variation in the importance of MR among both genetic loci and tumour types. Future work will further characterise the biochemistry of MR in mammalian systems, define the roles of GC and MXO as both anti- and pro-mutagenic processes and search for germline variants which influence the rate of MR, both as a general process and in a site-specific fashion.

Definition

The mitotic spindle is a special device essential for chromosome segregation (► [mitosis](#)) during ► [cell division](#). It consists of three parts, chromosomes, two asters and a spindle region (Fig. 1). The overall shape of the mitotic spindle is due to ► [microtubules](#), which are made of α and β -tubulin subunits. Microtubules are dynamic, changing their length all the time by repeating growing and shrinking cycles at both ends. This microtubule property is known as ► [dynamic instability](#). One end of the microtubule (minus end) is associated with the pole where the microtubule-organizing center (MTOC) called the ► [centrosome](#) is located. The other end (plus end) is attached to a special region of the chromosome called the ► [kinetochore](#) to form ► [kinetochore](#) microtubules. Some microtubules have a free plus end, ► [astral microtubules](#) splay out widely from each pole, other microtubules originate from opposite poles and overlap in the middle of the spindle to constitute ► [interpolar microtubules](#) (Fig. 1). The mitotic spindle is transient as it is assembled at the onset of cell division phase/M phase and disappears entirely after completion of mitosis. Because it is composed of dynamic microtubules, the mitotic spindle is also dynamic, undergoing continuous morphological alterations in mitosis. Mitosis is divided into five distinct stages, prophase, prometaphase, metaphase, anaphase and telophase (Figs. 1, Parts 2–8).

Characteristics

Macromolecular Composition

The spindle consists of a number of molecules, which have been identified using multiple approaches, including biochemical analysis of isolated spindles, genetic analysis of genes affecting spindle functions and immunological analysis of anti-spindle antibodies. A major component of the spindle is the microtubule, whose function is largely dependent on its associating molecules collectively called ► [microtubule-associated proteins](#), or MAPs. The spindle has an abundant variety of MAPs, which can be classified into two types, motor MAPs and non-motor MAPs. The mechanochemical motor proteins (cytoplasmic dynein and kinesin-like proteins) have been subjected to extensive analysis. Although less is known of the non-motor MAPs, evidence has been accumulated to indicate that they play an important role in modulating the dynamics of spindle microtubules, in particular at the kinetochore region. Phosphoproteins and kinase/phosphatase enzymes are numerous in the spindle, which is consistent with the fact that the M phase has been characterized as that with an increased level of protein phosphorylation and kinase activities. The mitotic spindle recruits signaling molecules important for controlling the mitotic progression and completion of cell division;

these components tend to be positioned at particular locations, such as poles, kinetochores and the spindle midzone. Although many other molecules have been detected in the spindle, their roles in the structure and function of the spindle have not yet been explored.

Spindle Poles

The pole has major three functions: 1) organizing spindle microtubules, 2) serving as the locus toward which the chromosomes move in anaphase and 3) specifying the axis that determines the orientation and position of the plane for cytoplasmic division. In animal cells, the morphological expression of the poles is the centrosome, which consists of a pair of centrioles and a surrounding dense pericentriolar material. By

serving as an MTOC, centrosomes are responsible for nucleation, orientation and anchorage of microtubules. Individual microtubules are nucleated from ~ 25 nm ring-shaped structures (γ -TuRC: γ -tubulin ring complex) composed of a ubiquitous centrosome protein, γ -tubulin, plus additional minor components. The microtubule-nucleating sites are held together and connected to coiled-coil proteins, which are abundant in the centrosome and presumably maintain the overall shape of the pericentriolar material by serving as the centrosome scaffold. To anchor the microtubule minus ends, molecules with an affinity for the end and/or wall of microtubules are embedded in the pericentriolar material. It has become apparent that the centrosome is involved not only in microtubule organization but also

Mitotic Spindles. Figure 1 (1) Diagram of the mitotic spindle consisting of chromosomes, two asters and a spindle part. The overall shape of the spindle is framed by three types of spindle microtubules: kinetochore microtubules (green), astral microtubules (blue), and interpolar microtubules (red). Microtubules are a polarized structure containing two distinct ends, the fast growing (plus) end and slow growing (minus) end. All minus ends are attached to the spindle pole where the microtubule-organizing center, the centrosome, is located. While astral and interpolar microtubules have a free plus end, kinetochore microtubules interact with the kinetochore on the chromosome at their plus end. The change in the shape of mitotic spindles in mammalian cells fluorescently stained with DAPI (DNA: blue), anti-tubulin (microtubules: red), and anti- γ -tubulin (centrosome: green) antibodies. At the onset of mitosis (prophase, 2), DNA-containing materials condense to form well-defined chromosomes. Each chromosome is composed of two genetically identical parts called chromatids and two sister chromatids are bound together back-to-back in a single unit. Toward the end of prophase, two mitotic poles separate and start to organize spindle microtubules. Prometaphase is defined as the stage of nuclear membrane breakdown (3 and 4). As a result of the disappearance of the nuclear membrane, the spindle microtubules, which have been lying outside the nucleus, are able to enter the nuclear region and interact with chromosomes through a special region called the kinetochore. Once linked to the microtubules, the chromosomes that are initially scattered throughout the nuclear region start to align in one plane midway between the poles. All chromosomes align at the metaphase plate in metaphase cells (5). Sister chromatids move toward the opposite poles in anaphase, which is traditionally divided into two phases, anaphase A and anaphase B. During anaphase A, the chromosomes move to the pole, causing the distance between the pole and chromosomes to decrease (6). During anaphase B, microtubules elongate and the distance between poles increases (7). In many cases, anaphase A and anaphase B occur simultaneously. After arriving at the pole, the separated chromatids, now called daughter chromosomes, decondense and a new nuclear envelope forms at the end of mitosis (telophase: 8).

in regulation of a wide range of cellular activities, such as signal transduction and cell-cycle control. A number of molecules with diverse functions are thus likely to be targeted to the centrosomes/poles in a stage specific manner.

Kinetochores

The kinetochore is a multiprotein complex assembled on the ►centromere located at the primary constriction of the chromosome. It consists of two distinct regions (inner kinetochore and outer kinetochore) and has three functions: 1) serving as the site where spindle microtubules attach to the chromosomes, 2) generating the forces necessary for chromosomes to align at the spindle midzone and move toward the pole and finally 3) determining the timing of anaphase onset. Because a kinetochore is included in each chromatid, two kinetochores are arranged back to back and the microtubule attachment sites face opposite directions in a single chromosome. To capture the microtubule end, both motor and non-motor MAPs reside in the kinetochore. They bind microtubules and alter the dynamic nature of microtubules, which ultimately leads to the changes in the relative position of the chromosome between the two poles in prometaphase cells and the distance between pole and chromosome in anaphase cells. Signaling molecules that control the time of anaphase onset become recruited to the outer region of the kinetochore.

Central Spindles

As chromosomes move toward the pole, the midzonal region of the spindle starts to organize the central spindle. It consists of highly bundled interpolar microtubules with a dense material surrounding antiparallel microtubules at the equator. With the progression of cytoplasmic constriction, the central spindle transforms to the midbody in the center of which is a coalesced dense dot. The central spindle/midbodies accommodate a number of components; some are shifting from the entire spindle region to the midzone during chromosome movement, whereas others are chromosomal passenger proteins that are centromere/kinetochore proteins but remain at the spindle equator after chromosome movement rather than shifting to the spindle pole along with chromosomes in anaphase. Recent evidence has suggested that the central spindle and midbodies play an important role in controlling cytoplasmic division, in particular completion of cell separation to liberate two daughter cells at the end of cell division.

Visualization of the Mitotic Spindle

Because it occupies a large part of the cell and changes its shape drastically during mitosis, the mitotic spindle

is easy to detect with a light microscope. Using microtubule-stabilizing reagents such as taxol/paclitaxel, hexylene glycol and glycerol, mitotic spindles have been isolated from naturally synchronized marine invertebrate eggs as well as synchronized cultured mammalian cells. Biochemical quantities of highly purified spindle isolates are useful for both morphological and biochemical analysis of the spindle. However, because no chromosome movement has yet been demonstrated, isolated spindles do not allow us to investigate the dynamic nature of the spindle and spindle microtubules *in vitro*. Individual microtubules have been successfully visualized by fluorescence microscopy using cells loaded with fluorescently tagged tubulin molecules. By monitoring the position of microtubules labeled by irradiation, it is possible to measure the dynamics of spindle and spindle microtubules by time-lapse video fluorescence microscopy.

Mechanism of Chromosome Movement

Because the mitotic spindle undergoes significant morphological alterations during mitosis, factors governing microtubule dynamics must be the key to the mechanism of chromosome movement. M phase onset triggers the global change in microtubule organization, which is caused by the increased level of both the microtubule-nucleating activity of the centrosome and the frequency of catastrophes defined as the transition from microtubule growth to shrinkage. MAPs and small molecular weight compounds (such as Kin I, XMAP215 and Op18) are likely to be responsible for the change in microtubule dynamics at the phase transition from interphase to M phase. This change results in the formation of many short microtubules from each spindle pole; while some keep growing at their plus end, others shrink rapidly. Once their plus end is captured by MAPs at the kinetochore, these kinetochore microtubules become stabilized by preventing shrinkage. Simultaneously, MAPs located at the spindle midzone crosslink antiparallel microtubules to stabilize interpolar microtubules. MAPs and motor activities are also indispensable for the assembly and maintenance of normal size bipolar spindles by separating spindle poles and generating forces acting at different parts of the spindle structure.

During prometaphase, chromosomes move back and forth between two poles until they align properly at the spindle equator, called the ►metaphase plate. Although no precise molecular mechanisms have yet been established, it is tempting to believe that a variety of molecules located at the kinetochores/centromeres participate in regulating the length of kinetochore microtubules by mediating addition (microtubule

growth) or removal (microtubule shrinkage) of tubulin subunits at the plus end. These molecules include motor proteins, such as the cytoplasmic dynein complex, CENP-E, Kin I and chromokinesin, as well as regulatory MAPs and kinases, including NuMA, EB1 and [▶chromosome passenger proteins](#).

The cell is ready to enter anaphase when all chromosomes are aligned at the spindle equator. A complex of signaling molecules, consisting of Mad1, Mad2, Bub1, Bub3, BubR1 and others, is recruited to the outer layer of the kinetochore. Upon attachment to the plus end of microtubules, these signaling molecules become silenced. This is the way in which cells sense that all chromosomes are associated with kinetochore microtubules and aligned at the metaphase plate. The presence of a single non-attached kinetochore causes the delay of anaphase onset. This surveillance mechanism is called the [▶spindle checkpoint](#). As long as this wait signal is on, Cdc20, a part of APC/C (anaphase promoting complex/cyclosome) required for protein degradation, is inactive and does not allow APC/C to recruit a substrate, securin. Securin binds to separase, resulting in the inhibition of separase activity in digesting SCC1. To activate the protease activity of separase, securin must be removed from separase. Because SCC1 is a part of the multiprotein complex called cohesin, which glues two sister chromatids together, SCC1 digestion causes cohesin cleavage and sister chromatid separation. Therefore, the activation of Cdc20 and APC/C is a prerequisite for chromosome segregation.

During anaphase A, chromosomes move toward the pole and the distance between pole and chromosome decreases. Two mechanisms have been proposed to account for the chromosome movement. One is that the minus-end-directed motor proteins present in the kinetochore generate the force necessary to pull the kinetochore towards the pole; the other is depolymerization of kinetochore microtubules at both plus and minus ends, which is probably mediated by microtubule destabilizing Kin I type motor proteins located at the kinetochores and spindle poles. As microtubule ends disappear, the kinetochore tends to slide toward the poles in order to retain the microtubule binding; this results in chromosome movement toward the pole. During anaphase B, the spindle elongates and the distance pole-to-pole increases. This is believed to be mediated by microtubule sliding at the spindle midzone. As new tubulin subunits are incorporated to the plus end, the length of interpolar microtubules increases. The motor proteins located at the area where microtubules originating from opposite poles overlap generate the forces necessary for antiparallel microtubules to push away. Thus, the degree of microtubule overlap decreases at the interzone as the spindle elongates.

Clinical Relevance

The mitotic spindle is responsible for faithful transmission of the genetic material from one cell to its progeny. Equal chromosome segregation is ensured by establishment of spindle bipolarity. Thus the proper number of spindle poles/centrosomes is strictly maintained in the cell. Any defects in the spindle and spindle poles/centrosomes induce cells with abnormal numbers of chromosomes, most notably cancer cells. In fact, genetic instability is a hallmark of all human cancers. It is easily imagined that molecules controlling the precise number of centrosomes and proper assembly and function of spindles play important roles in tumorigenesis. When over-expressed, the spindle/centrosome components malfunction, ultimately leading to genetic instability in cancer cells. This is consistent with the fact that many oncoproteins identified thus far have turned out to be spindle components, Aurora kinases, polo-like kinases, MAPs such as TACCs (transforming acidic coiled-coil proteins) and XMAP215/ch-TOG (colonic hepatic tumor-over-expressed gene) and spindle checkpoint proteins including Mad2 and Bub1. These components must be of great clinical potential as markers for molecular diagnosis of human cancers and as targets for therapeutic development.

Mode of Release

Definition

Neurotransmitters may be released from synaptic terminals in two different modes: the release may be uni-vesicular, i.e. one vesicle is released per synaptic contact per incoming action potential (all-or-none release), or the release may be multi-vesicular (more than one vesicle per incoming action potential).

►Neurons

Modified Antisense Oligonucleotide

Definition

Antisense reagents act through the complementarity between nucleic acid strands. Antisense oligonucleotides, however, are generally rapidly degraded. To increase their stability, and therefore biological efficacy, oligonucleotides can be modified. Typically, the phosphodiester bond between nucleotides is modified. In morpholinos, this linkage is replaced by a non-ionic phosphorodiamidate linkage. Another non-proprietary modification involves the use of phosphorothioate linkages.

Molecular Aging Research

CHRISTIAN BEHL

Department of Pathobiochemistry, Johannes Gutenberg University, Mainz, Germany
cbehl@uni-mainz.de

Definition

At the beginning of the last century the average life expectancy was about 37 years in the developed

countries. Today life expectancy is approximately 70 years with a tendency to increase in the next decades. As early as the year 2050, approximately 25% of the population will have reached an age over 65. Consequently, as people are getting older, more and more will be affected by various age-associated disease including

1. cardiovascular disorders,
2. cerebrovascular diseases,
3. malignant tumors and cancer
4. chronic progressive neurodegenerative disorders.

In human ►aging an increase in the incidence of age-associated disorders is the cause of a decreased survival rate or an increased mortality. In addition to life threatening disorders that may lead to death in elderly people, a variety of age-associated changes lead to dysfunctions of different organs that include the brain. In particular, various neuropsychiatric disorders that frequently occur in aged people are, although not directly life-threatening, a major burden for the aged human society. Important examples of this are the increased occurrence of depression and impairments of cognition. In summary, the actual phenotype of aged humans includes various pathological changes and is investigated experimentally in different model systems. Here the focus is on the cellular and molecular level of the analysis of the aging phenotype.

Different model systems have been developed to study aging processes at the cellular and molecular level. These include

1. cultivated fibroblasts
2. cultures of intact tissues (biopsies)
3. *Saccharomyces cerevisiae*
4. ►*Caenorhabditis elegans*
5. ►*Drosophila melanogaster*
6. *Mus musculus*

Employing these models the molecular and biochemical changes in the cell as well as in tissue can be investigated. Animal models of aging help to validate cellular and molecular findings in an intact organism. Based on such models different theories of aging have been developed.

Theories of Aging

By looking at the age-associated changes in cells and organisms from different angles the following main theories of aging have been developed

1. cross-linking theory that focuses on the chemical reaction between cellular proteins
2. immune theory that points to a dysfunction of the immune system leading to chronic inflammatory changes
3. senescence gene theory which defines specific age-associated gene products

4. free radical theory that focuses on the detrimental activity of accumulating free oxygen and nitrogen radicals
5. ►telomere theory which summarizes the continuing shortening of the cellular DNA (telomere shortening)
6. evolution theory concluding that aging is not genetically determined but rather a consequence of a continuing accumulation of somatic changes.

Although all these different theories have a wide experimental basis, the discussion will be continued with those research approaches that are at the moment followed most intensively.

Characteristics and Clinical References

Most of the actual research approaches that investigate age-associated changes in cells and organisms are based on three major theories, the senescence gene theory, the free radical theory and the telomere theory.

Senescence Gene Theory: Syndromes of Accelerated Aging in Humans

In the search for the genetic control of aging and correspondingly for the cause of long life syndromes of accelerated aging are mainly investigated. For example, ►Werner's syndrome is characterized through the early onset of different signs of human aging including the graying of the hair, skin atrophy, cataracts, arteriosclerosis, osteoporosis, benign and malign neoplasias and others. The patients mostly die early at approximately 47 years, either in consequence of a heart attack or due to cancer. Werner's syndrome is an autosomal recessive disease and the incidence of the homozygous occurrence is approximately 1–22 per million. Werner's syndrome is frequently also named progeria of the adult. The Werner's syndrome gene (WRN) has been identified and is in a mutated form responsible for the syndrome. WRN codes for a protein that belongs to the family of RecQ ►helicases and is localized on the short arm of chromosome 8. Further prominent examples of syndromes of accelerated aging are ►Down syndrome and ►Bloom syndrome.

Free Radical Theory

The free radical theory of aging is based on the detrimental effects of accumulated free oxygen and nitrogen radicals that attack macromolecules of the cell. Oxidation of functional cellular molecules leads to dysfunction and to detrimental changes. During evolution our life has developed under the continuous influence of the regulatory and destructive activities of molecular oxygen and oxygen radicals. Of course, a variety of fine tuned antioxidant systems have been developed for defence against free radical attacks. Such antioxidant systems include enzymes (e.g. catalase,

glutathione peroxidase, superoxide dismutase) as well as antioxidant compounds (e.g. vitamin C, vitamin E). The production of ►free radicals in the cell is a normal physiological process and such radicals also exert regulatory functions with respect to gene transcription. Their production is controlled and regulated and an accumulation of radicals is prevented by the activity of the antioxidant systems. Nevertheless, as a consequence of various exogenous and environmental changes or due to toxic stimuli, this fine tuned balance can be disturbed, leading to the accumulation of radicals that destroy vital functions in the cell. Such an unbalance is called oxidative stress. Interestingly, oxidative stress is not only a continuous companion of human aging but has also been nominated as one major player in a variety of non-neuronal and neuronal degenerative disorders including Parkinson's disease, Alzheimer's disease, amyotrophic lateral sclerosis, and stroke. The actual triggers for oxidative stress have been defined for a variety of neurodegenerative disorders and a common hypothesis of protein aggregation as one cause of an increased oxidative stress in neuronal tissue has been proposed. In consequence of the high impact of oxidations on nerve cell survival and on the development of chronic age associated neurodegenerative disorders, the concept of the use of antioxidants for the prevention of age-related dysfunctions has been intensively studied.

The most important antioxidants that contribute to cell protection in the human are vitamin C and vitamin E and these antioxidants have been successfully used in model organisms such as *Drosophila melanogaster* to increase life span. In addition, the combined over-expression of the gene Cu/Zn-SOD and of catalase in transgenic *Drosophila* flies also increased the average and maximal life of those animals. Furthermore, this model has been extended to mammalian organisms and synthetic SOD and catalase mimetica indeed increase the survival of transgenic mice that represent a model of amyotrophic lateral sclerosis. SOD and catalase mimetica also increase the life span of the nematode *Caenorhabditis elegans*. In summary, the following experimental findings strongly support the importance of the free radical theory of aging:

1. The over-expression of antioxidant enzymes delays age-associated damage and increases the maximal life span of model organisms.
2. The life expectancies of different species are indirectly proportional to the rate of increase of superoxide radicals and of hydrogen peroxide in mitochondria.
3. Caloric restriction and/or controlled fat and cholesterol metabolism decreases oxidative stress due to decreased metabolism in mitochondria and leads to decreased oxidative damage that consequently

delays age associated changes. Moreover, caloric restriction has been shown to increase the maximal life span in mammals.

Telomere Theory

The chromosomes of all eukaryotes are linear structures with telomeres at their end. The replication of cellular DNA during the S-phase of the cell cycle starts with the synthetic extension of small RNA stretches (RNA-primers) through the activity of DNA polymerase. RNA-primers are displaced after the synthesis of the DNA and gaps are filled up with DNA. The replacement of RNA-primer stretches with DNA can occur along the whole replication fork with extension of the five prime ends of the DNA stretch. In consequence, the newly synthesized DNA stretch is shortened by the corresponding length of the RNA-primers at the end of the stretch. This process is the molecular basis of the replication problem. These end stretches are called the telomeres. The DNA sequences of the telomeres do not carry coding sequences and can be missed on the basis of their genetic information. Nevertheless, they have important functions during replication. For instance, they prevent the chromosome end being recognized at double-strand break and influence the exact pairing of the nucleotide stretches, as well as the movement of the chromosomes through mitosis and meiosis. The structure of telomeres and different telomere binding proteins that can affect telomere function are known. The constant shortening of the telomeres is the biochemical basis of the ►Hayflick-limit. Among the telomere-associated and binding proteins ►telomerase is centrally involved in the regulation of telomere structure and function. The modulation of telomerase activity has been investigated as one possibility to prevent the replication problem and therefore the Hayflick-limit and to extend life span through the prevention of telomere shortening.

Mouse Models of Human Aging

As mentioned before, the phenotype of human aging involves a variety of different pathological changes. Consequently, a variety of mouse models that reflect single aspects of this phenotype of human aging have been developed. Some major models are mentioned here:

Klotho-Mouse: The Klotho gene codes for a transmembrane protein and its defect leads to a decreased life span, skin atrophy, infertility and osteoporosis as seen in Klotho knock-out mice.

Senescence accelerated-mice (SAM): mouse colonies that suffer from accelerated aging have been selected by breeding and experimental selection. The genetic changes in these mouse lines obviously appear to be of multigenetic origin and are under investigation. Some

of these colonies are associated with increased neoplasias, cataracts or brain atrophy.

Werner syndrome mouse: Mice that carry a mutated WRN gene were developed and the fibroblasts of these mice have a strongly reduced proliferative capacity. Otherwise these mice have no obvious phenotype.

Telomerase knock-out mice: Mice with a targeted disruption of the gene that codes for the RNA component of telomerase show infertility, reduced wound healing and increased incidence of spontaneous malign neoplasia among other changes. Despite the fact that these mice show a phenotype that reflects important aspects of human aging, these animals do not show any further signs of the age-associated diseases that can frequently be found in humans, such as arteriosclerosis, osteoporosis and brain atrophy. Therefore, it has been proposed that the shortening of the telomeres and the induction of cellular senescence *in vivo* do not directly lead to pathological changes characteristic of human aging.

Growth hormone overexpression: Chronic excess of growth hormone is associated with symptoms that are typical for mammalian aging. Transgenic mice that over-express growth hormone show signs of accelerated aging, including a decreased life span, loss of weight and reduced fertility.

In studying the different mouse models of human aging and the genotype *versus* phenotype it becomes clear that aging is a biological phenomenon that involves multiple genetic as well as environmental signals.

Frontiers of Aging—an Outlook

The next steps towards state of the art molecular and biochemical age research are the integration and combination of various expertises, including biochemistry, endocrinology, neuroscience, genetics, physiology, population biology, epidemiology and, last but not least, clinical gerontology. Novel technologies in functional genomics and proteomics will help to clarify functions of age-related genes and proteins. One example should show how powerful technology such as expression profiling could help to identify age-relevant gene expression by using gene chip technology; the gene expression changes in aging brain have been analyzed in mice. Interestingly, many expression changes have been found that reflect changes that have also been described for human neurodegenerative diseases (8).

What becomes of increasing importance is to not only try to identify genes that might be involved in the aging processes (if such genes really do exist), but rather to look at functions of genes and their gene products which are of vital importance under aged conditions. For instance, we need to investigate the activity of molecular signals in detail in young and aged cell model systems and organisms in parallel. Our own lab

is involved in the analysis of changes in intracellular signaling by comparing different young and aged cell types. Moreover, we are looking into functions of estrogen receptors and possible changes in estrogen receptor signaling depending on the age and proliferation states of cultured cells. Gene expression does change with age and the exact mechanisms that mediate these alterations need to be identified. Consequently, molecular aging research is not restricted to the study of cell free systems or cultured cells or even genetic models such as knockout and transgenic mice. From early in the investigations the human situation also needs to be included, which can be done by using human material, for instance cultivated primary human fibroblasts from human donors. Since the increased life span of the human society in industrial countries is a fact and the increased incidence of age-associated disorders is the direct consequence of this fact, the effort and the interdisciplinary approaches to studying the basis of human aging need to be implemented in order to circumvent and prevent age-associated diseases and to provide the possibility of a long and healthy life.

Definition

Molecular docking is the computer-aided prediction of the bound geometry of two or more molecules. Molecules may be docked manually with the aid of computer graphics or automatically by using computer algorithms.

Manual docking is done using molecular visualization software, often in conjunction with hardware for stereo viewing and sometimes with haptic devices that provide force feedback to the user's hand.

There are a variety of algorithms for automatic docking (for reviews of methodology and applications see 1, 2, 3, 4). Rigid-body and ► [flexible docking](#) procedures are distinguished by their treatment of molecular flexibility and conformational changes upon binding. Docking procedures are developed and chosen according to the types and numbers of molecules to be docked. Different algorithms are generally used for docking two macromolecules as opposed to a macromolecule and a low molecular weight compound. More computationally demanding and accurate procedures can be applied to the docking of a single ligand to a receptor than to the screening of a large library of compounds for those that bind to a macromolecular target.

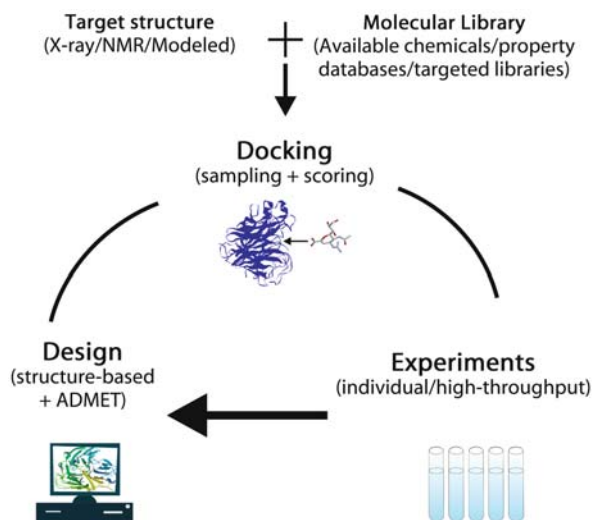

Docking is an established methodology in the structure-based drug design cycle (Fig. 1) and will play an increasingly important role in the exploitation of results from structural genomics and proteomics projects.

Description

The docking process can be divided into three steps: (i) identification of the ligand-binding site on the target macromolecular receptor, (ii) sampling of possible geometric arrangements of ligand and receptor and (iii) scoring of the sampled arrangements. These three steps are considered in turn here.

In most docking procedures, the ligand binding site on the target macromolecule should be defined prior to sampling. The binding site can often be identified by comparison with structures of the target protein co-crystallized with different ligands or with structures of homologues of the target protein. Putative docking sites may also be identified by automatic binding site detection algorithms. Potential small molecule binding sites can be found by searching for concave surfaces on the target protein structure. Protein-protein binding sites can be identified on the basis of a combination of properties including amino acid sequence conservation, amino acid type and surface curvature.

Sampling procedures can be separated into two classes, rigid-body docking and flexible-body docking. The rigid-body docking model is historically the first docking approach. The ligand and receptor molecules are treated as rigid bodies and the flexibility of the interacting partners is not considered explicitly.

Molecular Docking. Figure 1 Scheme showing the role of molecular docking in the structure-based drug design process.

However, molecular flexibility and conformational changes upon binding may be implicitly accounted for by, for example, reducing atomic radii or removing the side-chains of high mobility residues. In addition, rigid-body docking may be performed for an ensemble of rigid ligand or receptor conformations that represent the conformational variability of the molecules. The advantage of rigid-body docking is that the docking problem for two molecules is reduced to a search through three translational and three rotational degrees of freedom. There are many different techniques for performing this sampling. Major classes are complete enumeration, geometric hashing, and gradient-based techniques.

Complete enumeration

- Many rigid-body docking methods, particularly those applicable to protein-protein docking, make use of complete enumeration for shape-based docking. Typically, the molecules are discretized onto grids with values assigned at each grid point to show whether the grid point is buried on or near the molecular surface or outside in solution. Values to describe electrostatic or chemical properties can also be assigned to the grid points. For each relative orientation of the two molecules, all possible translations of the molecules are scanned by superposition of the grid points. The computational efficiency of this approach can be improved by applying a convolution strategy in which fast Fourier transforms are used to compute a correlation function for each relative orientation of the two molecules. Reverse Fourier transforming then permits scoring of geometric and electrostatic matching

of all possible translations at this particular orientation. After searching all orientations, a set of potential docked arrangements is ranked.

Geometric hashing

- As alternatives to complete enumeration, a number of techniques perform docking by matching important features of ligand and receptor. This strategy was adopted in one of the earliest approaches for using docking in structure-based drug design that was introduced in the DOCK program by Kuntz and colleagues. In this method, a binding site on a target receptor is filled with spheres that together represent the binding site's shape. A ligand is then docked by optimizing the superposition of its atoms onto the spheres in the binding site. Many docking programs make use of a computer-vision-based method called geometric hashing. Matching is performed for defined critical points in different parts of the ligand in local coordinate systems. These matches are ranked. Then full docking of the complete ligand is performed for the highest scoring local coordinate systems. Finally, the docked structures are filtered and re-ranked.

Gradient-based techniques

- Gradient-based techniques for docking make use of forces between the molecules that are defined by a [molecular mechanics force field](#) or by a simplified function. Sampling may be performed by energy minimization, Monte Carlo simulation, simulated annealing or Brownian dynamics.

Currently, most flexible docking procedures incorporate explicit treatment of the conformational flexibility of low molecular weight ligands only. Receptor conformational flexibility is usually neglected because of the large number of degrees of freedom of macromolecules. Flexible docking is computationally more demanding than rigid-body docking because more conformational degrees of freedom have to be taken into account. There are various algorithms that address the challenge of flexible docking. A few examples are:

- Incremental ligand construction. The ligand is assembled in the binding pocket by incremental connection of fragments (building blocks). Only energetically favorable additions enter the next iterative step. As a prerequisite, an initial base fragment should be positioned in the binding pocket; this is usually a rigid part of the molecule, such as a ring system.
- Distance geometry. In this formalism, the ligand conformation and location are described by a distance matrix containing intra- and inter-molecular distances; these distances are optimized to match the receptor binding properties.
- Genetic algorithms. These mimic the concept of Darwinian evolution and require the generation of an

initial population of ligand-receptor configurations that evolve by application of a fitness function aimed at improving the binding affinity.

- Monte Carlo simulation. At each step of a series of iterations, the ligand is randomly translated, rotated or distorted in the binding site of the receptor. The movement of the ligand is accepted if it results in a lower energy. If it results in a higher energy, the movement of the ligand is accepted or rejected according to a Boltzmann probability criterion.
- **►Molecular dynamics simulation.** Docking is based on molecular mechanics force fields that are used to calculate the forces on the atoms. Newton's equations of motion are solved at a series of time steps to generate the motions of the atoms resulting from the molecular mechanics forces. Simulated annealing, in which high temperature is used to sample many configurations and then the system is gradually cooled to identify energetically favorable configurations, is often used in docking. All classical degrees of freedom of the molecule can be considered but this can be computationally costly.

During a docking calculation, a large number of possible ligand orientations in the receptor-binding site are generated. Rigorous computation of the binding affinity of each arrangement using molecular dynamics simulation techniques is generally computationally infeasible. Consequently, approximate **►scoring functions** are used to rank the possible solutions by providing an estimate of their binding affinity. There are four major types of scoring function, shape complementarity, force field, knowledge-based and empirical regression.

- Shape complementarity is the first property that has been applied to score docking and is still widely used. It can be estimated in a variety of ways including burial of surface area, grid point matching of discretized molecules and minimization of inter-facial cavities.
- In the force field-based scoring functions, the potential energy (Lennard-Jones, Coulombic) is calculated using standard molecular mechanics force fields. Entropic and solvation effects are usually neglected but can be estimated empirically as terms dependent on the change in buried surface area upon binding. Good results have been obtained recently by using the MM/PBSA or MM/GBSA procedure in which the average binding energy, including Poisson-Boltzmann (PB) or generalized Born (GB) electrostatic solvation energy and surface-area (SA) dependent hydrophobic energy terms, is computed from a series of snapshots from a molecular dynamics simulation. However, this approach is

too computationally intensive for large-scale **►virtual screening**.

- Knowledge-based scoring functions exploit the large number of available 3-dimensional structures of protein-ligand complexes. The probability distribution functions of inter-atomic distances for different combinations of atom-types may be converted into energy functions by inverse formulation of Boltzmann's law. Preferred interactions score favorably, repulsive interactions are penalized.
- Empirical regression functions can be constructed as generally applicable scoring functions or as scoring functions for specific target systems. They are derived using a training set of experimentally determining structures of ligand-receptor complexes for which binding affinities have also been measured. A function is constructed that consists of the weighted sum of a number of terms that are chosen to describe the important physico-chemical properties contributing to binding affinity, such as hydrogen-bond formation and ionic and hydrophobic interactions. The weights of the various terms are derived by regression using the training set. Most functions derived for scoring give good results for some types of complexes and poor results for others. For lead optimization problems, when a number of similar ligand-receptor complexes should be docked, tailored scoring functions can be used. These can be trained on a small training set of related complexes. These functions can be derived by classical regression for a small number of terms or by partial least squares projection to latent variables (PLS) for models based on terms in a molecular mechanics force field.

Clinical Applications

The early applications of molecular docking techniques in drug design were as an aid to lead optimization and this is still an important application of molecular docking. A designed molecule is docked into the target protein and then the docked orientation is compared with that of other ligands. If the new molecule fits well in the binding pocket, further experiments (**►X-ray crystallography** and bioassay) and optimization of the biophysical properties (solubility, pharmacokinetic profile) can be carried out to obtain a more potent compound. Docking can also provide insights important for further optimization of the compound and can be used in conjunction with molecular design software. The anti-AIDS drug Indinavir, an HIV-1 protease inhibitor, provides an excellent example of the use of docking in lead optimization (5). Analogues of Indinavir were first designed based on the transition state mimic concept. Then a basic amine in a rigid ring

system was incorporated into the backbone of the known peptidomimetic inhibitor to increase the aqueous solubility and decrease the entropy lost upon binding. The proper fit of the modified inhibitor in the binding site of HIV protease was predicted by docking studies using energy minimization and confirmed by X-ray crystallography. Indinavir emerged from further optimization in which the amine ring was replaced by a more soluble pyridine moiety.

With the increased understanding of the rules governing receptor-ligand binding and the development of molecular docking algorithms, the docking technique has been used for discovering novel leads by virtual screening of molecular databases. Docking has been applied to many disease targets and successful results have been obtained (2). Here, we describe three illustrative examples.

The first example is the identification of non-peptidic CD4 protein inhibitors (6) for the treatment of autoimmune diseases. The DOCK program was used to automatically dock the 150,000 compounds in the Available Chemicals Directory (Molecular Design Ltd, San Leandro, USA) into the crystal structure of the human CD4 protein D1 domain. From this virtual screening, the 1000 compounds with the best shape complementarity scores and the 1000 compounds with the best force field scores were selected for visual inspection with molecular graphics software. 41 of these compounds, representing the diversity of chemical structure and receptor interactions found amongst the screening hits, were finally chosen for testing in an

inhibitory activity assay. Out of these, four potent compounds were identified. This 10% success rate is a significant improvement over the typical yield of ca. 0.01% from conventional random screening procedures. The second example is the discovery of the first active non-peptidic HIV entry inhibitors targeting gp41 (7). The DOCK program was again used but this time to screen a database of 20,000 compounds (ComGenex Inc., Budapest, Hungary) for binding to a hydrophobic pocket on the protein. 200 screening hits were inspected visually and 16 of these were selected for biological assays. Of these, two polysulfonic acid compounds displayed inhibitory activity at micromolar concentrations on the formation of the gp41 core structure and on HIV-1 infection. In the above two cases, docking was applied directly to the original diverse molecular databases and resulted in a large quantity of hits, most of which had to be filtered out manually. Screening a more focused targeted molecular database, generated by applying filters prior to docking, should increase the hit rate. This was the approach taken in the search for novel inhibitors of human carbonic anhydrase, a target for anti-glaucoma and anti-tumor drug design (8). The program FlexX was used to flexibly dock 100 compounds. These compounds were preselected by a 3D [pharmacophore](#) search of 90,000 compounds in the Maybridge and LeadQuest databases and a subsequent superimposition scoring. 13 hits with high docking rankings were experimentally tested and four of them showed comparable potency to the known drugs, Dorzolamide (Fig. 2) and Brinzolamide, with

Molecular Docking. Figure 2 Steric and chemical complementarity between a drug and its protein target are illustrated by the crystal structure of the complex of the anti-glaucoma drug Dorzolamide (stick representation) bound to human carbonic anhydrase II in the catalytic pocket. The yellow dashed lines show hydrogen bonds between the drug and the protein. The hydrophobic and the polar regions on the protein-binding site are shown in green and red, respectively. The Zn ion in the active site is shown by a purple ball. See text.

subnanomolar or nanomolar IC₅₀ values. A further seven compounds were micromolar inhibitors. Moreover, the predicted docking modes of two of the compounds were in good agreement with subsequent crystallographic structure determinations.

Therapeutic Consequences

A therapeutic drug needs not only to bind tightly and specifically to its macromolecular receptor. It also needs to have the appropriate properties to reach its site of action in appropriate amounts without causing undue side effects and toxicity problems. It is now recognized that the ►**ADMET** properties of a compound should be considered in parallel, rather than after, the structure-based drug design phase. Virtual compound libraries can be filtered before screening by docking so that compounds with known toxicity problems or those that may have poor physicochemical properties for oral availability are filtered out. Further, the metabolism of compounds identified by docking as ligands of a macromolecular target can be predicted by, along with other calculations, docking them to structurally characterized drug metabolism enzymes such as cytochromes P450.

Docking technology can also be used to investigate the potential for specific action and side effects. Hits identified by screening a compound library against a given macromolecular target can then be docked against a library of other macromolecular structures. These may be of related proteins, homologues or orthologues from different species or from a diverse set of protein targets.

While current docking techniques can be usefully applied in medical and agrochemical areas, they also have many shortcomings and, consequently, improving docking methodology is an area of active research. Nevertheless, it is now possible, using grid computing with PC workstations that can be widely distributed, to routinely screen molecular databases containing millions of compounds in short periods of time. This has been demonstrated for cancer and anthrax targets amongst others.

Molecular Dynamics Simulations

Definition

The motion of a set of atoms is simulated using a classical model with interatomic forces described by a molecular mechanics force field. Newton's equations of motion are solved at a series of time steps (typically at 1 fs time intervals) to generate a movie of the dynamics of the molecule(s).

Definition

Molecular dynamics (MD) is a computational tool to simulate the motions of a molecular system. The method requires an interaction potential from which interatomic forces can be calculated and equations of motion that govern the dynamics of the system. MD simulations sample the ► **configuration space** and generate a ► **trajectory** that follows molecular movements as a function of time. Originally developed to

study properties of the liquid state, MD simulations are nowadays routinely applied to macromolecular systems of biological and pharmaceutical interest. Applications include the refinement of experimentally determined structures, ►conformational analysis and protein ►homology modeling, the elucidation of biochemical and biophysical mechanisms at the atomic level, ►docking of biomolecular complexes and a variety of approaches for calculating ►free energy changes. Most of these tasks are of utmost importance in structure-based drug design.

Characteristics

Physical Principles and Computational Methods

At ambient temperatures, biological macromolecules are never at rest. Proteins, for example, are inherently dynamic systems (Fig. 1). They are characterized by a hierarchy of motions that range from small fluctuations of hundredths of an Ångström to large domain movements of tens of Ångströms and cover time scales from sub-picoseconds to seconds and more (1). Many of these motions are essential for function; ligand binding, enzyme catalysis and signal transduction would frequently be impossible without significant flexibility of the biological macromolecules involved. Since interfering with these processes is a common task in structure-based drug design, any insight into the dynamics of the investigated system comes as a significant support for rational design approaches (2). MD simulations can provide such insights, often at a level of detail that would be difficult or impossible to reach by experimental studies. Apart from following the time course of a dynamic process, however, it is often the ability to sample ►configuration space that makes MD simulations attractive for certain applications; examples include the exploration of thermally accessible ►conformations and the evaluation of thermodynamic quantities, most notably free energy changes. Classical MD simulations are based on Newton's equation of motion, $F_i = m_i a_i$, according to which the acceleration a_i of a particle (atom) i of mass m_i is directly proportional to the acting force F_i . Since the acceleration is the first derivative of the velocity with respect to time and the second derivative of the atomic positions with respect to time, expressions for the coordinates and the velocities of the particles as a function of time can be derived. Thus, given the interatomic forces as well as a set of starting coordinates $r_i(t_0)$ and velocities $v_i(t_0)$, the positions $r_i(t_1)$ and velocities $v_i(t_1)$ of the atoms at a shortly following time $t_1 = t_0 + \Delta t$ can be evaluated. The values calculated at t_1 will then serve to calculate positions and velocities at a subsequent time t_2 and so forth (Fig. 2). Various numerical integration algorithms are available to accomplish this task efficiently for appropriately chosen time steps Δt (3).

Molecular Dynamics Simulations in Drug Design.

Figure 1 Protein molecules are dynamic systems characterized by a hierarchy of different motions. Torsion angles of the backbone (ϕ, ψ) and the side chains (χ_n) show significant fluctuations at room temperature (a). If they are concerted over larger units of the protein structure, higher-order movements may arise, which are often of functional relevance, such as loop reorientations or hinge-bending domain motions (b). The potential energy landscape governing these motions is very complex and frequently characterized by a multitude of nearly isoenergetic conformational sub-states (c).

To carry out this integration, the forces between the particles must be known. Consequently, a suitable interaction potential that describes the energy of the

system as a function of the atomic coordinates must be assigned (the forces are then accessible through the first derivatives of the potential with respect to the atom positions). For biological macromolecules, this potential is usually provided by a ►**molecular mechanics force field**, which typically consists of empirically parameterized terms for bond lengths, bond angles and torsion angles, as well as terms for the non-bonded ►**van der Waals interactions** and ►**Coulomb electrostatics**. As the approach is entirely based on classical potentials, electronic degrees of freedom are not taken into account. Simulations of chemical reactions involving bond breaking or bond formation require quantum mechanical potentials.

Beyond the equation of motion and the interaction potential, practical MD simulations of biomolecules depend on a variety of further important issues. These include the definition of appropriate ►**boundary conditions** for the system, the handling of the solvent, the regulation of temperature and pressure and the treatment of long-range electrostatic forces. Detailed discussions of these topics can be found in the literature (3).

The primary result of an MD simulation is a trajectory of the simulated system, i.e. a series of atomic coordinates (and velocities) as a function of time. A trajectory can be analyzed with respect to a large variety of structural and energetic parameters (4). For any quantity Q of interest, the time course $Q(t)$ may be followed, averages $\langle Q(t) \rangle$ and fluctuations $\langle [Q(t) - \langle Q(t) \rangle]^2 \rangle^{1/2}$ can be calculated or an ►**autocorrelation** function $\langle Q(t')Q(t' + t) \rangle$ may be evaluated (angular

brackets denote average quantities). The results should always be complemented with and compared to available experimental data. In addition, any interpretation should be aware of the ►**convergence** and the relaxation properties of the analyzed quantity, as well as of the inherent approximations of the entire approach (4).

The main limitations of current MD simulations are inaccuracies in the potential energy function and insufficient ►**sampling** time. With respect to the first aspect, current research is focused on the reparameterization and optimization of ►**force fields** for simulations, as well as on the inclusion of ►**polarizabilities**. As for the simulation lengths, most is gained from the tremendous improvements in computer hardware. It is nowadays possible to routinely obtain multi-nanosecond trajectories for large macromolecules of many thousand atoms under the most realistic conditions (i.e. including explicit solvent molecules, counterions, periodic boundary conditions and long range electrostatic forces). The continuing increase in computing power and improvements in existing algorithms can be expected to progressively extend the current limits, eventually bringing within reach dynamic processes that take place on much longer time scales (5).

Applications in Drug Design

MD simulations are applied in three major areas of structure-based drug design: (i) structure determination and modeling, (ii) docking and ligand design and (iii) free energy calculations (some common applications are illustrated in Fig. 3).

Molecular Dynamics Simulations in Drug Design. Figure 2 MD allows simulation of molecular motion and generation of configurational ensembles. This is achieved by iteratively solving Newton's equation of motion for short, discrete time steps Δt to update the positions r_i and velocities v_i for every atom i in the molecular system. An appropriate potential energy function E_p is used to evaluate the forces F_i required for this purpose.

Molecular Dynamics Simulations in Drug Design.

Figure 3 Common applications of MD simulations are the conformational sampling and the refinement of macromolecular structures determined by X-ray crystallography or NMR (a), mechanistic studies on catalytic reactions or folding/unfolding processes in aqueous

Determination, Modeling and Analysis of Target Structures

Structure-based drug design depends on the availability of a 3D structure of the investigated target. Such structures are usually obtained *via* X-ray crystallography or NMR spectroscopy. Both methods frequently rely on MD simulations to refine the initial models obtained from the primary experimental data. Based on its ability to explore conformation space, MD is used here as a tool to optimize the simultaneous agreement of a structural model with observed data and with *a priori* chemical information (6). This is normally done in such way that the experimental data are transformed into energy penalties or constraints that are combined with the standard interaction potential. MD simulations are then carried out subject to these constraints, usually following a ►[simulated annealing](#) protocol.

If no experimental structure of the target is available, it may be theoretically predicted. For proteins, this is reasonable only if structures of other proteins with significant sequence homology are known. Homology modeling techniques may then be applied to obtain structural models of the target. MD simulations in the form of simulated annealing are used to refine these models. Conformational sampling is performed primarily for loop regions and areas of low sequence similarity in order to identify conformations corresponding to low energy minima.

Obviously, MD simulations are also of use if a high-resolution experimental structure of the target is already known. A single, fixed conformation, even the average provided by a crystal structure, may not be an adequate representation of a macromolecule, unless the system is very rigid. Instead, even under standard equilibrium conditions, the native folded state of a protein is best characterized by a collection or ensemble of energetically nearly equivalent conformations. MD simulations may be run to study the accessible conformations and reveal the inherent flexibility of the system. The dynamic results can be compared with experimental structural information and data from ligand binding or enzyme catalysis studies, providing clues for their interpretation and insights about the underlying structural mechanism. Thus, functionally relevant motions may be revealed that would not be evident from the crystal structure alone. Examples of such MD studies on pharmaceutically relevant proteins are included in Table 1.

solution (b) and research in the area of protein-ligand interactions and molecular recognition, including docking and free energy calculations (c).

Docking and Ligand Design

In the context of drug design, docking is mainly concerned with the prediction of protein-ligand interactions and the identification of small molecules binding tightly to a given macromolecular receptor. MD simulations could in principle be used to simulate the actual binding process, hence providing a “realistic” view of how the docking process proceeds, but this is computationally not yet feasible. Although pure MD docking approaches have been reported (e.g. Table 2:1,2), more often MD simulations are used to analyze and refine already docked complexes. This can be valuable to overcome simplifications of fast docking tools, most importantly the neglect of binding-site flexibility. As comparisons of experimental protein structures in the ligand-free and the complexed state show, ligand binding is, in fact, frequently associated with significant conformational changes in the protein. While most docking tools can not handle this appropriately, a few algorithms have been described where at some stage of the process, short MD runs are used to explore the local conformation space, often restricted to the vicinity of the binding site (e.g. Table 2:3). Alternatively, rigid docking runs may be performed with different conformations of a given protein. The required ensemble of conformations could be assembled from multiple crystal structures of the protein, from NMR studies or from MD trajectories. Apart from the protein, conformational sampling by MD may also be useful for the free ligand, either to generate low energy conformations as input for fast, but purely rigid docking or ►[virtual screening](#) routines or to perform a thorough conformational analysis of the ligand in order to estimate important conformational contributions to the overall affinity.

As mentioned above, most frequently MD simulations are applied as a post-docking tool to refine and analyze the generated complexes. This can help to identify more stable conformational substates and binding modes or, conversely, to reveal instabilities under dynamic conditions. Different ligands and ligand binding modes can be compared by analyzing, for example, the dynamics of contact distances, hydrogen bonds and solvent accessible surface areas, as well as the residual mobility and fluctuations of the ligands in the binding site (2). In addition, the important role of water molecules, which is rarely considered explicitly in docking, may be investigated.

Besides the identification of ligands by docking and database screening, an important field of drug design is concerned with the rational modification of known binders or the *de novo* design of new molecules fitting to a binding site. Even here, MD simulations can be of use. Current computational design methods usually work with a set of atoms, functional groups or

fragments that are first placed at favorable positions in the binding site and then connected in suitable ways to form new potential ligands. Among the large variety of approaches, some methods use MD simulations to identify low-energy configurations and localize favorable binding positions. Multiple-copy simultaneous search (MCSS) methods have been developed to speed up such searches by using numerous ligand copies, which are transparent to each other but subject to the full force of the protein. These and other MD applications in ligand design and docking are briefly listed in Table 2.

Free-Energy Calculations

The calculation of binding affinities is a common problem in drug design. Docking methods, for example, rely on estimates of the binding free energy provided by fast ►[scoring functions](#). The theoretically most rigorous and – in principle – most accurate approach to free energy differences is based on the evaluation of certain ►[ensemble averages](#) according to the principles of ►[statistical thermodynamics](#) (7). ►[Free energy perturbation](#) (FEP) and ►[thermodynamic integration](#) (TI) are the most prominent methods in this context (8). The required ensemble averages are typically obtained by MD. Sampling problems, however, preclude direct access to absolute free energies of binding. Instead, relative free energies are obtained by exploiting the fact that free energy is a ►[state function](#), which allows setting up a thermodynamic cycle to evaluate free energy changes by following unphysical pathways more amenable to simulation. Typically, a series of ligands binding to a given protein or the interaction of a ligand with a set of protein mutants is analyzed in this way. Besides the considerable degree of accuracy that can be achieved, a further advantage is the possibility for in-depth analysis of the results, which may provide clues with respect to the origin of the free energy changes. However, due to the slow convergence, both FEP and TI are suitable only for cases where the structural difference between the investigated ligands (or mutants) is small. Even then, the required computational resources remain significant.

Due to these restrictions, some less rigorous, but faster and often sufficiently accurate methods have been developed that are suitable to handle larger numbers of ligands. An example is the “one window free energy grid” (OWFEG) method. Here, an MD simulation is carried out with the ligand-free, solvated binding site of the protein, generating a free energy grid for a probe atom based on the FEP equation. Once such grids are calculated for different probes, ligand positions can be scored as fast as with any other grid-based scoring function. Other methods have been developed that try to obtain free energy estimates directly (without

Molecular Imaging

Definition

With the aid of molecular imaging, biological processes can be measured and characterized on a cellular level. In the context of diagnostic medicine, conventional imaging methods can only be used to detect anatomical developments, however, such molecular techniques may be used to access the causes of illness at a cellular level. Molecular imaging also differs from conventional techniques because it identifies specific gene products and intracellular processes. Above all, in the field of clinical diagnostics, the ►positron emission tomography (PET), the ►single photon emission computer tomography (SPECT), and the magnetic resonance tomography (►Nuclear Magnetic Resonance) (MRT) provide representative images at a cellular or molecular level in the living organism.

In the context of the basic cellular mechanisms (cellular signal transduction, protein-protein interactions, mobility and functionality of molecules, etc.), molecular imaging such as fluorescence microscopy is described as ►functional imaging.

Molecular Imprints

Definition

Molecular imprints are synthetic polymers synthesized in the presence of potential binding partners so that they can bind these molecules.

►Monoclonal Antibodies

Molecular Mechanics Force Field

Definition

Molecular mechanics force field refers to a classical, heuristic approach for the description of molecular structures and energetics. Molecules are handled as if they consist of charged spheres (atoms) connected by springs (bonds) of different elasticity (force constant). The energy is typically evaluated using expressions for bond stretching, angle bending, and torsional changes, as well as for van der Waals and electrostatic interactions. The terms must be empirically parameterized for all types of molecules that the force field should describe.

Molecular Mimicry

Definition

Molecular mimicry describes the phenomenon that structurally related molecules bind mostly to the same binding site. They can fulfil the same function (agonists) or can block the active site without any regular function (antagonist, competitive inhibitor)

Molecular Motors

MANFRED SCHLIWA

Institute for Cell Biology, University of Munich, Munich, Germany
schliwa@med.uni-muenchen.de

Definition

Molecular motors are enzymes that transform chemical energy into mechanical work. In the cytoplasm of eukaryotic cells, three different classes of motors that generate linear movement are known to exist – myosin, kinesin and dynein. Figure 1 shows prototypical representatives of these motor classes.

Characteristics

The three types of motors share several features (1). Firstly, they require a polar track along which they

Molecular Medicine: Genomics Encounters Classical Medicine

JÖRG T. EPPLEN

Department of Human Genetics, Ruhr University,
Bochum, Germany
joerg.t.epplen@rub.de

The present part of the encyclopedic reference for molecular medicine and genomics comprises 77 mostly disease-centered entries as composed by more than one hundred authors. The subjects range from chromosomes (►[Chromosome 21, Disorders](#)), many monogenic disorders (reviewed in ►[Hereditary Disease, Genetic Basis](#)) and common multifactorial diseases (see overview ►[Common Diseases, Genetics](#)) to ethical issues in the general context of medical genetics (►[Ethical Issues in Medical Genetics](#)). Thus a wide field of genome orientated basic and applied biomedicine is covered by exemplary articles illustrating that particularly active and competitive research efforts have yielded substantial progress, with one or the other even bearing on clinical medicine.

Molecular Medicine and Genomics

Molecular medicine and genomics are the virtual partners in this modern biomedical research scenario that drives progressive innovation. Molecular medicine gathers information from the study of the molecular, cellular and whole organism biology of man as well as of model organisms (►[Transgenic and Knock-Out Animals](#)). This assembled information, together with the knowledge obtained from the traditional fields of medicine from e.g. (molecular) cytogenetics (►[Microdeletion Syndromes](#)) to biochemistry (see e.g. ►[Acute Intermittent Porphyria](#); ►[Defective Protein Folding Disorders](#)) leads to a better understanding of a living organism in health and disease. The term genomics is obviously derived from ‘genome’, which comprises all the genetic material of an organism. Roughly speaking, genomics encompasses the research into the composition and function of the genetic material of all living organisms. Genomics covers a broad area that cannot be placed under the umbrella of one conventional scientific field. It is more than just biology, just chemistry or just medicine. Genomics is a new scientific field that covers a wealth of novel topics, innovative technologies and original approaches. Genomics is the science that studies genes and their function, but also the previously disrespected genomic desert (28), i.e. DNA sequences representing merely evolutionary junk. It is

not a great surprise to biological scholars that the ‘junky DNA desert’ is partly redefined by identifying therein a wealth of sequence elements with crucial regulatory functions for gene expression (►[Hypoxia Inducible Factors](#); ►[Transcription Factors and Regulation of Gene Expression](#)). Thus more specifically, genomics is the technology that sets out the map of all the genetic information of humans, animals, plants and microorganisms. It unravels their blueprint, for instance by means of DNA mapping and sequencing as well as by wide-scale research into the functions of genes and the manner in which hereditary characteristics are translated into the function of a cell – and furthermore ultimately into the function of an entire organism. Genomics also includes other high throughput technologies (as supplied by other fields like proteomics, metabolomics and bioinformatics among other ‘-omics’). Thus genomics comprises a set of technologies that has become an indispensable tool in the current field of life science research.

Undoubtedly, genomics is revolutionizing biomedical science and its applications to clinical medicine are starting to expand. Large-scale genomic sequencing has only been the basis of genomics in the genome projects. Translation of sequence information into an understanding of how the genome actually works in health and disease will dramatically alter the ways in which scientists and doctors think and work. With final regard to patient care, this accumulated knowledge has also to be transformed and applied integrally on higher organizational levels such as the immune system and the central nervous system (see e.g. ►[Autoimmune Diseases](#); ►[Addiction, Molecular Biology](#)).

Already ~150 years ago, Virchow in his famous book, *Cellular Pathology* wrote that ‘All diseases are reducible to active or passive disturbances in cells’ (26). Thus the key to every biological problem must finally be sought in the molecular changes in the cell. Before there is a cure for a disease, before drugs and/or life-saving procedures can be developed, even before clinical trials are commenced, there is always a crucial first step – research and discovery. Already today molecular medicine has become a central basic scientific discipline in biomedical research and in medical practice. It bridges biochemistry and structural biology to clinical medicine. Modern day scientists have the unprecedented opportunity to understand basic cellular processes as well as their derangements in diseases in molecular terms – often referred to as molecular cell biology and molecular medicine. Today researchers utilize information obtained from biochemical, genetic, molecular and sophisticated morphological techniques, such as deconvolution, confocal and video microscopies, in the study of basic problems in cell biology and molecular medicine. They also take

advantage of insights gained from ultramodern proteomic, genomic and bioinformatic analyses. After completing the human genome project (16, 34), the challenge of understanding the roles of all individual proteins and genes in coordinated cell function and disease remains. Thus the tempting frontier for the post-genomic era is centered in modern molecular medicine. A story of success in molecular medicine has been evidenced primarily by the progress in the diagnostics of monogenic diseases during the past two decades. Nearly all the 3000 human maladies inherited according to the Mendelian laws (see OMIM, Online Mendelian Inheritance in Man, a database of human genes and genetic disorders) can be diagnosed directly today, since they depend on a mutation in a given gene. Those few hundred disorders that still need to be tackled by the indirect approach should be prone to direct DNA analysis within the next year or two (►Hereditary Disease, Genetic Basis).

Monogenic vs Common Multifactorial Disorders plus Epigenetics

The conceptual gap between classical monogenic and common multifactorial diseases is bridged or even beginning to be closed by deeper insights into molecular basics as well as their pathogenetic consequences on the cellular and organismal levels. The 'monogenic disorder' *sensu stricto* is extremely rare, whereas 'common multifactorial disease' (►Common Diseases, Genetics) appears to be the general rule – and the latter ailments strike frequently. 'Multifactorial' comprises virtually all common diseases, although it is not yet known to what extent the individual disease entity is caused by very few (oligogenic) or many genes (multigenic). In addition, the critical environmental triggers especially but also other contributions remain largely elusive, so far. Thus, it appears that there rather exists a continuum between apparently strictly monogenic (Huntington disease, HD) and truly multifactorial disorders (multiple sclerosis, MS; inflammatory bowel disease, IBD). As early as 1983 the genomic region responsible for HD was defined on the tip of the short arm of human chromosome 4 (14). Only after a decade was the *huntingtin* gene and the relevant mutation described as a critical trinucleotide (CAG) expansion in an 'interesting transcript IT15' (30). Since then direct DNA and even prenatal diagnostics have been possible. Psychosocial counseling in combination with DNA testing for HD served as a model for other monogenic diseases. More and more of the causal pathogenesis can be defined, including the so far elusive genetic background (►Huntington's Disease).

With regard to the causal pathogenesis, eight other neurodegenerative diseases, including the spinocerebellar ataxias (►Repeat Expansion Diseases, Dynamic

Mutations Cause (Neurological) Model Disorders), are caused, like HD, by the expansion of a CAG repeat in the coding region of a transcribed gene. All these CAG expansion diseases are characterized by progressive neuronal dysfunction, starting usually during adult life and resulting in severe neurodegeneration. One of the hallmarks of the pathology of polyglutamine diseases is protein aggregation and formation of neuronal intranuclear inclusions in the affected areas of the brain (9). In addition to the repeat expansion, other factors, such as proteasomal activity and expression or recruitment of cellular chaperones, probably influence polyglutamine toxicity and disease development (35). Several findings point towards an involvement of the ubiquitin proteasome system (UPS) in the pathogenesis of polyglutamine diseases and to an enhancement of neurodegeneration by further impairment of the UPS (7). Thus inhibition of protein aggregation (►Acute Intermittent Porphyria; ►Defective Protein Folding Disorders) and proteasomal activation may turn out to be promising avenues for the treatment of polyglutamine diseases.

With regard to the genetic contributions to HD, the length of the expanded polyglutamine tract is clearly by far the most important factor in determining the age at onset (AO) of HD, although substantial variability remains after controlling for repeat length, particularly in cases where CAG repeat numbers range in the high 30s or low 40s (1, 2). These insights have prompted the search for additional genes influencing AO in HD. Defining such additional predisposition factors is important, since they may provide further clues pertaining to HD pathology arising from the expanded repeats. Neuronal death is obvious in various regions of brains of HD patients, including the neocortex and lateral hypothalamus accompanied by dramatic loss of GABAergic medium spiny neurons in the striatum. These neurons receive glutamatergic input from the cortex and dopaminergic input from the substantia nigra. A mechanism for the loss of these neurons in HD is excitotoxic cell death mediated by the release of glutamate from cortical afferents and activation of glutamate receptors (29). For example, excitotoxicity mediated by a N-methyl-D-aspartate (NMDA) receptor, in particular the GRIN2B subunit of the NMDA-type glutamate receptor, has implications for the pathogenesis of the neurodegenerative process in HD as a disturbance of neurotransmission. At least 10% of the genetic effect on the AO is attributable to combinations of the *GRIN2B* genotypes (2). Consequently, neuroprotective strategies for HD patients and persons at risk should be reconsidered.

In contrast to HD and other monogenic neurological and psychiatric disorders (►Neurofibromatosis Type 1 (NF1), Genetics; ►Hereditary Spastic Paraplegia), MS is a chronic inflammatory disease of the central

nervous system depending on a complex genetic background as do other multifactorial entities (see Baptista et al., this volume; Finckh, this volume; Nöthen, this volume; Norton and Owen, this volume; Pollmächer, this volume). Despite apparent genetic components, the responsible predisposing genes remained largely undefined. Only the *HLA-DRB1*15/16* alleles are well-established factors associated with susceptibility, conferring a nearly 4-fold relative risk for development of MS in northern European individuals (► [Genetic Predisposition to Multiple Sclerosis](#)). Disease manifestation and age at onset appear to depend on evasive environmental factors as well as on disease-modulating genes acting in genetically susceptible individuals. Although the etiology of MS remains to be understood, a plethora of putative candidate genes have already been screened with respect to mutations and polymorphisms associated with the disease itself or with clinical characteristics of the disease, such as severity of symptoms and disease course. The results of such candidate gene approaches have been unspectacular, as in most other autoimmune diseases, suggesting that MS is genetically complex. So far, no genes of major attributable risk have been found, but several genes probably confer a low or moderate effect (see *HLA-DRB1*15/16* alleles).

The genetic contributions to another group of multifactorial disorders, inflammatory bowel diseases (IBD), have already been clarified to a much greater extent. Hence, and also because of their model character for other multifactorial diseases, IBD are covered here in more detail. Both animal models and clinical investigations indicate that luminal bacteria play a pivotal role in the pathogenesis of morbus Crohn (► [Crohn disease](#), CD). This hypothesis of bacterial relevance is supported by the identification of the first susceptibility gene for CD. Single nucleotide polymorphisms (SNPs) have been identified in the *caspase recruitment domain 15* gene (*CARD15*, formerly known as *NOD2*) (reviewed in 15). Certain alleles of these SNPs increase the risk of developing CD. *CARD15* protein is located in the cytoplasm of mononuclear cells, where it is involved in the recognition of bacterial components, leading to subsequent activation of nuclear factor κ of B lymphocytes (NF κ B) by inactivation of its inhibitor NF κ BIA (see ► [NF- \$\kappa\$ B Pathway](#)). Disturbed activation of the innate immune system by bacterial antigens seems to be crucial in a subgroup of patients with CD. As rare alleles of the SNPs are not found in all patients with CD and as these alleles are found in healthy persons as well, variations in the *CARD15* gene are neither necessary nor sufficient for genetic predisposition to CD. Genome-wide linkage based screens with highly informative markers succeeded in identifying regions on chromosomes 1, 3, 5, 6, 7, 12, 14 and 16

linked to IBD (reviewed in 15). Yet the susceptibility genes located within the chromosomal regions still remain to be identified. Linkage of IBD to chromosome 12p13.2-q24.1 has been confirmed in several genome-wide screens. The *STAT6* gene is located within this chromosomal region. The transcription factor STAT 6 is involved in the regulation of the TH1/TH2 immune response and autoimmune reactions (► [Autoimmune Diseases](#)). Increased production of TH1 cytokines is crucial in the pathogenesis of IBD. In comparison to controls, certain *STAT6* and *NFKBIA* alleles are more frequent exclusively in CD patients without any predisposing variation in the *CARD15* gene (18, 19).

The study of human disease has focused on genetic mechanisms, but disruption of the balance of epigenetic networks can cause several major pathologies including cancer (► [Hereditary Nonpolyposis Colorectal Cancer](#)), syndromes involving chromosomal instabilities (► [Chromosomal Instability Syndromes](#); ► [Bloom Syndrome](#)) and mental retardation (► [Rett Syndrome](#); ► [Prader-Willi and Angelmann Syndromes](#); ► [Fragile X Mental Retardation Syndrome](#); ► [Inherited Mental Retardation Syndromes](#)). Epigenetic mechanisms, which involve DNA and histone modifications, result in the heritable silencing of genes without a change in their coding sequence (10). The development of new diagnostic tools might reveal other diseases that are caused by epigenetic alterations. Great potential lies in the development of ‘epigenetic therapies’ – several inhibitors of enzymes controlling epigenetic modifications, specifically DNA methyltransferases and histone deacetylases (► [Polyglutamine Disease, the Emerging Role of Transcription Interference](#)), have shown promising anti-tumorigenic effects in some malignancies.

In summary, major research efforts in genomics and molecular medicine will have to be concerned from now on with the identification of the complex genetic bases for the common multifactorial diseases. The so-called genetic background is critical or even decisive – not only for multifactorially caused diseases but also for the disorders due to ‘simple’ monogenic traits. Nevertheless the non-genetic contributions to disease manifestation and development (epigenetics and environment) will have to be simultaneously in the focus of major future research efforts.

Novel Developments in Genomics and Molecular Medicine – from Biobanks to Genome-wide Association Studies and Beyond

In addition to all modern methodological developments in the classical disciplines of biomedical research, specific new approaches and strategies are being established that virtually straddle genomics and molecular medicine. The definition of genetic and

environmental factors that contribute to health, disease and response to treatment is essential for the reduction of morbidity and mortality. The sequence of the human genome (16, 35) and increasing information about the genome's variation (31) and function provide a robust platform for the investigation of human health and disease. This information will be especially useful when combined with reliable and cost-effective (high throughput) methods that can be used to genotype these variations in large population samples. In parallel with the expansion of genomic tools and knowledge, methods for measuring non-genetic factors and environmental exposure have improved. Development of robust analytical methods for assessing disease risk relationships and interactions is beginning to allow the disentangling of such complex effects on a population scale (33). Together, these developments present opportunities to address unanswered questions related to the complex contributions of genes, the environment and gene/gene and gene/environment interactions. Large-scale national programmes to develop genomic epidemiological studies are already in place (UK (BioBank), Iceland (deCODE), Estonia) or planned (Canada, China, Japan, USA); international projects need to be launched in the near future (8).

On this basis of well-characterized patient and control cohorts, so-called disease association studies can be performed. In association studies, allele frequencies of polymorphic markers are compared in unrelated patients and healthy controls in order to identify markers that differ significantly between the cohorts (see also Vilmundur, this volume). Many studies used only a small number of polymorphisms, but most of the identified associations have been difficult to replicate (21) for a number of different reasons: First, there may be important differences in allele frequency and/or linkage disequilibrium structure across different populations. The situation may be further complicated by the presence of hidden stratification in some populations, producing spurious association or altering the pattern of a true association (12). Other sources of complexity are allelic heterogeneity, in which different alleles at the same locus are responsible for increased disease risk in different populations, and locus heterogeneity, in which alleles at different loci are responsible for increased disease risk in different populations. Both of these scenarios are likely when there are multiple rare variants that are fairly recent in origin. Currently, little is known about the true nature of allelic heterogeneity with respect to disease. Aside from these genetically driven phenomena, study design and publication bias may also lead to complex patterns (25).

Because it seems likely that common modest risk variants exist, developing tools such as high-density

genetic maps for whole genome association analyses is an important goal for analyzing the human genome. Comprehensive analysis of candidate regions and the whole genome should produce robust results. Meanwhile, the technical, informatic and statistical foundations have been laid for whole genome association analyses (6). It is important to understand that association analysis using dense maps, such as the HapMap, is fundamentally different from the family linkage studies used to identify rare high-risk alleles. In linkage analysis, any polymorphism between a pair of linked markers will be associated with both markers. As a result, linkage maps have a logical hierarchical structure wherein an initial genome scan can be performed at low density (<500 markers), with additional markers used to fine-map the boundaries of linked regions.

After decades of study, at least some facts have been learned about the genetics of common diseases, but most of this knowledge relates to rare families segregating high-risk alleles (5). Such alleles are generally very rare in the population and therefore explain relatively little of overall disease prevalence. Identification of the genetic polymorphisms that contribute to susceptibility for common diseases such as MS and inflammatory bowel disease will aid in the development of diagnostics and therapeutics. New (chip based) technologies and experimental resources make whole genome association studies more feasible (6, 13). Association studies of this type have good prospects for dissecting the genetics of common diseases, provided that the challenges, including multiple testing and study design, definition of intermediate phenotypes and interaction between polymorphisms are tackled successfully.

As a further development gene based approaches to association analysis are feasible and have many advantages. In contrast to SNP and haplotype approaches, a gene-based approach is less susceptible to erroneous findings due to genetic differences between populations. By capturing all or most of the potential risk conferring variations, a gene-based approach is capable of excluding association, subject only to the issue of power. Use of a gene-wide significance level should reduce the problem of chance findings due to multiple testing. Gene-based approaches lend themselves to meta-analysis of combined data from multiple studies. As the knowledge of the variation in genes grows, a gene-based approach will become the natural end point for association analysis and will provide pointers for genetic analysis at the functional level.

Gene-based approaches require detailed knowledge of genetic variation in coding sequences as well as regulatory and other regions affecting gene function. This level of knowledge is not generally available yet.

In the future, when knowledge of genetic variation allows a gene-based approach to be routinely employed, gene-based studies may become the preferred option for the genetic dissection of complex traits. At present, a gene-based approach should ideally be used for the replication of previous positive association findings or for the study of very strong candidate genes. The gene-based approach may not be necessary when there is very detailed knowledge about functional variation in the gene and would not be efficient for screening a very large number of genes (27).

Screening, Predicting and Preventing Diseases via Genomics and Molecular Medicine

For most diseases, medical treatment is offered only when the patient has visited the doctor with symptoms and complaints. By this time it is usually late in the natural history of the disease, and therapeutic intervention may be limited to alleviating symptoms and slowing disease progression. In the era of genomic medicine, physicians will have the opportunity to move from crisis-driven intervention to predictive medicine (17). It seems likely that entire populations or specific subgroups will be screened for genetic information in order to target interventions to individual patients that will improve their health and prevent disease. Until now, population screening involving genetics has focused on the identification of persons with certain Mendelian disorders before the appearance of symptoms and thus on the prevention of illness (screening of newborns for phenylketonuria etc.) and the testing of selected populations for carrier status and the use of prenatal diagnosis to reduce the frequency of disease in subsequent generations (Tay–Sachs disease among Ashkenazi Jews etc.). In the future, genetic information might increasingly be used in population screening to determine individual susceptibility to common disorders such as heart disease, diabetes and cancer. Such screening will identify groups at risk so that primary prevention efforts (diet, exercise etc.) or secondary prevention efforts (early detection, pharmacologic intervention) can be initiated. Such information could lead to the modification of screening recommendations, which are currently based on population averages (screening of people >50 years of age for early detection of colorectal cancer etc.).

In a few areas of medicine, standard approaches have progressed to incorporate multiple diagnostic tests that precisely identify disease mechanisms, indicate the most appropriate type of therapeutic intervention and evaluate therapeutic response as well as disease outcome. This is particularly evident in the management of infectious and metabolic diseases as well as cancer. Prediction, prevention and counseling of

individuals at risk of genetic diseases have been aimed largely at single gene disorders that have Mendelian patterns of inheritance. These disorders offer the advantage that the identification of genetic variations responsible for disease can lead directly to clinically helpful and reasonably accurate prediction or diagnosis of disease. Clinical genetics, however, will soon have to move on to aspects of genetics that are less ‘deterministic’ for a particular disease. Even apparently simple Mendelian disorders prove to have widely variable clinical phenotypes (see e.g. the genetic background of HD above). As a result of secondary genetic and environmental factors, individuals with exactly the same mutation may suffer either from a severe and early onset disorder or be affected relatively late in life and only modestly. Further examples pertain to situations when – on closer evaluation – genetic variants are not proved to have consistent levels of penetrance. Initially the genes such as the mismatch repair genes in hereditary non-polyposis colorectal cancer (HNPCC, ►[Hereditary Nonpolyposis Colorectal Cancer](#)) and *CFTR* in cystic fibrosis (see ►[Epistasis in Cystic Fibrosis](#)) have been identified because of their relatively high penetrance. Thus even single gene disorders have a significant level of heterogeneity (see ►[Hereditary Disease, Genetic Basis](#)) that limits any prognoses as asked for by the patient and/or his family.

Information valuable but also critical to patients and general practitioners is emerging from genomics (see Sass, this volume), especially in the form of future comprehensive genetic profiling. At present, this science is being accumulated in specialized university centers and it will need to be transferred more competently to a (routine) clinical setting, creating many different challenges for health professionals, both technically and educationally. Much of the recently generated genomic data that are clinically relevant are in formats that are inappropriate for diagnostic testing. The technology has not yet been established for rapid, inexpensive typing of most genomic biomarkers, with the exception of SNPs and too little is known about which SNPs to type for non-Mendelian disease. As stated above, very large epidemiological population samples followed prospectively for years and characterized for their biomarker and genetic variation will be necessary to demonstrate the clinical utility of these tools. Obstacles to the routine application of these data in clinical practice include an educational gap between the approach to clinical practice that is currently employed and that which is possible with these new tools. Diagnostic medicine that includes predisposition testing (►[Predictive Testing and Genetic Counseling](#)), early detection, individualized therapy (►[DNA-based](#)

Vaccination) and gene therapy (►Clinical Gene Transfer) as well as therapeutic monitoring is neither systematically applied nor well taught in the current health care system. Its implementation will require not just clear data demonstrating its benefits, but also demand by patients and acceptance by health care professionals. Cost effectiveness will have to be demonstrated. The opportunities for clinical genetics to become a mainstream component of clinical medicine are now apparent. This move to the clinic appears to be inevitable (3), but the transition will certainly take longer than another decade.

Partial Merger of Genomics and Molecular Medicine

Until recently, genomics and clinical research were independent areas, each with distinct intellectual traditions and communities of investigators. With the completion of the Human Genome Project, there is the need to combine these disciplines to study disease mechanisms and improve patient care, an endeavor that might be termed 'clinical genomics'. Genome sequence data are enabling clinical genomic investigation, in which the characteristics of human patients are explored using comprehensive inventories of biomolecules. Successful investigators must navigate through rapid technological change, collect and analyze large volumes of data and engage systems of clinical care. Such projects will increasingly rely on fully integrated multidisciplinary teams, demanding new organizational models in academic biomedical research. These facts apply also to pharmacogenetics and pharmacogenomics. Individuals respond differentially to drugs and sometimes the effects are unpredictable. Differences in DNA sequences that alter the expression or function of proteins that are targeted by drugs can contribute significantly to variation in the responses of individuals. Many of the genes examined in early studies were linked to highly penetrant, single gene traits, but future advances hinge on the more difficult challenge of elucidating multigene determinants of drug response (24). This intersection of genomics and medicine has the potential to yield a new set of molecular diagnostic tools that can be used to individualize and optimize drug therapy (►Idiosyncratic Drug Reactions).

If the use of medication is to evolve from a 'trial and error' approach to individualized therapy using genetics, at least two aspects of health care need to change. We must introduce protection against the misuse of genetic information and accept the added costs that may be incurred during the transition to genetically guided decisions about drug therapy. In the long run, decreasing the frequency of adverse drug effects and increasing the probability of successful

therapy will probably lower the cost of health care. Pharmacogenomics has the potential to facilitate this process by translating knowledge of human genome variability into more individualized therapeutics (11).

The Next Decade

While unimaginable only a decade ago, molecular medicine and genomics are now reality because of recent rapid progress and an enormous burst of new scientific opportunities. Thus, we are already beginning to gain ground in the fight against many dreaded diseases, including cancer and cardiovascular disorders and introduce more effective preventive measures, e.g. in the form of neuroprotection (32). One can realistically hope to develop increasingly effective treatments and preventive measures for these diseases as well as for the banes of diabetes (►Diabetes Mellitus, Genetics), obesity (►High-HDL Syndrome), Alzheimer disease (22), degenerative diseases of aging (►Molecular Aging Research) and emerging infectious agents.

The future is hard to predict, especially the longer it extends beyond a reasonably foreseeable span of 3–5 years. What will medical practice and patient care be like in 2014? Genomics and molecular medicine could grow as the basis for human health care in the next decade, especially if investments in biomedical research are increased substantially. The practice of molecular medicine will consist of new prevention, diagnosis and treatment methods that directly target the molecular, cellular or physiological defects causing disease. These medical methods will be based on precise, non-invasive imaging and other diagnostic techniques. They will be implemented with directed, rationally designed molecular and pharmaceutical therapies and they will be rooted in a deep understanding of normal human cellular and molecular physiology and genetics.

Most important in this context are new and far-reaching initiatives in functional and physiological genomics. Such new 'mega-projects' also involving the consolidated bio-medical industry sector would have the goal of understanding the normal functions of the many genes discovered in the complete genetic blueprints of humans and diverse model organisms by the Human Genome Project. These efforts will lead to a detailed understanding of normal cellular, molecular and integrative organismal physiology, which in turn will allow us to create therapies targeted directly to the cellular, genetic and physiological defects that cause disease and organ dysfunction. New achievements will also allow the defence of people against the ever-present and increasing dangers of emerging pathogens and viruses, by developing the next generations of vaccines and antibiotic drugs (see e.g. (23)).

This encyclopedic reference brings together several aspects of medicine that have significance at the molecular level with the advances in molecular biology that are relevant to medicine. With 77 separate primary entries, this comprehensive treatise covers the rapidly expanding field to a substantial extent, with well-studied examples. The coverage in this encyclopedic reference is multilayered, ranging from the organ to the cell to the molecular aspects and includes extensive cross-referencing. Molecular medicine covers diagnostics, epidemiology, pathogenesis, genomics, genetic testing, animal models, vaccines, gene therapy and drug design. The chapters in the Encyclopedic Reference of molecular medicine might be of interest to all those working in the fields of clinical medicine and medical research and to researchers in the pharmaceutical and medical biotechnology industries. Thus geneticists, biochemists, molecular biologists, medical researchers and doctors with either an academic or industrial background should find this an essential up-dated resource.

move unidirectionally – actin filaments for myosins and microtubules for dyneins and kinesins. The information on polarity is provided by the uniform molecular orientation of the subunit proteins, actin and tubulin respectively, within the track. Intermediate filaments, the third major structural component of eukaryotic cells, are non-polar and are not known to support oriented movement. Secondly, all motors move unidirectionally either towards the plus end or the minus end of the track. Thirdly, all motors use the energy derived from ATP hydrolysis to undergo conformational changes that result in directional movement. The initial conformational changes in this process are similar in kinesins and myosins but totally different in dyneins. Fourthly, the binding sites for both ATP and the track are located in a roughly globular

catalytic (or motor) **▶domain**, also referred to as the “head”. The two sites need to communicate with each other in the process of movement. In addition, the non-motor domains can harbor secondary structural elements important for motor function, including **▶coiled-coil** segments involved in dimerization and domains that function in mechanical amplification. Fifthly, most motors studied so far in some detail can generate a force that is sufficient to move even large objects through viscous cytoplasm. Finally, motors possess domains and/or associated proteins that confer specificity of function or are involved in regulation.

A combination of biochemical, molecular genetic and genomic approaches revealed that each of the three motor classes comprises superfamilies of motors of strikingly varied makeup and function outside the motor domain. Today, we can distinguish at least 18 different classes of myosins (Fig. 2), 10 different families of kinesins (Fig. 3) and two groups of dyneins, axonemal and cytoplasmic (Fig. 4). The complement of motors varies widely in different organisms (Table 1), ranging from 12 in yeast to over 100 in mammals. However, posttranslational modifications or various associated proteins may well increase the number of motors in a given cell several-fold. Many motors have not yet been characterized and clear functions are assigned to only a small subset. For a compilation of reviews, see (2).

The motor domain is the center of action in force generation and movement. Its size differs markedly between the three types of motors, being surprisingly small in kinesins (45 kD), about twice that size in myosins (100 kD) and exceptionally large in dyneins (500 kD). Structural information at atomic resolution has uncovered an unexpected similarity between kinesin and myosin. The central portion of the myosin head, which harbors the nucleotide-binding pocket, is virtually identical in structure to the core of the kinesin motor domain, despite a lack of significant sequence homology. In addition, both structures show similarities to the G-proteins in the region surrounding the nucleotide, the so-called switch I and switch II motifs. In all three proteins the switch regions shift position in

Data compiled from various sources

response to nucleotide hydrolysis and thus are instrumental in the catalytic process. These findings are consistent with a common evolutionary origin of myosin, kinesin and G-proteins.

Dyneins are different. The dynein heavy chain is a member of the ►AAA⁺ ATPases, a highly diverse superfamily of proteins involved in a wide spectrum of cellular activities. In its C-terminal portion it contains six AAA⁺ modules apparently arranged in a ring. Only the first highly conserved AAA domain is believed to hydrolyze ATP and thus represents the catalytic site.

Initial Events in Force Generation

The key to an understanding of motor action is intradomain movement within the motor domain. In kinesins and myosins, small, initial structural changes triggered by ATP hydrolysis are translated into larger conformational changes associated with movement. In this process, nucleotide-dependent changes at the ►active site and the filament binding are tightly coupled. In myosin, the conformational change is communicated to the C-terminal region of the motor domain, an α -helix stabilized by associated light

chains. This domain swings through an angle of $\sim 70^\circ$ and thus acts as a mechanical amplifier of the small conformational change initiated in the ATP-binding site. According to a widely held model this swing of the lever arm is the ultimate cause for a “step” of the myosin motor along an actin filament.

Kinesin does not appear to possess a lever arm, but it has an analogous element, the neck linker, a motif of ~ 10 amino acids at the C-terminus of the motor domain. According to the most popular model for the kinesin mechanism, the neck linker undergoes a positional shift in response to nucleotide hydrolysis, being docked along the motor domain in the ATP state or mobile in the ADP state (3). Thus the structural elements involved in sensing and transmitting hydrolysis-dependent changes are similar in kinesin and myosin, but the last step of translation into a large-scale conformational change differs.

In dynein, the microtubule-binding site is located at the end of a unique ~ 10 nm stalk on the opposite side of the ring of six AAA⁺ modules. How dyneins transmit a conformational change in the first AAA unit to a microtubule-binding site located 20 nm away is presently unclear.

Taking a Step

A spectrum of behaviors is observed in the translation into movement of the structural changes in the motor domain. For example, some motors, such as conventional kinesin or mammalian myosin V, can move along their respective tracks for long distances without dissociating, a property referred to as processivity. In these dimeric motors the two motor domains are strictly coupled and cooperate. However, certain other motors that are also dimeric are non-processive (e.g., myosin II, members of the KAR3 family of kinesins). Here the motor domains presumably operate independently of each other.

A basic concept to explain these differences is the concept of the duty ratio, which describes the fraction of the time a motor domain spends attached to its track during one hydrolysis cycle (4). A single step can be envisioned to consist of a working stroke (where the head is bound to the track) and a recovery stroke (where it is detached). The hydrolysis cycles of the two heads must be coordinated in such a way that one of the heads is bound to the microtubule while the other is moving

forward to find a new binding site, and the two heads have to be kept out of phase. For this “hand-over-hand” cycle to work, the duty ratio must be at least 0.5 and a phase must exist in which both heads are bound to the microtubule. This enables a single molecule of conventional kinesin to take several hundred steps of 8 nm, which corresponds to the spacing of tubulin dimers, without dissociating from the microtubule. Motors that have a low duty ratio are non-processive. The two best-studied non-processive motors are myosin II and the kinesin-like protein *ncd*. Both are dimeric, but the two heads apparently do not cooperate. In muscle, for example, cooperation of the heads of myosin II is unnecessary because they operate as part of a large ensemble of motors within the sarcomere. Processivity probably evolved as a result of a physiological requirement for long-range movement driven by only one or a few motor molecules. Indeed, several processive motors function in organelle transport.

Directionality

Though most myosins and kinesins move to the plus end of their respective tracks, both superfamilies also have motors that move in the opposite direction, whereas dyneins are exclusively minus end-directed. Motors that can switch the direction of movement apparently do not exist.

Analysis of minus end-directed motors has offered important insights not only into the basis of reversed directionality, but also motor mechanochemistry. Minus end kinesins have the motor domain at the C-terminus, as opposed to the N-terminus for plus end motors. This placement alters head-neck interactions, which, in turn, are the key determining factor for directionality. When motor domains of forward and reverse motors are swapped, the resulting chimaeras adopt the direction of movement specified by the neck. The reversed polarity of the minus end-directed myosin VI motor is attributed to a unique 53-amino acid insertion in the converter domain that is proposed to reverse the direction of the lever arm swing.

Force and Velocity

Force measurements have been made on only a subset of motors in each superfamily. To measure these forces, ingenious micro-devices were developed that operate with unprecedented precision and sensitivity. They show that the forces developed by kinesin, myosin and dynein motors – around 1–10 pN – are extremely minute by our macroscopic standards. For example, to lift a 5 kg weight about 10,000,000,000,000 myosin motors are required. However, in the realm of the cell, a single motor can move an object many times its own size through viscous cytoplasm at near maximum speed.

Molecular Motors. Table 2 Speed and ATPase activity of selected motors

	Species	Speed (µm/sec)	K _{cat} (ATP/head/sec)
Conv. kinesin	animals	0.6	80
Conv. kinesin	fungi	2.6	260

Cytoplasmic dynein	mammals	1.2	2

ncd and myosin VI are minus end-directed motors
Data compiled from various sources

Not surprisingly, the different families of motors exhibit a wide spectrum of motile properties, ranging from extremely slow to exceedingly fast movement (Table 2). Some motors are even unable to generate movement and instead have adopted a function in regulating microtubule dynamics (e.g. kinesins of the MCAK family).

Molecular Interactions

Molecular motors are involved in a wide variety of cellular activities, including contraction, organelle transport, cell movement, cell division, signaling, RNA localization, sensory transduction and basic developmental processes (Table 3). These activities are mediated by either direct or indirect interactions of the motor with its cellular targets (5). In both processes, non-motor domains and associated proteins play key roles and a spectrum of attachment mechanisms is observed.

Members of all three superfamilies of motors are implicated in organelle transport and membrane association, and various interaction mechanisms are known. Some motors, such as monomeric myosins, exhibit direct linkage to the phospholipid bilayer, notably acidic phospholipids. Likewise, a member of

the unc104/KIF1 family of kinesins interacts directly with lipids. Alternatively, motors such as conventional kinesin may bind directly to integral membrane proteins. Conventional kinesins from animal species co-purify in a 1:1 complex with a 70 kD protein termed kinesin light chain. *Via* these light chains, kinesin binds to amyloid precursor protein (APP), a transmembrane protein of certain neuronal vesicles. This link is of potential medical significance since APP has gained fame as the precursor of a proteolytic fragment that gives rise to amyloid plaques in patients with Alzheimer's disease.

In most cases, however, motors link with their target molecules *via* intervening proteins, often in the form of large assemblies. Thus conventional kinesin, again *via* its light chains, interacts with a class of scaffolding proteins that can bind certain components of signaling pathways. These scaffolding proteins in turn, may bind a transmembrane receptor of the LDL receptor family. Linkage *via* a subdomain in the non-motor region of kinesin heavy chain on the other hand, couples kinesin to the glutamate receptor. Two myosins involved in membrane transport likewise make use of linker proteins. Thus myosin VI forms a complex

Molecular Motors. Table 4 Molecular motors involved in disease aspects

Disease or defect	Motor involved
Myosin myopathies	Myosin II
User syndrome (USH1B)	Myosin VIIa

Virus transport	Conventional kinesin and cytoplasmic dynein
Anthrax susceptibility	K1F1C (unc 104 kinesin family)
Neurodegenerative disease	Kinesin and cytoplasmic dynein

with adaptor protein AP-2 and clathrin, promoting endocytosis. Myosin V, on the other hand, requires the small GTPase Rab27a and a recently identified Rab-binding protein, melanophilin, to bind to **melanosomes** in pigment cells. Here the GTPase binds to membranes first and recruits melanophilin, which then binds myosin V. Melanophilin binding is GTP-dependent, thus offering a means of regulating motor-cargo binding. A large protein assembly also seems to be involved in linking dynein to many of its sites of action. Through its intermediate chains, dynein interacts with a unique activator complex, dynactin. The dynactin complex seems to affect not only cargo binding but also motor activity *via* an as yet poorly defined mechanism.

Motors of all three superfamilies are also involved in mRNA localization. In yeast, certain mRNAs are transported in a complex with myosin V, whereas in neurons or insect oocytes microtubule motors are

required. The RNA is integrated into a ribonucleoprotein complex by RNA-binding and adaptor proteins, though the precise molecular interactions within this complex have yet to be determined.

Motors are increasingly being implicated in a number of human diseases (Table 4). These implications are firmly established in some cases (e.g., myopathies or hearing loss) and more tenuous in others (e.g., neurodegenerative diseases), but they suggest that motors may turn out to be useful targets for therapeutic applications (6).

Regulatory Mechanisms

The question of motor regulation is largely uncharted territory, though four different mechanisms have been identified to date, changes in calcium levels, post-translational modification, intramolecular inhibition, and modulation by accessory proteins (7).

The interaction of myosin with actin in skeletal muscle cells is regulated by calcium ions in cooperation with the accessory proteins troponin and tropomyosin. In response to a calcium spike, the troponin-tropomyosin complex associated with actin filaments is shifted, exposing the binding sites for myosin on actin and thus activating contraction. In mollusks, calcium binds to the light chains, turning on the ATPase activity and contraction. The light chains of vertebrate skeletal muscle on the other hand, do not bind calcium but can be phosphorylated, thus increasing force production. Other motors, or the proteins they interact with, may also be the substrate for kinases and phosphatases, affecting either the activity of the motors or interactions with other cell components. Thus phosphorylation of the intermediate chain of axonemal dynein inhibits its activity, whereas cytoplasmic dynein may be activated by phosphorylation *via* an as yet unspecified pathway. Phosphorylation affects the cargo binding of several motors. For example, phosphorylation inhibits docking of the globular tail of myosin V to melanosomes and releases dynein from membranes. There are hints that kinesin-based organelle movement can also be regulated by phosphorylation, but it is unclear whether cargo binding is affected directly.

A different mechanism that couples motor regulation and cargo binding is used by kinesin, where the tail folds up like a pocketknife to inhibit the motor domain. Binding to cargo de-represses tail inhibition and allows the motor to unfold, a process critically dependent on a flexible domain in the stalk. How the tail inhibits the motor is not known, but a crucial role is played by a tail motif conserved in all conventional kinesins.

Some organelles can either switch the direction of movement on the same track or even change tracks and move on both microtubule and actin filaments. This behavior requires the presence of opposite-polarity motors and/or motors from different superfamilies. Thus

in amphibian melanophores heterotrimeric kinesin and myosin V cooperate in the dispersion of pigment granules, while during aggregation myosin V is switched off, presumably by phosphorylation-dependent release from the granules. Myosin V and conventional kinesin have been shown to interact directly in their tail domains, but it is unclear whether motor coordination requires physical interaction in other instances as well. Small regulatory G-proteins are involved in several aspects of motor function. G-proteins may mediate motor-cargo interactions, as in the case of myosin V outlined above. Other studies likewise hint at a link between G-proteins or their effectors and several types of myosin motors. Since kinesin and dynein can also pair up with Rab effectors, a GTPase-dependent link between membrane traffic and motors is emerging.

Molecular Symptom

Definition

Molecular symptom describes genes that are characteristic for a certain group of patients; they allow for molecular stratification of patient cohorts.

► [Computational Diagnostics](#)

Molten Globule

Definition

The molten globule was originally defined as a structural state that has a significant secondary structure, but with no fixed tertiary interactions. The

definition is used nowadays in a more relaxed way, to describe an ensemble of conformations that are highly dynamic, with a limited number of native-like contacts and only a partial native-like secondary structure.

Monoclonal Antibodies

BURKHARD MICHEEL

Institute of Biochemistry and Biology, Department of Biotechnology, University of Potsdam, Germany
bmicheel@rz.uni-potsdam.de

Definition

Antibodies are molecules that specifically bind to those substances (antigens) against which an immune defence has been raised. Antibodies are synthesized by fully differentiated B lymphocytes (plasma cells). Each B lymphocyte and its descendants after clonal expansion produce a single antibody (a monoclonal antibody) that is identical in its amino acid composition and in its binding specificity to all the cells of that clone.

Characteristics

Production of Monoclonal Antibodies

Structure and Function of Antibodies

Antibodies or immunoglobulins (Ig) are globular glycoproteins that are produced by the immune system of vertebrates as a defence against foreign, non-self molecules, so-called antigens (antibody generators; 1). The antigens as targets of antibodies may be proteins, carbohydrates, lipids, nucleic acids etc. or completely synthetic compounds.

Under natural conditions antigens are in most cases parts or products of infectious agents. Antibodies are produced by fully differentiated B-lymphocytes that are called plasma cells.

Antibodies circulate in the body, bind to those antigens against which they have been produced and mediate the

Monoclonal Antibodies. Figure 1 Structure of antibodies of the IgG class. IgG molecules are composed of two identical heavy (H) and two identical light (L) chains which are linked by several disulfide bridges. The L chains contain one variable (v) and one constant (c) domain; the H chains contain one v domain and three c domains. A flexible region – the hinge region – between the first (CH1) and the second (CH2) domain of the H chain allows the free movement of the antigen-binding “arms” of an antibody molecule to different angles. Enzymatic cleavage may result in two antigen-binding fragments (Fab) and one crystallizable fragment (Fc). The Fc fragment mediates effector functions. A fragment containing only the v domains is called Fv.

neutralization and removal of foreign and potentially dangerous substances.

There is a very large number of different antibodies in the body (about 10^{11} different antibody specificities in one human individual) so that practically every potentially infectious agent can be controlled.

One B lymphocyte synthesizes only one antibody type, i.e. antibody molecules of unique structure and unique binding specificity. Daughter cells derived from such a lymphocyte (i.e. the corresponding B lymphocyte clone) therefore produce antibodies of the same specificity. The corresponding antibodies are called monoclonal antibodies.

Antibodies are relatively stable heterodimeric molecules built up by two identical heavy (H) and two identical light (L) chains. These chains associate in symmetric molecules with a “Y”-shaped structure (Fig. 1). This is the typical structure of IgG – immunoglobulin gamma – molecules, the most abundant antibody class in mammals.

Antibodies of different binding specificities have different amino acid sequences in the variable amino acid regions (V regions) in the N terminal part of both the heavy and light chains. Three hypervariable regions in the V regions of the heavy and the light chains (also called

CDRs, complementarity determining regions) constitute the antigen-combining site. The region that is detected by the antigen-binding site on an antigen is called the antigenic determinant or epitope. The binding specificity of an antibody is therefore determined by its ability to bind to a special epitope by means of its unique antigen-combining site. Each antibody of the IgG class has two identical antigen-combining sites, e.g. it is bivalent. Those regions of the antibodies not involved in antigen binding have identical amino acid sequences in any one Ig class or subclass (the so-called constant regions, C regions) and mediate binding to effector molecules and effector cells. These effectors mediate the elimination of the foreign substances from the organism. Antibodies are therefore bifunctional adapters between foreign antigens and the body’s own effector molecules and/or cells.

Since the immune system does not differentiate *a priori* between “dangerous” and “non-dangerous” substances, antibodies will also be produced after the injection of “harmless” antigens provided the antigens are foreign to the immunized vertebrate.

Since antibodies also bind their corresponding antigens *in vitro* or after transfer into other organisms, a large spectrum of useful applications for antibodies can be envisaged. ABO blood group determination, pregnancy assays and [passive immunization](#) against toxins during acute infections and after snakebites are well-known examples of antibody use.

Hybridoma Technique for the Production of Monoclonal Antibodies

Wide practical use of antibodies became possible after the hybridoma technique allowed the production of theoretically any antibody in high purity and large quantities (2). In the hybridoma technique, B-lymphocytes from immunized donors are fused *in vitro* with immortal myeloma cells (malignant B lymphocytes; Fig. 2). The resultant hybridoma cells contain the information for antibody production and unlimited multiplication. Those hybridoma cells producing the desired antibodies (because of their clonal origin called monoclonal antibodies) have to be selected and can then be propagated in large quantities for large-scale antibody production and also frozen for storage in liquid nitrogen. An uncountable number of different monoclonal antibodies against a multitude of antigens (including human tumor antigens) have been produced since the invention of the hybridoma technique. Most of these antibodies have been produced in mice because the immunization procedure is relatively easy and optimum myeloma cells for fusion are available. The production of human hybridomas by using human B-lymphocytes has turned out to be relatively complicated.

A breakthrough in solving this problem was the “creation” of the [XenoMouse](#), a transgenic mouse line that contains the complete human antibody gene

Monoclonal Antibodies. Figure 2 Hybridoma technique to produce monoclonal antibodies. After immunization of a mouse, spleen cells containing antibody-producing B lymphocytes are isolated and fused *in vitro* with “immortal” myeloma cells (malignant plasma cells). Fused hybridoma cells are selected by special selection media that kill non-fused cells. Hybridoma cells contain the information from both parental cells – for antibody production and unlimited cell growth. By a tedious screening process those hybridoma cells that produce the desired monoclonal antibody are identified. The cells can be mass cultivated to produce large amounts of antibodies and/or stored frozen in liquid nitrogen.

locus instead of the corresponding mouse locus (3). These mice produce fully human antibodies, even after the injection of antigens of human origin.

Production of Recombinant Antibodies

Antibody molecules can be conjugated with other proteins (e.g. enzymes) or small molecules (e.g. fluorescent markers and radioisotopes), which enhances the potential of use of antibodies as tools (Fig. 3).

In addition, DNA recombination techniques allow the cloning of antibody genes and the manipulation of antibodies at the gene level, which is a further step in enhancing the potential of the application of antibodies (Fig. 4).

A mixture of randomly generated primers (so-called degenerated primers) have to be used to clone and amplify by polymerase chain reaction (PCR) the variable region gene fragments of the heavy (V_H) and light chains (V_L) of antibodies – the unique and most important parts of antibodies. (Since all antibodies are different, one primer pair would not be enough for

amplification as in the case of genes coding for “normal” proteins and even when using a set of degenerated primers they do not “fit” for all antibody genes.) The V_H and V_L genes can be cloned in special expression vectors to allow the production of antibody fragments (e.g. single chain antigen-binding fragments – scFv) in prokaryotic (bacteria) or eukaryotic cells (yeasts, insect cells, mammalian cells, plant cells). Single chain antibody fragments (which are encoded by one gene in contrast to intact natural antibodies which are encoded by two genes) can be used as small binding molecules or can be linked on the level of the genes to other genes of interest.

The most important aspect of the cloning of antibody genes is the possibility of obtaining a large multitude of V_H and V_L antibody genes from normal and immunized human donors. These genes can be cloned as V_H - V_L -linked scAb genes in special display vectors. Thus one can create large antibody libraries, which allow, comparable to a normal immune system, the isolation of specifically binding antibody fragments (4). The

Monoclonal Antibodies. Figure 3 Modification of monoclonal antibodies. Monoclonal antibodies (in most cases of murine origin) can be modified in many ways depending on their intended use. They may be conjugated with specific markers (enzymes, radioisotopes, toxins, chemotherapeutics etc.) but it is also possible to produce bispecific antibodies with two different antigen binding sites by biochemical or cell fusion techniques (another possibility for producing bispecific antibodies is shown in Fig. 5). Two strategies are used to “transform” a murine antibody into a human or partly human antibody. The first is to fuse the variable regions of a murine antibody on the gene level with the constant regions of a human antibody. The results of this fusion are so-called chimeric antibodies. The second strategy is to insert the gene segments coding for the 6 complementary determining regions (CDR) into a human antibody framework; such antibodies are called humanized antibodies. By this method those parts of a human antibody that are responsible for antigen binding are replaced at the gene level by a murine sequence. Fully human monoclonal antibodies may be produced by hybridoma technology (using human B lymphocytes or B lymphocytes from transgenic mice containing a full set of human antibody genes) or by using human antibody gene libraries (as shown in Fig. 5).

binding variability of such libraries can be enlarged by site-directed mutagenesis of the CDRs or by inserting synthetic oligonucleotides (semisynthetic or synthetic antibody libraries).

Different display systems (using phages, bacteria, yeast, ribosomes) were developed to select a specific antibody from such a library. The most common one is the ►phage display where the antibody genes are cloned into vectors based on filamentous fd phages. *Escherichia coli* infected and transformed by such phage vectors (phagemids) produce phages, which contain antibody genes and display the corresponding antibody fragments on the phage’s surface (Fig. 5). Those phages binding to a specific antigen can be selected and enriched by multiplying in *E. coli*. The corresponding antibodies can then be expressed and produced as scFvs. One can also produce other recombinant antibodies (Fig. 3). ►Chimeric antibodies can be produced after recombining the V_H and V_L antibody genes of murine origin with the corresponding

constant human light and heavy chain genes and ►humanized antibodies can be created by transferring the gene segments coding for the 6 complementary determining regions (CDR) into a human antibody framework (5).

Two further possibilities regarding antibody production and manipulation are worth mentioning. ►Bispecific antibodies, which, in contrast to natural antibodies, have two different binding sites, can be produced by biochemical manipulation of the molecules, by fusion of two hybridoma cells or by connecting two different scFv genes (Figs. 3, 4). Recombinant techniques also allow the production of antibodies with even more binding specificities.

The other possibility is the selection of antibodies with catalytic properties (e.g. esterolytic antibodies). Such ►catalytic antibodies (also called abzymes-antibody enzymes) may be especially valuable for catalyzing reactions for which no natural enzymes are available.

Monoclonal Antibodies. Figure 4 Antibody gene cloning and production of recombinant antibodies. Antibody genes coding for the variable heavy and light chain regions (v_H and v_L) may be amplified by the polymerase chain reaction (PCR) and cloned into expression vectors to produce antigen-binding single-chain Fv fragments in *E. coli* or in eukaryotic cells. The antibody genes may be fused with other genes (shown in green; coding for a toxin, an enzyme, green fluorescent protein, other antibody constant regions etc) allowing the production of fusion proteins, which may be applied for an assay or for diagnostic or therapeutic purposes. Antibody genes of different origin may also be combined to result in antibodies that bind two antigens (bispecific antibodies resulting from one gene construct or bispecific diabodies resulting from two constructs). Other constructs may allow the expression of antibodies with more than two binding specificities (not shown in the scheme).

Clinical Relevance

Monoclonal Antibodies in Diagnostics

For diagnostic purposes only the binding specificities of antibodies are important. Monoclonal antibodies of murine origin are therefore sufficient.

In general, antibodies are applied for diagnostic purposes in immunohistology (or immunocytology), immunoassays and immunolocalization.

In immunohistology or immunocytology, specific antibodies are used to demonstrate specific foreign or self antigens in cells or on cell surfaces. The antigens may be normal cellular constituents or structures appearing because of pathological changes (tumor antigens, antigens of infectious organisms etc.). To visualize the antigens, the corresponding antibodies are labeled with enzymes (which convert a substrate into a visible product at the site of the antibody reaction) or fluorescent markers. The reactions can be visualized in a normal or fluorescence microscope. Especially valuable for hematological investigations is **cyto-fluorometry** where blood cells can be tested for their antigen profile under normal and pathological conditions. In some assays antibodies conjugated with

electron dense markers (colloidal gold, ferritin) can be used in electron microscopy, especially for the identification of virus infections.

In immunoassays, antibodies are used to detect soluble antigens (e.g. tumor markers, antigens of infectious organisms etc.) in body fluids or tissue extracts. The most commonly used test is the sandwich **ELISA** (enzyme-linked immunosorbent assay) where one antibody is linked to a solid phase (e.g. a plastic surface) as catcher and after incubating with the solution to be tested, the antigen bound to the first antibody is detected by a second indicator antibody. This second antibody is labeled with an enzyme that converts a nonvisible substrate into a colored (in some cases a fluorescent) product that can be measured. The intensity of the enzyme reaction is therefore a measure of the quantity of antigen in the solution investigated. There are several other test principles in use and in addition to enzymes other markers are used, including radioisotopes which were most popular in the past. In future **biosensors** and **microarrays** using antibodies will dominate many of the diagnostic tests at present still performed by conventional principles.

Monoclonal Antibodies. Figure 5 Antibody selection by phage display. Antibody genes coding for the variable heavy and light chain regions (v_H and v_L) are cloned in phage vectors (phagemids) which in *E. coli* allow the production of recombinant filamentous phages which display antibody fragments on their surfaces. Since a multitude of different v_H and v_L genes of natural and synthetic or mixed origin can be cloned into the phagemids, very large antibody libraries can be constructed. Phages displaying a specific antibody fragment can be isolated (e.g. by “panning” on the corresponding antigen adsorbed on plastic surfaces) and then multiplied by infecting *E. coli*. The genes coding for the specific antibody fragment now available from the corresponding phages may be used to produce single chain antibodies (scFv) in bacteria. They may also be cloned into vector cassettes containing the genetic information for the production of complete antibody molecules. These vectors can be used to transfect eukaryotic cells that may then synthesize intact whole antibody molecules.

Immunolocalization of diseased tissues *in vivo*, e.g. tumors, is based on the idea that, after injection of radiolabelled antibodies into tumor patients, the antibodies will be transported, as under normal conditions, to the tumor tissue and will then bind the tumor cells so that this site can be visualized scintigraphically. But under *in vivo* conditions, binding specificity is not the only prerequisite for the antibodies in use. Pharmacokinetics and especially the origin of the antibodies are important properties that have to be taken into consideration. These problems are especially obvious when using antibodies for therapy.

Monoclonal Antibodies in Therapy

The natural function of antibodies *in vivo* is to prevent dangerous substances from entering cells (neutralization of toxins and viruses), to mediate the removal of foreign substances (by binding to the foreign antigens and to the body's own phagocytic cells) and to destroy or to inhibit the growth of foreign, infected or abnormal cells (by inhibiting growth receptors, activating apoptotic signals and binding to foreign antigens and to the body's own effector molecules and/or cells). Antibodies are therefore regarded as “magic bullets” and were already used for passive immunization against acute infections (e.g. diphtheria) at the begin-

ning of the 20th century (6). The main obstacle in such a treatment is the very fast clearance of antibodies of non-human origin in the human body (production of HAMAs – human anti-mouse antibodies – after injection of murine monoclonal antibodies). Chimeric, humanized or fully human antibodies are therefore preferably used for immunotherapy (Fig. 3, Table 1). Immunotherapy by passively administering monoclonal antibodies is used for treating intoxications, infectious diseases, immunologically caused diseases and cancer (7). In the first examples, antibodies are injected which neutralize a toxin or a virus or destroy invading agents. To treat pathological immune reactions (transplant rejection, autoimmunity, allergies) antibodies are injected which bind to structures (molecules on immune cells, soluble mediators of immune reactions etc.) involved in overshooting immune reactions and thus diminish the effect. Antibody therapy of cancer uses in most cases the cytotoxic effects of anti-tumor antibodies and in a few cases the blocking of growth factors (Fig. 6). The antibodies are used as “naked”, conjugated or bispecific antibodies in a more or less “humanized” form. There are more than 10 monoclonal antibodies approved for clinical use in various countries at present, and about 200 antibodies in clinical trials.

Monoclonal Antibodies. Table 1 Therapeutically applied monoclonal antibodies¹⁾

Antibody ²⁾	Name	Used since ³⁾	Indication	Producer ⁴⁾
Humanized anti-F-protein	Synagis	1998	Viral disease ⁵⁾	MedImmune
Murine anti-CD3	OKT-3	1986	Organ transplants	Ortho Biotech
Chimeric anti-TNF- α	Remicade	1998	Chron's disease	Centocor
Humanized anti-IgE Fc	Xolair	2002	Allergy	Tanox
Murine anti-EpCAM	Panorex	1995	Colon cancer	Centocor
Humanized anti-ERBB2	Herceptin	1998	Mammary cancer	Genentech
Humanized anti-CD52	Campath	2001	B-cell leukemia	Mill. Pharmaceut.

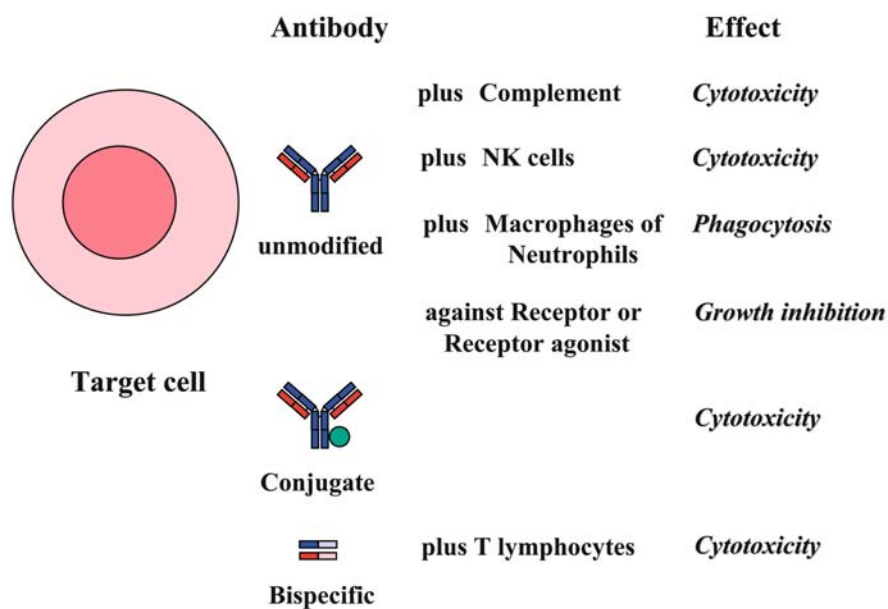

¹⁾ Modified after Brekke and Sandlie (2003)

²⁾ Indication of antibody type and target antigen

³⁾ Indication of approval date; in some cases only for some countries

⁴⁾ Company producing the antibody; full name not given in all cases, in some cases only the first producer is indicated

⁵⁾ Only against infection by respiratory syncytial virus

Monoclonal Antibodies. Figure 6 Efficiency of passively administered antibodies to inhibit the growth of target cells *in vivo*. Intact unmodified antibodies may lyse target cells with the help of complement or natural killer (NK) cells. The Fc part of the antibodies mediates the binding of the effector molecules or effector cells. Phagocytic cells may also take part in such reactions either by phagocytosing smaller cells or the remains of destroyed cells. Growth inhibition of tumor cells may be initiated by antibodies that specifically block the binding of a growth factor to its receptor at the tumor cell's surface (either by reacting with the growth factor or with the receptor). Killing of tumor target cells may also be possible by specific antibodies conjugated (directly or *via* genetic engineering) to a toxic molecule (a small toxic molecule or a toxic protein, a radioisotope, an enzyme which converts a harmless substance into a toxic one – the so-called ADEPT – antibody-dependent prodrug therapy etc.). Destruction of tumor target cells is also possible with the help of bispecific antibodies (this figure shows recombinant bispecific antibodies) that react *via* one “arm” with the tumor cells and *via* the other “arm” with T cells. The tumor cells are lysed by the activation of the cytotoxic potential of the body's own T cells after antibody binding. Other cytotoxic effector cells (e.g. NK cells) can also be activated by bispecific antibodies. In a few cases, bispecific antibodies have also been used in an ADEPT format with one antibody “arm” derived from a catalytic antibody that converts a harmless substance into a toxic one. All these possibilities have proven useful for many experimental models *in vitro*. Which of these mechanisms is most effective *in vivo* has yet to be clarified for most human diseases.

Concluding Remarks

Antibodies have proven to be valuable tools in many fields of biomedicine. The use of antibodies in therapy is promising but we are still far from having resolved all problems. For many diseases (e.g. infections, many forms of cancer) the antigens most suitable for attack still have to be identified and the corresponding antibodies still have to be isolated. It is obvious that in many cases one antibody is not enough for treatment (under natural conditions a polyclonal antibody response is initiated in all cases). It is not yet clear either for which purposes antibody fragments may be more convenient than intact antibodies and which of the many different antibody conjugates or fusion proteins may lead to better therapy.

For practical uses antibodies have to be produced in large quantities. Large fermenters used for the cultivation of bacteria and yeast can be applied for hybridoma cultivation in only a few cases. Because of their higher sensitivity to mechanical stress, cultivation in hollow fiber systems is a more gentle method for hybridoma mass cultivation. Since the production costs are very high, we have to look for cheaper alternatives, but it is not yet clear which of the methods developed so far (other expression systems as e.g. bacteria, yeast, insect cells, transgenic plants, larger transgenic animals) will be used in future. Efforts will also have to be intensified to develop quicker and easier selection methods for human monoclonal antibodies.

In addition to the applications mentioned, antibodies will also be used for other purposes, e.g. as mediators for specific [▶active immunization](#) or as intracellular binding molecules ([▶intrabodies](#) which may influence the metabolism of specific cells). It should also be mentioned that alternatives for antibodies might be possible in special cases. Other binding protein molecules have been selected and antibody mimetics with similar binding properties (peptides, [▶aptamers](#), [▶molecular imprints](#)) have been produced. The future will bring a mosaic of different and highly specific binders among which antibodies will surely play a very important but not the only role.

Monoclonality/Monoclonal

Definition

Monoclonality/monoclonal refers to a cell population derived from a single progenitor. The term is also used to describe antibodies that are produced by the identical offspring of a single, cloned antibody producing cell.

- ▶Autosomal Dominant (Inherited Disorder)
- ▶Hyper- and Hypoparathyroidism
- ▶Monoclonal Antibodies
- ▶Polycystic Kidney Disease, Autosomal Dominant

Monogenic Disorder/Monogenic

Definition

Monogenic disorder/monogenic describes a disorder that is caused by mutations in just one gene (such as hemophilia), as opposed to polygenic disorders (such as hypertension) that involve the interaction of several genes. Monogenic disorders are also known as “single-gene disorders” or as “Mendelian disorders”, because their inheritance patterns tend to follow the genetic laws first described by Gregor Mendel.

Monogenic Inheritance

Definition

Monogenic inheritance refers to the inheritance that is controlled by the alleles for one particular locus, as opposed to di- tri- or polygenic control exerted by two three or many non-allelic genes.

Monosomy 1p36 Syndrome

Definition

Monosomy 1p36 (Slavotinek syndrome) is a comparatively frequent (1:10,000 newborns), sometimes recognizable, subtelomeric deletion syndrome caused by monosomy 1p36. It is characterized by short stature, microcephaly, large fontanelle, and mild facial dysmorphism. The extent of mental retardation, mild to severe, depends on the actual deleted chromosomal portion.

► [Microdeletion Syndromes](#)

Mono-Ubiquitination

Definition

Ubiquitin is a polypeptide consisting of 76 amino acids which serves to tag proteins for degradation or intracellular trafficking. Ubiquitin is attached to ϵ -amino groups of lysine residues in the target protein by iso-peptide bond formation with its carboxyl-terminal glycine residue. Mono-ubiquitination can be extended by connecting the ϵ -amino group of lysine 48 of one ubiquitin molecule to the terminal glycine of another. Whereas mono-ubiquitin residues tag membrane proteins during endocytic and late endosomal sorting processes, poly-ubiquitinated proteins are degraded by the proteasome.

Morbus Wegener

JULIE M. WILLIAMS, CAROLINE O.S. SAVAGE
Renal Immunobiology, The Medical School,
University of Birmingham, Birmingham, UK
j.m.williams.med@bham.ac.uk

Synonyms

Small vessel vasculitis; Wegener's Granulomatosis

Definition

Morbus Wegener (hereafter called Wegener's Granulomatosis, WG) is an autoimmune disorder of incompletely understood pathophysiology. It is a member of a family of diseases, characterised by chronic inflammation of the blood vessels, which are classified by the term ► [vasculitis](#). Histopathological features include perturbations to the vessel wall, an infiltration of leukocytes into the perivascular space and fibrin deposition into the subendothelial area. WG comprises a triad of granulomatous inflammation of the respiratory tract, a systemic necrotising vasculitis and a

segmental necrotising ► **glomerulonephritis** (although forms can be limited to one organ). Aetiology of the disease is probably multifactorial including genetic and environmental causes.

Characteristics

The incidence of WG is estimated at 20/million adults with no sex or race distribution but increased frequency in people in their 50s and 60s. The pathogenesis has yet to be elucidated but the majority of patients present with autoantibodies against their ► **neutrophils** (anti-neutrophil cytoplasm antibodies, ANCA). In >70% these antibodies are raised against an intracellular protein termed ► **proteinase 3** (PR3) and in <25% they are against another protein, ► **myeloperoxidase** (MPO) (1). The presence of these ANCA correlates with disease activity and is a good indicator of the onset of relapse. Interestingly high ANCA titres have been observed in patients without active disease and additionally active disease can exist without the presence of ANCA. This would therefore imply that other ANCA-independent mechanisms are also operating.

The chief autoantigen PR3 is a serine protease found mainly in the azurophil granules of neutrophils (but also in monocytes). It is predominantly involved in the host response to bacteria and exhibits lytic activity. There are a number of naturally occurring inhibitors *in vivo*, including alpha1-antitrypsin (α 1AT). PR3 can be constitutively expressed on the surface of neutrophils but predominantly is translocated there after an inflammatory stimulus. This leads to binding of ANCA via its F(ab')₂ (fraction antigen binding) fragment. However this is inadequate to lead to neutrophil activation, there must also be engagement of the Fc (fraction crystallisable) region of the antibody with Fc γ receptors present on the neutrophil surface. This results in downstream intracellular signalling, ► **reactive oxygen species** production, degranulation and production of proinflammatory ► **cytokines**.

Once activated, neutrophils also show increased adherence to the ► **endothelium** and transendothelial migration. *In vitro* the neutrophils exhibit cytolytic activity towards endothelial cells leading to cell damage. Additionally, the neutrophils undergo an accelerated rate of ► **apoptosis** but without a concomitant clearance by macrophages, resulting in secondary necrosis and release of intracellular contents.

Animal models of vasculitis have provided only limited information and there are no useful models of WG induced by PR3 directed ANCA.

Cellular and Molecular Regulation

It is now widely recognised that genetic factors can play a major role in autoimmune diseases and a number of familial cases have been recognised for WG. No

particular genes have been identified to date but there are reported associations with ► **polymorphisms** in the genes for PR3, α 1-AT and other genes involved in the immune response.

Polymorphisms

The genes for the constitutively expressed Fc receptors found on neutrophils (Fc γ RIIa and Fc γ RIIb) and monocytes (Fc γ RIIIa) have been extensively examined (2). For Fc γ RIIa both a high affinity (H/H131) and a low affinity (R/R131) form are known, as well as a heterozygous intermediate. Fc γ RIIIa also has an interchange at 158 being either V/V V/F or F/F. Fc γ RIIb is known to be either NA1 or NA2 (neutrophil antigen 1 or 2). No significant associations of any of the polymorphisms with WG have been detected. However, combinations of these mutations may be important. One group showed that if the Fc γ RIIa H/H phenotype was combined with the Fc γ RIIIa V/V then this was an increased risk for WG. They postulated that these lead to a stronger interaction of ANCA with the receptors and therefore more activation. Another study looked at risk of relapse and detected a correlation between this and combined Fc γ RIIa R/R and Fc γ RIIIa F/F. The reasoning this time was that these patients were weak IgG binders and therefore less able to mount an inflammatory response, leaving them susceptible to infection by known risk factors such as *Staphylococcus aureus*.

Associations have also been shown with the complement system but with no clear functional significance. A relationship of WG with both the C3F and the C4a3 allele have been observed.

Other polymorphisms have been examined pertaining to the immune system such as CD18, tumour necrosis factor- α (TNF α), interleukin-2 and interleukin-5Ra but with no connection to WG.

Polymorphisms have been observed in the PR3 gene itself, with an amino acid change at position 119, an 84 base pair deletion/insertion, seven individual nucleotide polymorphisms and a microsatellite. The polymorphism in the promoter region has been found to be prevalent in WG but no downstream functional effects are noted. Neutrophils have been shown to have PR3 in the secretory vesicles as well as the azurophil granules and this can be easily translocated to the plasma membrane. The percentage of these neutrophils with membrane expression of PR3 on resting cells was constitutively determined for each individual and appears to have a genetic background based on familial studies. Neutrophils can exhibit three different patterns of membrane PR3 expression, low, high or bimodal whereby only a subset of cells are positive. The proportions of positive cells remain stable over time. High expression on resting neutrophils was found to be increased in vasculitis but the functional significance

was not clear, as it was not restricted to patients with WG. There was however an increased incidence of relapse in this cohort (3).

The inhibitor of PR3 α 1-AT is also polymorphic at its PI locus with its phenotypes classified as normal (MM), slightly deficient (MZ) or severely deficient (ZZ). In WG patients, an increased incidence of the Z in either form was determined although there was no increased risk factor associated. A linkage disequilibrium has also been exhibited on chromosome 14q32.1 that contains the serpin gene cluster.

Antibody

Increases in ANCA titre are a good indication of active disease or onset of relapse. Data on subclass distribution for the antibodies are controversial with some data showing an increase in IgG3 whilst others IgG1 and 4. There is, however, an overall predominance of aglycosylated IgG. This is purported to lead to activation of the mannose binding lectin pathway and complement activation. Anti-PR3 antibodies are polyclonal but have been shown to recognise a restricted number of epitopes that are closely related. Using computer simulations these are reported to be intimately linked with PR3's catalytic site. Epitope switching has also been observed between active and remission phases of WG.

Cellular Immunity

Disease activity has been shown to correlate with monocyte activation. Activated monocytes and macrophages participate in ►granuloma formation by synthesising and secreting a variety of chemokines, cytokines and growth factors. PR3-ANCA applied to monocytes can induce the release of TNF α , interleukin-1 β , interleukin-6, interleukin-8, monocyte chemoattractant protein-1 and thromboxane A $_2$. Additionally they may exacerbate vascular damage by the release of reactive oxygen species and lytic enzymes.

There is now increasing evidence for a role of T cells in systemic vasculitis and ANCA IgG subclass switching indicates T cell help. Active CD4 $^{+}$ cells are seen in patient sera that show enhanced proliferative responses and secrete cytokines. Additionally high soluble interleukin-2 receptor levels are seen in active disease. Autoreactive T cells have been observed in some patients but there is no evidence to date that they initiate damage. CD4 $^{+}$ /CD28 $^{-}$ T cells are found in granulomas and produce a Th1-type cytokine pattern of interferon γ and TNF α .

HLA is involved in immune recognition by T cells, with class I presenting to CD8 $^{+}$ cells and class II to CD4 $^{+}$ cells. Associations, however, are hard to demonstrate in WG. There are reports of positive associations with DQw7 and weakly with DR1 and

negative associations with DR3, DR13 and DR6 but none have been observed to be linked with progression and no significant and consistent pattern has emerged. Polymorphisms in the CTLA-4 gene have been strongly associated with WG and may lead to an increased activation of T cells. CTLA-4 (AT)n microsatellites were strongly associated in affected patients, with the shortest allele showing a decreased prevalence over healthy controls.

WG has also been positively associated with nasal carriage of *Staphylococcus aureus* but there is no link to involvement of superantigens.

Gene Activation

Real time PCR and DNA micro array on leukocytes from patients and leukocytes treated with whole and F(ab') $_2$ ANCA IgG, showed activation of a subset of genes (4). Some of these genes were common to the whole IgG, some only to F(ab') $_2$ and some responded to either. These included DIF-2 (differentiation dependent gene-2 or radiation inducible immediate early gene, IEX-1, gly96 in mice, pituitary adenylate cyclase activating polypeptide responsive gene PRG1 in rat) and IL-8 (interleukin-8) along with a number of molecules associated with inflammation and cell signalling. DIF-2 was upregulated in patients and strongly correlated with disease activity and ANCA titre but was not present in remission or controls. IL-8 was increased only in remission.

Clinical References

WG can be fatal if left untreated. ►Immunosuppressants play a large role in preserving organ function but toxicities can contribute to mortality. Treatments are tailored so as to induce a rapid remission from acute episodes by administering high doses short-term. This is then tapered or altered to less toxic alternatives for maintenance. Survival rates are now estimated to be above 75%. Adverse prognostic factors are known to be age, renal impairment and pulmonary involvement (5).

Morpholino Oligonucleotides, Functional Genomics by Gene 'Knock-down'

SALIM ABDELILAH-SEYFRIED

Max Delbrück Center (MDC) for Molecular Medicine, Berlin, Germany
salim@mdc-berlin.de

Definition

Morpholino oligonucleotides are chemically modified ►[antisense oligonucleotides](#) with a high affinity for binding to selected ►[messenger RNAs](#), thereby preventing ►[translation](#) or correct mRNA splicing (1). They are primarily used in a variety of species for the '►[knock-down](#)' of gene function (2, 3). Morpholino oligonucleotides consist of the four genetic bases (adenine, cytosine, guanine, and thymine) linked to a morpholine ring, from which the term morpholino oligonucleotide is derived. Typically between 18 and 25 bases are coupled by non-ionic phosphorodiamidate intersubunit linkages. This particular backbone moiety ensures resistance to ►[nucleases](#) and often has negligible toxicity that, unlike ►[nucleic acids](#), allows applications of high concentrations without reverse effects.

Characteristics

As a result of the tremendous pace of diverse genome sequencing projects, large sets of gene sequences that currently lack ascribed biological functions have been identified. Morpholino oligonucleotides present a tool for ►[reverse genetics](#) in model organisms that either lack ►[gene targeting by homologous recombination](#) ('►[knock-out](#)' technology) or in which gene inactivation through RNA interference or ►[siRNAs](#) are not reliably established. Moreover, morpholino oligonucleotides are a tool for *in vitro* and tissue culture systems. The term 'morphant' has been proposed to describe those animals in which a specific gene function has been inactivated by morpholino targeting

(4). The combination of genome sequencing projects and systematic 'knock-down' studies based on morpholino oligonucleotides in suitable model organisms allows for the cataloging of 'morphant' phenotypes of entire [▶transcriptomes](#). However, these studies are largely dependent upon injecting the morpholino oligonucleotides into early and accessible developmental stages of animals, thus limiting the use of morpholino oligonucleotides to genes that act early during development. Alternatively, square pulse [▶electroporation](#) and other modified delivery methods allow for the direct application of morpholino oligonucleotides for tissue-directed 'knock-downs' in chicken, mouse and rat (3, 5, 6). Titering the morpholino oligonucleotide concentrations applied for gene 'knock-down' experiments can provide a series of 'morphant' phenotypes ranging from mild to severe, the equivalent of an [▶allelic series](#).

Morpholino Oligonucleotide Design

The standard design is to generate antisense morpholino oligonucleotides that target between 18 to 25 bases of the mRNA [▶5' untranslated region \(5'UTR\)](#) prior to or overlapping with the [▶AUG translational start site](#) (AUG start). Efficiency of the [▶translational inhibition](#) is highly dependent upon the target position, enabling an almost complete translational inhibition provided that the target sequence is selected within about 85 base pairs 5' and 25 base pairs 3' of the AUG start. Target sequences that are selected more 3' to the AUG start show significantly decreased translational inhibition. To test the efficiency of inhibition, protein levels or activity levels of the target protein must be measured. Another application of antisense morpholino oligonucleotides is their use in blocking [▶pre-mRNA splicing](#) by targeting potential [▶exon/intron junctions](#), thereby forcing the splicing machinery to skip entire [▶exons](#) or to generate incorrect splice variants with unpredictable sequence alterations. Work by Schmajuk and colleagues (7) and by Draper and colleagues (8) has demonstrated the effectiveness of this method for gene inactivation in mammalian tissue-culture cell lines and in zebrafish, respectively. Advantages of this application are that splice alterations can easily be monitored by [▶polymerase chain reaction](#) techniques and that they can be assessed without the need for an antibody. Some applications may benefit from using splice variations for gene 'knock-down'. This approach can be applied if target gene sequences are incomplete, for instance when the 5'UTRs of gene sequences are unknown, precluding the standard morpholino oligonucleotide design for translational inhibition.

The cellular uptake of nonionic morpholino oligonucleotides is not feasible using the conventional lipid-based delivery systems. In contrast, pairing the morpholino oligonucleotide to a complementary

DNA and binding this compound electrostatically to partially ionized and weakly basic ethoxylated poly-ethylenimine (EPEI) provides a delivery system that is readily endocytosed and, upon reduction of pH levels within acidic [▶endosomes](#), results in the release of the morpholino oligonucleotides into the [▶cytosol](#) (9). This delivery system has been designed for efficient morpholino oligonucleotide uptake into tissue culture cells and may also result in more efficient cellular uptake during electroporation in chicken (3).

Morpholino Oligonucleotides Based Genetics

Gene inactivation through morpholino oligonucleotides targeting differs significantly in its mode of action from gene alteration through mutation. Importantly, the 'knock-down' by translational block causes the efficient inactivation of both maternal and zygotic transcripts, which, in zebrafish, can be fully penetrant through the first two days of development. Therefore, 'morphant' phenotypes have the potential to be both more severe and to have an earlier onset than zygotic mutant phenotypes. Moreover, fine-tuning the concentration of morpholino oligonucleotide applications may modulate the strength of 'morphant' phenotypes, providing the equivalent of an allelic series.

Morpholino oligonucleotides are highly amenable to genetic [▶redundancy](#) tests. 'Double-knock-downs' involving two morpholino oligonucleotides are feasible and can be used to determine genetic hierarchies or redundancy between genes based on the 'double-morphant' phenotypes. Morpholino oligonucleotide gene inactivation in true genetic mutants also provides a tool to determine potential genetic interactions. Moreover, morpholino oligonucleotide 'knock-downs' will become an increasingly important tool for testing candidate genes in [▶positional cloning](#) projects (4). In contrast to the standard method of translational inhibition, targeting pre-mRNA splicing specifically targets [▶zygotic transcripts](#) without affecting [▶maternal transcripts](#). Therefore, 'morphant' phenotypes generated by the latter method have the potential to be more closely related to zygotic mutant phenotypes. The inhibition of pre-mRNA splicing can also be deployed to specifically block splice variants and to study the function of different protein [▶isoforms](#) of a gene (8).

In developmental model systems, such as zebrafish, amphibians and sea urchin, the direct injection of morpholino oligonucleotides into the early [▶blastomeres](#) results in a general 'knock-down' of gene function throughout all tissues. In contrast, in chicken, square pulse electroporation has been successfully used to target morpholino oligonucleotides to only a subset of cells. Plans of both biotechnology companies and publicly founded consortia to employ large-scale

to genome-wide morpholino oligonucleotide ‘knock-down’ screens with the aim of inactivating the majority of genes within the respective model organisms will complement classic ‘►forwards genetics’ approaches such as those previously performed in zebrafish.

Limitations of Morpholino Oligonucleotide-based Gene ‘Knock-down’

Morpholino oligonucleotide mediated gene targeting has been reported for many genes with known mutant phenotypes. A special edition of the journal *Genesis* presented ‘morphant’ phenotypes of more than 20 known zebrafish mutants. The ‘morphants’ displayed phenotypic ranges but mostly had strong similarities to the true genetic mutant phenotypes. Nevertheless, a number of limitations have been reported in the usage of morpholino oligonucleotides. In some cases, gene inactivation is not achieved, possibly due to ►sequence polymorphisms in the targeting sequence. Strong polymorphic variations in the 5′ UTR sequences can occur in some genetic strains and may cause a reduced or highly variable efficiency of gene inactivation varying from animal to animal. The zebrafish *one-eyed-pinhead* locus appears to be an example of such a locus with, depending on the genetic background, 50%–100% of treated animals failing to respond to the morpholino oligonucleotide (2). Moreover, mistargeting of morpholino oligonucleotides toward unrelated gene sequences may be the cause for what appear to be unrelated ‘morphant’ phenotypes. One such example is the morpholino oligonucleotide against the zebrafish gene *bozozok/dharma* that reportedly resulted in additional phenotypes not observed in the mutant. These phenotypes may be due to the inactivation of another gene or other unknown morpholino oligonucleotide effects (2).

The targeting of pre-mRNA splicing has several limitations as well. Most importantly, aberrant splice variants generated by this method must be characterized in order to determine the type of mutation(s) introduced. Moreover, analysis can be clouded as targeting pre-mRNA splicing frequently results in several splice variants that may occur at different relative levels.

Due to these limitations, essential controls are routinely introduced when working with morpholino oligonucleotides. They include the design of a second morpholino oligonucleotide with an unrelated target sequence to ensure the specificity of the ‘morphant’ phenotype and to avoid the accidental loss of two distinct genes. In addition, rescue experiments, such as the injection of mRNA lacking the morpholino oligonucleotide target sequence, are essential and may reveal unrelated gene inactivation or non-specific defects.

Clinical Relevance

Morpholino oligonucleotides present the potential for ►functional genomics in tractable model organisms such as zebrafish, amphibians or chicken and in *in vivo* and tissue culture systems. The systematic analysis of medically relevant candidate genes or of genes with unassigned biological functions will result in a catalog of their early developmental functions as well as provide insight into general biological mechanisms. *In vivo* studies have indicated the feasibility of morpholino oligonucleotides for therapeutic applications. Examples are the application of morpholino oligonucleotides in mice by intranasal insufflation (5) or, in rat, by dermal absorption (6).

Mosaic/Mosaicism

Definition

Mosaic/mosaicism describes the occurrence of cells in an organism or a tissue that are derived from a single zygote, but with distinct genetic constitutions due to a post-zygotic event. For example, a patient may be

mosaic for trisomy 21, with the trisomy present in 40% of cells, and the other 60% of cells having a normal set of chromosomes.

Motor Proteins

Definition

Motor proteins are eukaryotic proteins that convert chemical energy derived from the hydrolysis of nucleotides (ATP) to mechanical energy for movement of cytoskeletal tracks. The respective motor domains are linked to their cargoes via adaptor proteins. Accordingly, motor molecules are classified into two groups: one group includes the myosins that move along the actin filaments, the other group includes the

kinesins and dyneins that move along the microtubules. The kinesin motors only move to the plus and dynein only to the minus end of microtubules. Motor proteins of the centromere attach to spindle microtubules and provide energy and force to move chromosomes during mitosis. When motors are immobilized at their cargo binding area, they can move microtubules or F-actin, respectively.

Institute, Cambridge, UK
abradley@sanger.ac.uk

Definition

'Mouse Genomics' is the study of the genetics of the laboratory mouse. An understanding of mouse genetics is essential to our understanding of human biology and disease, as the anatomical, physiological and genome similarities between mice and humans make the mouse an excellent experimental model for determining the function of human [genes](#). In addition, mice are small, easy to maintain and have a relatively short generation time compared to humans. The popularity of the mouse as a model organism also reflects the ease with which the mouse genome can be altered to generate models of human diseases.

Characteristics

Introduction to the Mouse Genome

▶ [Sequencing](#) of the Mouse Genome Since it began in 1990, the aim of the Human Genome Project was to sequence the genome of five key model organisms, one of which was the mouse. In 2000 the international Mouse Genome Sequencing Consortium began in earnest to sequence the genome of the [C57BL/6J](#) strain. Two years later, a high-quality draft sequence and annotation of the mouse genome was published in *Nature*. The mouse genome is estimated to be

2.6 billion base pairs, of which 97% can be aligned to the human genome sequence. This draft assembly of the mouse genome is freely available to the public and can be searched using sequence alignment tools such as ►http://www.ensembl.org/Mus_musculus/ssahaview or ►<http://www.ncbi.nlm.nih.gov/genome/seq/MmBlast.html>.

Manipulating the Mouse Genome

Genetic manipulation of the mouse genome can be performed using a random (phenotype-driven) approach or a sequence (►[genotype-driven](#)) approach (reviewed in (1)). In phenotype-driven approaches, the mice are exposed to a mutagen that generates mutations at random. The mutant mice are then screened with a battery of tests to identify any phenotypes. The responsible gene can then be localized by genetic mapping followed by detailed sequence analysis of genes in the region. Methodologies for generating random mutations in the mouse include exposure to radiation, chemicals or viruses (detailed below). In genotype-driven approaches, a gene hypothesised to be responsible for a particular function or trait is specifically mutated or altered and the resulting phenotype of the mouse can be characterised. Genotype-driven methodologies can be broadly divided into two categories, namely ►[transgenic](#) and ►[gene-targeting](#) strategies (detailed below). More recently, ►[chromosome-engineering](#) technology has allowed the generation of mice carrying specific chromosomal rearrangements (detailed below) and represents an additional method for manipulating the mouse genome.

Generating Random Mutations in the Mouse

Mutations occur spontaneously, however, they are very rare (occurring at a frequency of 5×10^{-6} mutations per gene per generation). Thus, mutagenesis strategies have been used to increase the mutation rate. Random mutations generated by these methods differ in their molecular nature and occur at varying frequencies.

Irradiation

X-rays induce mutations ranging from simple deletions to complex chromosomal rearrangements (such as translocations, inversions and duplications). Whilst chromosomal rearrangements have the advantage that they are relatively easy to identify/locate (using ►[FISH](#)), they often affect several genes on the chromosome, so it can be difficult to determine which gene is responsible for the phenotype of the mouse.

Chemical Mutagenesis

Two commonly used potent chemical mutagens are chlorambucil and N-ethyl-N-nitrosourea (►[ENU](#)). Whilst chlorambucil induces chromosomal rearrangements (frequently involving more than one gene), ENU

induces ►[point mutations](#), particularly in sperm precursor cells. Point mutations of DNA can result in ►[loss-of-function mutations](#), ►[gain-of-function mutations](#) or ►[hypomorphic alleles](#) (partial loss of function mutations). Thus ENU mutagenesis is a powerful genetic reagent for systematically analyzing the mouse genome (reviewed in (2)). ENU-mutagenesis experiments can be used in genome-wide screens for dominant or recessive mutations. In these experiments, male mice exposed to ENU are mated with numerous wild type females to produce large numbers of offspring, each of which carries a unique set of altered/mutated genes. These offspring will exhibit phenotypes caused by dominant mutations. Alternatively, these mice can be inter-crossed to generate mice with phenotypes caused by recessive mutations. Dominant screens are easier to conduct than recessive screens, however genetic reagents generated by chromosomal engineering have greatly facilitated recessive genetic screens (detailed below). ENU mutagenesis is efficient in generating mutations but does not provide molecular landmarks to identify the mutated genes. Thus these mutations must be mapped and ultimately confirmed by DNA sequencing.

Gene-Trapping

Gene-trap mutations are generated by ►[electroporation](#) or virus-mediated random insertion of vectors into the genes of mouse ►[embryonic stem \(ES\) cells](#), which are then used to generate mice that carry the mutated gene (reviewed in (3)). Gene-trap vectors consist of a ►[reporter gene](#) without a ►[promoter](#), such as *LacZ* or GFP, and a ►[selection marker](#), such as Neo or Puro. Mutagenesis and subsequent reporter expression occur when the vector inserts into an exon or intron of a gene to generate a fusion transcript between the upstream endogenous exonic sequence and the reporter gene. The fusion transcript generated by the trapping of a gene, serves as a template for techniques such as ►[RACE](#), which allows the trapped gene to be identified.

Generating Gene-Specific Mutations in the Mouse Transgenics

The ability to insert 'foreign' DNA (a transgene) into the mouse was first acquired in 1980 using the technique of '►[pronuclear microinjection](#)'. Mice carrying a transgene are termed "transgenic" (Fig. 1). This technique is robust and simple and relies on over-expression of the newly inserted transgene to produce a phenotype, which may not be physiologically relevant. However, the random integration site of the injected DNA will often result in variable expression of the transgene causing a variable phenotype. To generate a 'negative' effect, a mutant form of the gene (such as a ►[dominant negative](#)) can be used as the transgene.

Gene-Targeting

The ES cell genome can be modified by ►homologous recombination, also known as ‘gene targeting’, first achieved in mammalian cells in 1985 (Fig. 1). Using different strategies, it is possible to generate essentially any desired mutation and establish this genetic change in the germ-line of the mouse (reviewed in (1)). The different types of mutations and the vectors needed to generate such mutations are discussed below in more detail.

‘Knock-out’ Mice

1. One of the most common uses of gene targeting is to destroy (‘knockout’) a gene’s function and observe the effect this has on the phenotype of the mouse. This is usually achieved by introducing a selection cassette (such as Neo or Puro) into the target ►locus. Two basic types of targeting vector are used for knocking-out genes. These are ‘replacement’ vectors, which replace a portion of the targeted locus with a selectable marker and ‘insertion’ vectors, which mutate the target gene by ‘inserting’ into it and duplicating part of the locus. Both strategies disrupt the target gene and usually result in total loss of function of the gene (a ►null allele).

‘Knock-in’ Mice

2. Knock-in experiments are used to replace a targeted gene with a transgene, bringing the transgene under the transcriptional control of the targeted gene. The most commonly used transgenes include homologues of the target gene (to assess whether members of the same gene family have similar functions when expressed in the same spatial/temporal pattern) or reporter genes such as LacZ or GFP (to monitor expression patterns of the gene during development and in the adult mouse).

Conditional Mutations

3. Null mutations often cause ►embryonic lethality, precluding analysis of a gene’s function in adults. Conditional mutations can be generated which allow function to be examined in specific cell types *in vivo* (reviewed in (1, 4)). By regulating gene activity embryonic lethality is avoided, allowing gene function to be examined later in development or in adult life. Control over gene activity *in vivo* can be achieved using site-specific DNA recombination. The most widely used site-specific DNA recombination system is the enzyme ►Cre, which cleaves and ligates DNA at distinct target sequences known as ►loxP sites. LoxP sites can be incorporated into the targeting vector to flank (flox) the portion of DNA to be deleted, thus after homologous recombination these loxP sites will be incorporated into

the targeted locus. The ‘conditional’ nature of such a locus means that the ►floxed DNA will function normally until Cre is expressed and the floxed DNA is deleted (Fig. 2i). Deletion can be achieved in ES cells (using vectors expressing Cre) or in certain tissues in a mouse (by mating with a transgenic mouse expressing Cre). There are many established transgenic lines expressing Cre in different tissues (see ►<http://www.mshri.on.ca/nagy>). More recently, inducible forms of Cre have also been developed, such as ►Cre-ER^T, such that Cre-mediated recombination is additionally under the control of a drug such as tamoxifen and thus can be regulated temporarily as well as spatially.

Chromosomal Engineering in the Mouse

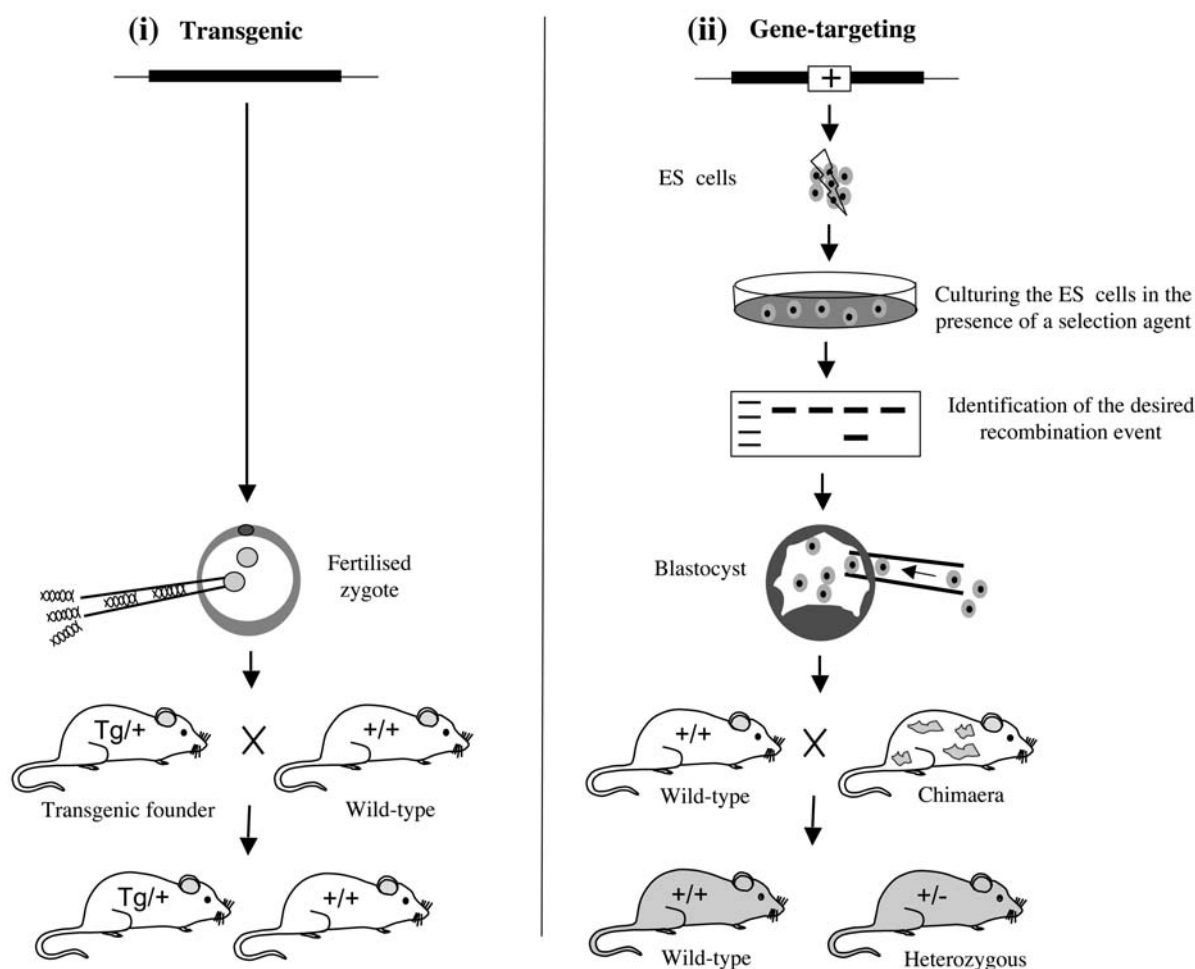

The combination of gene-targeting with the Cre-loxP recombination system resulted in 1995 in the emergence of chromosome engineering technology, which allows for modelling human diseases associated with chromosomal rearrangements, such as deletions, inversions, duplications and translocations (reviewed in (5)). Chromosome engineering requires the targeting of two ►HPRT vectors to defined sites within the genome (Fig. 3). The location of the 5’HPRT and 3’HPRT cassettes relative to each other (and hence the orientation of the loxP sites found on these vectors) dictates the structure of the mutant chromosome (Fig. 2).

Deletions

Together with duplications, deletions are the most common form of chromosomal abnormality in humans, and cause developmental syndromes such as DiGeorge and ►William’s syndromes (hereditary deletions) as well as tumorigenesis (►somatic deletions). Deletions can be engineered when the 5’HPRT and 3’HPRT vectors are targeted to the same chromosome and the loxP sites in the HPRT cassettes are facing in the same direction along the chromosome (Fig. 2i). Expression of Cre in these cells recombines the distant loxP sites, deleting the intervening segment of DNA. A conditional deletion can be engineered by expressing Cre in certain tissues in the mouse so that the deletion product is only generated in specific lineages. Deletions of many sizes have been engineered in ES cells. Although there is no limit on the size of deletion that can be engineered, larger deletions have often have biological problems such as ►haploinsufficiency and embryonic lethality that limit their use.

Duplications

Duplications are more commonly observed in human populations than deletions because the biological affects are often less severe. Duplications can be

Mouse Genomics. Figure 1 Generation of genetically modified mice by (i) pronuclear injection or (ii) gene-targeting methods. (i) To generate transgenic mice, a vector containing the gene of interest is generated. The vector is linearized and then injected into the pronucleus of a fertilised zygote. The injected zygote is then transferred into the oviducts of a pseudo-pregnant foster mother. The resulting pups are screened for the presence of the transgene and those containing the transgene are termed the 'founders'. The founders are mated with wild type (+/+) mice to check for germline transmission of the transgene to the F₁ offspring (Tg/+ mice). (ii) To generate knockout mice, a targeting vector containing a selection cassette (+), and sequences of homology with the target locus (thick black line) is generated. The vector is then linearized and electroporated into mouse ES cells. These cells are then cultured in the presence of a selection agent to remove any cells that have not stably integrated the construct into their genome. ES cell clones that carry the desired recombination event are identified (using molecular methods). ES cells with the targeted allele are injected into blastocysts, which are then transferred into the uterus of a pseudo-pregnant foster mother. Male chimaeras generated from the blastocyst injections showing high percentage chimaerism are then mated with wild type female mice to check for germline transmission (indicated by the coat colour) of the targeted allele to the F₁ offspring. For both techniques, the heterozygotes may then be inter-crossed to breed to homozygosity. The phenotypes of the heterozygous and homozygous progeny are characterised.

engineered when the 5'HPRT and 3'HPRT vectors are targeted to different homologous chromosomes as shown in Fig. 2 (iv). After expression of Cre, recombination generates one chromosome with a duplication and another with a deletion.

Inversions

Inversions cause disease less frequently because the loss or gain of genetic material is limited to the ends of the rearrangement. Inversions can be engineered by targeting the 5'HPRT and 3'HPRT vectors to the same

Mouse Genomics. Figure 2 The actions catalysed by Cre. (i) Deletion: when two *loxP* sites (black triangles) are facing in the same direction on a chromosome (*cis*), Cre-mediated recombination will result in excision of the floxed DNA (shaded region). (ii) Inversion: if the *loxP* sites are orientated in opposite directions in *cis*, the sequence between the *loxP* sites will be inverted. (iii) Translocation: recombination between two *loxP* sites on different chromosomes (*trans*) will lead to the reciprocal exchange of the regions that flank the *loxP* sites. (iv) Duplication: if the *loxP* sites are targeted to different chromosomes in the same orientation, Cre-mediated recombination between sister chromatids will result in a duplication of the floxed region on one chromatid and deletion of this region on the other chromatid.

chromosome but ensuring the HPRT cassettes and their associated *loxP* sites are placed in an inverted orientation (Fig. 2ii). *LoxP* sites in the reverse orientation will invert ('flip') the intervening DNA segment upon exposure to Cre. Experimentally, inversions are very useful reagents for genetics because a chromosome with an inversion cannot recombine with its homologue and produce a viable gamete. Chromosomes with inversions are known as 'balancer chromosomes'.

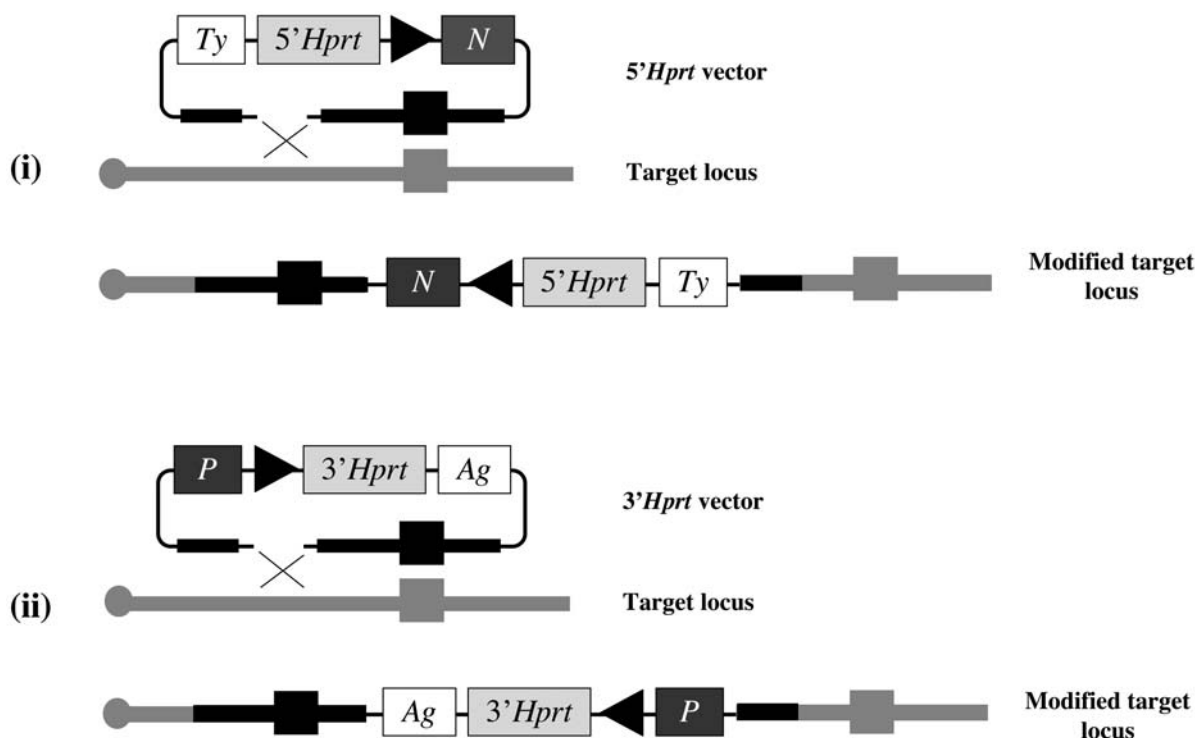

Translocations

Translocations are frequently observed in humans with infertility. Translocations are also important in malignant diseases, such as leukaemia. Translocations

usually have little or no net loss of genetic material, but genes that are normally tightly regulated are taken out of their normal context and novel fusion products can be generated which exert pathological effects. Translocations are generated when the 5'HPRT and 3' HPRT vectors are targeted to different chromosomes (Fig. 2iii). After the expression of Cre, a reciprocal exchange of the regions that flank the *loxP* sites will occur between the chromosomes.

matthias.friedrich@ucalgary.ca

Definition

Understanding the impact of genomics and proteomics on the human biological system requires more than a simple description of experimental findings on a molecular level. Experience in molecular medicine teaches us that we need more knowledge on the nature and interaction of molecules in their natural physiological environment. Many knock-out animal models did not match the expected pathology due to the multiple compensation mechanisms of the biological system. Thus, medical research asks for highly accurate and reproducible data *in vivo*. The value in reflecting molecular physiology *in vivo* is limited for every sample either bred in an isolated *ex vivo* system or removed from the body. Therefore, we encounter a tremendous interest in powerful imaging techniques.

Among them, magnetic resonance imaging (MRI) may be of special importance. Unlike other imaging techniques, MRI provides information on molecules without affecting their physiological actions *in vivo*. Furthermore, the technical approach can be focused on certain tissue types or even certain molecules. Finally, the safety profile is an ideal setting for imaging volunteers and follow-up studies. Thus, MRI provides unique features for molecular imaging.

This chapter will describe the utility of MRI in molecular imaging.

Description

Image formation is based on the fact that in a magnetic field, the magnetic axis of nuclei with a magnetic

moment (such as ^1H , ^3He , ^{13}C , ^{19}F , ^{23}Na , ^{31}P , ^{129}Xe) spins, like a gyroscope. Each of these nuclei has a specific spinning frequency (the so-called Larmor frequency), which is a product of a nucleus-specific constant and the external magnetic field. When an electromagnetic excitation pulse of their frequency is applied, the nuclei show a resonant behavior and the orientation of their spins is changed. After the pulse, the nuclei will return to their original position in a specific time (relaxation time). This is associated with the emission of a very small signal, which can be detected by a receiver and further processed into an image. Since surrounding atoms alter the frequency ("chemical shift"), the emitted signal of a given nucleus depends on its molecular environment.

Thus, the specific resonant behavior of nuclei within different molecules can be exploited to generate molecule- or even tissue-specific signals. As an example, in a given MRI technique, water-bound ^1H nuclei would reveal high signal intensity, whereas fat-bound protons would hardly be detectable.

Since modern MRI systems provide numerous options for modifying the excitation-relaxation sequence, there are many ways to acquire images that provide information on the molecular pattern of a given tissue.

A Brief History of Molecular MRI

After the first report of Gerlach and Stern on the magnetic momentum of silver atoms in 1921, it needed many years to explore this phenomenon further, before an assessment of the molecular composition of compounds became possible. The introduction of the Fourier transformation by Ernst and Anderson in 1966, a mainstay of modern MR techniques, required computer power which was not available until the 70's, when it eventually enabled modern MR imaging. Damadian was the first to describe a difference in relaxation times between normal tissue and tumors and stimulated the clinical application of MR imaging. The following years encountered many advances in experimental MR research, enabling the definition of molecular structures and complicated 3-dimensional conformations of proteins, making MR an integral part of drug development, since the development curve of MR imaging was dependent on hardware power and thus showed a more exponential shape. In 1973, Nobel Prize laureate Paul Lauterbur described a technical approach to using magnetic field gradients for imaging ^1H in water and, in 1977, Damadian published the first image of a human chest *in vivo*. But in the following years, uncoupled from spectroscopy, the development of MR imaging in medicine was hampered by the limited field strength and computer power. In the 80's, eventually, the development of surface coils and time-dependent gradients enabled volume-selective studies and paved the road for higher resolution imaging.

Industry's interest in a clinical application of MR imaging fostered the development of hardware, software and a variety of technical approaches and after a tremendous development during recent decades, MRI has become a cornerstone of modern diagnostic imaging.

Nowadays, experimental studies deal with a pixel size of $20,000 \mu\text{m}^3$ (or 0.00002 mm^3) and *in vivo* studies in humans allow for pixels as small as 0.35 mm^3 .

Potential and Limitations of MRI

The outstanding potential of MRI is based on the unique possibilities of obtaining molecule-specific information, in many cases without interfering with the targeted molecular processes. The small proportion of nuclei available for signal generation however, limits the sensitivity of MRI. Thus, imaging approaches are still mainly confined to ^1H (which is highly abundant in tissue compounds), whereas the absolute number of other nuclei is often insufficient. Numerous approaches have addressed an increase in the sensitivity and, although the theoretical borders of sensitivity are not reached yet, reliable techniques have been developed to visualize tissue composition and molecular mechanisms.

MRI Systems

There are mainly two classes of MRI systems available, experimental, small-bore ($<20 \text{ cm}$) systems for probe and animal imaging and clinical, large-bore (around 60 cm) systems for whole body imaging of humans. Small systems generally offer a higher spatial resolution, but a smaller field of view.

The magnetic field strength depends on the purpose of the system. Experimental scanners often have high field strengths of $4.7\text{--}9.4 \text{ T}$; for *in vivo* imaging of humans, mostly 1.5 T and 3 T systems are currently in use.

Signal Contrast Mechanisms and Applications in Molecular Imaging

The specific changes in the nuclear relaxation properties offer numerous options for visualizing and quantitatively assessing molecules.

Nucleus-Specific Imaging

First of all, the study can be targeted on certain molecules by the frequency of the excitation pulse, e.g. in a 1.5 T field, a frequency of 63.87 MHz will excite ^1H nuclei, whereas 25.85 MHz would give ^{31}P images. Whereas ^1H nuclei have an unmatched abundance in biological tissue, other nuclei do not and thus are subject to limited sensitivity in the corresponding MR approaches.

Since the mere quantity of protons often does not provide specific information on molecules, the number

of applications is limited. Examples of MRI using nuclei other than ^1H include ^{31}P , ^{13}C and ^{23}Na .

The use of stronger magnetic fields such as 3 T or 7 T increases the sensitivity and eventually may lead to a more successful application *in vivo*.

Sodium MRI

^{23}Na ions have been subject to MR imaging for more than 20 years and were used to investigate multiple body areas such as the brain, muscular tissue, heart, and kidneys (1).

^{23}Na MRI has been used to quantify static sodium concentrations *in vivo*, but also during functional studies. It was applied to assess tissue viability in the heart. It may be of special importance in the follow-up of tumors.

Although the abundance of ^{23}Na ions is 100%, their inherent MRI sensitivity is low (due to a quadrupole electric moment), which leads to long acquisition times, limited spatial resolution and difficulties in accessing areas distant from the coils. Reliable separation of extracellular from intracellular sodium remains a challenge. Furthermore, as with MRI of other ions, broadband capability of the MRI hardware is required. More recent developments such as multiple quantum filters, shift reagents, new transmit-receiver systems and novel coil concepts are likely to facilitate ^{23}Na use in research and future clinical application.

MRI of Other Nuclei

Besides studies on rubidium (^{87}Rb) MRI in myocardial ischemia (2), there are reports on using potassium (^{39}K) to generate MR images related to the assessment of intracellular K^+ concentrations in myocardial infarction. The inherent sensitivity, however, limits its usefulness.

Relaxation-Time Based MRI

Making use of the difference in relaxation times (in the range of ms to seconds), it is possible to delay signal reception until a chosen time point, e.g. fat has shorter relaxation times, whereas components rich in water have longer relaxation times. Thus, a later temporal window will exhibit a strong signal coming from water and *vice versa*. Selecting specific imaging parameters, allows for acquiring images with known signal intensity properties. Basic types of images are called T1-weighted, T2-weighted or proton density-weighted. Additional high frequency pulses (e.g. inversion or saturation prepulses) allow for a more specific selection of image contrast.

BOLD (blood-oxygen-level-dependent) MRI has become an important tool to assess small changes in tissue blood supply. The underlying principal is based on the fact that the oxygenation status of hemoglobin defines its magnetic properties. In contrast to its

oxygenated counterpart, deoxygenated hemoglobin destabilizes the surrounding magnetic micro field and thus can be used as an internal contrast medium. The so-called BOLD effect has been exploited to visualize brain activity in the field of functional MRI as well in the diagnosis of stroke. More recently, BOLD MRI has been successfully applied to visualize myocardial ischemia (3) (Fig. 1).

Diffusion-weighted MRI is based on the phenomenon that the directional arrangement of molecules in ordered tissue structures leads to an alteration in relaxation times. This change of relaxation time is a source of error, but can yield information on the extent and direction of proton diffusion. The most important diagnostic use is in the detection of acute cerebral stroke.

Magnetization transfer MRI can be used to visualize pathological leakage from membranes, exploiting altered relaxation properties of protons bound to immobile tissue. The selective saturation of these protons is transferred to adjacent, mobile protons, acting as contrast agent, which indicates cellular injury. This approach has been applied to numerous diseases such as optic neuritis.

Contrast-Media Enhanced Approaches

The relatively low spatial resolution of molecular MRI represents a serious limitation and is faced with a much lower concentration of the metabolites to be studied.

MR Imaging. Figure 1 Hemorrhagic myocardial infarction as visualized by signal loss (arrows) as compared to normal tissue (asterisk) in this BOLD-sensitive image (gradient echo/echo planar imaging hybrid sequence). The signal loss reflects the local presence of degradation compounds of hemoglobin.

The current sensitivity limit of MRI is 0.5 mmol/kg, whereas the molecular concentration of the addressed targets or reporters is in the low nanomolar or even picomolar range.

Contrast agents may be used to increase the sensitivity and specificity of molecular MR. MR contrast media change the magnetic relaxation properties of the surrounding microenvironment. Gadolinium-III (Gd-III) complexes have a strong magnetic moment and have been the most frequently used compounds (4). A concentration of about 10–100 μmol is required to be detectable by present MRI systems *in vivo*, but recent reports indicate that MRI can even be applied in cell culture models.

More specific contrast agent complexes may be used to identify pathology on a molecular level. Gd-labeled antibodies were used to detect CA 19-9 and carcinoembryonic antigen in colorectal carcinoma. Gd-labeled mesoporphyrins have shown a selective affinity for necrotic cells and were applied for the detection of tumors and scarred tissue (5). Other studies addressed tumor angiogenesis using polymerized liposomes, which were targeted to the endothelial $\alpha\beta_3$ receptor by specific antibodies.

However, the sensitivity of these approaches is still limited in many situations firstly by the impact of most agents on magnetic relaxation, i.e. the relaxivity of the agent and secondly by the actual concentration of contrast-generating complexes in the region of interest which is still very low, especially when considering the small proportion of bound molecules within the equilibrium state of *in vivo* systems.

Consequently, current research is focused on the development of agents with high relaxivity and target affinity.

A novel fibrin-binding Gd complex with a high relaxivity was successfully used to visualize intravascular thrombi *in vivo* (6).

The use of nanoparticles containing specific antibodies and a large number of MR contrast agent molecules may provide an adequate sensitivity and enable detection of targets in the picomolar range (7). Liquid perfluorocarbon emulsions, containing nanoparticles with several tens of thousands of Gd molecules, have been used to image neovasculature and vulnerable plaques.

Newer developments have raised interest in so-called “smart molecules”, which are activated *in vivo* by certain pathology-related or reporter gene-related enzymes, but further results have to be awaited.

Perspectives

Due to ongoing technical advances, the role of MRI in molecular imaging is likely to become more and more important. Considering the limited spatial resolution and sensitivity of current MRI techniques *in vivo*, further development is to be expected. In several areas

of research, the current status may suggest a combination of MRI with other modalities such as optical imaging.

Synonyms

5' end processing

Definition

Gene transcripts synthesized by RNA polymerase II, as well as other nascent pre-mRNAs including most viral mRNAs, are processed at the 5' end at an early stage of formation. The enzymatic addition of a m⁷GpppN ►cap structure marks the ►transcription initiation site, enhances RNA stability and splicing and promotes other downstream events, notably translation initiation through the action of cap binding proteins.

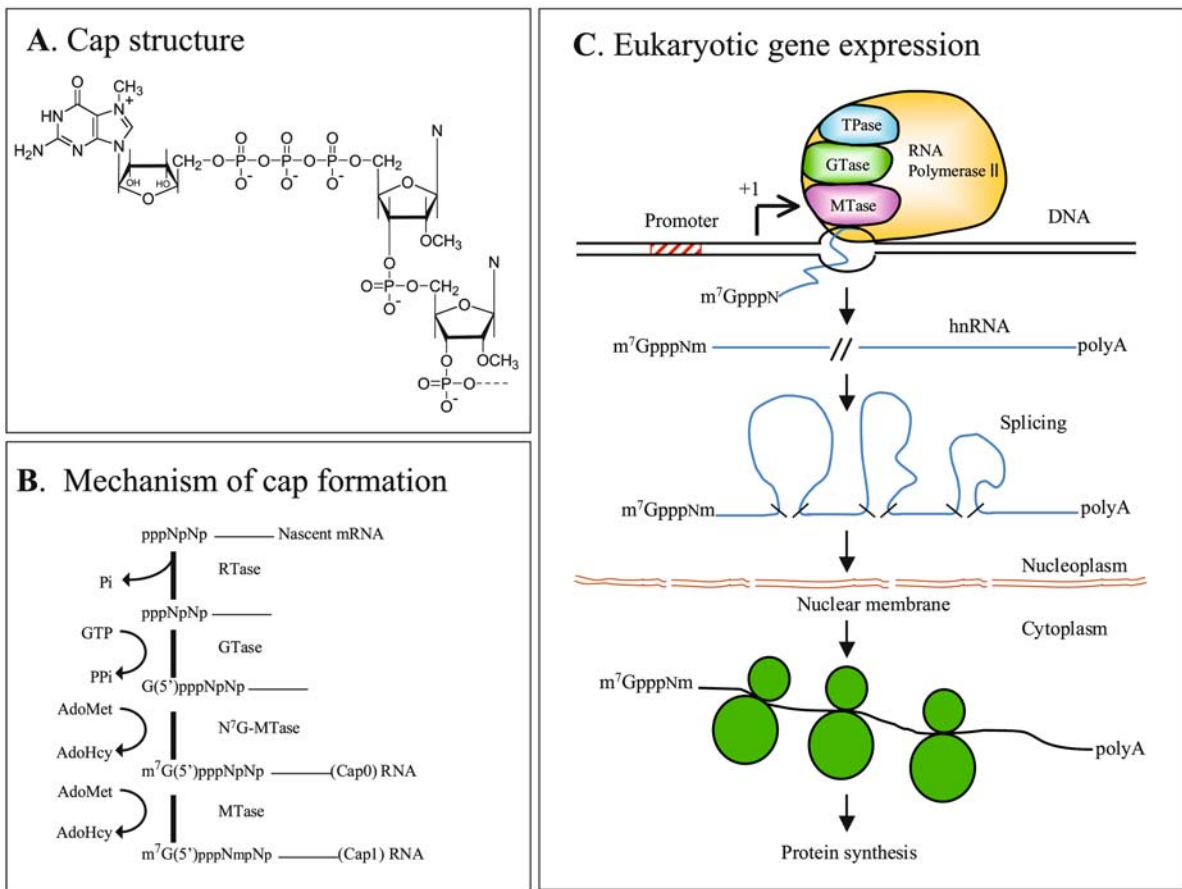

Characteristics

Discovery of the mRNA Cap from Virus Research

A blocked and methylated m⁷G(5')ppp(5')N structure, dubbed the cap, is present at the 5' ends of all eukaryotic cellular mRNAs and most but not all viral mRNAs (Fig. 1A). The 5' cap is a hallmark of eukaryotic mRNAs and is not present in rRNA or tRNAs or in prokaryotes. It has been 30 years since the discovery of this unexpected structure (1). This short review focuses on the impacts of this novel finding on the others that followed in the mid-70s and 80s. The story behind the discovery of the cap and how such a so-called “bizarre” structure was identified is described in our previous review “Viral and Cellular mRNA Capping: Past and Prospects” (2).

Although it is unclear why and how eukaryotes acquired the mRNA 5'-terminal element during evolution, studies from many laboratories have documented its crucial roles in several steps of gene expression. Elucidation of the cap also contributed significantly to the progress of molecular biology research and led to many other important findings. Indeed, molecular biology in the 1970s was filled with exciting surprises by a flood of discoveries on the fundamental structures of cellular components and the basic mechanisms by which genetic information is elicited from DNA *via* mRNA to generate the proteins needed for life.

Historically, new findings in science are related not only to those past but also mutually to each other, one-by-one and one-after-another. Accordingly, finding the cap was a consequence of a series of other discoveries, which then opened new avenues for exploration. Here it is important to note that virus systems played a pivotal role in defining the structure of the cap, its mechanism of synthesis and the biological functions of the cap in cells. Viruses such as insect cytoplasmic polyhedrosis virus and human reovirus, that contain as integral parts both genomic double-stranded RNA and a mRNA synthesizing system, played highly significant roles in elucidating the cap structure because one strand of the duplex genome RNA is identical to the viral messenger and the purified viruses produced capped mRNAs in the test tube when incubated with nucleoside triphosphates and the methyl donor S-adenosyl-methionine (Fig. 1B). Studies by Moss'

mRNA Capping. Figure 1 (A) Cap structure. N represents the nucleoside base in mRNA. (B) Enzymatic processes to form cap structure (AdoMet, S-adenosyl-methionine; AdoHcy, S-adenosyl-homocysteine). (C) mRNA formation and function in eukaryotic cells.

group on vaccinia virus, a DNA virus that also contains its own RNA polymerase and capping enzymes, similarly resulted in the identification of the enzymes and reactions involved in cap formation.

Fundamental Structure and Biological Functions of the Cap

We and others including the laboratories of Adams and Cory, Darnell, Miura, Moss, and Perry found that a cap is added to mammalian cell mRNA precursors synthesized by RNA polymerase II *via* a series of reactions catalyzed by a capping enzyme complex consisting of guanylyl transferase and methyltransferases in association with the polymerase (Fig. 1C). The reactions occur during the initial phases of transcription and before other processing events that include internal N6A methylation, 3'poly(A) addition and exon splicing. Most capped mRNAs have a single methyl group on the terminal G residue at the N7 position, but the adjacent nucleotides can also be 2'-O-methylated to different extents. Because capping

appears to be completed at a very early stage of transcription, co-transcriptional rather than post-transcriptional capping is likely for cellular mRNA synthesis *in vivo*. Biochemically, post-transcriptional capping can occur *in vitro* on 5' triphosphorylated RNA or oligonucleotides, or even on pppNpN dinucleotide structures, by the action of purified RNA 5' triphosphatase (RTase), guanylyl transferase (GTase) and methyltransferases (MTases) (Fig. 1B). However, this may not occur *in vivo* because a strong 5'-exonuclease activity that hydrolyzes uncapped RNA exists in the nucleus. Consequently, nascent mRNAs would be readily digested before completion of transcription unless their 5'-ends were protected by a m7G cap. Methylation of G at the N7 position prevents decapping, the GTase reverse reaction. In this context, it is interesting to mention that uncapped bacterial mRNAs have a short half-life (~ a few minutes) while capped eukaryotic mRNAs generally have half-lives of several hours to days, depending on the species and cell type. Thus one important function of cap is to help

stabilize mRNA. Also, in contrast to bacterial messengers, most eukaryotic mRNAs are produced from large nuclear precursor RNAs by complex, time-consuming splicing reactions that remove intronic sequences but with retention of the 5' cap as a transcription start site marker (Fig. 1C). Thus, the 5' cap in eukaryotic mRNAs might have arisen with the acquisition of nuclear compartmentalization and post-transcriptional processing systems including splicing.

In many lower eukaryotes including yeast, mRNAs contain a simple m⁷GpppN (cap 0) while higher organisms usually have more extensively methylated caps such as m⁷GpppNmpNpN (cap 1) or m⁷GpppNmpNmpN (cap 2). Similar structures with multiple methyl groups on the terminal G, i.e., 2,2,7m³GpppNm, are also present on small nuclear (sn)RNAs U1, U2, U3, U4, U5 and U8 which are synthesized by RNA polymerase II and act as scaffolds for RNA splicing. Despite the variations in the degree of methylation, the important biological consequences of a cap structure correlate with the N⁷-methyl group on the terminal G and the two pyrophosphoryl bonds that connect m⁷G in a 5'-5' configuration to the first nucleotide of mRNA (Fig. 1A). As noted above, caps increase [▶ mRNA stability](#) by protecting against 5' to 3' exonucleolytic degradation. Unmethylated caps can also stabilize mRNA to a certain extent, but unless the 5'-terminal GpppN is converted to m⁷GpppN, it can be hydrolyzed to (p)pN with the RNA becoming susceptible to subsequent degradation. Splicing accuracy and efficiency are both increased in the nucleus by the presence of the 5'-terminal m⁷GpppN and the mature mRNA enters the cytoplasm "head-first", all facilitated by nuclear cap-binding proteins analogous to the cytoplasmic cap-binding initiation factor eIF4E that is required for eukaryotic protein synthesis (Fig. 2A).

Reovirus with its associated RNA polymerase and capping enzymes proved extremely useful for deciphering how eukaryotic mRNAs initiate protein synthesis. Comparisons of reovirus RNAs containing various types of 5'-ends indicated that molecules with 5'-terminal m⁷GpppGm were preferentially translated in extracts of either plant or animal cells. Virus mRNAs with 5'-GpppG or 5'-ppG were not efficiently translated. Selection of capped over uncapped RNAs occurred during mRNA binding to the small ribosomal subunit. These data clearly demonstrated that cap recognition plays an important role in translation and, as shown later, in selection of the cap-proximal AUG as the initiator codon (3).

Impacts of Cap Discovery on Other Major Findings Caps in Virus Replication

Viruses reproduce in host cells by redirecting cellular systems that are lacking in the virus particle but needed for replication. Thus there exist a variety of virus

replication strategies. While the cap was discovered in studies on viruses, subsequent cap-related research in turn helped elucidate virus replication and pathogenesis mechanisms, information essential for developing antiviral drugs (4). Described below are some examples involving several well-studied viruses.

Poliovirus

Unlike many viruses that infect eukaryotes, Wimmer and others found that the picornaviruses including human poliovirus and mouse encephalomyocarditis virus do not have capped mRNA. Further studies led to the finding that infection by poliovirus and other picornaviruses converts the cap-dependent cellular translation system to cap-independence by inactivating the cap-binding protein important for host protein synthesis. These findings provided new insights on how pathogenic viruses redirect cellular systems for viral replication. Hepatitis C virus (HCV) notorious for causing chronic hepatitis, cirrhosis and finally a high frequency of human hepatocarcinomas also does not have capped mRNA and may follow a poliovirus-like strategy for proliferation and chronic infection. Further studies are needed as a basis for designing antivirals targeted to intrinsic replicative features of HCV and other life-threatening viruses.

Influenza Virus

The virus core particles containing the single-stranded genome RNAs (negative strands) and viral RNA polymerase penetrate into the nucleus of infected cells. There the influenza complex that includes a cap-binding protein, endonuclease and polymerase binds to the capped ends of nascent cellular mRNAs, cleaves them ~10–20 residues downstream of the cap and utilizes the resulting capped fragments as primers of viral mRNA synthesis. This "[▶ cap-snatching](#)" mechanism results in viral messages containing short, diverse 5' sequences of cellular origin covalently linked to virus coding sequences. These findings showed clearly that influenza virus compensates for the absence of virus-associated capping enzymes by snatching capped oligonucleotides from the host, which also allows use of the [▶ cap-dependent translation](#) system for production of virus proteins required for replication. This unusual mechanism provides a possibility for drug intervention to prevent a major cause of human morbidity and mortality as well as worldwide economic damage.

Corona Virus

The recent SARS pandemic in Southeast Asia was caused by a new corona virus, the severe acute respiratory syndrome virus. It contains a positive-sense, single-stranded RNA genome that functions as mRNA and is infectious. The virus replicates in the

VPg is the virus protein covalently bound to poliovirus genomic RNA.

cytoplasm of infected cells and the genome RNA is capped. Capped viral RNAs of various sizes are synthesized by a viral polymerase, the individual mRNAs sharing a common 5' leader sequence of ~60–90 nucleotides corresponding to the 5' end of genomic RNA. These observations suggest that capped 5' leader fragments prime initiation of individual corona virus mRNAs, although other possibilities include post-transcriptional trans-splicing between leader RNA and pre-mRNAs or a polymerase jumping mechanism. In any case, SARS corona virus appears to contain a specific transcription system that could be a target for new drugs.

Retroviruses

The AIDS virus, HIV and many RNA tumor viruses contain enzymes, including reverse transcriptase (RT), packaged with the single-stranded RNA genome (positive strands). Upon infection, RT transcribes the genome and the resulting DNA copy gets integrated into the host genome to be transcribed by the host transcription machinery consisting of RNA polymerase

II and capping enzymes. Thus, like cellular mRNAs, the viral mRNAs and genome RNAs are capped as shown first for B77 avian sarcoma virus 35S RNA in our collaborative studies with Bishop's laboratory. The presence of cap similarly facilitates viral [mRNA translation](#), and protects the genome RNAs from exonucleolytic degradation until encapsidated in progeny viral particles. These and other findings on how retrovirus replication strategies resemble or differ from cellular processes helped to provide basic information leading to the development of HIV RT and protease inhibitors.

Adenovirus and Discovery of mRNA Splicing

Large, precursor mRNAs in the nucleus of mammalian cells were found by us in collaboration with Darnell's laboratory and by Perry's group, as well as by others in later studies on viral and cellular transcripts, to be capped at the initiation of transcription. Although these findings confirmed a hypothesis that mRNAs in the cytoplasm are processed from large nuclear RNAs (at the time called hn or heterogeneous nuclear RNA), the

pathway remained obscure, due to the complexity of cellular systems including the large numbers of mRNA species as well as the nuclear membrane separating the nuclear and cytoplasmic compartments (Fig. 1C). This challenging problem was approached successfully using adenovirus systems to reduce the complexity issues. Roberts' Cold Spring Harbor (CSH) group digested adenovirus-specific mRNAs, purified from infected cells by hybridization to viral genomic DNA, with RNaseT1 and separated the resulting fragments by two-dimensional DEAE-paper electrophoresis. They found a prominent spot corresponding to capped 5'-terminal oligomer that was apparently shared by multiple virus mRNAs transcribed from the same promoter but containing a variety of downstream (exon) sequences. Sharp's group, also then at CSH, obtained direct visual evidence for RNA splicing by electron microscopy. They demonstrated the presence of conserved (exon) and excised (intron) regions by examination of adenovirus DNA hybridized to viral mRNAs. These landmark virus findings dramatically changed our understanding of all eukaryotic gene expression.

Discovery of Two Types of Initiation in Protein Synthesis

Most eukaryotic proteins are produced by cap-dependent translation in which only capped mRNAs are recruited to ribosomes (like "beads on a string"). mRNA binding assisted by cap-binding protein initiates protein synthesis by accurate selection of AUG near the capped terminus (Fig. 2A). On the other hand, the absence of cap in some viral mRNAs prompted researchers to look for alternative ways to initiate protein synthesis. A cap-independent ribosome recruitment mechanism was soon reported by Sonenberg, Wimmer and others in which uncapped viral mRNAs could attach to ribosomes at an internal ribosomal entry site (►IRES, Fig. 2B, C). For example, HCV protein synthesis is initiated on a ~330-nucleotide IRES structure located downstream of the 5' uncapped end of the viral genome RNA. The protein initiation factors required for these two distinct modes of translation differ (Fig. 2A, B). IRES elements can also be present in capped mRNA and such mRNAs can presumably function in both translation systems.

Identification of Transcription Start Points Using the Cap to Prepare ►Full-Size cDNAs

Since transcription starts from the ►capping site downstream of the promoter region in a gene (Fig. 1C), the cap can be used as a "handle" to produce full-size cDNA containing the 5' terminal sequences often missing in the reverse-transcribed cDNA copy of the

mRNA or in cDNA libraries. An oligo-capping method by Sugano's group used tobacco nucleotide pyrophosphatase to remove 7mGp(p) from the 5' end of mRNA. The resulting 5' monophosphorylated end allowed fusion of the decapped RNA to a ribo-oligomer of defined sequence by RNA ligase. By using the "oligo-capped RNA" as template for reverse transcription, the cDNA produced necessarily included the capping region sequence of a given gene. The same "decapitation" method was used by Furuichi's group to locate the promoter and accurately identify the transcription start site on the Werner syndrome gene. A very similar procedure but employing a chemical reaction to remove m7G from capped mRNA was applied by Hayashizaki's group for high-throughput analysis of transcriptional starting points and frequencies of promoter usage in tissue-specific libraries of mouse genes.

Conclusion

As reflected in this short review, it is interesting to note that so many amazing findings followed the epochal discovery of caps on eukaryotic mRNAs. This flow of new, cap-related information continues even after 30 years and promises more surprises in the future. Clearly, molecular biology research is alive and well across the globe.

Clinical Relevance

Capping and caps are essential for eukaryotic life, and their absence is lethal. Thus no human diseases have yet been ascribed to capping defects. However, capping represents a novel target for drug development against yeast, fungi and some parasites because in these organisms the RNA 5' triphosphatase, unlike the mammalian enzyme, requires a cation cofactor. Among pathogenic viruses, capping by alpha viruses differs from cellular capping in that GTP is methylated before, rather than after, linkage to the 5' end of the RNA. Another antiviral possibility is the development of small molecules that interfere with cap snatching by influenza polymerase.

mRNA Decay

Definition

mRNA decay describes the process by which mRNAs are degraded. In eukaryotic cells, the major pathways of mRNA decay start with the exonucleolytic shortening of the poly(A) tail.

► Polyadenylation

mRNA Processing

Definition

Cellular mRNA transcripts are made in the nucleus as precursor molecules that need to be processed extensively to be fully functional during translation in the cytoplasm. This processing includes the capping of the mRNA at its 5' end, excision of intron sequences (splicing) and addition of a polyA tail at the 3' end, and N6-methylation of specified adenosine residues.

Multidimensional NMR Spectroscopy

PETER SCHMIEDER

FMP, Institute for Molecular Pharmacology, Berlin, Germany

schmieder@fmp-berlin.de

Definition

Multidimensional NMR spectroscopy (1) forms the basis of the determination of the three-dimensional structure of biomolecules (proteins, DNA, RNA) (2) by providing the resolution necessary to analyze their complex spectra. One-dimensional NMR spectra result from a Fourier transform (FT) of a directly detected time domain signal, the ► [free induction decay](#) (FID) that is recorded at the end of ► [pulse sequence](#) during the ► [acquisition time](#). Higher-dimensional spectra are created by indirectly detecting further time domains. This is accomplished by systematic and independent variation of one or several delays in the pulse sequence while repeatedly acquiring an FID. In between the variable delays that result in the indirect detected dimensions are mixing sequences of varying complexity. They enable a transfer of magnetization *via* several mechanisms resulting in correlations between signals from different nuclei. Depending on the type of interaction used to accomplish this transfer the evaluation of the spectra allows for the extraction of either a resonance assignment or structurally relevant parameters.

Description

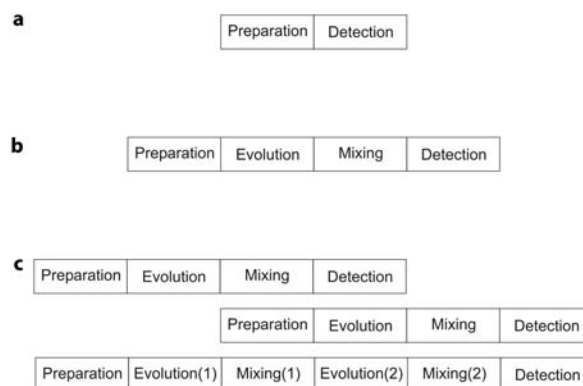

Basics

The basis of every modern NMR experiment is a pulse sequence, a series of radio frequency pulses and delays that ends with an acquisition time, during which the

FID is recorded. This is independent of whether solution state or solid state NMR is employed. For a one-dimensional experiment the pulse sequence can be divided in two major sections, the preparation period and the detection period (Fig. 1a). While the detection period always consists of the detection of the free induction decay (FID), the preparation period can be of varying complexity. In the simplest case it consists solely of the relaxation period followed by a pulse to create detectable magnetization. The relaxation period is necessary to allow the sample to return to its initial state before repeating the acquisition of the FID for improved signal-to-noise ratio. The preparation period can, however, also contain a large number of delays and pulses that together form a complex pulse sequence designed to prepare the desired state of magnetization prior to detection. This is, in particular, accomplished by varying the pulse phases from one acquisition of an FID to the next in form of a phase cycle.

Two-Dimensional NMR

The step from one-dimensional to two-dimensional NMR spectroscopy introduces two additional sections into the pulse sequence, namely the ► [evolution time](#) and the ► [mixing time](#) (Fig. 1b). The indirect detection of an additional time domain takes place during the evolution time. After completion of the acquisition of the FID including the repetitions necessary to perform

Multidimensional NMR Spectroscopy.

Figure 1 Schematic representation of multidimensional spectra. (a) A one-dimensional NMR experiment consists of a preparation and detection period. (b) A two-dimensional NMR experiment is created by inserting an evolution period and a mixing period. During the evolution period the frequencies of the indirect dimension are recorded, during the mixing time a transfer of magnetization takes place. (c) A three-dimensional NMR experiment is catenated from 2 two-dimensional ones and contains two evolution and two mixing periods.

the phase cycle of the experiment and to achieve sufficient signal-to-noise, the experiment is repeated numerous times (Fig. 2). A delay in the pulse sequence is incremented systematically from one experiment to the next and the intensities detected in the FID during the acquisition time are thus modulated according to the length of this delay. The result is a two-dimensional time domain data set, one dimension from direct detection, one dimension from systematic incrementation of a delay. It is processed using two subsequent Fourier transformations along both time domains. First the directly detected FIDs are converted into a series of one-dimensional spectra, the interferogram. Then the interferogram is converted into a two-dimensional spectrum that exhibits two independent frequency axes. Both axes will usually contain the chemical shift of nuclei in the sample, the type of chemical shift as well as the appearance of the two-dimensional spectrum results from the design of the mixing period. During the mixing time the magnetization that has been created during the preparation period and has been modulated by a frequency during the evolution time is converted into another type of magnetization that is subsequently detected during the acquisition. This is accomplished using some type of interaction (scalar or J-coupling, dipolar coupling) between one or several spins in the sample.

Homo- and Heteronuclear NMR

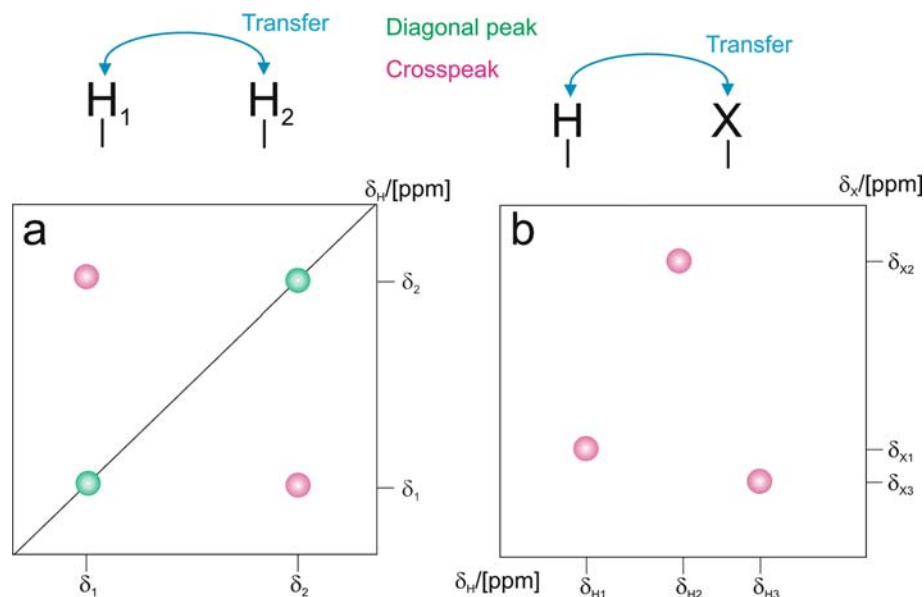

The simplest two-dimensional experiment possible in solution NMR is the COSY (correlation spectroscopy)

Multidimensional NMR Spectroscopy. Figure 2 The indirect dimension of a multidimensional experiment is created by systematic variation of a delay in the pulse sequence. Here, the simplest possible two-dimensional NMR experiment, the COSY, is shown. For each value $k_n \Delta t_1$ the full phase cycle is executed and a separate FID is recorded. k ranges from zero to a finite number (typically 128–1024 FIDs are recorded), Δt_1 is called the increment and determines the spectral window in the indirect dimension.

experiment; the pulse sequence is shown in Fig. 2. It is most commonly performed to create correlations between hydrogen nuclei (protons). The preparation period contains the relaxation period and a pulse to create detectable magnetization. During the evolution time a modulation by chemical shift takes place, in addition homonuclear, scalar coupling will be active and creates types of magnetization that enable a partial transfer from one spin to the next based on this interaction. This is accomplished by the subsequent pulse that represents the mixing period. Finally two types of signals are detected during acquisition. In one case, magnetization has not been transferred from one spin to another during the mixing time. The chemical shifts detected during the evolution time and the acquisition time are therefore the same and the frequencies resulting from the two Fourier transformations are identical. The signal will appear on the diagonal of the two-dimensional spectrum. The other type of signal results from magnetization that has been transferred from one spin to the next during the mixing time. The chemical shifts detected in the two dimensions will therefore differ and the signal will appear away from the diagonal. The first type of signal is termed “diagonal peak” while the second is termed “cross peak”. A schematic spectrum is shown in Fig. 3a. Since the frequencies on both axes result from the same type of nucleus, this kind of spectrum is called a “homonuclear spectrum”.

The occurrence of cross peaks is of major importance and represents the key feature of multidimensional NMR spectroscopy. In COSY-type spectra these peaks indicate a scalar coupling interaction between the nuclei that are represented by the two chemical shifts and thus allow the establishment of a connectivity between these nuclei, which forms the basis for resonance assignment. Other homonuclear spectra can be created by either modifying the manner of transfer *via* scalar coupling (e.g. in the so-called TOCSY experiment (total correlation spectroscopy)) or by utilizing a different kind of interaction. An important example for another type of interaction is the nuclear Overhauser enhancement effect (NOE). It results from the interactions of spins through space based on dipolar coupling and is dependent on the distance between the two nuclei involved in the interaction. Allowing for a NOE-effect during the mixing period results in a NOESY spectrum (nuclear Overhauser enhancement spectroscopy). In this kind of spectrum the appearance of a cross peak indicates spatial proximity of the nuclei represented by the chemical shifts. Moreover the intensity of the interactions is dependent on the distance and the analysis of NOESY spectra therefore yields structurally highly relevant information. Other types of interaction are utilized in solid state NMR, where dipolar coupling is of major importance to establish connectivities used for resonance assignment.

Multidimensional NMR Spectroscopy. Figure 3 Two types of two-dimensional NMR spectra exist. (a) In a homonuclear experiment, chemical shifts of the same type of nucleus (δ_H) are recorded in both dimensions. If no transfer takes place during the mixing period, the same chemical shift is recorded in both dimensions resulting in a diagonal peak. If there is transfer of magnetization, different chemical shifts are recorded and a cross peak appears, indicating a connection between the nuclei corresponding to the chemical shifts. (b) In a heteronuclear experiments two different chemical shifts (δ_H, δ_X) are recorded and in the case of a transfer of magnetisation during the mixing time, a cross peak appears, again indicating a connection between the nuclei involved.

Another type of spectrum is called a “heteronuclear spectrum” and is schematically depicted in Fig. 3b. Here the chemical shifts detected in the two time domains result from different types of nuclei. During the preparation period magnetization of the first type of nuclei is created. The chemical shifts of these nuclei are then recorded during the evolution time. Subsequently a transfer of magnetization between the two different types of nuclei is accomplished by proper choice of the mixing sequence. Mostly heteronuclear scalar coupling are used to create heteronuclear spectra in solution state NMR, while again dipolar interactions play a vital role in heteronuclear solid-state techniques. Unlike homonuclear spectra, heteronuclear spectra only contain cross peaks. If magnetization prepared for one nucleus during the preparation period is not transferred to the other type of nucleus during the mixing period, it will not be detected and thus only cross peaks with different frequencies on both axes can appear. Again the presence of a cross peak indicates an interaction between the two types of nuclei, which can be utilized to assign the chemical shift of the nuclei involved in the interaction or to extract structurally relevant information. In the case of proteins, two nuclei of major importance besides protons are carbon and nitrogen. Since the natural abundance of the two isotopes well suited for NMR spectroscopy, ^{13}C and ^{15}N , is quite

low, isotopic enrichment becomes mandatory. Two types of heteronuclear NMR spectra are of importance for the study of biomolecules using solution state NMR spectroscopy. One is the correlation between protons and a heteronucleus that is achieved by utilizing the direct scalar coupling between the two nuclei. The techniques to record these correlations in solution are called HMQC (Heteronuclear Multiple Quantum Correlation) or HSQC (Heteronuclear Single Quantum Correlation). The other type of spectra is the large family of triple resonance experiments (3, 4, 5) that are recorded utilizing the scalar interactions not only between protons and heteronuclei but also between heteronuclei. These spectra are standard spectra for the assignment of proteins in solution.

Three-Dimensional NMR

A major advantage of two-dimensional spectra compared to one-dimensional spectra is the increased resolution. Since the signals of interest are spread out over a two-dimensional plane rather than a one-dimensional line, the possibility of overlap is strongly reduced. Since overlap is a major obstacle in the analysis of NMR spectra of biopolymers, the introduction of two-dimensional techniques was instrumental in determining the structure of biomolecules using NMR. To further increase the resolution the techniques can be

extended to three-dimensional experiments (6). This is done by combining two two-dimensional experiments in the manner depicted in Fig. 1c. The resulting spectrum contains two evolution and two mixing periods. Both evolution periods are created, independently but otherwise identically, as in a two-dimensional experiment by variation of two separate delays in the pulse sequence. First a delay is systematically incremented and the acquisition of the FID is repeated for every increment to create the first indirectly detected dimension. Once the desired number of incrementations has been performed for this delay, it is set back to its original value. The other delay that is used to create the second indirectly detected dimension is now incremented once and the incrementation of the first delay is repeated, again with the acquisition of an FID for every increment. This is done until the variation of the second delay has been completed as well. The resulting three-dimensional data set is processed using a sequence of three Fourier transformations resulting in a three-dimensional spectrum with three independent chemical shift axes (Fig. 4). Again the spectra can be classified as homonuclear and heteronuclear spectra. Homonuclear spectra exhibit the chemical shift of the same nucleus on all three axes. These spectra are rarely recorded since the two transfer steps increase the number of possible correlations in the

three-dimensional space considerably. The analysis is thus too complicated to be practical. Heteronuclear spectra exhibit two or three different nuclei on the three axes. In triple-resonance spectra of proteins in solution the three chemical shifts are those of protons, carbons and nitrogen. Heteronuclear edited NOESY spectra result from a combination of a two-dimensional heteronuclear correlation and a two-dimensional NOESY. The major advantage of these types of spectra is the increased resolution due to the third dimension that is not compromised by an increased number of correlations.

Four-Dimensional NMR

The extension of a three-dimensional experiment by another dimension is straightforward (7), again another delay in the pulse sequence is incremented independently of the other two delays. The pulse sequence now consists of three evolution times and three mixing times. Again only heteronuclear spectra are recorded with at least two dimensions exhibiting the chemical shift of nuclei other than protons. While the analysis of two-dimensional spectra is quite straightforward using either paper printouts or computer assistance, this is not as simple for three and four-dimensional spectra. They are therefore dissected into planes extracted from the higher-dimensional spectra. These planes correspond to two-dimensional spectra and are extracted by keeping the chemical shift in one or two dimensions constant. They can be analyzed as two-dimensional spectra, but since the information in the spectrum is spread out over a large number of planes, computer assistance for the analysis of the spectra becomes mandatory. This includes a database to contain all the information about chemical shifts and structurally relevant parameters.

Resolution in NMR Spectra

A major difference between a directly detected dimension and indirectly detected ones is the effort required to obtain sufficient resolution, i.e. to record a sufficient number of data points. There are only minor limitations on the size of the data array in the acquisition dimension since the acquisition of additional points does not necessarily extend the time of the experiment. In the indirect dimension a doubling of the number of data points results in a doubling of measurement time, since the experiments have to be repeated twice as often. The number of data points, however, is directly related to the resolution in the spectrum, therefore a high number of data points is desirable. A compromise between experiment time and resolution is required and the data array in the indirect dimensions is usually reduced. To compensate for the reduced number of data points, several solutions have been suggested. Either the size of the spectral window is reduced in a controlled manner thereby folding some

Multidimensional NMR Spectroscopy.

Figure 4 Three dimensional triple resonance experiment correlating the chemical shifts of amino protons, carbonyl carbons and nitrogens in a fully labeled protein. The name of the experiment shown here is HNCO; cross peaks appear as three-dimensional objects distributed in a three-dimensional space. The analysis of this type of spectrum is performed by dissecting the three-dimensional spectrum into two-dimensional planes.

of the resonances back into the spectral window but increasing the resolution of the spectrum or the resolution of the spectrum is enhanced using special processing techniques other than the Fourier transformation. Another approach is the recording of two or more indirect dimensions simultaneously. Two or more frequencies are then encoded in the FID of an indirect dimension and some means to disentangle the information is necessary. This approach, termed “reduced dimensionality”, works best with spectra that exhibit simple signal patterns and a limited number of peaks and has thus been successfully used in combination with triple resonance spectra.

Multidimensional NMR in Structural Genomics

In the context of structural genomics projects the acquisition and analysis of NMR spectra of proteins in solution in a high throughput manner is required (8). Several approaches for an automated acquisition, data analysis and structure calculation have therefore been presented. The assignment of all proton, carbon and nitrogen resonances is almost exclusively performed using triple resonance experiments. Because of their relatively high sensitivity and their good intrinsic resolution, these experiments are well suited for an automated resonance assignment. The analysis of heteronuclear three- and four-dimensional NOESY spectra provides the distance information essential for structure determination. These spectra are difficult to analyze automatically because of the high amount of signal overlap and sophisticated algorithms have been developed to cope with this problem. It has been shown to be very efficient to supplement the distance information from NOESY spectra with orientational restraints from residual dipolar couplings. Using strategies for automated analysis of the spectra and automated structure calculation, the time for a protein structure determination is in the range of several weeks.

Multidrug Resistance

ULRIKE STEIN

Max-Delbrück-Center for Molecular Medicine, Berlin, Germany
ustein@mdc-berlin.de

Definition

Multidrug Resistance and Cancer

To date, treatment of most locally confined malignant tumors is based on surgical and radiotherapeutic approaches. For advanced and metastatic tumors, ►chemotherapy is the most effective treatment. However, clinical success has been observed to differ from patient to patient. Some patients are cured, others respond transiently and a third group show incomplete responses. Furthermore, clinical oncologists noted that cancer patients treated with multiple anticancer drugs developed cross-resistance to many other chemotherapeutics to which they had never been exposed. As a consequence, the possibility of curing these patients with chemotherapy is dramatically reduced. This phenomenon of the ability of a tumor cell to resist typically lethal or sublethal doses of multiple, usually cytotoxic drugs is called multidrug resistance (MDR) (1, 2). MDR is defined as simultaneous resistance to structurally and functionally unrelated natural product anticancer drugs. MDR may occur intrinsically without any treatment or may be acquired during therapy. To

date, MDR of human tumors to a variety of chemotherapeutic agents represents the major cause of failure of cancer chemotherapy. Therefore, the ability to understand MDR and thus predict, circumvent and overcome drug resistance is desirable for the improvement of chemotherapy.

Characteristics

Cellular Mechanisms of Drug Resistance

Multiple mechanisms of drug resistance may occur in parallel or sequentially, leading to intrinsic (without any treatment) or acquired (therapy-induced) resistance towards cytotoxic drugs. Anticancer drugs have different possibilities for entering the cell. Uptake of hydrophilic drugs into the cell depends on transporters, carriers or channels, since these drugs are not able to cross the cell membrane by themselves. Defects in drug uptake proteins lead to reduced influx, resulting in lowered intracellular drug concentration; the cell becomes resistant to a single drug. Natural anticancer products such as ►**anthracyclines** (doxorubicin, daunorubicin, epirubicin), ►**Vinca alkaloids** (vinblastine, vincristine), ►**podophyllotoxins** (etoposide, teniposide) and ►**taxanes** (paclitaxel, docetaxel) are hydrophobic and enter the cell by diffusion across the cell membrane. Resistance towards these drugs develops by increased drug efflux depending on the activity of efflux pumps, such as transmembrane energy (ATP)-dependent transporter proteins. Thus, intracellular drug concentration is reduced and the cell becomes resistant to a panel of hydrophobic drugs. Furthermore, activation of proteins that are involved in metabolism or detoxification of drugs may cause drug resistance without affecting drug accumulation. Intracellular drug redistribution, e.g. the nucleocytoplasmic drug transport by nuclear pores is reported to contribute to drug resistance. Moreover, cytostatics-induced activation of nuclear proteins such as mismatch repair genes involved in enhanced repair of drug-induced DNA damage may lead to drug resistance. Cells may also become resistant to drug-induced cell death by activation of anti-apoptotic proteins and by affecting the cell-cycle and checkpoints.

Multidrug Resistance and ABC Transporters

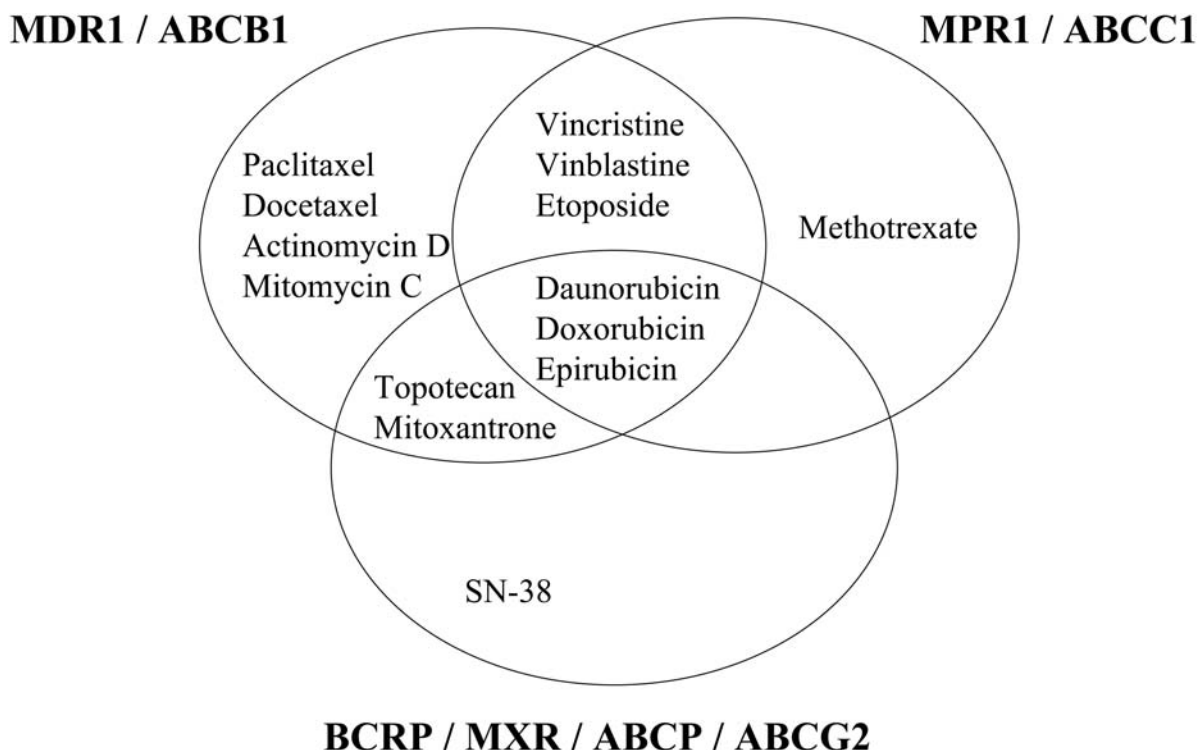

Thus, several mechanisms might be able to contribute to the drug resistance phenotype. However, within the last two decades one resistance mechanism was identified as very likely representing the most frequent cause of the development of MDR in cancer cells, the over-expression of ATP-dependent transporter proteins in the cell membrane acting as drug efflux pumps, thereby lowering the intracellular concentration of the cytotoxic drugs due to increased drug efflux. These drug efflux pumps belong to the intensively studied protein family of the transmembrane ►**ATP-binding**

cassette (ABC) transporters (3, 4). They transport multiple anticancer drugs such as anthracyclines, *Vinca* alkaloids, podophyllotoxins, taxanes, etc. out of the cell making it multidrug resistant. In the human genome, 48 ABC transporters have been identified so far. Based on sequence similarities – they share common features such as nucleotide binding sites and transmembrane domains – they have been classified (ABCA-ABCG). ABC transporters associated with the MDR phenotype are encoded by the following genes. The *multidrug resistance gene 1 (MDR1) alias ABCB1* encodes P-glycoprotein, causing the so-called classical, P-glycoprotein-mediated MDR, the genes for the *multidrug resistance-associated proteins 1-9 (MRP1-9) alias ABCC1-6 and ABCC10-12*, as well as the gene for the ►**breast cancer resistance protein (BCRP) alias ►ABC transporter** in placenta (ABCP) *alias* mitoxantrone-resistance protein (MXR) *alias* ABCG2, all lead to the so-called atypical, non-P-glycoprotein-mediated MDR. Their causal role in generation of the MDR phenotype was demonstrated for some of these MDR-associated ABC transporters, e.g. MDR1, MRP1 and BCRP; for others, their ability to transport multiple cytotoxic compounds was reported. Interestingly, the drug spectra of individual MDR-associated ABC transporters are, although overlapping, not identical (Fig. 1). Moreover, it has been shown for several transporters that their substrate specificities may vary due to defined point mutations within the MDR-associated genes.

Molecular Interactions

MDR1/P-Glycoprotein: Drug Transport, Gene Expression and Therapy-caused Induction

The ABCB subfamily of ABC transporters contains 11 members including the most prominent *MDR1* gene, which was first described more than two decades ago. *MDR1*/P-glycoprotein was the first cloned human ABC transporter for which the generation of the MDR phenotype was shown directly by gene transduction. The *MDR1* gene encodes P-glycoprotein, a drug efflux pump with two nucleotide binding sites and two transmembrane domains each consisting of 12 membrane spanning α -helical regions and believed to determine the substrate specificity of the drug transported. P-glycoprotein is able to bind a wide spectrum of hydrophobic, neutral or positively charged substrates, such as anthracyclines, *Vinca* alkaloids, podophyllotoxins and taxanes. After binding the drug, ATP hydrolysis leads to conformational changes in the protein as an essential prerequisite for the release of the substrate from the cell. A second ATP hydrolysis is necessary for resetting of the transporter molecule. *MDR1* gene expression has been analyzed in an enormous number of studies. High expression levels

Multidrug Resistance. Figure 1 Selected chemotherapeutic drugs which are substrates for a single or multiple multidrug resistance-associated ABC transporters MDR1 / ABCB1, MRP1 / ABCC1 and BCRP / MXR / ABCP / ABCG2 (from references 1–5).

have been repeatedly detected in normal tissues with excretory or secretory functions. In tumors of these tissues, such as colon, kidney, adrenocortical and hepatocellular cancers, over-expression of this protein has also been demonstrated. This is a major reason for the limited selection of chemotherapeutics for tumors of these organs. Moreover, for a variety of tumor entities, such as breast cancer, bone and soft tissue sarcomas and non-solid cancers, e.g. acute myelogenous leukemia, *MDR1* expression levels and treatment-caused inductions have been correlated to clinical outcome.

Furthermore, besides the basal expression levels of the P-glycoprotein, external factors such as components of multimodal cancer therapy are able to induce the expression of the *MDR1* gene. Thus, cytostatics, but also heat or radiation, may lead to elevation of *MDR1* gene expression. Several studies have shown, that in approximately 50% of all treated tumors inductions of *MDR1* expression have been observed. By identification of the *MDR1* gene promoter and generation of promoter deletion mutants thereof, drug responsive elements and heat responsive elements have been identified, mediating therapy-caused stress signals into transcriptional activation of the *MDR1* gene. This is in agreement with chemotherapy- or

hyperthermia-induced elevations of *MDR1* gene expression that have been detected in patients.

The MRP Family: Drug-Transport and Clinical Implications

The ABCC subfamily of ABC transporters consists of 12 members with 9 *MRP*-related genes (MRP1–9). The most studied member MRP1 was identified more than a decade ago in a non-P-glycoprotein expressing, but multidrug resistant human tumor cell line. MRP1 is structurally similar to P-glycoprotein, however, with an amino terminal extension of 5 membrane spanning α -helical regions. Like MRP1, MRP2, MRP3 and MRP6 also harbor these extra amino terminal transmembrane regions as compared with P-glycoprotein. The spectrum of hydrophobic natural anticancer drugs transported overlaps with those transported by P-glycoprotein and also includes compounds of anthracyclines, *Vinca* alkaloids and podophyllotoxins. Like P-glycoprotein, the substrate specificity of MRP1 and MRP2 is altered by single amino acid substitutions within the transporter proteins. However, the mechanism of drug transport is different. These MRPs transport anionic and neutral drugs conjugated to acidic ligands, such as glutathione, glucuronate or

sulfate. Alternatively, they can cause resistance to neutral drugs without conjugation but by co-transporting these drugs with free glutathione. MRP4, MRP5 as well as MRP7 lack the additional helical regions, but show higher sequence similarities to MRP1 than to P-glycoprotein or other ABC transporters. Both MRP4 and MRP5 are also organic anion transporters like MRP1, 2 and 3, which have been shown to pump nucleotide analogues.

The causal role for *MRP1* in conferring the MDR phenotype to previously chemosensitive cells has been shown by gene transduction. Basal expressions of *MRP1* have been found to be ubiquitous in human tissues and basal *MRP1* expression levels have also been found in almost all malignant tissues analyzed. However, the clinical importance of *MRP1* is still a matter of discussion. Studies have both confirmed and rejected a correlation of outcome and *MRP1* expression. However, for several tumor entities, correlations of high *MRP1* expression with clinical outcome parameters, such as response to chemotherapy and disease-free survival, have been reported, e.g. in mammary, lung and ovarian carcinomas, as well as for leukemias. In refractory hematological malignancies, increases in *MRP1* have been observed.

BCRP/ABCP/MXR/ABCG2: a Half-Transporter

The breast cancer resistance protein (BCRP) or ABC transporter in placenta (ABCP) or mitoxantrone-resistance protein (MXR) was originally identified in a mitoxantrone-resistant, but P-glycoprotein and MRP1-negative human carcinoma cell line and was named differently due to its almost simultaneous discovery by 3 independent groups. This gene, now named *ABCG2*, also encodes an ABC transporter and, together with 5 additional members, makes up the ABCG subfamily. This so-called “half-transporter” harbors only one nucleotide binding site and only one transmembrane domain with 6 membrane spanning α -helices regions, whereas “full-transporters” such as P-glycoprotein and the MRPs contain 2 nucleotide binding sites and 2 transmembrane domains, suggesting ABCG2 homodimerization may be required to gain full transport activity. Transduction of *ABCG2* cDNA caused the resistance phenotype. The drug spectra of ABCG2 considerably overlap with those of P-glycoprotein, including mitoxantrone, topotecan and doxorubicin, with however, differing efficiencies. ABCG2 showed high affinities for mitoxantrone, thus representing the long sought transporter for this cytotoxic compound. Defined point mutations leading to amino acid substitutions affect substrate specificity. However, other typical P-glycoprotein substrates, such as vincristine and taxanes, are not included in the ABCG2 drug spectrum.

ABCG2 has been mainly detected in human tissues such as placenta, colon, mamma and liver. So far, in human tumors, *ABCG2* expression has been most frequently found in carcinomas of the digestive tract, lung carcinomas and melanomas. Its clinical relevance remains to be elucidated.

Regulatory Mechanisms

Reversal of MDR

Failure of cancer chemotherapy is most of all linked to basal and/or induced expression of P-glycoprotein. Thus, the inhibition of P-glycoprotein in order to aim at reversal of the MDR phenotype has been extensively studied for more than two decades. Several approaches have been made to target the function and the expression of MDR-associated genes and proteins, such as the employment of specific antibodies, inhibiting the drug transport, the introduction of antisense oligonucleotides and ribozymes or, one of the newest developments, the transduction of small interference RNA molecules. However, the most promising attempts to reverse the MDR phenotype have been made with inhibitory compounds targeting P-glycoprotein function (5).

MDR Modulators of the First, Second and Third Generations

Numerous approaches have been made with so-called first-generation ►MDR modulators of P-glycoprotein. These are antagonists that have already been used for other purposes. First-generation modulators are themselves substrates for P-glycoprotein and compete with the cytotoxic drug for binding and efflux by the P-glycoprotein pump thereby limiting the efflux of the drug. As a consequence, intracellular drug concentrations increase, leading to elevated cytotoxicity; the cell becomes chemosensitive. These modulators worked with great success on cultured cells to overcome MDR. In the clinic, they produced disappointing results, due to the requirement for extremely high modulator concentrations to reverse MDR, which caused unacceptable toxicity. Furthermore, these modulators are not exclusively transported by P-glycoprotein, resulting in unpredictable pharmacokinetic interactions when coadministered with the drug.

►Second-generation MDR modulators were generated with the aim of specifically overcoming the P-glycoprotein-mediated resistance. Compared with first-generation modulators, they showed less toxicity and greater potency for inhibition of P-glycoprotein. Clinical trials have demonstrated that administration of second-generation modulators together with the anticancer drug may lead to reversal of the MDR phenotype when treating refractory cancers. However, as seen with the early modulators, some limitations such as

unacceptable toxicity and interaction with additional transporter molecules could not be avoided.

Thus, ►[third-generation MDR modulators](#) were developed, based on structure-activity relationships. These newly generated compounds inhibit P-glycoprotein more specifically and with greater potency and do not usually interact with other transporter molecules. They are not substrates for a defined ABC transporter themselves as are first- and second-generation modulators. Modulators of the third-generation bind noncompetitively to the pump thereby causing conformational changes in the transporter protein that hinder ATP hydrolysis. Consequently, drug transport out of the cell is prevented, leading to increased intracellular concentration of the cytotoxic drug and enhanced cytotoxicity. Moreover, it has been demonstrated for several of these newly created modulators that the pharmacokinetics of classical MDR-associated drugs, such as doxorubicin, vincristine, etoposide and paclitaxel, were not affected in patients. Based on these data obtained with the third-generation modulators, MDR of cancer cells might represent a potentially surmountable obstacle to improved chemotherapy. If the mechanisms of resistance can be overcome, the spectrum of conventional agents and of treatable tumor entities will certainly be extended.

Multidrug Resistance - Associated Protein 1

Definition

Multidrug resistance-associated protein 1 (MRP1), alias ABCC1, belongs to the ABC transporter family, subfamily ABCC (16p13.1). It is an integral membrane protein of 1531 amino acids, acting as an energy-dependent drug efflux pump responsible for decreased drug accumulation in multidrug resistant cells. Additional MDR-related family members are MRP2–9, alias ABCC1–6 and ABCC10–12.

Multidrug Resistance Gene 1

Definition

Multidrug resistance gene 1 (*MDR1*), alias ABCB1, belongs to the ABC transporter family as the most prominent member, subfamily ABCB (7q21.1), encoding the gene product P-glycoprotein. It is an integral membrane protein of 1280 amino acids, acting as an energy-dependent drug efflux pump responsible for

Multifactorial Threshold

Definition

According to the multifactorial threshold model (or MF/T), the occurrence of a phenotype depends on a very large number of genes (each of equal minor and additive effect) and on environmental factors. An accumulation of these genes and environmental factors is tolerated, e.g. by the developing fetus to a point

termed the threshold beyond which there is the risk of malformation.

Multiple Endocrine Neoplasia Type 1

Definition

Multiple endocrine neoplasia type 1 (MEN1) is an autosomal predisposition to combinations of parathyroid tumors, pancreatic islet cell tumors, and pituitary hyperplasia or tumor formation. Other endocrine and non-endocrine neoplasias can be involved but with a lower frequency. It is an autosomal dominant disorder, but it may also occur sporadically as a result of new mutations. Synonym: Wermer's syndrome.

Multiple Sclerosis

Definition

Multiple sclerosis is a demyelinating disease of the human central nervous system.

► [Genetic Predisposition to Multiple Sclerosis](#)

Multiple Sequence Alignment

Definition

Multiple sequence alignments are computational alignments of three or more peptide sequences, such that conserved regions or patterns like the dominance of hydrophobic residues etc. are highlighted. Alignment is thus helpful for protein structure prediction. Sequence alignment also enables the inference of the evolutionary history of the sequences.

Multi-Wavelength Anomalous Diffraction

Definition

Multi-wavelength anomalous diffraction denotes a method to determine the diffraction phases in protein crystallography, from several data-sets that are measured at two or more wavelengths near the absorption edge of natural or artificially incorporated anomalous scatterers. A tunable radiation source (synchrotron) is required for recording high anomalous and dispersive signals from the scatterer. The method allows determination of macromolecule structures of up to 200,000 M_r .

Definition

The main function of muscle is to contract, i.e. to generate force and to shorten, thus producing work and heat. Contractions can be isometric (force generation without shortening) or isotonic (shortening at constant load/force generation). According to their appearance in the light microscope, there are cross-striated muscle (skeletal muscle and cardiac) and smooth muscle types.

Characteristics

Roughly 40% of the body mass is skeletal muscle, another 10% smooth and cardiac muscle. Skeletal muscle is made up of muscle fiber bundles, which consist of muscle fibers (around 50 μm in diameter) and up to 12cm length. A muscle fiber consists of a plasma membrane (sarcolemma, with regular invaginations called the T-tubuli), an endoplasmic reticulum (sarcoplasmic reticulum consisting of longitudinal and terminal cisternae storing large amounts of Ca^{2+} , which

communicate with the T-tubuli, thus forming “triades”) and **myofibrils** (tubular cross-striated structures around 1 μm in diameter extending along the whole length of the muscle fiber). The sarcolemma is stabilized by the dystrophin-glycoprotein complex (DGC). The DGC consists of a cytoplasmic syntrophin complex, a transmembrane sarcoglycan complex, a transmembrane/extracellular dystroglycan complex (which binds to the extracellular matrix proteins laminin and agrin at the neuromuscular junction) and the huge cytoplasmic rod-shaped protein dystrophin (utrophin at the neuromuscular junction), which is linked to cytoskeletal actin and the myofibrils. Myofibrils mainly consist of longitudinally arranged contractile thin filaments (polymerized g-actin molecules, around 1 μm in length and 50 nm thick), thick filaments (polymerized Type II myosin molecules, around 1.6 μm in length and 100 nm thick), filaments made of titin and nebulin and vertically arranged Z- and M-lines (Fig. 1). The distance between the Z-lines is called a sarcomere and has a length of 2–2.4 μm in the resting muscle. The actin filaments anchor in the Z-lines, the myosin filaments locate within the sarcomeres vertically interconnected by a central M-line. Titin filaments connect Z- and M-lines (therefore called connectin), while nebulin filaments are tightly bound to the thin filament. Hence, the myofibrils show regions with high birefringence where thick and thin filaments overlap (“A-bands”) and low birefringence with no overlap (“I-bands” generated by actin filaments and “H-bands” generated by thick filaments) (Fig. 1). Besides, 7 vertically arranged N-lines in the I-band, and

Muscle Contraction. Figure 1 Structure of the myofibril. Top: Electron microscopy; Bottom: Schematic representation. Please note the fibrillar structure of the contractile apparatus, which is organized in sarcomeres in series. Actin (thin) filaments are anchored into the Z-line, while myosin (thick) filaments are fixed by a M-line in the middle of the sarcomere. The A-band corresponds to the overlapping region of thick and thin filaments. The I band corresponds to the non-overlapping region of actin filaments. The H-zone corresponds to the non-overlapping regions of the myosin filaments.

9 C-zones stripes made of protein C, -H, and -X with 43 nm spacing in the A-band exist in the sarcomer. The thin filament is associated with filamentous tropomyosin (35 nm length) and troponin complexes each composed of troponins I, C and T with an axial repeat of 38.5 nm. The Z-line with its characteristic zigzag structure is mainly composed of globular alpha-actinin, but contains many more structural and regulatory proteins. The M-band appears in longitudinal sections as a set of 3–5 prominent stripes spaced at about 22 nm axial intervals. The main non-myosin proteins of the M-band are a muscle-specific creatine kinase, M-protein and myomesin. ▶**Type II myosin** (myosin) is the motor protein of all muscle types. It is a hexamer composed of two heavy chains (MHC) and 4 light chains MLC (regulatory and essential MLC) (Fig. 2). The heavy chains (200 kD each) consist of a 150 nm alpha-helical C-terminal rod, which associates to form the thick filaments and a pear-shaped 20 nm N-terminal head domain with the ATP and actin binding sites and a converter domain (motor domain). The MLCs (16–28 kD) bind at the alpha-helical rod/head junction, the neck domain, which functions as a lever arm to amplify rotational movements of the converter domain during ATP hydrolysis (1). The thick filaments are of opposite polarity with the tails of the myosin molecules pointing

towards the center of the filament. The myosin heads project from the thick filament except for a 0.15 μm bare zone, where there are only overlapping myosin tails. Each thick filament contains about 300 myosin molecules. The heads project from the thick filament forming a helical array with a periodicity of 42.9 nm and an axial interval of 14.3 nm. Actin is a 5.5 nm globular protein (g-actin, 42 kD) with ATP bound. It polymerizes under physiological conditions to a filamentous structure (f-actin) with 13 actin molecules (with ADP bound) arranged on left-handed turns with a 36 nm crossover repeat.

Regulatory Mechanisms

Mechanochemical Energy Transformation

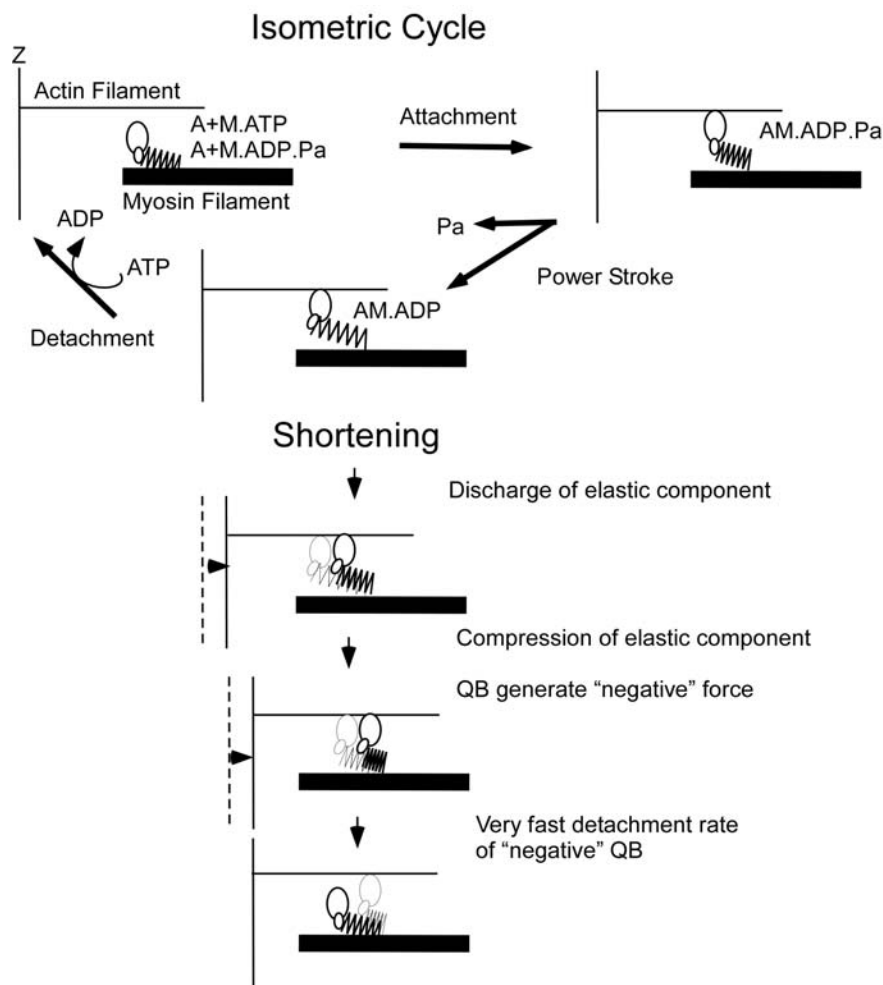

Muscle contracts by the relative sliding of thick and thin filaments (2). Thus the distance between Z-lines, the sarcomere, decreases during shortening. The sliding force is generated by the pear-shaped motor domain of the myosin molecules, which bind as the “▶cross-bridges” to the thin filament. Mechanochemical energy transformation is performed by a cyclic interaction of the cross-bridges with actin, in which cross-bridges bind, generate force upon a conformational change (the power stroke) and detach from the thick filaments (3). Each cycle is driven by the

Muscle Contraction. Figure 2 Structure of myosin. Top: Scheme of the native myosin molecule. The carboxyterminus (C) of the myosin molecule is an alpha-helical coiled coil 150 nm long, while the N-terminus (N) is the pear-shaped 17 nm motor domain. Bottom: 3D structure of the head portion of myosin (1). See text for details.

hydrolysis of 1 ATP molecule at the catalytic site of the myosin cross-bridge (Fig. 3). The ATP bound to myosin (M.ATP) is hydrolyzed very fast to ADP and Pi (M.ADP.Pi), which stick to the catalytic domain. M.ADP.Pi may bind to actin, initially in a pre-force generating state (AM.ADP.Pi). Actin accelerates the releases of Pi from the cross-bridge, which is associated with an increase in actin affinity and the power stroke of the cross-bridge. The power stroke is executed by a conformational change in the elastic lever arm of the myosin molecule of roughly 10 nm (1). Detachment of the force-generating cross-bridge from the actin filament is achieved by the release of ADP and the binding of ATP, which reduces the actin affinity of the cross-bridge. In the absence of ATP, the cross-bridges remain bound to the actin filament in a specific

force-generating conformation, the **rigor** (AM) state. In muscle, ADP release from the AM.ADP complex is the slowest (rate-limiting) step, which enables the cross-bridges to accumulate in force-generating states with high actin affinity. The isometric force of muscle contraction (F) during steady state therefore depends on the number of cross-bridges in the force-generating state and the force a cross-bridge can exert (F' , 1–4 pN). During activation, there is always a fraction of the total cycling cross-bridges (N) in force generating, and another in non-force generating states (Fig. 3). The fraction of force-generating cross-bridges “n” depends on the rate of cross-bridge detachment “g” and the rate of attachment “f”, namely $n = f/(f + g)$ (3). Thus F equals $F = F' \times N \times f/(f + g)$. The force of muscle contraction therefore also depends on the overlap

Muscle Contraction. Figure 3 Scheme of mechanochemical energy transformation during isometric force production and shortening due to a quick release. For simplicity, part of a sarcomere is shown with one Z-line, actin filament, myosin filament and a single cross-bridge with an elastic component. See text for details. A, actin; M, myosin; ATP, adenosine triphosphate; ADP, adenosine diphosphate; Pi, inorganic phosphate.

between thick and thin filaments. Furthermore, the kinetics of cross-bridge cycling and hence the fraction of cross-bridges in the force-generating state can be varied by the expression of genes coding for different myosin isoenzymes.

If an isometric contracting muscle is allowed to shorten quickly (in less than 1 ms, “quick release”), there is an instantaneous fall in tension, due to the discharge of the elastic element of the force-generating cross-bridges (Fig. 3). A quick release of roughly 1% of muscle length at optimal overlap, which equals a step size of around 10 nm per half-sarcomere, causes a complete fall of isometric contraction to zero force. Larger release amplitudes cause the compression of the elastic spring component of the cross-bridges (Fig. 3), thus generating force in the reverse direction. The fraction of these “negative” cross-bridges increases, while that of positive cross-bridges decreases, with increasing shortening velocities. The decline in positive cross-bridges with increasing shortening velocities, which can be directly demonstrated by stretching a muscle with very small amplitudes (stiffness measurements) during isotonic shortening, could partially explain the hyperbolic force-velocity relationship of muscle contraction, i.e. the experience that a small load can be lifted faster than a big load. Hence, to allow fast shortening, the detachment rate of “negative” cross-bridges (“ g_2 ”) should be very much higher than the detachment rate “ g ” of positive cross-bridges during **isometric contraction**. As a consequence, the **maximal shortening velocity** V_{max} of a muscle depends on “ g_2 ”. Different V_{max} values of fast and slow muscles

types (see below) are partly due to distinct gene expression of myosin isoenzymes with higher and lower g_2 values.

The work that can be performed by the cross-bridges is around 22 kJ/mol cross-bridges. Since the free energy change of ATP splitting is about 50 kJ/mol, cross-bridges convert roughly one half of the free energy of ATP as work; one half is liberated as heat.

The passive elasticity of a muscle fiber, i.e. the tension generated upon stretch during rest, depends mainly on titin filaments, which have spring-like elements, in particular in the I-band region (Fig. 4). Furthermore, compression of titin spring elements during sarcomere shortening could provide the restoring force that sets the sarcomere length to resting levels if activation ceases.

Excitation-Contraction Coupling

Skeletal muscle fibers are innervated by large myelinated nerve fibers, the motor neurons that originate from the anterior horn of the spinal cord. Each nerve fiber branches many times and stimulates several muscle fibers by specific contacts, the motor end plates. Acetylcholine (ACh) secreted from the motor neuron binds to nicotinic ACh-receptors (ACh-gated non-specific cation channels) in the sarcoplasm, thus increasing the open-probability of its channel domain. Depolarization of the subsynaptic sarcolemma elicits an action potential, which has a duration of around 1–5 ms and a conduction velocity of around 3–5 m/s and spreads all over the sarcolemma. Specific L-type calcium channels, located mainly in the T-tubular

Muscle Contraction. Figure 4 Scheme of a sarcomere with three filaments in resting, stretched and shortened states. Please note the elastic spring in the I-band region of titin, which becomes distended or compressed during stretching or shortening respectively.

membrane of the sarcolemma, physically link calcium release channels (ryanodine receptors) inserted into the terminal cisternae of the SR. These L-type calcium channels mainly function as voltage sensors (but cf “The Heart” in this volume), which change their conformation in response to an action potential and, as a consequence of its direct interaction, increase the open-probability of the RyR. Large amounts of Ca^{2+} are then released from the SR into the myoplasm, increasing the free Ca^{2+} from around 10^{-7} M in the resting state to above 10^{-5} M at maximal contraction. This triggers muscle contraction by binding to troponin C. The subsequent conformational changes in the whole troponin-tropomyosin complex, associated with a change in the location of tropomyosin on the thin filament, turns the actin filament from an “off” into an “on” state that permits the force-generating interaction with the myosin cross-bridges and contraction (4).

A single action potential elicits a transient contraction (twitch) with low force, while increasing the stimulation frequency causes prolonged contraction, first unfused, later fused, tetani, which generate much higher contractile forces than twitch contractions. This phenomenon is based (i) on the different durations of action potentials and twitch-time and (ii) on the much higher myoplasmic free Ca^{2+} reached during tetanic, as compared to twitch, contractions.

EC-coupling in smooth muscle differs from that in striated muscle types. Although a rise of free Ca^{2+} also triggers smooth muscle contraction, the Ca^{2+} receptor is calmodulin rather than troponin C. The Ca^{2+} -calmodulin complex activates myosin light chain kinase (MLCK), which specifically phosphorylates the 20 kD myosin light chain of smooth muscle myosin. Phosphorylation of the 20 kD myosin light chain allows actin activation of the myosin cross-bridge, leading to cyclic actin interaction and contraction (5).

Skeletal muscle fiber types mature according to their innervation with fast (high firing frequency) or slow (low firing frequency) alpha-motor neurons during maturation and develop distinct contractile and energetic features. Thus slow-twitch fibers (long twitch time) have high concentrations of enzymes for oxidative energy metabolism, while fast-twitch fibers (short twitch time) have high glycolytic activities. They express different myosin isoenzymes with low and high ATPase activities respectively. Furthermore, fast fibers have higher fiber volumes of the T-system SR as well as a higher Ca^{2+} uptake rate by the SR than the slow fibers. Fast and slow muscle types have similar mechanical efficiencies of around 35%. The distinct firing pattern of fast and slow motor neurons causes different spatial and temporal changes in intracellular free Ca^{2+} , which may be transduced into distinct changes in gene transcription and fiber maturation.

Thus the level of calcineurin activation as well as the activation of the different multifunctional Ca^{2+} -calmodulin-dependent kinases depend on the temporal mode of muscle activation (6).

Clinical Relevance

Use and disuse of muscle cause hypertrophy and atrophy, which cause increase and decrease in muscle strength respectively. Stimulation of the expression of insulin-growth factor-1 (IGF-1) and its paracrine/autocrine release upon increased muscle work, as well as the calcineurin-NFAT pathway, turned out to be important in skeletal muscle (7).

Hereditary muscle diseases comprise myotonic and dystrophic diseases (8). In particular mutations of the Na^+ and Cl^- channels cause myotonic syndromes. Mutations of the genes coding for β -myosin heavy chain, tropomyosin and nebulin are associated with central core disease and nemaline myopathy respectively. Myotonic dystrophy is associated with a trinucleotide (CTG) repeat on chromosome 19 coding for a protein kinase. Mutations of genes coding for proteins of the dystrophin-glycoprotein complex are associated with several forms of muscle dystrophy (MD), e.g. Duchenne and Becker MD (dystrophin mutations), limb-girdle MD (sarcoglycan mutations), congenital MD and Emery-Dreifuss MD (laminin mutations). Mutations of the Ca^{2+} channel and the ryanodine receptor are associated with malignant hyperthermia. Deterioration of the nicotinic acetylcholine receptor – by mutations or autoantibodies – causes myasthenic syndromes. Disorders of glycogenolysis, e.g. McArdle’s and Tarui’s diseases are caused by mutation of glycogen phosphorylase and phosphofructokinase, respectively.

Muscle Development

HANS-HENNING ARNOLD

Cell and Molecular Biology, Technical University of Braunschweig, Braunschweig, Germany
h.arnold@tu-bs.de

Definition

This essay focuses on development of the skeletal musculature in vertebrates and disregards the formation of other muscles, such as the ►myocardium and smooth muscles, as they follow entirely different developmental strategies. Specification of distinct cell types during embryogenesis is usually triggered by signals from adjacent tissues leading to a cascade of gene activations that ultimately generate the differentiated cellular phenotype. Development of the skeletal musculature conforms to this scheme and constitutes a paradigm for molecular mechanisms underlying ►lineage determination of cells as a first step and their entrance into the specific ►differentiation programme as a second step. Formation of skeletal muscle involves myogenic ►commitment of distinct mesodermal cell populations to generate proliferating myoblasts which eventually withdraw from the ►cell cycle, switch on the expression of muscle-specific genes, as for instance those of the contractile apparatus, and fuse into large multinucleated myotubes or fibers, the functional units of muscle. Cell culture models have been established which allow the study of both the commitment and the differentiation of muscle cells *in vitro*. A gene family encoding four myogenic regulatory factors (MRFs) is essential to control the recruitment of progenitor cells to the myogenic fate as well as their subsequent differentiation into contractile muscle fibers. The MRFs, referred to as Myf5, myogenin, Mrf4 and MyoD, are ►transcription factors of the ►basic helix-loop-helix type, which are expressed specifically in the muscle-forming regions of the embryo with overlapping but distinct spatiotemporal expression profiles. Genetically altered mouse models have helped to determine the developmental roles of individual MRF genes and other important factors in myogenesis.

Characteristics

All Skeletal Muscles are Derived from Defined Mesodermal Progenitor Cell Populations in the Vertebrate Embryo

The skeletal musculature, although subdivided into multiple individual muscles, constitutes by far the largest organ in the body. In vertebrates, most skeletal muscles including those of the trunk, limbs, tongue,

and ►diaphragm are derived from somites which are transient embryonic structures generated from unsegmented ►paraxial mesoderm on both sides of the ►neural tube in ►rostrocaudal sequence by progressive segmentation into epithelialized tissue blocks (Fig. 1). Head muscles, such as the jaw muscles, arise from paraxial head mesoderm and prechordal mesoderm. The myogenic precursors of facial muscles are initially present in the ►branchial arches. Shortly after somite formation, the ventral half of somites transforms to the mesenchymal sclerotome which gives rise to the axial skeleton of the vertebral column and ribs. The dorsal part of somites, adjacent to the surface ectoderm, develops the dermomyotome harboring progenitor cells for skeletal muscle and dermis. Beginning in cranial somites (at embryonic day 8.0 in the mouse embryo) and subsequently proceeding along the body axis, cells of the dermomyotome segregate first from the dorsomedial lip (adjacent to the dorsal neural tube) and somewhat later also from the ventrolateral lip to form the myotome underneath the still epithelial dermatome (Fig. 1). Although the myotome, the first differentiated skeletal muscle in the embryo, appears to be a homogeneous cell layer with no obvious histological distinction, it is clearly patterned along its dorso-ventral axis. While the dorsal myotome, frequently referred to as the epaxial myotome, later develops into the intrinsic back muscles, the ventral, hypaxial myotome grows into the somitic bud, which contributes the progenitors of intercostal and ventral body wall muscles. In somites at limb levels muscle progenitor cells delaminate from the ventral (hypaxial) dermomyotome and migrate to the limb buds providing the muscle masses for arms and legs. Migratory muscle precursors also delaminate from occipital/cervical somites to form the ►hypoglossal cord, which contributes to tongue and pharyngeal muscles and possibly to the diaphragm. Most of this information has been obtained from avian embryos but a growing body of evidence supports the notion that the same principles apply to myogenesis during mammalian development (for review, see 1). In summary, primary myogenesis in the vertebrate embryo is initiated in three distinct territories, the branchial arches, somites and limb buds in a defined temporal sequence (Fig. 2). Following the formation of skeletal muscle in the embryo, further growth and functional maturation of muscle fibers ensues during secondary myogenesis in the fetus by recruitment and differentiation of committed myoblasts. Innervation of muscles by motor nerves also occurs during this developmental period and contributes to the specification of ►slow and fast muscle fiber types. Postnatally, enlargement and regeneration of the skeletal musculature involves ►satellite cells, a population of myogenic stem cells that resides under the basal lamina of muscle fibers in a quiescent state,

Muscle Development. Figure 1 Schematic representation of somite development. Removal of surface ectoderm reveals the consecutive steps of somitogenesis. Note that the most differentiated somite consisting of mesenchymal sclerotome, myotome (in red), and epithelial dermomyotome is the oldest at the anterior end, while the paraxial mesoderm at the posterior end is still unsegmented. First myotomal cells appear at the dorsomedial lip.

until they are activated through signals evoked by muscle activity or tissue damage.

Molecular Interactions

The MRF Family of Four Basic Helix-Loop-Helix Transcription Factors Dictates Skeletal Muscle Development

Skeletal muscle development requires the coordinated expression of numerous transcription factors but the myogenic regulatory factors (MRFs) are particularly important and play key roles in directing mesodermal progenitor cells to the myogenic lineage and mediating their subsequent differentiation into contractile muscle (for review, see 2). The potent myogenic activity of all four MRFs was first recognized when they were introduced individually into a variety of non-muscle cells thereby converting these cells to the muscle phenotype in an astonishingly dominant fashion. *In vivo*, however, the roles of individual MRFs in myogenesis appear to be more refined. While Myf5 and MyoD are absolutely essential to specify myoblasts from mesodermal progenitors, the two other members of this transcription factor family, myogenin and Mrf4, are necessary for differentiation of myoblasts. This has been concluded from [targeted gene disruptions](#) of individual MRF genes in mice and from pair wise

combinations in double mutant mice. During embryogenesis, Myf5 is the first of the MRF proteins to be expressed in branchial arches and somites, followed 0.5 and 1 day later by myogenin and Mrf4, respectively. MyoD expression in somites starts approximately 2.5 days after Myf5. Expression of all MRFs is progressively down-regulated during fetal muscle development and ceases postnatally with the exception of Mrf4, which increases in the fetus and persists in adult skeletal muscles. Consistent with these temporal patterns, Myf5-deficient mice fail to form myotomes, lack muscle precursor cells, and do not activate the downstream MRF genes, *myogenin* and *Mrf4*. Interestingly, MyoD expression starts at the correct developmental time in head and limbs and somewhat late in somites of *Myf5* mutants. Embryonic myogenesis proceeds almost normally from this point onwards. This suggests that MyoD can also recruit mesodermal cells to the muscle fate in a Myf5-independent pathway. In line with this apparent [genetic redundancy](#), double mutants lacking both Myf5 and MyoD are completely unable to develop any skeletal muscle precursor cells. In these double mutant embryos, cells that switch on the *Myf5* gene (without making the protein) and would normally be destined to become muscle are misplaced into adjacent territories and take on alternative fates,

Muscle Development. Figure 2 The skeletal muscle-forming regions in the mouse embryo marked by β -galactosidase activity (blue) from a *Myf5-nlacZ* transgene. (a) Myogenic cells are seen in branchial arches (ba) and myotomes (m) of a mouse embryo at embryonic day 9.5. (b) At day 12.5 myogenic cells are also present in fore (fl)- and hindlimbs (hl), and in hypoglossal cord (hc). The asterisks denote regions of ectopic transgene activity in head mesenchyme.

such as cartilage or dermis. These observations clearly indicate the unique roles of *Myf5* and *MyoD* genes in muscle cell determination, which is further supported by the demonstrated capability of both transcription factors to remodel [chromatin](#) and open up gene loci that will be transcribed during differentiation. In contrast to *Myf5* and *MyoD*, the *myogenin* gene is not required for the determination of muscle precursor cells but it is necessary for the differentiation of myoblasts. Mouse mutants lacking myogenin accumulate myoblasts in all muscle forming regions of the embryo but these cells fail to undergo fusion and do not express muscle-specific genes, such as those of the [sarcomeres](#). Although some evidence suggests that *Mrf4* is also involved in the terminal differentiation of myoblasts, its precise function in muscle development is not clear due to complicating cis-effects on the adjacent *Myf5* gene in all three available *Mrf4* mutant alleles. In particular, *Mrf4* gene function in postnatal muscle cannot be assessed in these mouse mutants as they usually die at birth. The fact that *Myf5* and *MyoD*

are expressed in undifferentiated but committed myoblasts, whereas myogenin and *Mrf4* expression only starts with the onset of differentiation or later (*Mrf4*) is entirely consistent with the genetic evidence for their respective roles in muscle development.

Members of the Myocyte Enhancer Factor 2 (MEF2) Family of Transcription Factors Collaborate with MRFs in Myoblast Differentiation

In order to activate the transcription of downstream target genes, all MRFs form heterodimers by combining with a related class of basic-helix-loop-helix transcription factors that are present in almost every cell type including myoblasts. These heterodimeric complexes then bind to a distinct DNA sequence motif, the so-called E-box, present in control regions of many muscle-specific genes, and activate their transcription. Interestingly, E-boxes are not only present in muscle genes but also in others which are not transcribed in muscle, raising the question as to how selective transactivation might be achieved. At least part of the specificity for muscle genes appears to be associated with a conserved peptide motif within the helix-loop-helix domain of MRFs that is required for the combinatorial function of MRFs with members of the MEF2 family in activating transcription and myogenesis (3). Indeed, MEF2 factors are essential for muscle differentiation in *Drosophila* as well as in mouse and the majority of skeletal muscle genes depend on both MRF and MEF2 family members for activation. Consistent with this notion, muscle-specific enhancers frequently contain E-boxes and MEF2-binding sites in close proximity allowing for cooperative interactions of the bound protein complexes. It is reasonable to assume that MRFs can also recruit MEF2 factors to the enhancer in the absence of a MEF2 DNA binding site and *vice versa*, since both proteins have been shown to form complexes *via* direct protein-protein interactions. Undoubtedly, formation of myoblasts and the correct execution of the complete differentiation programme of muscle cells involves multiple transcription factors in addition to MEF2 and MRF family members, but the available evidence strongly suggests that these proteins are absolutely crucial in a cascade of events that ultimately results in the fully functional skeletal muscle cell. In particular *Myf5* and *MyoD*, possibly in a parallel pathway, appear to act at the nodal point where the prospective myogenic fate of mesodermal progenitor cells is to be decided. It is interesting to note that the same players responsible for myogenesis in the embryo are reactivated in satellite cells, when these stem cells are challenged to make new muscle in the adult. It should also be mentioned that the transcription factors involved are subject to molecular modifications by several signaling pathways, which regulate their biological activity in various physiological and

pathological conditions, such as muscle aging, regeneration and hypertrophy (4).

Regulatory Mechanisms

The Transcriptional Circuitry Underlying Skeletal Muscle Development

The highly conserved structure of the four MRF proteins not only argues for a common ancestral gene but also for their similar, albeit not identical, biochemical properties and biological activities as transcription factors. Indeed, replacing the coding exons of the *myogenin* gene by the *Mrf4* coding sequence restores myoblast fusion indicating that Mrf4 protein can compensate for the loss of myogenin, if expressed at the correct developmental time and location. This then implies that the decision where and when muscle develops in the embryo is at least in part determined by the distinct spatial and temporal expression patterns of individual MRFs rather than by their intrinsic biochemical differences. Although precise molecular mechanisms of MRF gene regulations are not clear, cis-acting control elements are beginning to emerge. Since Myf5 functions at the top of the myogenic cascade marking the initiation of skeletal muscle development in the embryo and during muscle regeneration in the adult, its regulation represents the decisive step for myogenesis. *Myf5* and *Mrf4* genes are closely linked in one genetic locus and key regulatory elements are widely dispersed in a modular fashion over 140 kb of sequence. The complex set of control elements orchestrates Myf5 expression in various phases at each site of myogenesis under the influence of signals produced by adjacent tissues and reveals an unexpected heterogeneity of myogenic precursor cell populations. This heterogeneity in origin may be related to physiological differences of muscle groups in the adult organism and their differential susceptibility to myopathies. Distinct enhancers for Myf5 expression in branchial arches, limb buds and different domains in somites have been identified, but most cognate transcription factors are still unknown (5 and references therein). The early epaxial enhancer driving the earliest, transient wave of Myf5 expression in the epaxial dermomyotome contains a binding-site for the transcription factor Gli that mediates regulation by the sonic hedgehog (Shh) signal emanating from the notochord and floorplate. This is the first example of direct signal integration in *Myf5* gene expression and muscle development and supports the notion that axial structures (notochord and neural tube) are necessary for epaxial myogenesis, as shown by surgical removal in the chicken embryo. *Wnt* signals produced in the neural tube and dorsal surface ectoderm also promote myogenesis and have been implicated as positive regulators of Myf5 and MyoD

expression. BMP signals produced in lateral plate mesoderm inhibit MRF expression and may help to delimit the lateral border of skeletal muscle formation.

The *myogenin* gene appears to be a direct target of Myf5 consistent with a cascade model of sequential MRF gene activation. In addition to Myf5, MEF2 family members and the homeobox transcription factors *sine oculis* (*Six1* and *4*) are also required for correct spatiotemporal myogenin expression. Essential binding sites for these transcription factors are present in the promoter proximal region of the *myogenin* gene. Following the initial activation, myogenin probably stabilizes the differentiated muscle phenotype by maintaining its own expression and further stimulating expression of MEF2. Circumstantial evidence suggests that the *Mrf4* gene may also be controlled directly or indirectly by Myf5 and/or MyoD.

The *MyoD* gene is regulated by two collaborating enhancers located approximately 5 and 20 kb upstream of the promoter. Several essential E-box consensus binding sites have been identified within the core enhancer sequence, one of which seems to specifically mediate Myf5-dependent expression of MyoD in somites. Interestingly, in mouse double mutants lacking both Myf5 and the transcription factor Pax3 that is expressed in the dermomyotome, *MyoD* is not activated in somites and muscles are missing in the trunk. This is in contrast to single mutations in either *Myf5* or *Pax3*, which do not prevent MyoD expression. These observations provide evidence that *Pax3* and *Myf5* define two distinct myogenic pathways in somites and *MyoD* acts genetically downstream of these genes. However, no Pax3 binding sites have yet been detected in the *MyoD* gene enhancers suggesting that Pax3 action may be indirect. Alternatively, deficiency of Pax3 might affect cell proliferation, survival, or short-range migration, which may lead to loss of the myogenic progenitor cell population.

Myogenic Determination Occurs Independently in Somites and Limb Buds

Skeletal muscle development in the limbs differs from that in trunk considerably (for review, see 6). While most muscles of the body develop from the myotome, the muscle groups in limbs derive from the lateral dermomyotome and do not go through the myotomal intermediate. These myogenic progenitors delaminate from the epithelial dermomyotome and migrate as single cells into the limb buds without expressing Myf5 or MyoD until they have reached their destination in the limb mesenchyme. This independent regulation of MRF expression reflects distinct enhancer activities, which have been identified approximately 60 and 20 kb upstream of the *Myf5* and *MyoD* promoters,

respectively. While BMPs and Shh signals present in limb buds have been shown to affect positioning, proliferation and differentiation of muscle precursor cells in limb buds, transcription factors, which may integrate these signals in MRF gene control, are still elusive. The homeobox transcription factors Lbx (related to ladybird in *Drosophila*) and Mox2, which have no role in the myotome, are expressed in the migratory progenitor cells and mutations of these genes strongly reduce or eliminate Myf5 expression and muscle development in limbs. MyoD expression in the appendages, however, is controlled neither by Mox2 nor by Myf5. In contrast to myotomal myogenesis, Pax3 is absolutely essential for muscle development in limbs. Its role here appears to be at least partly mediated by the tyrosine-kinase-receptor c-met, which together with its ligand scatter factor (SF) is essential for the release and migration of muscle progenitors from the dermomyotome. Later, Pax3 also seems to be involved in controlling the homeostasis between proliferation and differentiation of myoblasts, possibly in response to graded BMP signals. The requirement of FGF signaling for correct limb muscle differentiation has been appreciated recently. The regulatory influence of other signaling molecules that are expressed plentifully in limb buds must await further investigations. In conclusion, the elucidation of molecular details underlying muscle development constitutes a prime example of complex developmental strategies of cell type specification and organ development. Moreover, this knowledge may help to establish rational approaches to therapeutic intervention in muscle-wasting diseases.

Mutagenesis Approaches in Medaka

HIROYUKI TAKEDA

Department of Biological Sciences, Graduate School of Science, University of Tokyo, Tokyo, Japan
htakeda@biol.s.u-tokyo.ac.jp

Definition

Medaka, *Oryzias latipes* (order Beloniformes), is a small, egg-laying freshwater teleost fish (Fig. 1) found in brooks and rice paddies in eastern Asia, primarily in Japan. Breeding medaka in small basins has been one of the traditional hobbies in Japan, often seen in old Japanese prints known as Ukiyo-e of the Edo period (17th to 18th centuries). There has been a long history of medaka for culture and science in Japan (most information on medaka is found at the Medaka Fish Homepage, ►<http://biol1.bio.nagoya-u.ac.jp:8000/>).

Characteristics

The adult fish are about 3 cm long and the female lays a cluster of eggs (10–30 eggs) every day. The embryos develop externally, and the embryos and chorions are transparent. Thus, the phenotype of the mutants can be easily evaluated. The embryos hatch 7 days after fertilization at 25°C and they grow to sexual maturity in 2–2.5 months. These biological features, shared by zebrafish, have made the medaka a suitable model animal, particularly for developmental biology and genetics. There are several advantages of medaka over the commonly used zebrafish. First, the medaka genome is relatively smaller in size (800–1000 Mb), only one-third of the human genome and less than half

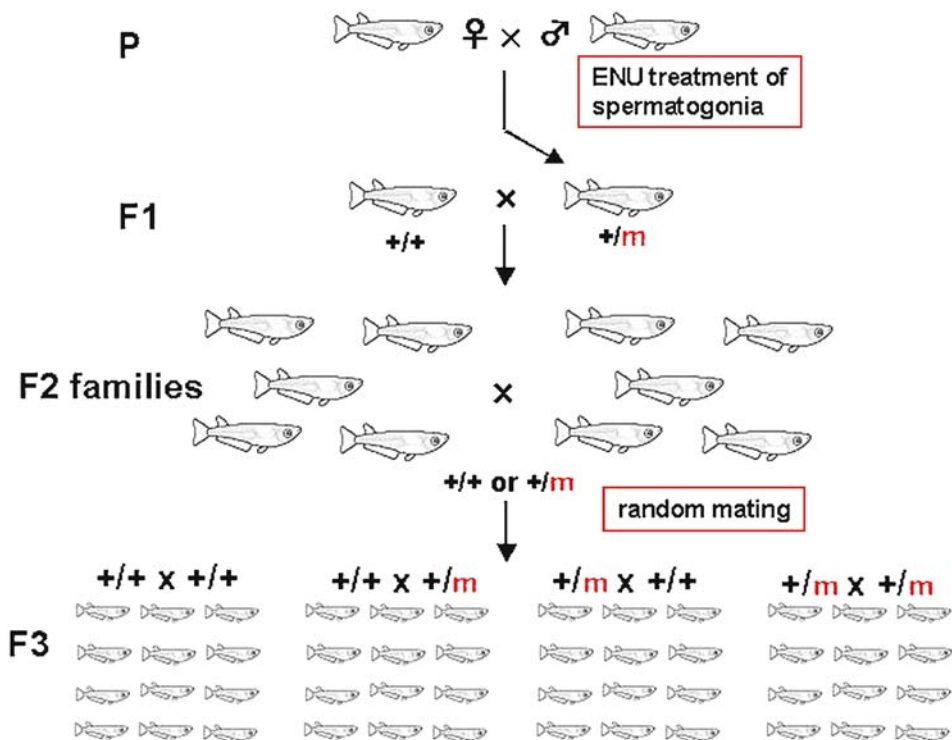

Mutagenesis Approaches in Medaka. Figure 1 Adult medaka. Female of orange-red variety with fertilized eggs. A cluster of eggs remains attached to the belly of the female for some hours after spawning at dawn. A photograph is a courtesy of Drs. Kiyoshi Naruse and Kenichi Ijiri (University of Tokyo).

the size of the zebrafish genome. Second, there are highly polymorphic ►[inbred strains](#) available in medaka, which can be used for mutagenesis screening and genetic mapping. Finally, unlike zebrafish (tropical fish), medaka (temperate fish) embryos can develop at wider range of temperature, 6–40°C, which facilitates isolation of ►[temperature-sensitive mutants](#).

Early comparative analysis revealed a genome-wide gene duplication in the ancestry of teleosts during evolution. Indeed, zebrafish and medaka have seven ►[hox clusters](#) while mouse has four. It has been thought that gene duplication could play a vital role in providing new genetic material for natural selection to act upon. Duplicated genes have been subjected to non-functionalization, neo-functionalization and sub-functionalization, providing a great genetic diversity in fish species. From the evolutionary point of view, zebrafish, closely related to carp, is a relatively old fish, 110–160 million years apart from the modern fish, medaka. Considering this long evolutionary distance between the two fish, one would expect that medaka and zebrafish would have a different repertoire of genes, and thus a different spectrum of mutant phenotypes would be obtained. Together with recent development of genomic resources (see below), the medaka becomes an attractive model system complementary to zebrafish. For a recent review, see (1).

Mutagenesis Approaches

The genetic screen is a means to completely analyze the genome, but based primarily on phenotype rather than sequence. The ability to perform genetic screens is one of the main reasons for using teleost fishes as vertebrate models. Early work on medaka has identified more than 90 spontaneous mutants, most of which were collected by Dr. Hideo Tomita and kept at the Laboratory of Freshwater Fish Stocks, Bioscience Center, Nagoya University (►<http://biol1.bio.nagoya-u.ac.jp:8000/mutant.html>). They are mostly pigmentation mutants. However, some organ-specific mutants are included, such as *pectoral fin-less* (*pl*), *eyeless* (*el*) and *double anal fin* (*Da*, a homozygous adult with ventralized caudal structures in the dorsal region) (2). In addition to spontaneous mutants, mutagenesis screens using ►[ENU](#) (N-nitroso-N-ethyl urea) or X-rays followed by three-generation crosses were carried out recently, in the expectation of novel mutants not found in zebrafish (3, 4). As with zebrafish, in mutagenesis screens, male fish mutagenized with ENU or X-rays were outcrossed to wild type females and the F1 offspring were used to establish F2 families. F2 siblings were intercrossed and the F3 progeny were scored at certain stages after fertilization for morphological alterations (Fig. 2). For the induction of

Mutagenesis Approaches in Medaka. Figure 2 Family inbreeding scheme for mutagenesis screening. Males mutagenized with ENU are used to produce F1 carriers. These are intercrossed to produce F2 families. Crosses between F2 siblings produce F3 clutches that can be screened for a new phenotype. Homozygosity for newly induced mutations occurs in 1/4 of the embryos in 1/4 of the F3 crosses.

mutations affecting single genes, chemical mutagens are generally preferred over X-rays. X-rays result in large deletions or chromosomal rearrangements and induce recoverable mutations at a much lower rate than ENU. Furthermore, ENU, which induces point mutations, offers the possibility of hypomorphic mutations in addition to complete null mutations, which might be useful for functional analysis of genes of interest. The mutagenesis rate using ENU is very high, around 1×10^{-3} . Thus, for most of the screens, ENU mutagenesis is the method of choice. Loosli et al (4) first reported the systemic mutagenesis approach to isolate embryonic-lethal developmental mutants in medaka, focusing on eye and brain phenotypes. In any screens reported so far, ENU induced mutations were recovered efficiently in medaka, suggesting that medaka, as well as zebrafish, is a suitable vertebrate for mutagenesis approaches. As expected, some of the medaka mutants exhibit phenotypes similar to those recovered from zebrafish screens. However, some, such as *Da*, *kepke* (the trunk and tail fail to develop) (1) and *headfish* (similar to *kepke*, Fig. 3), are remarkably different,

indicating a non-overlapping spectrum of embryonic mutant phenotypes between medaka and zebrafish.

Inbred Medaka Strains

The first step towards identifying genes responsible for mutant phenotypes involves the establishment of linkages between the mutated locus and a polymorphic marker. The wild populations of the medaka in Japan are divided into two major genetic groups, the northern and southern populations. The two populations are different in many morphological, behavioral and genetic characteristics. In spite of these, they normally cross and produce hybrid offspring. Sequencing comparisons of orthologous loci revealed ▶single nucleotide polymorphisms (SNPs) between the two populations at a frequency of 1% in ▶exons and 3% in ▶introns. Considering the 1–2% difference between human and ape, the SNPs between the two medaka populations are quite high. So far, twelve inbred medaka strains from various origins including wild populations have been established, e.g. HNI and Kaga from the northern populations and Hd-rR, Cab and

Mutagenesis Approaches in Medaka. Figure 3 Medaka tail-less mutant, *headfish* (*fdf*). Dorsal views of 9-day *wild type* and *fdf* embryos are shown. In *fdf*, the trunk and tail fail to development, which has not been reported in any zebrafish mutants.

AA2 from the southern populations. Unlike zebrafish, most of the medaka inbred lines are highly fertile and can be used for mutagenesis screening. Furthermore, since the inbred lines are highly polymorphic to those derived from other populations, they are extremely useful for genetic mapping of genes and mutants. Most of the inbred strains, produced by Dr. Hyodo Taguchi, have been maintained at the National Institute of Radiological Sciences (3) ([▶http://biol1.bio.nagoya-u.ac.jp:8000/RadMut.html](http://biol1.bio.nagoya-u.ac.jp:8000/RadMut.html)).

Large-Scale Analyses of mRNAs

The [▶expression sequence tag](#) (EST) approach is powerful in massive cloning of cDNAs as well as in large-scale characterization of cDNA sequences for functional genomics. Several groups have attempted large-scale isolation of ESTs from medaka embryos, adult, liver, ovary and so on. At March 2003, about 100,000 entries of medaka ESTs can be found in public databases. Some of the ESTs are being mapped to the [▶linkage map](#) and *in situ* hybridization screening with isolated ESTs is also underway ([▶http://medaka.lab.nig.ac.jp](http://medaka.lab.nig.ac.jp); [▶http://www.embl-heidelberg.de/mepd](http://www.embl-heidelberg.de/mepd)).

Linkage Map and Positional Cloning

Genetic linkage maps are very effective tools for identification of mutant responsible genes and for

comparative and evolutionary genomics. Usually, markers used for linkage maps are phenotypic traits, ESTs, [▶random amplification of polymorphic DNA markers](#) (RAPDs), [▶amplified fragment length polymorphic markers](#) (AFLPs) and [▶microsatellite markers](#). A medaka linkage map first described by Aida (1921) (5) demonstrated that the male-determining factor (Y locus) was linked with the gene controlling carotinoid deposition in [▶xanthophores](#) (R locus). In 2000, a detailed and genome-wide linkage map of medaka was constructed by the use of 633 markers (488 AFLPs, 28 RAPD markers and so on) (6). The linkage map utilized the high degree of polymorphism between the two inbred strains, AA2 and HNI, derived from southern and northern populations, respectively, and was constructed with a reference typing DNA panel from 39 cell lines derived from back cross progeny. The number of linkage groups was 24, which is the same as medaka's haploid chromosome number. Since markers in this linkage map are mostly derived from non-coding regions or anonymous, a large-scale mapping of randomly selected ESTs is now in progress. By the end of 2004, about 2,000 ESTs will be mapped onto the linkage map (K. Naruse and HT, a personal communication), and if the total genome size of medaka is 800 Mb, the estimated density of genetic markers would be around

470 kb per marker, which would provide reliable anchor points for ►positional cloning. Part of these mapping data is available at ►http://mbase.bioweb.ne.jp/~dclust/medaka_top.html. The data also demonstrate that there are large regions of ►conserved synteny between chromosomes of zebrafish, medaka and human (K. Naruse et al, a personal communication).

The detailed linkage map and high quality of BAC libraries that are prerequisite for identification of mutated genes are now available in the medaka system. Using these genetic resources, successful positional cloning for several spontaneous medaka mutants was reported in 2001. The first one was *b* locus; a mutation in *b* reduces melanin content in medaka and *b* turned out to encode a novel transporter protein that was also found in mouse (7). Second and third were *el* (eyeless) and *rs* (reduced scale) that encode the ►homeodomain protein Rx3 and the ectodysplasin-A receptor (EDAR), respectively (8, 9). More recently, the sex-determining region of the medaka Y chromosome has been positionally cloned (10). The region harbors a transcription factor, *DMY* that contains the highly conserved ►DM domain and plays a critical role in testis development. So far, *DMY* is the only gene identified as a non-mammalian counterpart of ►*Sry*, which is required for mammalian male development. Positional cloning of ENU-induced medaka mutants is now being carried out in several laboratories.

Genome Sequencing Project

To further promote mutant-based research and comparative genomics of medaka, a genome-sequencing project for medaka has started at the Academia Sequencing Center of the National Institute of Genetics (Mishima, Japan) in collaboration with the medaka research community. The project is supported by a Grant-in-Aid for Scientific Research on Priority Areas "Genome Science" from the Ministry of Education, Culture, Sports, Science and Technology of Japan. The strain for sequencing is a southern inbred strain, Hd-rR, and sequencing is being conducted by the whole-genome shotgun strategy. By May 2005, there was a 10× coverage of sequences completed (►<http://medaka.utgenome.org/>). In parallel, end sequencing of BAC clones and construction of BAC contig and mapping of SNPs and ESTs onto the linkage map are now underway in several laboratories in Japan and Germany (►<http://medaka.dsp.jst.go.jp/MGI/>). Hopefully, in the near future, all these data will be integrated to produce a high quality draft sequence of the medaka genome.

Clinical Relevance

It is already clear that fish orthologs exist for most human genomes and that there are large regions of conserved synteny between fish and human. Furthermore, unlike *Drosophila* and *C. elegans*, fish has all of the tissues (except for lung) afflicted by common human diseases and fish organs are functionally and morphologically similar to those of the human. As compared with targeting of genes for disruption in mice, ENU-induced mutations in fish are more relevant to human disease, because ENU often causes partial loss-of-function or hypomorphic mutations. Many common human diseases are not due to null mutations. Therefore, it is hoped that mutagenesis approaches in fish might unveil mechanisms and pathways directly relevant to human diseases and therapy. In fact, in mutagenesis screens of medaka, many organ-specific mutants (e.g. heart, liver, thyroid and so on) are being recovered (3, 4; HT, a personal communication; see also (11)). With the growing pool of medaka genomic resources that should facilitate rapid identification of the candidate genes, these medaka mutants could serve as good models for human diseases.

Mutagenesis Approaches in the Zebrafish

ALEXANDER GRUNDT, WOLFGANG ROTTBAUER
University Clinic Heidelberg, Inner Medicine III,
Heidelberg, Germany
wolfgang.rottbauer@med.uni-heidelberg.de

Definitions

► **Mutagenesis** is defined as a directed or random alteration in DNA at a specific site in the genome of an organism, to study the mutation's effect on organ morphology or function. Different mutagenesis approaches such as chemical, insertional and irradiation induced mutagenesis, have been used successfully for functional genome analysis in zebrafish.

Significant progress has been made over the last decade in sequencing the genomes of several vertebrates, including human, mouse, and zebrafish. In parallel, new approaches have been developed for elucidating the function of all genes in the genomes. The ► **genetic screen** is a tool to completely analyze the genome, but based principally on ► **phenotype** rather than sequence. By identifying unitary defects associated with ► **mutations**, and in a manner complete enough to reflect a large proportion of all genes involved in the target process, the screen can provide the logical elements of a complex biological process.

There are two opposing concepts for characterizing gene functions namely “reverse” and “forward” genetics. The idea of reverse genetics is to identify gene functions (phenotypes) by genetically manipulating known genes using transgenesis, gene “knock-out” and gene “knock-in” targeting techniques. In contrast, in forward genetic screens phenotypes are induced by random mutagenesis first, and then the gene mutation causing the phenotype is identified by ► **positional cloning** or ► **gene trap** approaches.

Characteristics

Large-scale forward genetic screens have been one of the most efficient methods for identifying novel genes and pathways controlling the development of embryonic form and function and inherited diseases. The first genetic saturation screens based on phenotypes have been performed in invertebrate model systems such as *Caenorhabditis elegans* and *Drosophila melanogaster*, resulting in an impressively large number of newly identified genes and pathways essential for fundamental processes in biology. Initially, in vertebrates such as *Mus musculus*, only small-scale screens were performed, since the number of animals that must

be raised, maintained and screened to achieve saturation in a screen is some millions. This problem has been solved by the successful use of zebrafish (*Danio rerio*) as a vertebrate model system. Because of its small size (from about 3 cm) and modest character the zebrafish can be easily managed in large numbers in laboratory environment. Several advantages, such as a short generation time of only three months and the fact that mature females lay hundreds of eggs at weekly intervals, mean that zebrafish are particularly suitable for genetic studies. The externally fertilized zebrafish embryos allow unobstructed access to the researcher and develop extraordinarily rapidly. Furthermore, simple visual screening of the synchronously developing and optically clear zebrafish embryos in the first 5 days after fertilization can reveal essential mutations in the development of most of the major organ systems. In addition, mutations can be induced highly efficiently throughout the zebrafish genome. So far, many small-scale forward screens and two large-scale screens have been carried out in zebrafish leading to the isolation of hundreds of unique and organ-specific phenotypes. Together, the two large-scale Boston and Tübingen screens (1, 2), starting from about 300 ► **ENU** (N-ethyl-N-nitrosourea) treated founder males, involved raising more than 5,000 F₂ families and analyzing more than 6,000 mutagenized genomes and selected more than 2,000 ► **recessively** inherited new development mutants for characterization. Today, basically three different approaches are used for forward genetic screens in zebrafish, ► **ENU mutagenesis**, ► **insertional mutagenesis** and irradiation mutagenesis. Reverse genetic screens in zebrafish were started recently.

ENU Mutagenesis Screens

Most of the zebrafish large-scale forward genetic screens were performed with the chemical mutagen N-ethyl-N-nitrosourea (ENU), which induces genome-wide ► **point mutations** in pre-meiotic ► **germ cells** (spermatogonia) in a random pattern. ENU transfers ethyl groups to O⁶-guanine, O⁴-thymine, N³-adenine and the PO₄-backbone of DNA. The repair of mismatches during replication and transcription resulting from lost H-bonds and steric interferences can lead to the exchange of the non-alkylated base, resulting usually in hundreds of point mutations throughout the targeted genome. To achieve an optimal ratio of mutagenicity to toxicity in zebrafish, several pre-screens have been performed, varying ENU concentrations and incubation times and using four different pigmentation loci as markers for the mutagenicity. In the most efficient protocol, adult male fish are mutagenized by exposing them three times for one hour periods within one week to 3 mM ENU in water. The estimated frequency of independent mutations per locus per gamete is $0.9\text{--}1.3 \times 10^{-3}$ and 2.1×10^{-6} per

base pair (bp) per gamete. In other words, about 1300 mutagenized genomes must be analyzed for one locus (gene) to find one mutation induced by ENU. Three weeks after ENU treatment, males are crossed to wild type females at weekly intervals and the progeny (F_1 founder) originating from mutagenized pre-meiotic germ cells are raised. The F_1 founder males are crossed again to wild type females. A random sibling cross of the F_2 progeny leads to 25% ▶**homozygous** wild type embryos, 50% ▶**heterozygous** embryos and 25% homozygous mutant embryos for each point mutation induced by ENU (Fig. 1A) (1, 2).

Haploid Screens

Phenotype detection of a recessive allele within a F_3 generation requires many crosses in F_2 families. To avoid the cumbersome step of screening thousands of progeny for recessive mutations in conventional F_2 screens (Fig. 1A), methods have been devised to uncover recessive alleles in a single generation by exploiting the ability to create ▶**haploid** or homozygous ▶**diploid** zebrafish embryos suitable for genetic screening. Zebrafish can live up to 3 days post-fertilization as haploid organisms. Recessive alleles in F_1 fish are therefore exposed within a generation, streamlining the screens for both size and time. In a haploid screen, female F_1 fish (derived from the cross between a wild type female and an ENU-mutagenized male) are squeezed gently to release their eggs, which are fertilized with ultraviolet (UV)-treated sperm to generate haploid embryos. UV treatment breaks down the parental DNA, without affecting the ability of sperm to activate eggs. A haploid clutch derived from a heterozygous female will contain 50% mutant and 50% wild-type embryos (Fig. 1B). The disadvantage of this approach is the induction of abnormal phenotypes in embryonic development usually on the second day post-fertilization, due to the single set of chromosomes rather than an ENU induced point mutation. Although haploids have the same body plan as diploids, they are shorter, contain more and smaller cells than diploids and can have other morphological defects that may complicate screening.

Homozygous Diploid Screens Using Early Pressure or Heat Shock Treatment

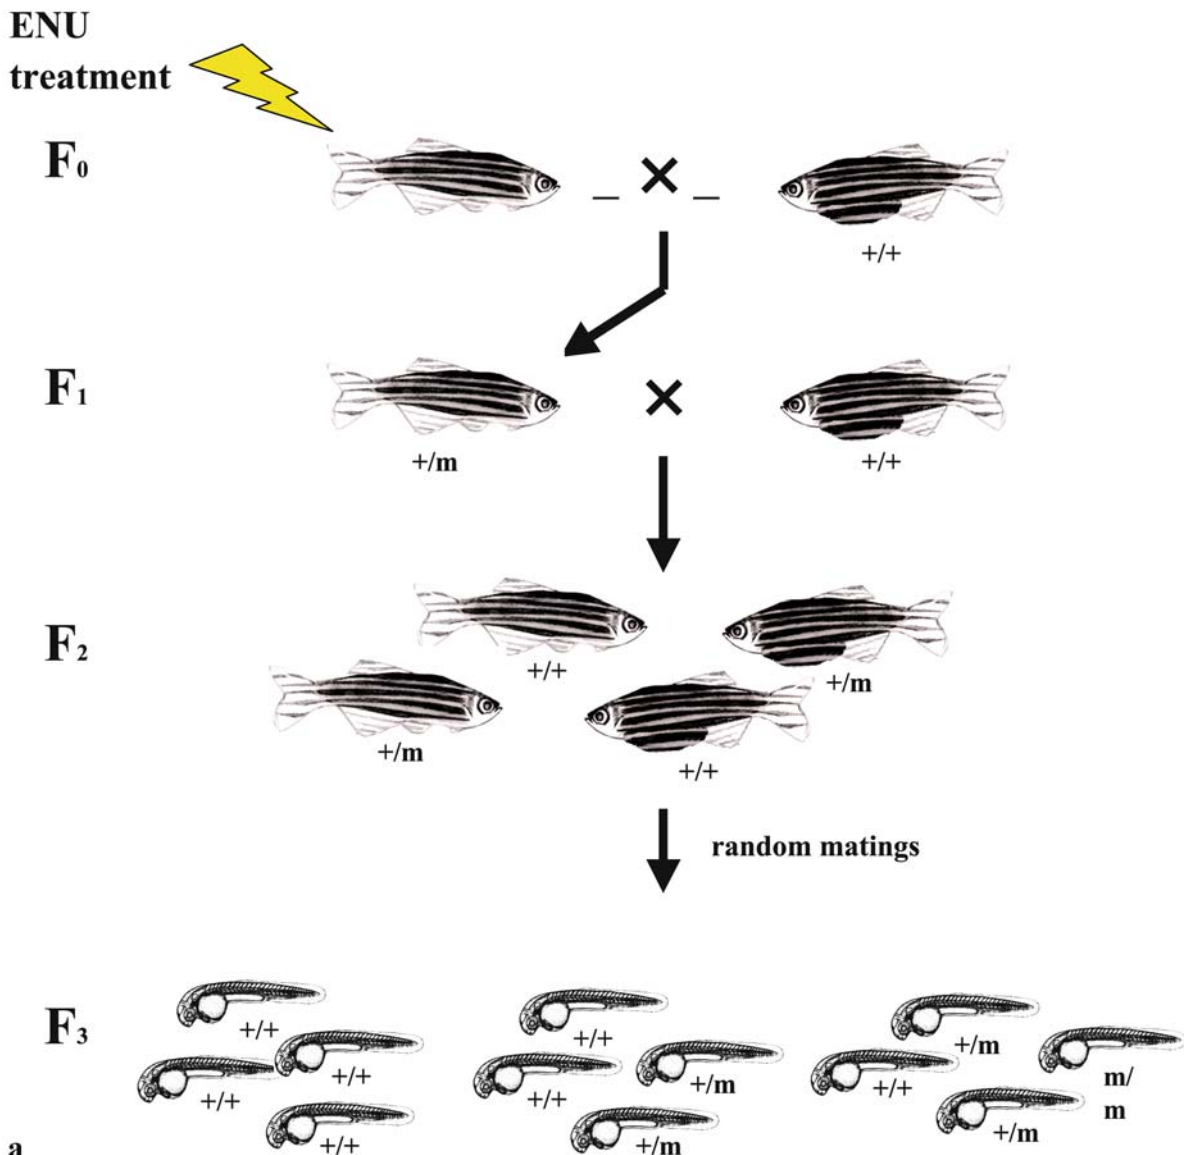

Eggs extracted from a female have completed meiosis I (the separation of homologous chromosomes) during ovulation, and initiate meiosis II (the separation of sister chromatids) on fertilization. ▶**Early pressure** (EP) applied to embryos a few minutes post-fertilization breaks down the meiotic spindle and the egg maintains both sister chromatids. Subsequently, eggs undergo their first mitosis as diploids, with two sets of maternal chromosomes. By contrast, ▶**heat-shock** (HS) treatment of eggs during the first cell-cycle inhibits the

first mitotic division. Eggs activated with UV-treated sperm enter the first mitotic division as haploids, abort mitosis by HS and enter the second mitotic division directly as diploids. In meiosis, recombination and chiasma interference occur between homologous chromosomes during alignment as tetrads. Because of this, there is on average one single crossover event per chromosome arm. Therefore, embryos that are derived from EP treatment will be homozygous for loci that are proximal to the crossover event that occurred at meiosis I and heterozygous for loci that are distal to it. Similar to haploid clutches, a gynogenetic diploid clutch that is derived from a heterozygous female and generated by HS will contain 50% mutant and 50% wild type embryos. However, in contrast to EP treatment, embryos generated by HS are homozygous at all loci. Therefore, they would be preferable to embryos generated by EP for use in genetic screens. However, embryos generated by HS usually have a poor viability of 10–20%.

Mosaic Screens

Standard ENU mutagenesis involves mutagenizing pre-meiotic germ cells in adult males, then keeping these fish for several weeks to fix the mutation through several rounds of DNA replication before the development of mature sperm cells. As ENU alkylates the bases on only one DNA strand, mutations in the ENU-treated post-meiotic germ cells become fixed only during cell divisions after fertilization. Therefore, if the mutagenized males are bred immediately or early after exposure to ENU, the resulting F_1 generation will be genetically ▶**mosaic** for numerous ENU induced mutations, increasing the efficiency of identifying specific mutations due to an estimated tenfold greater mutational load in the mosaic F_1 generation. It is thought, that mosaic fish are able to carry a greater mutational load than non-mosaic heterozygous fish, because wild type cells within all tissues compensate for the heterozygous mutant cells. However, several mutations in haploid embryos and the unpredictable phenotypic representation within a clutch can complicate screening and allele recovery in mosaic screens. If the F_1 females are mosaic, a variable proportion of the F_2 haploid embryos are mutant (Fig. 1C). The exact number of mutant embryos depends upon the proportion of the F_1 germ-line cells that is heterozygous for the mutation. Nonetheless, mosaic screening has proven to be a robust and rapid method to identify several unique cardiac mutations (3).

Over the last decade, ENU saturation mutagenesis has proven to be one of the most efficient tools for forward genetics in zebrafish, revealing at least 2000 unique genes required for proper embryonic development. Several of these mutated genes have already been cloned, which assists in the dissection of the gene

Mutagenesis Approaches in the Zebrafish. Figure 1 ENU based crossing schemes to breed homozygous mutant zebrafish. (a) The classical three generation breeding scheme. ENU treated males are crossed to wild type females. The F₁ males are also crossed to wild type females and the F₂ progeny paired with each other. In the F₃ generation, recessive mutations are revealed. m, mutation, +, wild-type. (b) Generation of haploids and gynogenetic diploids. ENU treated males are crossed to wild type females. Eggs from F₁ females are released by gently squeezing and fertilized with UV inactivated sperm resulting in haploid embryos. Treating the fertilized eggs in the one-cell-stage with hydrostatic pressure or exposing them to heat results in diploid embryos. (c) Mosaic screen. Zebrafish males are crossed to wild type females immediately or early after exposure to ENU, resulting in a F₁ generation that will be genetically mosaic for numerous ENU induced mutations. Eggs from F₁ females are released by squeezing and fertilized with UV-inactivated sperm. Since the F₁ females are mosaic, a variable proportion of the F₂ haploid embryos will be mutant, depending upon the proportion of the F₁ germ-line cells that is heterozygous for the mutation.

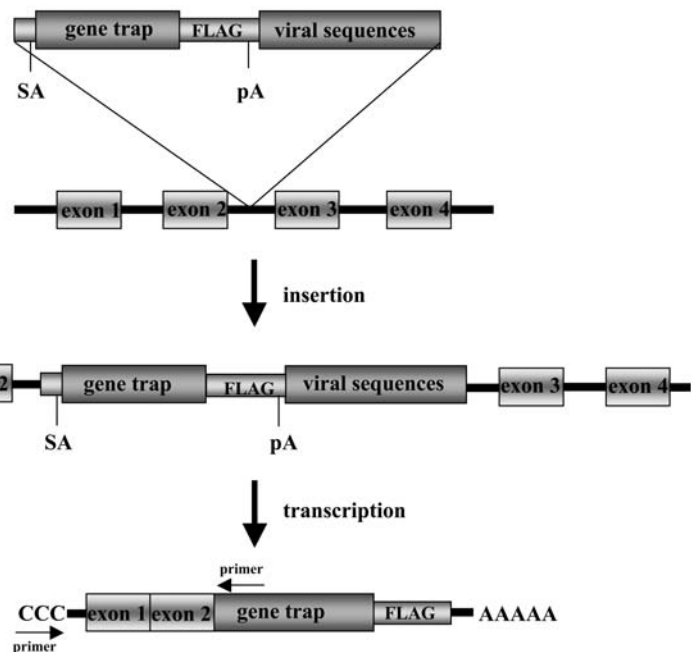

gene trap targeting construct

gene before the insertion

mutagenized gene

mRNA after insertion

Mutagenesis Approaches in the Zebrafish. Figure 2 Insertional mutagenesis using a gene trap approach. The viral insertion construct includes a gene trap (GT) at the beginning of the vector. The GT contains a splicing acceptor element (SA), the sequences for FLAG epitopes in all reading frames and a polyadenylation element (pA) to stop the transcription. After successful insertion into intronic sequences, as well as proper transcription and mRNA splicing, the gene trap is fused to upstream exon sequence of the targeted gene. This exonic sequence can be recovered by PCR using a CCC-anchor and GT specific primers (displayed as arrows) in the 5'-RACE. Using an anti-FLAG antibody the tissue specific expression pattern of the targeted gene can be evaluated by whole-mount immunostaining of zebrafish embryos or Western blot analysis of defined tissues.

networks that control early development and disease. Positional cloning of mutations generated with ENU has been highly successful, although it remains very laborious and expensive. However, the development of an excellent genomic infrastructure, including several meiotic and radiation hybrid (RH) maps of the zebrafish genome, where thousands of simple sequence length polymorphisms (SSLPs) and expressed sequence tags (ESTs) have been mapped to the 25 zebrafish chromosomes, as well as the ongoing sequencing of the zebrafish genome by the Sanger Centre, UK greatly facilitate positional cloning efforts.

Insertional Mutagenesis Screens

An alternative approach to chemical mutagenesis is insertional mutagenesis using gene trap (GT) approaches. Viral DNA containing a GT construct is injected into zebrafish embryos and then integrates randomly into the genome, thereby disrupting expressed sequence and serving as an anchor for primers to identify the disrupted gene by cloning and sequencing. The GT, a short open reading frame or reporter gene such as β -galactosidase, placed at the beginning of the viral construct provides all important splicing

elements, such as splicing acceptor and pA-element, to fuse to the last **exon** upstream of the targeted **intron** (Fig. 2). Therefore, the resulting mRNA, consisting of residues of the targeted gene and the GT, can readily be cloned, sequenced and identified by 5'-rapid amplification of cDNA ends (5'-RACE). Using a GT with FLAG epitopes in all three reading frames, the tissue specific expression pattern of the targeted gene can be estimated using *in situ* hybridization or Western blot analysis.

At first, two Moloney murine leukemia virus (MLV) based pseudotyped viruses with envelopes containing the vesicular stomatitis virus (VSV) G-protein, SFG and NK, which are able to infect zebrafish cells and integrate stable proviral DNA into the zebrafish genome, were used to infect mouse 3T3 fibroblasts to get high titer virus stocks. The virus stocks (about 10^9 cfu/ml) were microinjected into zebrafish embryos at the 512-2048 cell stage. After 24 h 50–80% of the embryos survived. The majority of these grew to adulthood. To detect germ-line transmission of proviral DNA, the injected fish were mated and the F₁ progeny tested for the presence of proviral sequences by PCR. The percentage of transgenic offspring from the

mosaic SFG founders was on average 24% and from NK founders 13%. The SFG founders transmit on average eleven proviral ►insertions to their F₁ progeny. However, only about one in 85 proviral insertions inactivates a gene essential for embryonic development. Therefore, to improve the efficiency of large-scale insertional screens, fish with multiple insertions were used to identify developmental mutation. For this purpose a new viral construct with a unidirectional VSV G-pseudotyped SFG-nLacZ virus as backbone was developed and transiently transfected into zebrafish cell lines A7 and F5 by lipofection (7.5 µg pCMV-G and 50 µl Lipofectamine). Using virus stocks from the most efficient cell clones, the average number of proviral insertions in the surviving F₀ founders was up to 25 and the F₁ gametes contained eight or more insertions with a 57% survival rate after 2 days. About 96% of all gametes contained multiple insertions (4). In one large-scale viral insertion screen, nine recessive and two dominant embryonic lethal mutations were obtained from an estimated 760 insertions in 92 F₂ families. In contrast to ENU mutagenesis, the targeting efficiency using viral insertion is about nine times lower. However, the targeted genes can be identified quicker and more easily by inverse PCR or 5'-Race. Estimating the size of the zebrafish genome to be approximately 1.6×10^9 bp, about 500,000 randomly placed integrations have to be analyzed in a saturation screen. A screening of about 100,000 randomly placed integrations resulting in approximately 1000 essential loci is in progress since 1999 in the Nancy Hopkins Laboratory at the MIT, Boston, USA. (5)

Ionizing Radiation Mutagenesis Screens

The mutagen selected to manipulate the founder fish affects the number and types of mutations that are passed on to subsequent generations. As outlined above, ENU induces mainly point mutations throughout the whole genome, although the mutation frequency can vary widely between loci. Ethyl methane sulphonate (EMS), although a potent mutagen in *Drosophila*, is much less potent in zebrafish. Ionizing radiation, such as γ -rays and X-rays, also induce genetic alterations, which can vary from point mutations through large genomic ►deletions to translocation events. Large genomic deletions and translocations, however, can alter more than one gene and generate several phenotypes in a clutch of embryos, complicating a robust and reliable identification of genes and mutations associated with phenotypes and gene functions.

Earlier forward genetic screens in zebrafish used predominantly γ -irradiation as mutagen. In these small-scale screens, haploid mutant embryos derived

from heterozygous F₁ females crossed to UV-treated sperm were used to identify specific phenotypes. Although elegant in principle, as described above, haploid screens have the disadvantage that specific phenotypes caused by a single mutation must be recognized against a high background of retarded and often abnormally developing embryos after the second day post-fertilization. Altogether, less than 30 loci essential for embryonic development have been identified so far using irradiation screens in zebrafish (6).

Reverse Genetic Screens – Target Selected Mutagenesis

In reverse genetics, gene functions (phenotypes) are usually identified by genetically manipulating known genes using transgenesis, gene “knock-out” and gene “knock-in” targeting techniques. Another reverse genetic approach, now used in zebrafish is target-selected mutagenesis. In this approach, male zebrafish are ENU mutagenized and paired with wild type females. Frozen sperm and genomic DNA from several thousand heterozygous F₁ founders is then collected and cryo-preserved, providing a mutant library from which mutations of almost all zebrafish genes should be identifiable. Now these samples can be evaluated for heterozygous mutations in any gene of interest. Using the ENU mutagenesis protocol described above, recessive embryonic lethal mutations per locus occur at a frequency of one in 1600 mutagenized genomes, so that the cDNA of 1600 founders has to be analyzed to find one gene knockout mutation in the gene of interest. The method described was used successfully to identify mutations in the zebrafish *rag1* gene (7). With the establishment of this technology, the zebrafish is now the second vertebrate model organism in which reverse genetics can be applied on a large scale. The advantage of multiple alleles, including partial loss-of-function mutants, may establish target-selected mutagenesis as the preferred approach.

Clinical Relevance

Using forward large- and small-scale mutagenesis approaches in zebrafish thousands of unique phenotypes have been identified, resulting in more than a 1000 different genetic loci mutagenized, of which an impressive number have already been cloned and characterized. Improving the efficiency of insertional mutagenesis using better integration systems and of positional cloning by finishing the zebrafish genome sequencing project, the functional aspect of all estimated 35,000 vertebrate genes might be revealed in the near future. Many of the identified zebrafish mutants already serve as animal models for human genetic diseases.

Mutagenesis Approaches in Yeast

MICHAEL BREITENBACH, PETER LAUN
Department of Cell Biology, University of Salzburg,
Austria
michael.breitenbach@sbg.ac.at

Definition

The single-celled, free-living eukaryotic microorganism, *S. cerevisiae*, has been studied as a convenient model system for molecular biology and cell biology since the 1970s. It is hardly necessary to repeat here the advantages of the yeast system over many other biological model systems, such as an extremely short generation time, growth under many well-controlled conditions, well-researched metabolism, a detailed genetic map based on ►meiotic mapping and a fully developed sexual cycle, ease of transformation with plasmids and with foreign DNA, and so on. Yeast is perhaps the organism, in which the construction of ►knockout and ►knock-in mutations is most highly developed and most easily done. Based on these techniques, a huge number of advanced techniques for functional analysis of genes has been developed. All this became even more important when the first eukaryotic chromosome sequence (chromosome III of *S. cerevisiae*, (1) and the first eukaryotic genome sequence [that of *S. cerevisiae*, in April, 1996 (2)]

became known. It was relatively easy to annotate the yeast genome, as evidenced by the fact that a fully annotated yeast genome sequence was made publicly available shortly after sequencing was finished (2, 3). Problems remain, but they are minute compared to the problems of annotating the human genome. At the time of assembling and annotating the yeast genome sequence, more than half of the genes that were clearly recognizable were of unknown function, constituting a major challenge to the yeast community to analyze these unknown functions. Most surprisingly, many human genes that had been identified by the study of human hereditary disease, shared close homologs with yeast. Even several years later, with many more human “disease genes” discovered, still at least 40% of single-gene determinants of human heritable diseases find homologues in yeast (4). Given these facts, it is obvious why one would like to study these genes in yeast. It is possible to reveal functional data that are not easily obtained by the study of human cells and which could help to understand the ►pathomechanism of the disease, which is a prerequisite for any medical intervention. Examples will be given (see below and Table 1). However, this is not the only scenario in which the yeast system is useful. It is also possible to introduce authentic human genes (that have no yeast homologs) into yeast cells in order to study their behavior. A prominent example is huntingtin, another the apoptosis inducers of the bax family. And finally, we want to mention that the yeast system is also successfully being used to define virulence factors of fungal pathogens and drug targets that are needed to develop new antifungal antibiotics.

Characteristics

The roughly 6000 protein-encoding genes on the *S. cerevisiae* genome consist to a large degree of gene pairs, which are functionally redundant or have similar but slightly different functions, thus reflecting a gene duplication event that occurred relatively recently in evolutionary history. For this reason, the basic set of genes needed for a free-living single-celled organism is somewhat smaller than 6000. Roughly, the yeast genes can be divided into a large group of eukaryotic ►housekeeping genes defined as genes for which homologs are clearly recognizable in all eukaryotes for which genome sequences have been determined and a smaller group of fungi-specific genes, which are needed for the specific lifestyle of fungal organisms. Homologs of such genes are found in close relatives of *S. cerevisiae* that have been sequenced (*S. mikatae*, *S. bayanus*, *S. paradoxus*, *S. kudriavzevii*) or even in distantly related fungi (*S. pombe*), but not in plants or animals. Studying the non-coding regions of homologous genes in closely related species is a powerful tool for annotation that could also be applied to the

human genome once our closest biological relative, the chimpanzee, has been sequenced. This method is also a powerful tool to define functional regulatory motifs in the non-coding upstream regions of genes.

The disease gene homologs in the yeast genome obviously belong to the eukaryotic housekeeping genes. In many cases the disease-causing alleles are not nulls, but ►**hypomorphs**, as could be expected because the housekeeping genes often have vital functions.

The DNA repair pathways of eukaryotic cells are remarkably well conserved (despite some additional functional diversification in higher eukaryotes as compared to *E. coli* and *S. cerevisiae*) and their defects give rise to some interesting disease patterns. They will be mentioned only briefly because they are now general textbook knowledge. About ten years ago the eukaryotic ►**mismatch repair** pathway was elucidated by researchers studying repair in yeast and by human molecular geneticists studying the hereditary cancer predisposition HNPCC (hereditary non-polyposis colon cancer). These lines of research converged in a spectacular way. The human genes, *MSH2* and *MLH1*, were isolated by *positional cloning* based on family studies. They showed homology to the newly cloned yeast mismatch repair genes and the actual biochemical activity in mismatch repair was subsequently shown through yeast studies. Subsequent work yielded a coherent picture of the disease. Cancer predisposition is caused by the heterozygote state of the individual (therefore the pattern of inheritance is autosomal dominant, although the mutation is a loss of function mutation). The primary event causing cancer is the loss of heterozygosity at the locus involved which then leads to mutation accumulation in those cells and eventually to the cancer-causing mutations in human ►**proto-oncogenes** etc. Human mismatch repair recognizes frameshifts and short repeat elongation caused by slippage of DNA polymerase very well. This model nicely explains why the tumors, but not the patients present with an increase in ►**microsatellite** heterogeneities caused by un-repaired unstable repeats of tandem short nucleotide sequences. A very similar story could be told about nucleotide excision repair and the hereditary cancer predisposition and neurological diseases, Xeroderma pigmentosum (8 complementation groups) and Cockayne syndrome (2 complementation groups).

A large number of methods has been developed during the past 10 years, in particular in connection with the European and international joint effort to perform a genome wide functional analysis of yeast.

Part of this effort was to supply the yeast community with a collection of *bona fide* deletion mutants corresponding to all known yeast genes. This monumental task was accomplished by developing high-

throughput PCR methods for making precise deletions of the ORFs creating about 6000 heterozygous diploid deletion strains marked with ►*KanMX4* (G418 resistance) and with a “molecular barcode” (5). From the primary heterozygous deletion strains, haploids of both mating types (“sexes”) and the homozygous diploids were derived by classical meiotic analysis. In about 17% of the cases, the genes were haplo-lethal (“essential”) and the only strains available are the heterozygous diploids. On the other hand, haploinsufficiency on rich media (meaning that a heterozygous diploid would be unviable) is practically unknown in yeast, with the possible exception of the genes coding for the core histones. The huge collection of deletion strains is curated and is commercially available from EUROSCARF (►<http://www.uni-frankfurt.de/fb15/mikro/euroscarf/>). In addition, a set of cognate genes on plasmids and of disruption cassettes is available.

The bar codes are unique 20-mer sequences inserted together with *KanMX4*. One can apply selection of any kind to a mixture of all viable haploid deletion strains and analyze bulk DNA from the survivors on special microarrays containing the complementary barcodes. In this way, a relatively simple experiment can determine which genes on the yeast genome are needed for survival under certain conditions (e.g. heat shock), which is important functional information (5). About 600 strains that carry genes with affinity tags are available for the community, enabling researchers to purify and analyze large protein complexes by micro-bore HPLC/ion spray mass spectrometry. The global organization of metabolism (and its regulation) in many cases works through such large protein complexes (some of them larger than ribosomes!) and there can be little doubt that this is a general eukaryotic principle. The protein-protein interactions that build up the large protein complexes have also been mapped in a systematic way by applying various kinds of two-hybrid analyses.

Generally applicable methods have been developed to create useful conditional mutants for each essential gene of yeast. This is based on the bacterial tTA transactivator, which is expressed under the CMV promoter in yeast and by PCR-based insertional mutagenesis replacing part of the cognate promoter of the gene in question by the tetO₇-CYC1 hybrid promoter. Binding of the transactivator is abrogated by doxycycline so that gene expression can be titrated by adding doxycycline, which doesn't influence cellular metabolism at the concentration used, but switches off the target gene. A large number of phenotypic tests (limited only by the imagination of the experimenter) can be performed with the deletion mutants or with the conditional mutants just described. An indispensable part of functional analysis, which is generally applicable and easy to do, is the

determination of the intracellular location of the gene product. This is generally done by N-terminal or C-terminal GFP (green fluorescent protein) fusion and viewing the live cells under a laser-confocal microscope. Problems arising before the method optimally worked for yeast cells were overcome by creating several new forms of GFP by *in vitro* mutagenesis and by devising the appropriate yeast vectors that could express the fusion proteins from a plasmid or preferentially from a chromosomally integrated version. Quantum yield had to be improved by site-directed mutagenesis of this co-factor-independent naturally fluorescent protein, because it has been shown that many essential yeast proteins exist in the cell in only 1–10 copies whilst over-expression of the GFP fusion protein often leads to incorrect localization. Therefore it is preferable to express the protein in question under its own promoter on the chromosome. Differently colored versions of GFP were developed to enable double GFP-labeling and co-localization studies *in vivo*. Codon usage had to be optimized to ensure normal expression of the fusion protein in yeast. Finally, experience was gained pertaining to the biological function of GFP-fusion proteins. In many (but not all) cases the fusion proteins still complement the corresponding deletion mutation, which is of great advantage, because experiments can be performed in a cell expressing only the GFP fusion protein without competition by the wild type version.

With the advent of genome-wide transcriptional expression analysis on DNA microarrays and the corresponding new bioinformatics tools, functional analysis gained another dimension. Knowing not only the location of the protein but also the time course of expression under various physiological and developmental conditions can lead to a reliable prediction of function. An excellent example is the large group of ribosome-associated proteins involved in ribosome biogenesis, many of which are also needed for translational regulation and many of which were predicted by pattern matching techniques using microarray data. We have mentioned a few methods of major importance for functional analysis, but it must be stressed that many more exist. Many of these methods were pioneered in yeast, and in many cases the yeast cell serves as a testing ground for foreign (human) genes, because of the ease of experimentation in yeast.

Clinical Relevance

As an example we describe the successful functional analysis of frataxin, the yeast orthologue of a human disease gene *FRDA*. Friedreich's ataxia is a severe autosomal recessive disease that presents with neurological symptoms and frequently with dilated heart disease. Typically, the onset of the disease is in young adults and there is a very large phenotypic variability.

The disease is the most frequent of the ataxias with an incidence of about 2×10^{-5} in all studied populations. When the frataxin gene (*FRDA*) was identified through positional cloning in afflicted families in about 1996, the complete genome sequence of yeast had just been published and it became immediately clear that a very close homolog existed in yeast. Two competing groups undertook a functional analysis of the gene and, in fact, the yeast data made it very clear that frataxin is located in mitochondria in both systems. The defect leads to respiratory deficiency through loss of the mitochondrial genome. The mitochondria in the mutant cells over-accumulate iron, although the cellular iron is not increased. It is still unclear, whether frataxin is the mitochondrial iron transporter or maybe is in some other way involved in iron homeostasis. This question will also be answered easily with the help of the yeast system in the near future. Thus, although *FRDA* is a nuclear gene showing Mendelian inheritance, Friedreich's ataxia is a typical mitochondrial disease. It is striking in this example that all of the phenotypic peculiarities mentioned above can be explained by a pathomechanism based on known mitochondrial function. Iron over-accumulation in mitochondria leads to an excess of free radical or ROS (reactive oxygen species) production, which in turn leads to mitochondrial mutation and respiratory deficiency. The affected organs are those rich in mitochondria (heart) and those where other mitochondrial diseases cause typical symptoms (specific parts of the nervous system). The primary mutation identified in the diseased human allele is not a complete loss of function, but a hypomorph caused by trinucleotide GAA expansion in the first intron of the gene. The earlier the age of onset of the disease the larger is the number of the GAA repeats. The ▶intrinsic mutation leads to a diminished synthesis of an otherwise WT gene product. Typical patients are a somatic mosaic of different size trinucleotide repeats. The phenotypic variability is caused by this mosaicism and subsequently by the slow segregation of defective and still functional mitochondrial genomes during mitotic cell cycles, as in other mitochondrial diseases. As there are several thousand mitochondrial genomes per cell, this takes many cell generations. The gene deletion was studied in the robust yeast cell that can easily survive as a respiratory deficient "petite" cell. While the K.O. mouse devoid of frataxin showed embryo-lethality, the disease allele (230 GAA repeats) when introduced into the mouse, was stable there and caused no apparent phenotype.

We have begun to understand the pathomechanism of Friedreich's ataxia and "for the patients and their families the possibility of developing a rational treatment of the disease may turn out to be a legitimate hope". This treatment would be an intervention prohibiting the severe oxidative stress in the diseased cells.

Mutant (Phenotype)

Definition

Mutant is a term that is applied to a gene or phenotype altered by mutation; and/or an individual carrying a mutation.

- Cell Polarity
- Large-Scale ENU Mutagenesis in Mice

Mutation

Definition

Mutation denotes a process through which genes undergo a structural change that potentially results in a change in the function of one or more genes. Examples include chromosome rearrangement, deletion, insertion, inversion, nucleotide repeat expansion, nucleotide substitution, point mutation (transition or transversion), translocation, and transposition.

Mutations arise by the action on the DNA of endogenous factors (e.g. DNA Polymerase Incorporation errors, DNA transaction mistakes, and oxidation) and exogenous factors (e.g. X-ray irradiation, UV irradiation, and chemical mutagens). Deletions or insertions of bases in protein-encoding DNA sequences lead to a totally different amino acid sequence, as downstream of the mutated position the reading frame is shifted (frameshift mutation). Base exchanges in the first and second codon positions frequently result in an exchange of the amino acid incorporated at the mutated codon. Base exchanges that lead to the incorporation of

chemically related amino acids are referred to as neutral mutations. There is no change in the amino acid sequence when a base exchange, mostly in the third codon position, creates a codon that specifies the same amino acid (silent mutation).

Mutation Rate

Definition

Mutation rate refers to the rate at which new inheritable changes in DNA arise in the population in a given gene.

- Duchenne Muscular Dystrophy

Mutator Phenotype

Definition

Mutator phenotype defines the condition of having an elevated spontaneous mutation rate.

- Base Excision Repair

Myalgia

Definition

Myalgia means pain in one or several muscles.

- Mitochondrial Myopathies

Myelin

Definition

Myelin is a three-layered protein-lipid-protein complex that is produced by Schwann cells (PNS) and oligodendrocytes (CNS) and ensheaths many axons with multiple layers. Myelin insulates the axonal membrane, and speeds nerve conduction by restricting action potentials to the so-called nodes of Ranvier (interruptions at regular intervals in the myelin sheath that contain Na^+ and K^+ channels in high density).

- Glial Cells and Myelination
- Neurons

coronary artery and often characterized by severe chest pain.

- Cardiac Signaling: Cellular, Molecular and Clinical Aspects

Myocardium

Definition

Myocardium refers to the striated muscle components of the heart, between endo- and epicardium, which perform the pumping action.

- Heart
- Muscle Development

Myelination

Definition

Myelination refers to a process by which nerve fibres are enwrapped by myelin sheaths enhancing the conduction of nerve impulses.

- Glial Cells and Myelination
- Multiple Sclerosis
- Schizophrenia Genetics

Myocytes

Definition

Myocytes are single muscle cells, which form the muscle fibers.

- Ion Channels/Excitable Membranes

Myeloperoxidase

Definition

Myeloperoxidase is a myeloid cell enzyme that is responsible for the hydrolysis of hydrogen peroxide in presence of halide ions.

- Morbus Wegener

Myofibrillogenesis

Definition

Myofibrillogenesis describes the formation of myofibrils and cylindrical elements that are formed by a series of sarcomeres.

- Limb Girdle Muscular Dystrophies

Myocardial Infarction

Definition

Myocardial infarction describes a sudden interruption or insufficiency of the supply of blood to the heart, typically resulting from occlusion or obstruction of a

Myofibrils

Definition

Myofibrils are filamentous contractile protein bundles (1.2 μm diameter) running along the long axis of a muscle cell, and are composed of numerous myofilaments.

- Heart
- Muscle Contraction

Myofilament

Definition

Myofilament defines a longitudinally arranged filamentous protein of the myofibril (actin, myosin, nebulin, and titin filaments).

- Heart
- Muscle Contraction

Myoglobinuria

Definition

Myoglobinuria refers to the urinary excretion of the oxygen binding myoglobin. Myoglobinuria is caused by rhabdomyolysis.

- Mitochondrial Myopathies
- Rhabdomyolysis

Myosin

Definition

The myosins comprise of a large family of motor proteins. Myosin is a heteropolymer composed of two heavy chains (approximately 200,000 MW) and two pairs of light chains. The light chain pairs are called light chain 1 (25,000 MW) and light chain 2 (19,000 MW). Myosin combines with actin. The complex formed is called actomyosin.

- Focal Complexes/Focal Contacts
- Molecular Motors
- Muscle Contraction
- Type II Myosin

Myotome

Definition

Myotome refers to the central ►somite compartment in a vertebrate embryo, which is populated by cells from the dermomyotome and differentiates into skeletal muscle. The term is also used to anatomically define a muscle, or group of muscles, derived from one somite and innervated by a single segment of a spinal nerve.

- Somitogenesis

Myotonic Dystrophy Protein Kinase

Definition

Myotonic dystrophy protein kinase (DMPK) is the product of a gene encoding a serine/threonine protein kinase, which contains the instable (CTG)_n repeat causing myotonic dystrophy type 1 in its 3' UTR exon.

- Myotonic Dystrophy

Myotonic Dystrophy Type 1

Definition

►Myotonic dystrophy (DM), first described about one hundred years ago, is the most common form of muscular dystrophy among adults, with an estimated incidence of 1:8000 (2). Manifestation of the disease is highly variable and typically consists of a combination of muscular, neural and endocrine features, each of which may vary in severity with much variation in the age of onset. Myotonia, muscle degeneration, cataracts, testicular atrophy, endocrine abnormalities, cardiac conduction defects, hypersomnia, neuropsychiatric disturbances, smooth muscle dysfunction and insulin resistance are among the most prominent features (1, 2). Although generally considered a muscle disorder, it should be mentioned here that brain-based problems in DM, including behavioral and personality changes, and excessive daytime sleepiness form perhaps the major burden of disease manifestation for patients and their environment.

Characteristics

DM patients have been categorized into different subgroups on the basis of age of onset and presenting symptoms (Fig. 1). Mild or senile DM has its onset in middle to old age (50 years or over) and is characterized by the occurrence of cataract and minimal or no muscle abnormality. Classical or adult DM has its

onset in adolescence or early adult life and is characterized by muscle weakness and myotonia, often accompanied by cataracts, gonadal atrophy and minor intellectual impairment. The most severe form of the disease is the congenital form, characterized by a high neonatal mortality and symptoms like facial weakness, delayed motor development, hypotonia, mental retardation and respiratory distress. Novel histopathological findings point to a situation where in congenital cases consequences of developmental arrest of myofiber or CNS differentiation are intermixed with cell-degenerative manifestations. In late onset cases the cell-degenerative effects of disease predominate, leading to muscle wasting, brain atrophy and white matter lesions. About one decade ago, the genetic mutation underlying myotonic dystrophy (now called ►DM1, MIM 160900) was identified as an expanding (CTG)_n repeat on chromosome 19q13.3. Above a critical threshold, this (CTG)_n repeat has a greater than 95% chance to expand from one generation to the next, causing 'anticipation', i.e., progressive earlier onset of disease and worsening of symptoms in subsequent generations (2, 6). Importantly, shortly after the development of (CTG)_n repeat diagnostics, a category of patients with a myotonic dystrophy phenotype similar to DM1, but

without an expanded (CTG)_n repeat, were identified (3). The mutation in patients with this form of DM, designated ►DM2 or PROMM (MIM 602668), was recently characterized as an expanding (CCTG)_n repeat and mapped to chromosome 3q21.3. How (CTG)_n or (CCTG)_n repeat expansions cause the overtly similar, but clinically distinct constellations of features in DM1 and DM2 is still an intriguing open question.

Cellular and Molecular Regulation

The DNA-Chromatin Level

The chromosomal segment in which the unstable (CTG)_n repeat in DM1 patients is located represents a gene-dense area on human 19q13.3. This entire area is evolutionarily well conserved in other mammalian species like mouse (situated on proximal chromosome 7) (1). The (CTG)_n repeat itself is contained within the last 3'-untranslated exon of the human ►myotonic dystrophy protein kinase (*DMPK*) gene, but also located just 5' of the homeodomain-protein-encoding gene ►*SIX5* (Fig. 1). Furthermore, immediately upstream of the *DMPK* gene in both species lies the *DMWD* gene. It has been reported that, possibly due to the presence of weak polyadenylation sites, transcription of the *DMWD* gene can extend into the *DMPK* gene, thus creating another possible transcription unit in which the repeat area is included. The (CTG)_n repeat proper is located within a relatively short segment of DNA with distinct features, characterized by the presence of a CpG island and a Dnase I hypersensitive site. Presumably, this segment, flanked by two binding sites of the zinc-finger protein CTCF, serves as an insulator element by blocking enhancer-promoter communication necessary for independent transcription regulation of *SIX5* and *DMPK*. Other studies suggested a role for the expanded (CTG)_n repeat in abnormal chromatin folding and assembly. In congenital DM1, in contrast to classic DM1 with an adult onset, CpGs in this insulator are hypermethylated and the insulator function is abolished. Although there are species differences at the nucleotide sequence level, it has been shown that expression of each of the three genes *Dmwd*, *Dmpk*, and *Six5* is independently and similarly regulated in mice and humans. Exactly how (CTG)_n repeat expansion affects transcriptional efficiency for each of these genes in patients is not known. How then is (CTG)_n repeat length at the DNA level, or (CUG)_n repeat dosage at the RNA expression level, determined and correlated to the severity and variability in manifestation of clinical features? All we currently know is that unaffected individuals have fewer than 37 repeats, while repeat sizes in affected individuals range from ~100 into the thousands (Fig. 1). Global disease severity and age of onset correlate reasonably well with repeat length in blood: alleles in the 35–49 repeats range are considered

Myotonic Dystrophy Type 1. Figure 1 Schematic representation of the DM1 locus and effects of an unstable (CTG)_n-repeat.

The DM1 locus is strongly conserved between mouse and man and contains three genes located closely together in a gene-dense region: *DMWD*, *DMPK* and *SIX5*. *DMWD* encodes a WD-repeat protein, *DMPK* a serine/threonine protein kinase and *SIX5* a homeodomain transcription factor. An unstable (CTG)_n repeat is situated in exon 15 of the human *DMPK* gene, whereas the mouse gene contains a (CTG)₂(CAG)₂(CTG) sequence at the cognate position. The length of the repeat in blood ranges from 5 to several thousands of CTG triplets and is correlated with the age of onset and severity of DM1 disease manifestation (see box). Effects of the (CTG)_n repeat may be exerted *in cis* via chromatin effects on the levels of *DMWD*, *DMPK* or *SIX5* gene products, or - when expressed as *DMPK* mRNA with a long expanded (CUG)_n repeat - *in trans* via toxic influence on splicing or transport of any other cellular transcript.

premutation alleles, mild or very late onset of disease is seen in individuals with (CTG)_{50–150} repeats, “classic” disease manifestation is associated with (CTG)_{100–1000} and in congenital DM1 patients the repeat contains several thousands of CTG triplets (1, 2). Patients with moderate or long expansions demonstrate age-dependent, expansion-biased mosaicism in repeat length, presumably mediated *via* multiple small length change events. Thus, besides being highly unstable in germ line tissue, repeat length also varies considerably within and between somatic tissues. For example, repeats in muscle cells (skeletal muscle and heart) are generally greater than in blood lymphocytes, but currently no clear picture exists for the relative stability in other tissues, simply because this has not been studied in a large enough cohort of patients.

Mouse models of repeat expansion are more easily accessible and presumably mimic the molecular mechanisms underlying expansion in DM1 patients fairly accurately (6). From in depth study of these models it has become clear that progressive repeat expansion occurs upon aging, and that there is tissue-type preference and cell-type dependence. Early in embryogenesis there may be a tendency to repeat contraction. Together with genetic background effects that have been observed, this is indirect evidence to support involvement of trans-acting modifiers in repeat instability. Direct evidence for the existence of such factors was obtained from study of expanding repeat models showing that deficiency or proficiency for DNA repair proteins Msh2, Msh3 and Msh6 may have differential effects on somatic repeat instability, particularly in post-mitotic events. Involvement of the DNA repair, replication and recombination machinery is now a salient feature of many reports. Better understanding of the relationship between repeat instability, and the role of the DNA repair, replication and recombination machinery therein, may therefore ultimately reveal new entry sites for somatic therapy.

The RNA Level

An important stimulus for understanding DM1 molecular pathogenesis was the finding that *DMPK* transcripts bearing long (CUG)_n repeats in their 3'-UTR were retained in nuclear foci of cells from myotonic dystrophy patients. As a consequence, cytoplasmic *DMPK* transcripts with long (CUG)_n repeats drop to almost undetectable levels, which has been shown to be essentially a post-transcriptional process. In addition, next to the cis-effect of the (CUG)_n repeat on *DMPK* mRNA production, dramatic trans-effects on production and use of other mRNAs with profound influence on alternative splicing and translation of mRNAs have been reported (4). This RNA gain-of-function mechanism, also termed ‘►RNA dominance’, is currently the favored model

to explain the major features of DM1 disease manifestation. This RNA dominance theory was further strengthened by the recent identification of a (CCTG)_n repeat as the genetic defect in DM2, the notion of DM symptoms in the different mouse models with long repeats (the HSA^{LR}-mouse, which has only the repeat area in common with human patients and the DM300 mouse, which has complete transgenic copies of the human repeat area (6)) and by the finding that long (CUG)_n repeats in differentiating myoblast cultures may have severe consequences for late myotube differentiation.

RNA dominance effects are best explained by a mechanism whereby, at the level of RNA, the expanded (CUG)_n repeat interferes with processing or translation of many (primary) non-*DMPK* transcripts. In this mechanism, interaction with RNA-binding proteins, like CUG-BP, ETR-3 or muscleblind proteins, may play a determining role leading to overall perturbation of nuclear RNA metabolism (4). Circumstantial evidence suggests that misregulation of CUG-BP by the (CUG)_n repeat may have the most severe consequences, with effects on late skeletal muscle differentiation, chloride-channel evoked myotonia, and insulin resistance *via* transcription and splice factor regulation. In another scenario, a (CUG)_n length-dependent activation of dsRNA-activated protein kinase (PKR), with toxic effects on myocyte differentiation or survival has been proposed. Since also the neurodegenerative disease spinocerebellar ataxia type 8 (SCA8) is caused by an untranslated (CTG)_n repeat, it may be that SCA8, DM1 and DM2 (where the (CCUG)_n repeat is expressed in the intron of primary *ZNF9* transcripts) share a common disease pathway (4).

The Protein Level *DMPK*

Central in the DM1 area is the *DMPK* gene (MIM 605377; Fig. 1), specifying a serine/threonine protein kinase, which is expressed mainly in skeletal muscle, heart, stomach and in particular regions of the brain (5). *DMPK* transcripts are subject to extensive cell-type dependent alternative splicing. This process is conserved between mouse and man and results in six major splice isoforms (1). All isoforms contain a (CUG)_n repeat in the 3'-UTR of the mRNA. A minor *DMPK* splice isoform, lacking the (CUG)_n repeat was identified in humans. Alternative splicing defines presence or absence of the five-amino-acid motif val-ser-gly-gly-gly and the nature of the C-terminus, for which three different variants exist among the major isoforms. The VSGGG-motif and different C-termini confer distinct cellular properties to the six *DMPK* isoforms related to function(s) at the endoplasmic reticulum and the mitochondrial outer membrane. According to sequence homology in the kinase domain, *DMPK* is a member of the AGC group of kinases and is

most homologous to myotonic dystrophy kinase-related Cdc42-binding kinase and Rho kinase. Various *in vitro* substrates were reported for DMPK, including the dihydropyridine receptor, DMAP, MKBP, phospholemman, CUG-BP and myosin phosphatase targeting subunit, but whether members of this rather diverse set of proteins are *in vivo* substrates needs to be investigated. Because of its presumed role in cell motility, contraction or cell-organelle dynamics, and the observed loss of DMPK in DM1 patients, the DMPK protein is still a likely candidate for being involved in various aspects of disease manifestation, perhaps most probably the developmentally-determined disease features in muscles and brain of congenital DM1 (6).

SIX5

The (CTG)_n repeat is located virtually in the promoter of the *SIX5* gene (formerly known as *DMAHP*), a vertebrate homologue of *sine oculis*, a gene encoding a homeodomain transcription factor essential for development of the visual system of *Drosophila*. Transcription of *SIX5* initiates downstream of the DM1 repeat, excluding inclusion of the (CUG)_n repeat in *SIX5* mRNA. Experimental studies using patient material have indicated that, as for *DMPK*, expansion of the (CTG)_n repeat results in down-regulation of *SIX5* levels. *Six5* is mainly expressed in skeletal muscle, heart, eye, kidney, liver, lung and small intestine. Expression patterns of *Six5* and *Dmpk* are essentially overlapping, albeit that *Six5* levels are generally 5–50 fold lower than those of *Dmpk*. A screen for downstream targets of *Six5* revealed several candidate genes expressed in somites, skeletal muscle, brain and meninges. In *Drosophila*, the *Six5* homologue *D-Six4* was found to play a role in gonad and muscle development. In conclusion, the presumed function of *Six5* in tissues involved in DM1 pathology (e.g., skeletal muscle, eyes, testis), and the finding that expansion of the (CTG)_n repeat has a negative effect on *SIX5* expression levels has opened the possibility that DM1 should be considered a multigenic (-locus) disease. Evidence to support this hypothesis was found in two independently generated *Six5*^{-/-} transgenic mouse models, which display ocular cataracts (6).

Clinical Relevance

DM1 is a highly complex and variable multisystemic disorder. We know now that a rather unpredictable dynamic behavior of mutations in (CTG)_n repeat length in somatic tissues of gene carriers is underlying disease manifestation. Individual differences in genetic background, cell type and developmental or adult age may play an important role in the dynamics of the repeat. This makes it currently virtually impossible to establish reliable genotype-phenotype correlations for individual

members of DM1 families. Prediction of disease development based on repeat length typing in blood is therefore impossible, and considered unethical. Based on current knowledge, our future hope for treatment is based on (i) a reduction of disease incidence in DM families *via* accurate and early carrier-diagnosis and (ii) the development of therapeutic strategies. Given the widespread occurrence of problems in many tissues and organs, our efforts must be primarily directed towards the use of pharmacological rather than gene-therapeutic approaches.

Myotonic Dystrophy Type 2

Definition

Myotonic dystrophy type 2 (DM2), also called proximal myotonic myopathy (PROMM), is a tetranucleotide repeat disorder very similar to myotonic dystrophy type 1, which is caused by an instable (CCTG)_n repeat in the zinc finger protein 9 (ZNF9) gene.

thomas.pollmaecher@klinikum-ingolstadt.de

Synonyms

Narcolepsy-cataplexy; Maladie de Gélineau

Definition

Narcolepsy is a rare human sleep disorder (life time prevalence about 1:2000) characterized by 2 major symptoms. These are excessive daytime sleepiness of episodic, often irresistible character, and ►cataplexy (4), a sudden and short-lasting loss of muscle tone triggered by emotions. The pathogenetic background is complex and multifactorial (Fig. 1). Narcolepsy has a genetic background closely associated to the ►human leukocyte antigen (HLA) DQB*0602, which can be found in more than 95% of Caucasian patients. Due to this close HLA association, autoimmunity has been suggested to play a causative role. Although positive evidence for immune processes directed against self-antigens is still lacking, recent studies have identified a putative target, which is a small group of hypothalamic cells producing ►orexins (also called hypocretins). These are recently discovered neuropeptides involved in the regulation of feeding, metabolism and sleep. The vast majority of patients with narcolepsy display a complete and selective acquired orexin deficiency.

Narcolepsy. Figure 1 Current pathogenetic model of narcolepsy. Based on a genetic predisposition external factors induce an orexin deficiency (e.g. through an autoimmune process). Orexin deficiency leads to sleep related symptoms and disturbances of endocrine and metabolic networks which interact in a yet poorly defined manner (for details see text).

However, the definitive pathophysiological role of these peptides remains to be unraveled. Although there is no cure for narcolepsy, there are a number of effective drug treatments that considerably improve sleepiness and cataplexy.

Characteristics

Narcolepsy was first described by Gélineau in the late 19th century and since then has remained a stable clinically defined disease entity. However, as discussed in detail below, the cause and many aspects of the pathophysiology still remain an enigma, although recently there has been tremendous progress in this field.

Symptoms

The hallmarks of narcolepsy are excessive daytime sleepiness and cataplexy. Sleepiness in narcoleptic patients is severe and might lead to irresistible sleep attacks. However, the patients are not continuously sleepy; therefore, their vigilance is not impaired between periods of increased sleep pressure. These might occur at multiple times during the day, often in a more or less regular temporal pattern. Typical daytime sleep episodes are short (10–20 min) and refreshing. The second clinical hallmark is cataplexy defined as a sudden and short-lasting (seconds to minutes) loss of muscle tone, which is triggered by strong emotions. The most typical trigger is laughter, but anger and surprise may also provoke a cataplectic attack. It is important to note that patients are fully conscious during cataplexy and aware of their surrounding. Due

to the strong dependence on triggers, the frequency of cataplectic attacks is highly variable within and between patients. The same holds true for severity, which varies between very subtle weakness in the knees or blurring of speech to the complete inability to remain in the upright position.

Other symptoms of narcolepsy include automatic behavior (the continuation of behavioral acts while almost sleeping), ►**hypnagogic hallucinations** (frightening, realistic hallucinations while falling asleep), ►**sleep paralysis** (a short-lasting inability to move upon awaking) and disturbed night sleep. Only very recently has it been recognized that narcoleptic patients do not only suffer from symptoms related to sleep-wake regulation, but in addition display endocrine and metabolic abnormalities (2). Most prominent are a high incidence of obesity and an increased rate of type II diabetes. The underlying causes are not fully understood, but they are probably related to the deficiency in hypothalamic orexin production described in detail below.

Epidemiology and Course of Narcolepsy

There are no robust estimates about the frequency of the disorder, but lifetime prevalence is likely to be around 0.05% worldwide. Typically, disease onset is in late adolescence and early adulthood, but children may also be affected, and a second, smaller peak of incidence occurs in the 3rd to 4th decade of life. In the majority of patients sleepiness precedes cataplexy by several years. Narcolepsy is a life-long chronic disorder, although the severity of symptoms might show considerable fluctuations. In the vast majority of patients narcolepsy induces considerable disability.

Since the very early descriptions it has been known that narcolepsy sometimes runs in families. The risk of first-degree relatives developing narcolepsy is 10–40× greater than in the general population. Due to the low overall lifetime prevalence, however, the absolute risk is still below 1%. Although these figures indicate a causative genetic contribution, no clear-cut inheritance pattern could be established. The fact that the majority of monozygotic twins investigated are discordant for narcolepsy clearly suggests that non-genetic factors are pivotal.

Differential Diagnosis

Recognition of typical narcolepsy is an easy task if the physician is aware of daytime sleepiness and cataplexy as the hallmarks of the disorder. However, cataplexy might occur for the first time years after daytime sleepiness, or cataplexy might be so subtle that it escapes the patients' or the physicians' attention. In these cases polysomnographic sleep recordings are very helpful to distinguish narcolepsy from other disorders of excessive hypersomnolence. The typical

and quite specific finding in narcoleptic patients is an early occurrence of rapid-eye-movement (REM) sleep during sleep episodes. These so-called sleep-onset ►**REM** episodes can be detected during night sleep or during daytime naps. HLA typing is only helpful to exclude narcolepsy in clinically doubtful cases because the typical genotype (HLA-DQB*0602, for details see below) is present in more than one third of normal people. The absence of orexin-A in CSF (for details see below) is probably highly specific for narcolepsy, although normal orexin levels do not definitively exclude the diagnosis.

Cellular and Molecular Regulation Immunogenetics of Narcolepsy

Based on the knowledge of familial cases of narcolepsy Japanese and European researchers conducted immunogenetic studies in the 1980s and reported a more than 90% association of narcolepsy with the human leukocyte antigen (HLA) DR2 carried by about one third of healthy people. The association is even stronger to a related class II antigen (DQB1*0602) and represents the tightest link of a disease to an immunogenetic marker that has ever been discovered. Additional HLA subtypes also increase (DQB1*0301) or reduce (DQB1*0601 and 0501) disease susceptibility (3). Familial clustering of narcolepsy cannot be explained exclusively by sharing of HLA haplotypes, because some families are negative for the DQB0602, suggesting that non-HLA genes modulate disease susceptibility. Although very little is known about these genes so far, there are interesting candidates such as genes related to the tumor necrosis factor- α cytokine system.

The strong association of narcolepsy with an HLA marker has suggested that autoimmune processes might play a pathophysiological role. Although no clear-cut evidence supporting this assumption could be established so far, the recent discovery of a complete deficiency in orexin production has renewed the interest in the autoimmune hypothesis of narcolepsy.

Orexins and Narcolepsy

In the 1970s an animal model of narcolepsy was discovered in dogs, where cataplexy and, to a lesser extent also sleepiness, are transmitted as an autosomal recessive trait with full penetrance. It took until 1999 for the underlying genetic defect to be identified as a missense mutation in a neuropeptide receptor. This ORX-2 receptor was one of 2 receptors for a pair of novel hypothalamic neuropeptides (1). Orexin-A and B, also called hypocretin-1 and -2, are derived from one common precursor peptide called preproorexin. At the same time as the ORX-2 receptor defect was discovered in narcoleptic dogs, it was found that mice with a targeted disruption of the preprohypocretin

gene display periods of behavioral arrest resembling cataplexy.

Very shortly after these findings in animals, it was reported in humans that narcolepsy is associated with a complete loss of orexin production in the vast majority of patients affected, suggesting that in the human disorder orexins play a pivotal pathophysiological role. In contrast to animals, however, defective orexin signaling is due to a secondary loss of peptide production, rather than due to a genetic defect. No mutations have been found in the human orexin receptors, nor is there an association between narcolepsy and hypocretin polymorphisms in humans. Only one single case of a child with very early disease onset at 6 months of age was found to carry a mutation in the ►[preproorexin](#) gene.

Hence, human narcolepsy in the vast majority of cases is associated with a secondary, acquired orexin deficiency. But, it is unclear what causes this defect. On the level of the hypothalamus, neuroanatomical studies, which so far have been based on very few brains, suggest that, indeed, orexin production is almost or completely absent. However, it is unclear, whether this is due to a lack of orexin-producing neurons or due to an arrest of orexin production within the hypothalamus. One group described gliosis in this area, which is compatible with an earlier inflammatory process, but no signs of active inflammation have been found.

Although it is now clear that orexin deficiency plays an important role in the pathophysiology of narcolepsy, details of this role have been poorly defined so far. This is not surprising, because these peptides were discovered only five years ago and their physiological functions are just starting to be understood. Acute administration of orexins stimulates food intake, and the orexin system interacts with multiple endocrine networks including the hypothalamo-pituitary-adrenal and the hypothalamo-pituitary-somatotropic axes (5). However, a pivotal role in the physiological regulation of food intake is less likely, because mice with defective orexin-signaling are either of normal weight or even obese. Obesity is also a typical feature of narcolepsy in humans, who in addition display endocrine and metabolic abnormalities such as type II diabetes and hypo►[leptinemia](#).

Orexins have potent arousing properties, which might explain why orexin deficient narcoleptic patients are sleepy. However, the symptomatology of narcolepsy is much more complex and the common denominator of the divergent symptoms is a disturbance of the transitions between the different states of vigilance (wakefulness, ►[nonREM](#) sleep and REM sleep). These transitions might be too fast (e.g. from wakefulness to nonREM sleep during a sleep attack) or they might be qualitatively disturbed (e.g. the occurrence of cataplexy

which represents an incomplete and inappropriate transition from wakefulness to REM sleep). On the level of classical neurotransmission, sleepiness might be due to a reduced stimulatory effect of orexins in the dopaminergic system. Cataplexy, in contrast, might be caused by a reduced input of orexin-producing neurons to cholinergic and noradrenergic brain stem centers involved in REM sleep regulation. However, how orexins really control these transitions between vigilance states remains to be elucidated.

Clinical Relevance

Although narcolepsy is rare, it is of considerable clinical relevance due to its chronic and disabling course. Moreover, it is a prototypic disorder of sleep-wake regulation important for our general understanding of sleep in health and disease. Finally, narcolepsy qualifies as a very attractive disease model to study the complex interactions between genes and environment, because the disorder involves a highly specific peptide deficiency occurring on a clearly defined immunogenetic background.

Natural Antisense Transcripts

ANDREAS WERNER

Institute of Cell and Molecular Biosciences, University of Newcastle, Newcastle upon Tyne, UK
andreas.werner@ncl.ac.uk

Definition

Natural antisense transcripts overlap their related sense transcripts in reverse complement orientation. Both coding and non-coding antisense RNAs are found. Natural antisense transcripts are very heterogeneous in length and may be spliced. If sense and antisense transcripts are expressed in the same cell, RNA-RNA hybrids are believed to be formed. Nucleic acid base pairing guarantees the exquisite specificity of this interaction. The RNA duplexes trigger various mechanisms that lead to the down-regulation of both RNAs or the silencing of the gene at a transcriptional level.

Genome sequencing efforts and computational screens have identified about 2000 overlapping [transcriptional units](#) that give rise to sense/antisense pairs (1). The physiological relevance of [bi-directional](#) transcription at the observed scale is unclear. Only a few examples are experimentally characterised, however increasing evidence suggests that natural antisense transcripts have a pivotal role in gene regulation. An altered ratio of sense/antisense RNA may result in an aberrant expression pattern of the related protein. The pathological phenotype depends upon the nature of the protein.

Natural antisense transcripts as described above relate to cis-encoded RNAs. Trans-acting molecules such as [microRNAs](#) that do not exhibit full complementarity are not discussed here. Nevertheless, natural antisense RNAs and microRNAs may feed into similar cellular gene silencing pathways.

Characteristics

Cellular Consequences of RNA-RNA Hybrids

The transcription of a natural antisense RNA causes down-regulation of sense RNA encoded protein. The RNA-RNA duplexes trigger two cellular mechanisms, [RNA interference](#) and RNA editing, that lead to the degradation of both RNA strands and eventually to gene silencing. RNA interference involves an RNase-III-type recognising double stranded RNA (Dicer), which cleaves the target into small oligonucleotides of 21–23 base pairs. The oligonucleotides trigger various mechanisms that eventually suppress the expression of the cognate gene. In human (and many other eukaryotic species) an RNA-induced silencing complex (RISC) is

formed that degrades both strands of the targeted RNA. Other mechanisms involve the silencing of gene expression at transcriptional and translational level. The mechanism of RNA interference is well conserved throughout eukaryotes. However, considerable variations may occur between organisms.

Double stranded RNA is also recognised by an enzyme that converts adenosine (A) into inosine (I), called ADAR (adenosine deaminase acting on RNA). Such modifications may lead to [point mutations](#) or altered splice sites. Alternatively, edited mRNA is prevented from nuclear export and eventually degraded. Recent evidence suggests that I-rich (edited) RNA binds to components of the [DNA methylation](#) machinery and leads to [epigenetic](#) gene silencing. The link between RNA interference/RNA editing and gene silencing at the transcriptional level by chromatin modification is hypothesised, however, direct experimental evidence is missing. A model that amalgamates RNA interference and RNA editing to explain how double stranded RNA leads to gene silencing is presented in Fig. 1. The number of RNA-RNA hybrids is a critical determinant of which of the indicated pathways is activated.

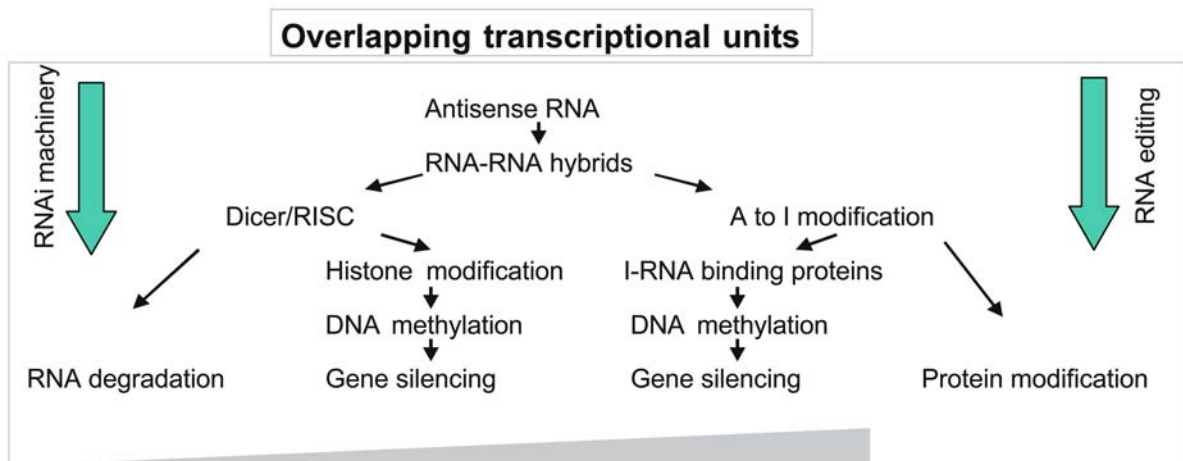

Natural antisense transcripts also interfere with the processing of the related sense RNA. [Splicing](#), [polyadenylation](#) and the export of the mRNA from the nucleus to the cytoplasm are affected. In the cytoplasm, translation efficiency is reduced by RNA duplex formation. However, natural antisense transcripts are thought to exert their regulatory function predominantly in the nucleus.

Physiological Consequences of Antisense RNA

The consequences of antisense RNA expression are relatively well established in the context of epigenetic gene silencing phenomena including DNA methylation (2), [genomic imprinting](#) (3) and [X chromosome inactivation](#) (4).

DNA methylation is closely linked to the transcriptional activity of specific areas of the genome. [Promoter](#) regions of genes that are actively transcribed are poorly methylated. The expression of antisense transcripts can induce the methylation of the sense promoter and silence the gene. An individual suffering from α -[thalassemia](#) was recently found to display a normal α -globin (*HBA2*) gene that was silenced by a juxtaposed antisense transcript. The antisense RNA derived from the widely expressed *LUC7L* gene that was incorrectly localised a few hundred base pairs downstream of *HBA2*. The expression of the antisense transcript leads to hypermethylation of the *HBA2* promoter and concomitantly to the silencing of the gene (2).

Imprinted genes express either the maternal or the paternal [allele](#). More than 60 human imprinted genes

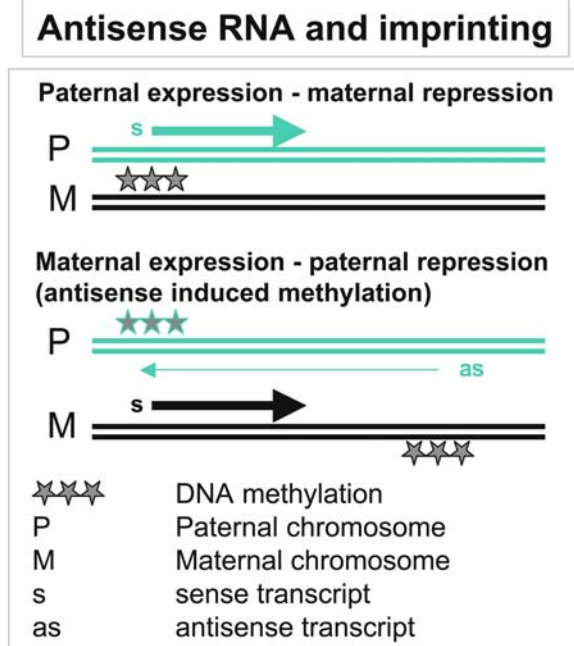

Natural Antisense Transcripts. Figure 1

have been reported so far. They are grouped in clusters and often display both DNA methylation and antisense transcripts. The phenomenon of genomic imprinting is restricted to marsupials and placental mammals. An elegant hypothesis integrates DNA methylation, antisense transcription and maternal/paternal expression. In contrast to the methylated maternal DNA, the paternal chromosome becomes actively demethylated after fertilisation; transcriptional inhibition of paternal genes due to methylated promoters is abolished. In order to reinforce mono-allelic maternal gene expression, an antisense transcript is expressed. Accordingly, most of the antisense transcripts within imprinted gene clusters are paternally expressed (Fig. 2). A mouse gene knock out study focusing on the paternally expressed *Air* antisense transcript has corroborated the importance of antisense expression in imprinting. *Air* is expressed in antisense direction of the maternally expressed genes *Slc22a2*, *Slc22a3* and *Igf2r* and overlaps with the first exon of *Igf2r*. Premature termination of the *Air* RNA resulted in both maternal and paternal expression of *Slc22a2*, *Slc22a3* and *Igf2r*. The transgenic animals showed 15% reduced birth weight; a phenotypic alteration shared by mice with bi-allelic *Igf2r* expression (3).

Dosage compensation is necessary to balance the expression of X chromosome encoded genes in XX (female) and XY (male) individuals. A process called X chromosome inactivation leads to the silencing of one X allele in females. A large non-coding RNA (*Xist*) recruits proteins that modify histones and DNA to one of the X chromosomes thus leading to the suppression of transcriptional activity. An antisense transcript (*Tsix*) plays a crucial role in dictating which X chromosome becomes inactivated.

The antisense transcripts that have been characterised in the context of ►DNA methylation, imprinting or X chromosome inactivation constitute less than 5% of the

Natural Antisense Transcripts. Figure 2

estimated 2000 overlapping transcriptional units (1). This leaves a large number of antisense transcripts that carry the potential to interfere very specifically with the expression of the sense-encoded protein. A general hypothesis predicts that an antisense RNA is an instrument for tight spatial or temporal regulation of the sense transcript. Several reports have quantified sense/antisense transcription of selected genes, under varying physiological conditions and confirm the regulatory impact of the antisense transcripts. Generally, the impact of the antisense RNA is restricted to the

regulation of the cognate sense transcript. The physiological consequences of a given antisense RNA are therefore intimately related to the biological importance of the sense-encoded protein. Natural antisense transcripts are thought to trigger the degradation of the related sense transcript. Consequently, aberrant regulation of antisense RNA expression and mutations affecting the sense transcript may result in similar phenotypes. A few examples of a rapidly increasing list of experimentally characterised bi-directionally transcribed genes are described below.

The cardiac muscle contains two forms of myosin heavy chains, denoted α MHC and β MHC. The proportion of the two proteins is tightly regulated during development and may be altered in pathological situations. The genes encoding the two proteins are located closely together (~5 kb). The promoter driving α MHC expression shows bi-directional activity giving rise to the α MHC encoding transcript and a β MHC related antisense RNA. This arrangement couples the expression of α MHC with the silencing of β MHC. The proportion of the three transcripts, α MHC encoding mRNA, antisense β MHC RNA and β MHC encoding mRNA, are altered in response to physiological and pathophysiological changes (development, diabetes) (5).

The gene encoding the basic fibroblast growth factor 2 (bFGF-2) is transcribed in both directions. Both transcripts give rise to a protein, the sense transcript to bFGF-2 and the antisense transcript to a DNA repair enzyme of the MutT family called GFG. Antagonising effects of the two gene products have been observed on both the RNA and protein levels. Patients with endometriosis show altered bFGF sense/antisense RNA ratios in endometrial stromal cells. On the protein level, the normal pituitary expresses the antisense encoded protein (GFG) but not bFGF-2 whereas pituitary adenomas express bFGF-2 and have reduced levels of GFG (6).

The expression of thyroid hormone receptors (TRs) including the two splice isoforms TR α 1 and TR α 2 is highly regulated. TR α 1 binds thyroid hormone whereas TR α 2 antagonises thyroid hormone action. A natural antisense transcript influences the proportion of the two splice isoforms and consequently the responsiveness of the cell to thyroid hormone (7).

Natural antisense transcripts are a widespread phenomenon in both prokaryotes and eukaryotes. However, prokaryotic antisense RNAs, despite the fact that bacteria show extensive bi-directional transcription, hardly compare to those of eukaryotes. Whereas prokaryotic antisense transcripts often exert their activity without the aid of proteins, the handling of RNA-RNA duplexes in eukaryotic cells requires specific protein machineries. The RNA interference pathway in particular is limited to eukaryotes. Since this mechanism and other aspects of bi-directional transcription have only very recently been discovered and fully

recognised, a general picture of gene regulation by natural antisense transcripts is still emerging.

Neural Crest Cells and their Derivatives

CHAYA KALCHEIM

Department of Anatomy and Cell Biology, Hebrew University-Hadassah Medical School, Jerusalem, Israel
kalcheim@nn-shum.cc.huji.ac.il

Definition

The neural crest (NC) is a major cell type arising in the lateral tips of the neural folds during the process of neurulation. Upon fusion of the folds and formation of the ► [neural tube](#), the NC temporarily resides in its dorsal midline, being an integral part of the pseudostriated neuroepithelium (1) (Fig. 1a). The significance

of the NC stems from the immense variety of derivatives that this discrete group of cells yields during ontogeny. Most of the peripheral nervous system arises from the NC including all the glia of the ►sensory ganglia, all neurons of the dorsal root ganglia and the majority of neurons of the cranial sensory ganglia. The ►autonomic nervous system derives entirely from the NC, comprising all sympathetic and parasympathetic branches and also the specialized ►enteric nervous system. Lying along peripheral nerves are the ►Schwann cells, a subset of peripheral crest-derived glia (Fig. 1c). In addition to specific neural derivatives, NC cells also develop into distinct endocrine and paraendocrine cells, among which the adrenomedullary chromaffin cells are the most studied ones. Notably, except for the retinal pigment, all the melanocytes of the body, which provide the vertebrate organism with a rich diversity of colors, also arise from NC. Most strikingly, at cranial levels of the axis, the NC gives rise to most of the skeleton and connective tissue of the head, face and neck. So, it appears that during evolution, the NC, rather

than cells of mesodermal origin that normally differentiate into skeletal derivatives, was able to provide a skull to cover and protect the increasing volume of the vertebrate brain (2). Furthermore, recent evidence supports the notion that the NC is also the source of molecular information that patterns certain aspects of craniofacial development through interactions with adjacent tissues (3).

Characteristics

The development of the NC embodies a multistage process initiated by the specification of neuroepithelial cells to a NC fate and followed by the separation of these progenitors from the neural tube and the onset of cell migration. Migratory progenitors follow stereotyped pathways, which differ among axial levels and species. After reaching their homing sites, NC cells finally differentiate into distinct derivatives. A central question concerning the mechanisms that control the migration of NC cells is whether there is a relationship between the directionality of cell migration and the

Neural Crest Cells and their Derivatives. Figure 1 Successive stages in NC development. (a) Slug-positive NC cells (blue product) are located in the dorsal midline of the neural tube following specification but preceding emigration. (b) In a slightly older embryo, NC cells expressing the HNK-1 epitope (brown color) are migrating through the somite. (c) Two days later, NC cells have formed the sensory dorsal root ganglia (DRG), the sympathetic ganglia (SG) and Schwann cells lining along the peripheral nerves (PN). Abbreviation: SC, spinal cord.

degree of cell specification. More precisely, do NC cells migrate in a stochastic manner along the different paths to become specified by local cues present at their homing sites, or alternatively, are there predetermined progenitors responding differentially to signals expressed along the pathways leading them to migrate in a directional fashion. Although generally considered as multipotent stem cells at the population level, it has become increasingly evident that already at the beginning of emigration from the neural tube, the NC is composed of heterogeneous populations of cells, some multipotent and others already restricted to different degrees in their developmental potential, including precursors committed to one particular fate. These results suggest that environmental signals encountered during migration and homing are likely to operate both by instructive and also by permissive mechanisms on target cells with varying degrees of developmental restriction. Thus, unraveling the relative influence of the environment *vis-à-vis* the state of commitment of the migrating progenitors is an essential issue for understanding how an initially discrete population of embryonic cells segregates into such an extensive variety of derivatives.

Cellular and Molecular Interactions

NC Specification

Formation of the NC is the result of interactions between cells of the neural plate and the non-neural ectoderm. Using expression of the *Slug* transcription factor to follow NC generation, experiments were performed in which pieces of epidermal ectoderm and neural plate were brought into contact. This juxtaposition resulted in the generation of *Slug*-positive NC cells, which were not observed in explants of each tissue separately. The possibility that the mesoderm also plays a role in NC generation has also been put forward. What molecules mediate induction of the NC phenotype? In avian embryos, treatment of naïve neural plate explants with BMP4 and BMP7, two members of the TGF β superfamily, were shown to stimulate the formation of NC cells. A \blacktriangleright BMP gradient was also suggested to act in amphibians; yet other studies highlighted the need for additional factors of the FGF and Wnt families whose exact roles remain to be resolved (4).

Emigration of NC Cells from the Neural Tube

Although being initially an integral part of the neuroepithelium (Fig. 1a), specified NC cells segregate from the dorsal midline of the neural tube and adopt a mesenchymal morphology, which is required for generating cell movement away from their source. A key issue for understanding early NC ontogeny is, therefore, elucidating the mechanisms that regulate the separation of these cells from the CNS epithelium.

Being basically a process of \blacktriangleright epithelial-to-mesenchymal conversion, the onset of migration of NC cells is spatiotemporally coordinated with the development of the \blacktriangleright somites that subsequently serve as substrates for the migrating progenitors at trunk levels of the axis.

It was found that an interplay between BMP4 and its inhibitor noggin in the dorsal neural tube generates graded concentrations of the former that in turn trigger the delamination of NC progenitors. Consistent with this suggestion, disruption of the gradient by over-expression of noggin inhibited emigration of HNK-1-positive NC cells without affecting their state of specification. BMP-4 activity is required for maintenance of a variety of dorsal neural tube genes among them *cadherin 6B*, *rhoB*, *Pax3*, *Msx 1* and *2*, etc. suggesting that at least some of these molecules are likely candidates to mediate a BMP-dependent cascade leading to NC delamination. Recently, a pivotal role for the cell-cycle in NC delamination was suggested, based on the observation that NC cells synchronously emigrate in the S-phase of the cell-cycle and that successful G1-to-S transition is a prerequisite for cells to delaminate (5).

Migration of NC Cells

NC cells advance through pathways of diverse natures. They move on extracellular matrices, along basement membranes that delimit various epithelia and blood vessel endothelia and are also able to advance by intermixing with mesenchymal cells of mesodermal origin (Fig. 1b). Most notably, several embryonic anlagen were found to inhibit the migration of NC cells and recent evidence supports the notion that these inhibitory mechanisms are pivotal to the patterning of NC migration, which in turn determines accurate morphogenesis of its derivatives.

The identity and mode of action of molecules that govern NC migration are beginning to be unraveled. In the trunk, migration of NC cells is characterized by a polarized entrance of progenitors into the rostral, but not into the caudal, domain of each somite. Embryonic manipulations of the neural tube and somitic environments have shown that differences inherent in the somitic mesoderm are responsible for the metamereric pattern of cell movement and for the consequent formation of segmented ganglia. It has been well documented that the Delta-Notch pathway is required for the formation of intra- and inter-somitic boundaries, thereby specifying initial rostrocaudal identity of somites and indirectly, the segmental migration of crest progenitors. Additional molecules were found to be differentially expressed in the somites. The majority of them are located in somitic regions that are avoided by the migrating cells, suggesting that migration of NC cells in the trunk is largely patterned by inhibitory signals. These areas include the caudal halves of the sclerotome, which convey segmental patterning, the

paranotochordal mesenchyme and the dermomyotomal epithelium. Signals with the potential to inhibit the migration of NC cells include ►**extracellular matrix**-associated molecules such as chondroitin sulfate proteoglycans bearing chondroitin 6-sulfate chains, versican, collagen IX and F-spondin. Other proteins may act *via* a cell contact-mediated mechanism. These include specific ephrins (Eph ligands), whose localization is restricted to the caudal halves of the sclerotome in several species, and Eph receptors. The interaction between them was shown to have a repulsive function towards NC cells and growing neurites. Notably, these proteins exert an avoidance behavior only when presented in a gradient-like fashion or in stepwise discontinuous concentrations but not uniformly. These results suggest that restriction to migration of NC cells on Eph ligand members is not an absolute behavioral pattern but reflects a sensitivity to the presence of a boundary between relatively repulsive and permissive substrates.

NC Cell Differentiation

Sensory and Sympathetic Lineages

Ongoing research on the molecular requirements for differentiation of peripheral neurons in sensory and sympathetic ganglia has led to the identification of neurogenic factors whose activities are specific either to sensory or to autonomic neuroblasts. Neuregulins are EGF-like growth factors that signal through tyrosine kinase receptors of the ErbB family. Mice homozygous for either the neuregulin-1, *erbB2* or *erbB3* genes reveal severe hypoplasia of the sympathetic ganglia, suggested to result from a migratory defect that leads to a failure to colonize the sympathetic primordia. In addition, BMP-2 and BMP-4, two factors present at sites of sympathetic ganglion development, were shown to act instructively on promotion of autonomic neurogenesis. The MASH-1 transcription factor is a nuclear regulatory protein of the ►**basic helix-loop-helix** class, expressed in autonomic but not sensory progenitors. Consistently, analysis of homozygous embryos with a deletion in this gene revealed that the MASH-1 product is involved in promoting differentiation of a sympathetic neuronal progenitor following its arrival in the sympathetic primordia, but it does not affect sensory neurogenesis.

The generation of sensory neurons from the NC requires the function of another class of bHLH transcription factors, the neurogenins. Neurogenin-1 was shown to be necessary for the development of proximal cranial sensory neurons while neurogenin-2 was required for distal neurons. In dorsal root ganglia, neurogenin-1 accounts for the generation of most neurons expressing the neurotrophin receptor *trkA* characteristic of small nociceptive neurons, whereas the function of neurogenin-2 is necessary for generating

trkB- and *trkC*-expressing cells that transmit proprioceptive, temperature and pressure sensations. Moreover, neurogenin-1 is required for the activation of a cascade of downstream bHLH factors including *NeuroD*. While over-expression of both factors in *Xenopus* embryos can induce ectopic neurogenesis, the timing of expression of *NeuroD in vivo* suggests that it is more likely to play a role in neuronal differentiation, while neurogenins are more likely to behave as neuronal determination genes for the sensory lineage (6).

Enteric Progenitors

The intrinsic innervation of the gastrointestinal tract derives entirely from two distinct levels of the NC, the vagal level from somitic regions 1–7 and the sacral level caudal to somite 28. While the vagal cells migrate in a rostrocaudal direction to colonize the entire length of the gut, the sacral contribution is restricted rostrally to the level of the umbilicus. It is now well established that both vagal and sacral cells have the capacity to generate neurons as well as glial cells. In recent years, significant progress has been achieved in understanding several factors that affect development of enteric progenitors. Availability of mouse mutants lacking innervation of the distal hindgut was also valuable in this respect because aganglionic megacolon is a congenital disease of humans (Hirschsprung's disease), which can be either sporadic or familial. The *lethal spotted* and *piebald lethal* mouse loci were found to encode for the endothelin-3 peptide and the endothelin-B receptor respectively. Another essential factor is glial-derived neurotrophic factor (GDNF), which signals through the c-ret receptor. Deletion of either gene caused a dramatic lack of enteric innervation. Although an initial colonization of the esophagus and stomach occurred in these mutants, these cells disappeared by the time of birth, consistent with a role of GDNF in cell survival. In contrast, no innervation of more distal regions of the gut could be detected at any stage of embryogenesis, suggestive of a primary defect in gut colonization. Based on the relative severity of the GDNF/c-ret mutations when compared to the endothelin mutations, one can postulate that GDNF acts earlier in development on a less restricted population of NC cells. *In vitro* studies revealed both mitogenic and differentiative effects of GDNF and, although endothelin-3 was also found to be mitogenic for enteric NC cells, its primary effect was to modulate the action of GDNF by inhibiting neuronal differentiation of NC cells, thus maintaining the precursor pool and ensuring that sufficient cells are present to colonize the entire gut. Furthermore, neurotrophin-3 (NT-3), a factor with multiple activities on proliferation of early NC cells and differentiation of sensory and sympathetic progenitors was also found to influence the development of NC-derived cells in the gut. NT-3 was shown to stimulate

an increase in the proportion of both neurons and glial cells by affecting their survival and/or differentiation but not as a mitogen.

Pigment Cells

Melanocytes, the pigment forming derivatives of the NC, develop following progenitor migration along a dorsolateral pathway underneath the ectoderm. This spatially distinct distribution of NC cells could result from two alternative mechanisms. First, multipotent NC cells could undergo progressive restrictions as they advance along this path or after they colonize the skin and differentiate into melanocytes in response to local cues. Alternatively, NC cells may be fate-restricted prior to dispersion, which, for melanocyte progenitors, in fact begins relatively late, after migration of the main neurogenic stream of cells has taken place. ► **Clonal analysis** of NC cells taken from the lateral path revealed the coexistence of melanoblasts along with cells expressing neuronal traits. The latter were, however, found to be relatively few in number and were removed by an episode of ► **apoptosis**. On the other hand, melanogenic precursors back-grafted into the migratory paths of early embryos precociously and preferentially dispersed along the lateral pathway, suggesting an early specification towards the melanogenic fate. Consistent with this notion, the microphthalmia (*mitf*) gene product, which encodes a bHLH transcription factor that regulates melanogenesis, is expressed in avian embryos both prior to and during NC dispersal along the lateral path.

Two well-known mouse coat color mutants with defects in melanogenesis are *white dominant-spotting* (W) and *Steel* (Sl), which encode for the c-kit receptor and for steel factor, respectively. While steel factor is expressed along the pathway of melanoblast migration, c-kit is expressed by the migrating NC cells. There is evidence that different alleles of steel factor are required to support survival and/or migration of NC cells along the subectodermal space. Another ligand-receptor system involved in melanogenesis is endothelin-3 and the endothelin-B and B2 receptors. Mutations in the first two genes produce both aneural megacolon and defects in pigmentation. *In vitro* studies revealed that endothelin signaling elicits generalized NC cell proliferation and also melanogenic differentiation.

Future Perspectives

During the past few years, significant progress has been achieved in uncovering the molecular basis of NC specification, delamination, migration and differentiation. In spite of having attained only an initial knowledge of these intricate processes, new tools are rapidly emerging which will greatly assist in this endeavor. Screens at the genomic level could potentially lead to the identification of an array of

NC-specific genes characteristic of particular developmental stages and processes of interest (7). These genes could then be assembled into functional networks. To understand their function, genomic approaches should be complemented with state of the art techniques in experimental embryology. The latter field has also developed significantly. For example, the avian embryo, which is particularly suited for cell biological studies, can now also be exploited for spatiotemporally controlled gene misexpression by ► **electroporation** of DNA constructs, dsRNAs or antisense morpholinos. The evolutionary conservation of genes and genetic networks should enable us to exploit the most successful techniques in each species in order to obtain an integrated picture of the mechanisms underlying NC ontogeny.

Neural Development

THOMAS MÜLLER

Department of Medical Genetics, Max Delbrück Center for Molecular Medicine, Berlin, Germany
thomu@mdc-berlin.de

Definition

The nervous system consists of several structural and functional subdivisions. The central nervous system, comprised of the brain and spinal cord, fulfils complex

tasks like cognition, acquisition of memory and behavior. The peripheral nervous system consists of somatic and autonomic divisions. The somatic division gathers and transmits sensory information from the periphery to the central nervous system. The autonomic division mediates visceral sensation and motor control of the viscera, smooth muscles and exocrine glands. Cells of the nervous system derive from the neural plate, with the exception of a few components of the peripheral nervous system that are generated from ectodermal placodes.

The tasks performed by the mature nervous system depend on precise connections between neurons. The neurons and their connections are generated during embryonic and postnatal development. Neural development proceeds in several steps. During gastrulation, the primitive ectoderm gives rise to the neural plate that contains neural progenitor cells. During neurulation, the edges of the neural plate rise and fuse to form the neural tube. Neuroepithelial cells acquire a particular molecular identity, which reflects their position along the antero-posterior and dorso-ventral axes. They then produce postmitotic neurons and glial cells in a spatially and temporally controlled manner. Neurons migrate to their final positions, mature, extend axons and form synapses with their target cells. Synaptic connectivity is subsequently refined by activity dependent mechanisms.

Characteristics

For a developmental biologist, it is always amazing to see how the mammalian nervous system, composed of thousands of neuron types, billions of neurons and trillions of specific connections, develops with only little variability between individuals of a particular species. How can this be achieved, given that only a limited number of genes are available that can be used to specify all neuronal characteristics? Many mechanisms involved in neural development are widely conserved and are used in flies and worms, in frogs and fishes, in birds and humans. The observed increase in the complexity of the nervous system during evolution is not paralleled by an increase in genome complexity. Thus, strategies must have evolved which allowed the controlled development of more and more complex brains using only a limited number of regulatory genes.

Development of the nervous system depends on the expression of particular genes at particular positions and times during development. Both exogenous signals and the cell-intrinsic programmes regulate the spatial and temporal pattern of gene expression in the developing nervous system. Neural development can be viewed as a series of inductive interactions between groups of cells. Due to their restricted diffusion capacity, inducing signals act over limited distances

only and the signals received by a particular cell therefore depend on its position. The competence of a cell to respond to an inducer depends on its repertoire of receptors and signal transducing molecules, which in turn reflects its developmental history.

The complexity of the nervous system develops gradually from the simple ►neural plate. By progressive compartmentalization, the developing nervous system is subdivided into increasingly smaller units. Compartmentalization is a basic developmental strategy that is used repeatedly to generate diversity. Furthermore, molecules act in combination, thus generating a complex code. For instance, combinations of transcription factors define progenitor cells in the spinal cord. Finally, signals can be used repeatedly in consecutive steps of development, for example, FGF8 (fibroblast growth factor 8), which patterns the neural tube at different developmental stages.

Initially, progenitor cells of the developing nervous system possess a high level of plasticity that allows them to adapt their fate to extracellular cues. Subsequently, negative and positive feedback mechanisms consolidate fate decisions and thereby guarantee the stability of developmental processes. A second mechanism that ensures stability is redundancy. For instance, several signals can be employed to provide directional cues during axonal pathfinding. In this way, organisms can compensate for genetic and epigenetic variability and ontogenesis can proceed reproducibly. We will now consider in more detail the following successive steps of neural development: (1) induction and patterning of the nervous system, (2) proliferation and differentiation of neural cells, (3) guidance of neuronal migration and axon growth, (4) synapse formation.

Regulatory Mechanisms & Molecular Interactions Induction and Patterning of the Nervous System

Early in development, the neural tube is established and the neural progenitors assume positional identities. This process can be described in three major developmental steps: induction of neural progenitor cells in the neural plate, formation of the neural tube and establishment of the antero-posterior and dorso-ventral axes.

Induction of the Nervous System

The primitive embryonic ectoderm (epiblast) gives rise to neural tissue and epidermis. Neural induction, i.e. the specification of neural tissue from naïve ectodermal cells, starts at the late blastula stage and proceeds during ►gastrulation. It depends on two signals, one provided by the organizer, which resides in the epiblast in the anterior region of the primitive streak, and the other provided by the extraembryonic hypoblast, called the anterior visceral endoderm in the mouse.

As yet, there is no consensus about the molecular mechanisms that control neural induction. Diverse signaling pathways might cooperate. In frogs and fish, abrogation of ►BMP (bone morphogenetic protein) signaling promotes neural specification and high levels of BMP suppress neural development. The “neural default model” proposes that ectodermal cells become neural unless exposed to BMPs. It is suggested that BMP antagonists suppress BMP activity and allow neural induction. However, studies in other species suggest that suppression of BMP activity is not sufficient to induce neural identity and that earlier signals, most likely FGFs, establish a “preneural” state prior to gastrulation. Furthermore, suppression of Wnt signaling seems to be required for neural induction (1).

Anterior and Posterior Neural Plate

In parallel with neural induction, an early antero-posterior pattern is established in the neural plate. Nodals, FGFs, Wnts, BMPs and retinoic acid have been proposed as factors that impose a posterior character on the neural plate. The anterior visceral endoderm and the anterior axial mesoderm produce inhibitors of such signals, for instance Noggin, Chordin, Cerberus, Frzb1 and Dickkopf-1. These molecules protect the anterior neural plate from posteriorization. The presence of the transcription factor Otx2 in the anterior visceral endoderm and the anterior mesendoderm is essential to induce and maintain anterior character in the neural plate. A combination of several signals establishes the early antero-posterior division of the neural plate (2).

Neurulation

During the process of neurulation, the neural plate bends at the ventral midline. The lateral edges of the neural plate thicken, fold upwards and form the neural folds, which eventually fuse to create the neural tube. The original latero-medial axis of the neural plate becomes the dorso-ventral axis of the neural tube. At the time of neural tube closure, the neural crest becomes specified at the border of the neural plate and the surface ectoderm. Subsequently, the neural crest cells emigrate to form the peripheral nervous system. The current knowledge about molecules involved in neurulation was reviewed recently (3).

Patterning of the Neural Tube

Two general sets of patterning mechanisms along the antero-posterior and dorso-ventral axes establish a grid-like organization in the neural tube. Along the antero-posterior axis, six subdivisions of the central nervous system can be distinguished morphologically in the mouse at embryonic day E9.5 (five vesicle stage): (i) telencephalon, (ii) diencephalon (telencephalon and

diencephalon together constitute the prosencephalon or forebrain), (iii) mesencephalon (midbrain), (iv) metencephalon (which will give rise to the pons and cerebellum), (v) myelencephalon (which will give rise to the medulla) and (vi) the spinal cord. Metencephalon and myelencephalon together form the rhombencephalon (hindbrain).

Different paradigms are used for the patterning along the antero-posterior axis. The myelencephalon is segmented into rhombomeres. The mes- and metencephalon are patterned by gradients of ►morphogens, which are secreted by the isthmus organizer at the junction of mid- and hindbrain. ►Morphogens are paracrine signals that act over distance in a concentration-dependent manner. In the forebrain, the two mechanisms have been combined; the forebrain is segmented into prosomeres, which are patterned by morphogens that are released by the anterior neural ridge and the zona limitans intrathalamica.

Non-neural tissues correspond to early signaling centers that pattern neural tissues along the antero-posterior axis. Signals from non-neural ectoderm, the organizer, axial and paraxial mesoderm are involved. In response to these, secondary signaling centers arise within the neural tube (2). The isthmus organizer is a secondary signaling center that is formed at the mid-/hind-brain border and secretes the patterning signals FGF8 and Wnt1. Another signaling center, the anterior neural ridge, arises at the border of the anterior neural plate and the ectoderm. FGF8 is an important morphogen secreted by this structure. Reduction in the FGF8 level leads to forebrain truncations. The zona limitans intrathalamica, a further secondary signaling center, forms in the diencephalons. One important morphogenic molecule produced in the zona limitans intrathalamica is Sonic hedgehog (Shh).

Along the dorso-ventral axis, four subdivisions, the floor, basal, alar and roof plates, can be distinguished in the entire neural tube. Initially, signals that establish the dorso-ventral polarity are provided ventrally by the prechordal plate and notochord and dorsally by the surface ectoderm. The ventral signaling center is subsequently transferred from the prechordal plate and notochord to the floor plate. Similarly, the dorsal signaling center is transferred from the surface ectoderm to the roof plate.

Shh is the principal ventralizing signal (4). It is initially expressed by the axial mesoderm and later by the floor plate. Shh acts as a morphogen, i.e. it induces ventral neuronal and glial cell types in a concentration dependent manner. Members of the TGFβ (transforming growth factor-β) family provide dorsalizing signals (5). BMPs, dorsalin-1 and growth differentiation factors (GDFs) are secreted in the roof plate. BMPs induce dorsal neuron types in naive spinal cord explants.

Homeobox and bHLH Transcription Factors Define Regional Identity

A general readout of the patterning signals in the neural tube is the expression of patterning genes encoding mainly ►homeobox and ►basic-helix-loop-helix transcription factors in restricted progenitor domains. In the ventral spinal cord, for instance, graded Shh signaling specifies the identity of progenitors by regulating the expression of transcription factors that fall into two major groups, a set of class I proteins that are repressed by Shh signaling and a set of class II proteins that are induced by Shh. These proteins function primarily as transcriptional repressors and their selective cross-regulatory interactions help to establish specific neural progenitor domains and to sharpen the boundaries between these domains. The established subdivisions manifest themselves by the presence of a specific combinatorial code of transcription factors. This code subsequently instructs the fate of the cells generated by the progenitors, i.e. different neuronal and glial cell types (6).

A particular subfamily of homeobox factors encoded by the genes of the *Hox* clusters patterns the hindbrain and the spinal cord. The hindbrain is segmented into rhombomeres and the anterior border of the expression of many *Hox* genes coincides with rhombomere boundaries. A combinatorial code of Hox factors thus defines the rhombomere identity and the types of neurons generated therein. The most posterior rhombomeres and the spinal cord are not obviously segmented. Nevertheless, expression of *Hox* genes shows antero-posterior specificity and *Hox* gene expression instructs axial level specificity in the generation of motor neuron subtypes (7). A hallmark of *Hox* gene expression in the hindbrain is the regulation by retinoic acid. Furthermore, ephrins and their Eph-receptors are expressed in specific rhombomeres and are targets of patterning genes in the hindbrain. Eph signaling is suggested to mediate repulsion between cells of neighboring rhombomeres and to compartmentalize the hindbrain.

Generation of Neuronal and Glial cells

In parallel to the patterning mechanisms that control regional identity, mechanisms exist that control the timing of proliferation and differentiation of progenitor cells in the neural tube.

Proliferating progenitor cells of the central nervous system reside within the ►ventricular zone of the neural tube. They have stem cell features, i.e. they can self-renew, are multipotent and give rise to multiple types of postmitotic neurons and glial cells. Postmitotic neurons migrate out of the ventricular zone and into the mantle layer of the neural tube. Different neuron types, oligodendrocytes and astrocytes are generated in a

defined temporal order and at particular positions in the neural tube. Neuronal cells are generally produced in an overabundance and the superfluous cells are removed by apoptosis.

Proliferation and differentiation of neural progenitor cells is regionally and temporally controlled during development. Cell numbers in the nervous system are determined by the decision of a dividing progenitor cell to generate two proliferative progenitors or to generate one or two postmitotic daughter cells. ►Proneural transcription factors and Notch signaling influence the decision as to whether a neuroepithelial cell continues to proliferate or begins to differentiate.

Proneural bHLH Factors

Members of the achaete-scute and atonal families, such as Mash1, Math1 and Neurogenins 1 and 2, are bHLH transcription factors that have proneural activity (8). They function as heterodimers with ubiquitous bHLH factors known as E proteins. Once proneural factors have accumulated at a sufficient level, they induce cell-cycle exit and differentiation. The expression of proneural genes in individual neural progenitors is only transient. Proneural genes are down-regulated before progenitor cells exit the proliferative zone and begin to differentiate. The ability of proneural genes to promote neuronal differentiation thus relies on the induction of target genes that implement the differentiation programmes. Genes of the bHLH family, such as *NeuroD*, or homeobox genes, such as *Hb9*, can consolidate the neuronal differentiation programme.

Proneural genes are often expressed in restricted progenitor domains in the neural tube. This observation and the structural diversity of these factors suggested that they possess not only proneural activity but also specify neuronal identity. The dorsal embryonic spinal cord provides an example of the functional differences between the different bHLH factors Math1, Neurogenin-1 and -2 and Mash1. The factors are expressed in discrete, neighboring and non-overlapping progenitor domains that produce distinct types of dorsal interneurons. The analysis of Math1 and compound Neurogenin-1 and -2 mouse mutants has shown that these proneural factors are indeed essential for the correct specification of specific interneurons. Thus, proneural bHLH genes appear to determine also the acquisition of particular neural fates.

Proneural factors do not only trigger the differentiation of neural progenitors, but are also instrumental in coupling the onset of differentiation with cell-cycle exit. Induction of the cell-cycle exit by proneural factors coincides with the expression of genes that encode cyclin-dependent kinase inhibitors, such as p16, p21 and p27, which inhibit the entry into S-phase.

Notch Signaling Mediates Lateral Inhibition

The activity of proneural factors has to be tightly controlled to preserve the progenitor pool over the extended period of neurogenesis. This is achieved by an inhibitory feedback mechanism called ►**lateral inhibition**, i.e. differentiating cells provide signals to their neighbors that instruct them to remain progenitors. Proneural factors not only induce differentiation but also the expression of genes that encode the Notch ligands Delta and Serrate/Jagged. The presence of these ligands in one cell activates Notch in the neighboring cells. Notch activation induces the expression of target genes, for instance those that encode the Hairy-Enhancer-of-split/Hes bHLH factors, which inhibit the proneural factors. Thus, a cell that receives Notch signals maintains its progenitor status. Since cells that express proneural factors and Notch ligands differentiate and leave the ventricular zone, Notch is only transiently activated, which allows the selection of new cells for the next round of differentiation.

Lateral inhibition has been well studied in *Drosophila* and illustrates the mechanism by which single neural precursor cells are selected in the ectoderm from a cluster of equivalent cells. Subsequently, Notch regulates the acquisition of different fates by the two daughter cells that are generated by a single precursor cell. In this context, Notch signaling is regulated by other proteins, among them the cytoplasmic protein Numb that binds to Notch and inhibits Notch signaling. During division of a precursor cell, Numb becomes asymmetrically distributed to one of the two daughter cells where it antagonizes Notch signaling. The difference in Notch activity determines the distinct cellular identities of the daughter cells.

Two Numb homologs, Numb and Numb-like, are found in vertebrates. Compound Numb/Numb-like mutant mice show hyperproliferation of cortical progenitor cells and impaired neuronal differentiation (9). The proportion of progenitor cells that gave rise to two progenitor daughter cells, as opposed to progenitors that generated one or two differentiating daughter cells, was greatly increased. Thus, Numb and Numb-like control asymmetric cell divisions in the nervous system of vertebrates and have similar functions to *Drosophila* Numb.

Patterning and Differentiation

The expression of most patterning genes ceases when neural precursor cells exit the cell-cycle and begin to differentiate. Patterning information is passed from the progenitors to their progeny by induction of a new set of transcription factors, which instruct the subsequent differentiation of postmitotic neurons. This mechanism is understood best in the spinal cord for the induction of motor neurons. There, the expression of the *Pax6*, *Nkx6* and *Olig2* genes defines the motor neuron

progenitor domain. *Olig2* acts as a bHLH factor that has patterning function and also induces the proneural bHLH factor Neurogenin-2. Together these factors induce in the emerging motor neurons the synthesis of transcription factors, such as *Lhx3*, *Isl1/2* and *Hb9* that specify and consolidate the motor neuron identity. Depending on the axial level, motor neurons subsequently acquire different identities. Axial level specific expression of genes of the *Hox* clusters specifies this identity. Visceral motor neurons that innervate sympathetic ganglia develop only on thoracic spinal cord levels. Their differentiation is induced by *Hoxc9*. The lateral motor column arises only at limb levels and contains motor neurons that innervate limb muscles. Differentiation of brachial lateral motor column neurons is specified by *Hoxc6* (7).

Generation of Glial Cells

Glia comprises 10–20% of the cells in the *Drosophila* nervous system and more than 90% of the cells of the human brain. The major glial types in the central nervous system are ►**oligodendrocytes** and ►**astrocytes**, which derive from the neuroepithelium. Oligodendrocytes form myelin sheaths, which allow faster conductance. Astrocytes are diverse in phenotype and function and, for instance, maintain the blood-brain barrier, produce neuropeptides and modulate synaptic transmission. Glia of the peripheral nervous system comprises ►**Schwann cells**, the myelinating cells in peripheral nerves, and non-myelinating cells, for instance the satellite cells in the ganglia. Like peripheral neurons, ►**glial cells** of the peripheral nervous system derive from the neural crest.

Oligodendrocyte precursor cells are specified in the neural tube by a mechanism that is similar to the specification of neurons. In the spinal cord and hindbrain, oligodendrocytes derive from the same set of progenitors that generated motor neurons at earlier stages. The functional analysis of *Olig-1* and *-2* genes provided an insight into the molecular link between motor neuron and oligodendrocyte development (10). In the mouse spinal cord, *Olig-2* is essential for specification of motor neurons between E9 and E10.5 and for the subsequent specification of oligodendrocyte precursors at E12.5. *Olig-1/2* positive progenitors in the brain and spinal cord appear to be restricted in their fate and generate neurons and oligodendrocytes but not astrocytes. Astrocytes are thought to arise in the central nervous system after neurogenesis has ceased. On a molecular level, the specification of astrocytes has not been characterized.

Peripheral glial cells differentiate from pluripotent ►**neural crest cells**. *Sox10*, a member of the ►**high-mobility-group transcription factor** family, is a key regulator in the differentiation of peripheral glial cells (11). In *Sox10* mutant mice, neuronal cells form in

dorsal root ganglia, but Schwann cells and satellite cells are not generated. Sox10 controls the expression of *Notch1* in neural crest cells. The expression of activated Notch in undifferentiated neural crest cells inhibits neuronal and promotes Schwann cell differentiation. Thus, Sox10 could control the acquisition of glial fates in the peripheral nervous system *via* induction of Notch, which subsequently promotes glial differentiation. Sox10 also controls the expression of *ErbB3*, a Neuregulin-1 receptor in Schwann cells, that controls growth and proliferation during their development. Motor and sensory neurons produce Neuregulin-1 and this neuron-derived signal adjusts the number of Schwann cell progenitor cells during development. Neuron-derived Neuregulin-1 also influences the thickness of the myelin sheath and thus regulates Schwann cell function in adulthood.

Neurotrophic Factors and Neuronal Survival

Neurons are produced in an overabundance during development and their number is adjusted by apoptosis in both vertebrates and invertebrates. What might be an evolutionary advantage of this? The peak of neuronal cell death is observed during the establishment of neuronal connections. The complexity of the nervous system is high and the correct connectivity might not be ensured solely by neuronal identity and controlled axonal pathfinding. Instead, correct connectivity appears to be achieved by an elimination of those neurons that made inappropriate contacts. In addition, the final numbers of neurons in a neuronal circuit can be adjusted by this mechanism.

The ►**neurotrophic factor hypothesis** suggested that the target of innervation of a particular neuron produces a limited amount of a neurotrophin, i.e. a molecule that is essential for the survival of the neuron. Originally it was assumed that neurotrophic factors are essential nutrients for neurons, but their subsequent characterization demonstrated that they are signaling molecules that act anti-apoptotically. The classic neurotrophins are members of the nerve growth factor family and signal *via* the Trk tyrosine kinase receptors and *via* the low affinity NGF receptor p75; p75 acts as a Trk co-receptor but can also signal on its own. Other factors, many of which signal *via* ►**tyrosine kinase receptors**, for instance glial-derived neurotrophic factor (GDNF) and hepatocyte growth factor (HGF), were also shown to possess neurotrophic activity. Genetic analysis in mice has demonstrated that neurotrophic factors act in a neuron type specific manner. For instance, muscle spindle derived neurotrophin-3 (NT3) is required for the differentiation and survival of proprioceptive sensory neurons.

Mutational analysis in mice has not provided clear evidence for a function of neurotrophic factors in the regulation of neuronal survival in the central nervous

system. This may be due to the redundant actions of various neurotrophins. Ectopic application of neurotrophic factors can, however, reduce *in vivo* and *in vitro* cell death of neurons. The importance of neurotrophic factors goes beyond a regulation of apoptosis and includes functions in synaptogenesis and synaptic plasticity (12).

Guidance of Neuronal Migration and Axon Growth

Neurons and glial cells can migrate from their place of origin to their final position over large distances. Within the central nervous system, two principal modes of neuronal migration can be observed, radial migration, in which cells migrate from the ventricular zone towards the surface of the brain, and tangential or non-radial migration. Most structures of the brain integrate neurons that arrive *via* radial and tangential migrations. Cues used to direct tangentially migrating neurons appear to be similar to those that direct axon pathfinding. Distinct molecular mechanisms are used during radial migration.

Radial Migration

Processes of radial glial cells guide migrating neurons during the formation of the cortical plate. Radial glial cells arise throughout the neural tube during early development. Their cell bodies are located in the ventricular zone and they elaborate a process that spans the wall of the neural tube from the ventricular (apical) to the pial (basal) surface. The term “glial” can be misleading, since these cells represent progenitor cells that can give rise to neurons and glial cells.

Layers in the cortical plate are established according to an inside-outside pattern, where deeper layers are formed by neurons of early origin and superficial layers by later born neurons. Cohorts of migrating neurons pass over previously developed neurons until they reach the marginal zone, where they detach from the radial glia. Cajal-Retzius cells are a particular neuronal cell type that originates before the cortical plate forms and resides in the marginal zone. These cells secrete Reelin, a high affinity ligand for receptors of the LRP family, VLDLR and LRP8 (also known as ApoER2). The Reelin signal is transduced by the intracellular adaptor protein Disabled-1. Mice lacking Reelin, the VLDLR and LRP8 receptors or Disabled-1 have similar migration defects in the cortex and in other brain regions. Reelin and its receptors are therefore important components in the control of radial migration of neurons.

►Axon Guidance

Many neurons extend axons over great distances before they form synapses on the appropriate target cells. Some general strategies are employed to guide growing axons to their target area. One strategy is the use of

pioneer axons, which correspond to axons that grow early in the embryo and serve as a scaffold for later growing axons. Another strategy is to break the long journey of an axon into segments and to use guidance cues for each of the intervals. Furthermore, axons grow in bundles before successively smaller groups of axons diverge at specific sites along the path. This strategy allows the iterative use of a limited number of signaling molecules for axon guidance. Furthermore, axons are able to modulate their responsiveness along their route and guidance cues are often multifunctional depending on cellular context.

The growth cone is the essential cellular compartment for the steering of axons. It constitutes a specialized terminal apparatus and fulfils both sensory and motor functions. Growth cones contain numerous receptors for environmental cues and transmit them to cytoskeletal proteins and actin-based motors that generate either forward movement or growth cone collapse (13). Molecules that Direct Axon Pathfinding

Growth of axons is guided by their substrate preferences and by directional cues. Substrates for growing axons can be extracellular matrix, cell surface or other axons in axon fascicles. Molecules of the extracellular matrix like laminins, collagens and fibronectin are recognized by receptors of the integrin family. Proteoglycans can modulate axon growth through interactions with neural adhesion molecules. Cadherins and immunoglobulin-like adhesion molecules mediate differential cell-cell adhesion.

Directional cues may act over long or short distances, may be bound to the extracellular matrix or to the cell surface or may be soluble and produced by a spatially defined source. They can act as chemoattractant or chemorepellent. Here, I will briefly summarize the major families of guidance cues and their receptors (13).

Netrins were discovered as soluble chemoattractants for vertebrate commissural axons. Across species, their function of attracting axons toward the midline has been conserved. Netrins can also act as repulsive factors. One netrin receptor, deleted-in-colorectal-cancer (DCC), mediates attraction to netrins but can also participate in repulsion. The second netrin receptor, *unc-5*, transmits repulsive signals alone or in combination with DCC.

Slits are secreted proteins that signal through Roundabout (Robo) family receptors. Slits and Robo receptors were identified as mediators of short-range signals that repel axons at the midline. Slit was also purified as a factor that stimulates sensory axon branching and elongation.

Semaphorins are a family of ligands encoded by more than 20 genes in mammals and were initially purified as inducers of growth cone collapse in sensory

neurons. Semaphorins seem to act predominantly as short-range or contact-mediated repulsive cues. Semaphorins can be secreted, attached to the cell surface through a GPI-anchor or be transmembrane proteins. Transmembrane semaphorins can back-signal, i.e. they can also function as receptors. Semaphorins signal through multimeric receptor complexes. Transmembrane semaphorins bind to receptors of the plexin family. Secreted semaphorins require neuropilins as co-receptors.

Ephrins were identified in the search for graded signals that instruct the formation of the topographic map of retinotectal projections in the optic tectum. They signal through a large family of tyrosine kinase receptors, the Eph-receptors. Ephrins are membrane anchored either by a GPI-anchor (ephrinA) or through a transmembrane domain (ephrinB), and they can function as back-signaling receptors. Ephrins and Eph-receptors mediate repulsive and attractive cues.

Recently, morphogens such as Shh, BMPs and Wnts and neurotrophins like NGF were also shown to possess axon guidance activity. The canonical signal transduction pathways by which these factors control cell fate are well studied and involve transcriptional regulation. Non-canonical pathways coupled directly to the cytoskeleton are expected to mediate the axon guidance activity of these morphogens.

Synapse Formation

How are precise synaptic connections between specific pre- and postsynaptic neurons established? In 1963, Roger Sperry proposed that “highly specific cytochemical affinities” between an axon and its target cell determine the establishment of axonal connections. One key feature of this model is that the precise connectivity develops as a predetermined process and is independent of neural activity. Instead, the establishment of proper connections between a neuron and its target is thought to rely on a recognition process, i.e. the matching of adhesive surface molecules. These molecules might include cadherins, immunoglobulin superfamily cell adhesion molecules and ephrins and Eph receptors (14, 15). Further synapse formation relies on signals exchanged between axon and target cell. Activity-dependent mechanisms refine the pattern of connectivity after synaptic connections are established. The [▶neuromuscular junction](#) is the best-understood synapse and provides a paradigm for understanding the molecular mechanisms of formation and activity-dependent refinement of synapses.

Initiation of Synapse Formation

The neuromuscular junction constitutes a specialized cholinergic synapse between a motor neuron and a skeletal muscle cell (16). It comprises a motor axon

terminal, a muscle fiber and glial cells. All three acquire specialized features in the neuromuscular junction. The axon terminal is rich in synaptic vesicles, which are clustered at dense patches on the presynaptic membrane called active zones, where they can fuse with the plasma membrane to release neurotransmitter into the synaptic cleft. The surface of the muscle fiber forms a series of indentations opposite to the active zones, called junctional folds. These postsynaptic sites are rich in acetylcholine receptors and specialized cell adhesion and signaling molecules and contain an intricate cytoskeletal network. A muscle fiber (also called a myotube) arises through fusion of myoblasts and is therefore a multinucleated cell. mRNAs coding for components of the postsynaptic apparatus, such as the different subunits of the acetylcholine receptor, are only transcribed in synaptic nuclei underlying the neuromuscular junction after the synapse has formed. The formation of the neuromuscular junction is initiated when a motor axon approaches a muscle fiber. The axon terminal senses some as yet unidentified cue on the muscle cell, the contact is made and pre- and post-synaptic differentiation begins. Most synaptic components of the motor neuron and the myotube are already synthesized before the synapse forms. For example, motor neurons form synaptic vesicles and produce neurotransmitters in the absence of muscle. Uninnervated myotubes synthesize functional acetylcholine receptors, which can form clusters and associate with components of the cytoskeleton. Exchange of signals between motor axon and myotube is however required to coordinate the assembly of the pre- and post-synaptic apparatus in a spatially and temporally controlled manner.

Agrin is a large proteoglycan that is secreted by motor neurons and incorporated into the synaptic basal lamina. Agrin induces postsynaptic differentiation and the number, size and density of acetylcholine receptor clusters is severely reduced in *Agrin* mutant mice. The observed phenotype indicates that Agrin provides the initial signal for the assembly of the pre- and post-synaptic apparatus.

The muscle-specific tyrosine kinase (MuSK) appears to be required for the recognition of Agrin and for the formation of neuromuscular junctions. Agrin induces the kinase activity of MuSK, can be chemically crosslinked to MuSK, but does not bind MuSK directly. The phenotype of *MuSK* mutant mice is very similar to that of *Agrin* mutants, i.e. postsynaptic specialization is severely impaired. Moreover, motor axons behave abnormally in *Agrin* and *MuSK* mutant mice, i.e. they continue to sprout after reaching the muscle and do not initiate presynaptic differentiation.

Rapsyn is required for postsynaptic differentiation and acts downstream of the MuSK signal in the muscle. It is

a peripheral membrane protein that colocalizes with acetylcholine receptors. MuSK concentrates at postsynaptic sites and becomes activated in the absence of Rapsyn, but clustering of acetylcholine receptor and other postsynaptic components fails. MuSK is thus a critical component of a primary postsynaptic scaffold, which recruits Rapsyn, as well as acetylcholine receptors and other proteins.

Postsynaptic specialization of neuromuscular junctions includes synapse specific gene expression, which appears to be independent of Rapsyn and the clustering of acetylcholine receptor. Neuregulin-1 (also known as acetylcholine receptor inducing activity, ARIA) can stimulate acetylcholine receptor expression in muscle cells *in vitro* and was proposed to regulate synapse-specific gene expression. While transcription of genes encoding acetylcholine receptor subunits is increased in synaptic nuclei, their expression is suppressed in non-synaptic nuclei. Activity induced changes in intracellular Ca^{2+} concentrations are thought to trigger a signaling cascade that reduces acetylcholine receptor gene expression in non-synaptic nuclei.

The muscle fiber organizes the differentiation of the presynaptic axon terminal. The change in transmission efficacy, accumulation of synaptic vesicles and formation of active zones require retrograde signals from the muscle fiber. Little is known about the nature of these signals. Candidate molecules include cell adhesion molecules like N-CAM and N-cadherin, soluble factors like brain-derived neurotrophic factor (BDNF) and components of the synaptic basal lamina like laminin-11.

Synapse Elimination at Neuromuscular Junctions

In the adult skeletal muscle, one motor neuron innervates many muscle fibers, but the majority of muscle fibers are typically innervated by a single axon. During development, however, several axons synapse with one muscle fiber, and all but one axon contact are eliminated postnatally. This is not a consequence of neuronal death.

Polyneuronal innervation of target cells and subsequent elimination of synapses are often observed when groups of neurons with similar or identical function innervate homogenous populations of target cells. This is, for instance, the case when motor neurons innervate individual muscle fibers. Apparently, mechanisms of axon guidance and target specificity do not explicitly instruct the connectivity pattern within a particular muscle. Synapse elimination occurs gradually over time and requires muscle activity. The process of synapse elimination seems to begin in the postsynaptic membrane, with a decrease in density of acetylcholine receptors and other postsynaptic proteins. The muscle fiber becomes gradually unresponsive to stimulation by

this axon terminal. Loss of the postmitotic apparatus causes the retraction of the motor axon, but the nature of the retrograde signal is currently unclear. Synapse loss is initiated by an activity dependent competition between different motor axons that innervate a single muscle fiber (18). This form of heterosynaptic depression satisfies the Hebbian rule; synaptic efficacy is stable or strengthened if pre- and post-synaptic activities are coincident and weakened if they are non-coincident. The molecular mechanisms leading to synapse destabilization are as yet unclear, but it is known that repetitive elevation of Ca^{2+} levels in the muscle fiber is necessary and sufficient for heterosynaptic depression.

Concluding Remarks

Developmental neuroscience is an exciting and diverse field of research. Recent advances in technologies such as mouse genetics, microarray expression profiling and imaging have promoted our molecular understanding tremendously. In this essay, I have tried to give a general overview of developmental strategies and molecular mechanisms that guide neural development. More detailed information is provided in the review articles cited. For more comprehensive descriptions of neural development, I would refer the reader to two textbooks (18, 19).

Neural Networks

Definition

Neural networks are paradigms for computing based on the processing/memory abstraction of human information processing. The approach is represented by a multi-layer structure composed of widely connected nodes with the ability to learn. Neural networking derives meaning from complicated or imprecise data, and can be used to extract patterns too complex to be detected by other techniques.

► [EST Mining for Expression Analysis](#)

Neural Plate

Definition

Neural plate describes a portion of the dorsal ectoderm that is specified to become neuroectoderm during gastrulation. Its cells become columnar by appearance. This region of the embryo is called neural plate.

Gerd Kempermann, Max-Delbrück-Center for Molecular Medicine (MDC) Berlin-Buch, Berlin, Germany
gerd.kempermann@mdc-berlin.de

Definition

Neural **stem cells** are self-renewing and undifferentiated cells, from which the nervous system or parts of it can develop. Neural stem cells are **multipotent**, which means that their potential for differentiation is limited to cell types of their own germ layer, the neuroectoderm, but not of mesoderm or endoderm. Embryonic stem cells, in contrast, are **pluripotent**, because they can generate cells for all three germ layers. The main lineages of neural tissues into which neural stem cells can develop are neurons, astrocytes and oligodendrocytes. Brain cells that are not of neuroectodermal origin, such as microglia, macrophages, lymphocytes, meningeal cells and the vasculature are not derived from neural stem cells. Neural

stem cells can be found in the developing brain, but they persist during adulthood. In two regions of the adult brain, hippocampus and olfactory bulb, neural stem cells continue to produce neurons throughout life (**adult neurogenesis**) (Fig. 1).

Characteristics

General Principles

A number of defining principles apply to neural stem cells as to all other types of stem cells. In general, stem cells have two characteristics, the ability to self-renew and the potency to generate two or more different tissue or cell types (multipotency). Self-renewal means that cell division generates at least one identical copy of the mother cell. Symmetric stem cell divisions produce two identical copies; asymmetric divisions yield one stem cell identical to the mother cell and one cell which is relatively more determined towards a specific lineage of differentiation than the stem cell. These daughter cells show reduced self-renewal but increased lineage restriction and are referred to as "**progenitor cells**". Irrespective of their limited **self-renewal**, progenitor cells are more proliferative than stem cells and can vastly expand the number of new cells. They are thus often referred to as "transiently amplifying progenitor cells". Cells with different "degrees of stemness" can be

Neural Stem Cells. Figure 1 Neural stem cells are stem cells within the neuroectoderm. They generate neurons, oligodendrocytes and astrocytes. Like all other somatic or tissue-specific precursor cells they are multipotent. Embryonic stem cells, in contrast, are found in the inner cell mass of the blastocyst, before the germ layers have formed. Embryonic stem cells are pluripotent. Neural stem cells can be found in the developing and adult brain.

identified in the brain (and elsewhere), but in a concrete situation the categorization of a cell as a stem cell or a progenitor cell is impossible. The term “▶precursor cell” is used as an umbrella term encompassing both stem and progenitor cells. In most contexts of brain research the use of the term “stem cell” can be misleading, because tests of “stemness” have not actually been carried out.

Stem cells are cells in which more of the genomic information is accessible than in differentiated cells. Increasing tissue and lineage restriction of precursor cells is equal to an increasing limitation of this accessibility. It is not known how the stem cell potential is regulated on the chromatin level. But precursor cells are heterogeneous and their developmental potential is context-sensitive with regard to both space and time. Precursor cells from the ventricular wall produced hippocampal granule cells upon implantation into the dentate gyrus. Hippocampal precursor cells, when implanted into the olfactory system, generated new olfactory neurons. The earlier in development the transplantation occurs the greater the developmental potential. Early neural precursor cells implanted in later stage embryos integrated site and time specifically. In contrast, precursor cells from later stages implanted into earlier developmental stages failed to differentiate to the same extent as the early precursors. This argues in favor of an increasing limitation of potentials with progressing development. In principle, temporal identity is less flexible than spatial identity.

Neural Stem Cells *In Vitro* and *In Vivo*

In the developing and adult ▶brain, stem cells are found in the germinative matrices that originate from the ventricular wall.

Two protocols exist to bring neural stem cells into culture, adherent cultures and cell suspensions in which aggregates form (so-called “neurospheres”). The ability to form these aggregates alone does not prove the “stemness” of the cells. Rather it has to be demonstrated that single cells isolated from such spheres can clonally generate new secondary spheres. Cells are grown in serum-free conditions with fibroblast-growth factor 2 (FGF2) or epidermal growth factor (EGF) as mitogens. Both isolation strategies differ fundamentally from the isolation of hematopoietic stem cells for which a number of surface antigens that can be used for a prospective isolation based on the binding of specific antibodies are known. Stem cells are then defined as cells of a particular antigen profile (1). A similar strategy has been applied to identifying stem cells in the brain but had only a low yield. The relationship of the isolated cells to stem cells identified by the other methods is not known.

In vitro, multipotency is routinely assessed after inducing differentiation in stem cell cultures by withdrawing growth factors and adding serum to the culture

medium. The detection of cells from the three main neural lineages is taken as proof of multipotency. In most studies the identification of neurons, astrocytes and oligodendrocytes is based on the immunocytochemical detection of key antigens, such as beta-III-tubulin, Map-2 or ▶NeuN for neurons, O4 for oligodendrocytes and glial fibrillary acidic protein (▶GFAP) for astrocytes. Electrophysiology has also been used to confirm the function of stem cells and their progeny.

One important concern besides the marker sensitivity and specificity is that the culture conditions themselves might induce multipotency in the precursor cells. There is so far no direct evidence that neural stem cells are multipotent *in vivo*, because this conclusion is based on an analogy drawn from *in vitro* studies. Transplantation studies have generally indicated that local cues direct the realization of the developmental potential. Similarly, it has been argued that culture conditions determine the properties of the precursor cells, with different sets of culture conditions yielding incommensurable results. This does not mean that precursor cell identities are “culture artifacts”, but that precursor cell properties can be determined by external cues. This is in contrast to the view that “stemness” is entirely an intrinsic property. The extreme version of this idea is that “stem cell” is not a cellular property at all, but a functional state (2). In this sense, a population of cells, susceptible to these local stemness-inducing cues circulates through the body and context-dependently performs different types of stem cell function.

Neural Stem Cells in the Adult Brain

Although neural stem cells can be isolated from many brain regions including white matter tracts, in only two neurogenic regions of the adult brain, the ▶hippocampus and the olfactory system, are new neurons generated throughout adulthood. This “adult neurogenesis” has been confirmed for most scientifically relevant mammalian species including primates and humans. The functional relevance of adult neurogenesis is under intensive investigation. The hypothesis for the hippocampus is that the new neurons contribute to the adaptation of the hippocampal network to meet the levels of complexity and novelty experienced by the individual, thus optimizing information processing during learning. Consequently, a failure of adult hippocampal neurogenesis has been connected with hippocampus-related disorders such as dementias, major depression and temporal lobe epilepsy.

Except for the dentate gyrus and the olfactory system the adult brain appears to be non-neurogenic under normal conditions. Reports about physiological neurogenesis in other brain regions have so far remained controversial.

The lack of prospective stem cell markers causes particular problems when studying stem cells *in vivo*.

Intermediate filament ►**nestin** can be used to identify putative stem or progenitor cells, but neither sensitivity nor specificity are known. Nestin shows a surprising overlap with the expression of the astrocytic marker GFAP.

Neural stem cells of the adult subventricular zone have astrocytic properties, express GFAP and have a cilia-bearing process contacting the ventricular surface. They are called B cells and generate a population of transiently amplifying progenitor cells, called C cells, which in turn produce migrating neuroblasts, called A cells (3). The latter continue to divide while they migrate along the rostral migratory stream to the olfactory bulb, where they differentiate into two types of interneurons.

The putative neural stem cells of the adult dentate gyrus show astrocytic properties and GFAP-expression, and have a radial glia-like morphology. They are named type-1 cells (4). Like B cells of the subventricular zone they rarely divide, but generate populations of transiently amplifying progenitor cells that, depending on their expression of immature neuronal markers, can be distinguished as type-2a, type-2b and type-3 cells. Regulatory stimuli affect these stages differently. After exit from the cell-cycle the new neurons mature into functional granule cells over a period of several weeks. The populations of the putative transiently amplifying progenitor cells of both neurogenic regions are negative for GFAP, but positive for doublecortin and the polysialylated form of the neural cell adhesion molecule (PSA-NCAM). When adult hippocampal neurogenesis is stimulated, the expansion occurs in these intermediate populations. Similarly, an intermediate progenitor cell exists in the glial lineage.

Many nestin-expressing cells can be found throughout the adult brain, but it is not known which of these have precursor cell properties.

Molecular Interactions

Neural stem cells during development are characterized by their “positional identity”, that is the role they play within a coordinate system defined by rostro-caudal, left-right and ventral-dorsal axes. Depending on environmental cues, precursor cells take on different identities. In the developing brain, ►**bone morphogenic proteins** (BMPs) are expressed at the dorsal midline, whereas sonic ►**hedgehog** (Shh) is expressed at the ventral midline. Their antagonistic effects define positional identity in the ventral-dorsal orientation. As development proceeds, cells seem to remain sensitive to some of these cues; ventralized stem cells could be re-specified to a dorsal phenotype after delayed exposure to BMPs, indicating that regional specification is not terminally fixed in progenitor cells. Wnt signaling, as well as different forms of fibroblast growth factor (FGF) and retinoic acid, which are secreted by the

organizer regions of the neural tube, define the rostro-caudal axis.

Within their given position, precursor cells are instructed to divide and expand. Many of the morphogens mentioned such as the BMPs and Shh double in function as mitogens. For Wnt signaling a gradient exists that induces precursor cell proliferation near the site of Wnt expression in the roof plate and exit from the cell-cycle at greater distances. Consequently, cell differentiation during development shows a gradient inverse to Wnt signaling (5). In the dorsal brain Wnt acts as a mitogen downstream of BMPs. The receptors for FGF2, EGF and transforming growth factor alpha (TGF α) are expressed throughout the developing nervous system and they strongly induce proliferation. But even classical mitogens such as FGF2 are involved in defining differentiation patterns.

►**Basic helix-loop-helix** proteins (bHLH) are involved in balancing the exit from the cell-cycle and the initiation of differentiation. Notch expression maintains stem cell properties and inhibits neuronal differentiation by tilting the balance of *Hes* gene expression against the neurogenic isoforms of *Hes*. Similarly, activation of the LIF/STAT pathway maintains precursor cells in a multipotent state. Besides its function in determining positional identity, Shh is expressed in brain regions that undergo late and massive cell expansions, most notably the cortex. Here BMP signaling acts pro-differentiation.

Most newly generated cells during brain development die by apoptosis, especially during the early gestational expansion phases. This early phase is also characterized by symmetric divisions of the precursor cells. Pax6 and Emx2 are two examples of transcription factors that are involved in regulating the transition between the expansion phase and the neurogenic phase during development. Both maintain symmetric divisions. After the transition, mostly neurons are generated in midgestation. Glia is predominantly produced in late gestation and postnatally. The latter two stages are characterized by asymmetric cell divisions. *In vitro* data suggest that during brain development, neural precursor cells dramatically change their responsiveness to extracellular factors. Whereas exogenously applied BMPs induce apoptosis in rat E13 precursor cells, they promote neurogenesis as well as gliogenesis around E16 and only gliogenesis after birth (6).

BHLH transcription factors like Mash1, Ngn 1/2 and NeuroD are required for neuronal differentiation and the inhibition of gliogenesis. But bHLH functions are temporally specific, too. Olig2, for example, is co-factor to Ngn2 for motor neuron differentiation, but later in development together with Nkx2.2 involved in inducing the production of oligodendrocytes. Thus, during development oligodendrocytes and astrocytes might not generally be derived from a common glial

precursor cell but rather from neural precursor cells with different positional identities (7).

Both Notch and LIF signaling that maintain stem cell properties early in development take on new roles in determining cell fate in late development, when both act pro-gliogenically. The current hypothesis is that progenitor cells in the neuronal lineage as well as differentiated neurons secrete factors that direct neural precursors towards gliogenesis. The neurogenic regions in contrast might be defined by a "stem cell niche" comprising astrocytes secreting pro-neurogenic factors (8). In addition, the neurogenic niche of the adult hippocampus is characterized by a close proximity of the putative stem cells to the vasculature, much like precursor cells in the subventricular zone have contact with the ventricular surface. Circulating factors might be involved in determining precursor cell identity and activity in these regions throughout adulthood.

Generally, however, only limited information is available today about the transcriptional regulation of stem cell activity in the adult brain. The reason is that study of normal adult neurogenesis requires normal embryonic brain development. Due to the redundant use of many transcription factors at different developmental stages most conventional mutant models cannot be used; their developmental phenotype precludes the clear establishment of an adult phenotype.

Regulatory Mechanisms

Neural stem cell activity is regulated on several conceptual levels from transcriptional regulation as described above to behavior of the entire individual. Neural stem cells in the adult brain take part in neural plasticity, i.e. the structural adaptation of the brain according to functional demands. They respond to many physiological and pathological stimuli, and a vast literature describes these effects. On a behavioral level physical activity and exposure to environmental enrichment stimulate precursor cell activity and adult neurogenesis *in vivo*. Neurotransmitters from different transmitter systems, hormones, circulating and locally secreted growth factors, etc. can all influence the different stages of neuronal development. The underlying pathways are still largely unknown as are the genetic and molecular determinants of stem cell activity in the adult. What has become clear, however, is that development continues throughout life. Neural stem cell activity and neuronal development in the adult can be seen to be in line with embryonic brain development. Regulation of adult neurogenesis appears to be more strongly influenced by external stimuli than embryonic development. But many transcription factors known from embryogenesis appear to play a role in adult neurogenesis and its regulation as well. Pax6 for example is a likely candidate to maintain the neurogenic potential of radial glia-like precursor cells

both in development and adulthood. In the adult subventricular zone the BMP antagonist noggin inhibits gliogenesis and promotes neurogenesis. Many more details of these molecular pathways have to be elucidated in the adult in order to relate them to the observed macroscopic net regulation of adult neurogenesis. To date, it is difficult to link external regulatory cues to specific effects on the precursor cell level. However, the finding, that stem cells are regulated in the adult brain makes it promising to apply the knowledge about embryonic brain development to the situation in the adult.

Definition

► Neurofibromatosis Type 1 (NF1), Genetics is one of the most common dominantly inherited neurogenetic disorders, affecting about 1 in every 3500 individuals worldwide. The condition is characterised by multiple café-au-lait spots, benign ►neurofibromas and Lisch nodules (1). The café-au-lait spots tend to arise during infancy with ~80% of individuals with NF1 manifesting café-au-lait spots by one year of age. Dermal neurofibromas tend to arise during adolescence and are always benign. Lisch nodules are benign nodules on the surface of the iris and do not affect vision. They are best detected using an ophthalmic slit lamp examination. Other clinical manifestations include abnormalities of the cardiovascular, gastrointestinal, renal and endocrine systems, major orthopaedic problems, facial and body disfigurement, cognitive deficit and malignancy in the form of tumours of the peripheral nerve sheath and central nervous system. The less common features of NF1 include optic pathway gliomas (15%), ►plexiform neurofibromas (25–40%), malignant peripheral nerve sheath tumours (10%), learning problems (30–50%), tibial pseudoarthrosis (5%), dysplastic scoliosis (5%) and renal artery stenosis (1–2%). Individuals with NF1 have a 4- to 5-fold increased risk of developing malignancy (2). Clinical expression is highly variable even within the affected members of a family with identical mutations in the ►NF1 gene. The appearance of many manifestations of NF1 appears

to be age-dependent, although NF1 is fully penetrant by the age of 5.

Characteristics

NF1 Tumours

Neurofibromas are a hallmark feature of NF1 and are associated with the peripheral nerve sheath. Plexiform neurofibromas are associated with major nerve trunks and usually appear in young children; they differ from neurofibromas in having an expanded extracellular matrix. About 10% of these become transformed to malignant peripheral nerve sheath tumours (►MPNSTs), which are soft tissue tumours (sarcomas). Benign and plexiform neurofibromas comprise ►Schwann cells (60–80%), fibroblasts, perineural areas, axons and mast cells. About 15% of NF1 patients have optic gliomas, which rarely become symptomatic. Other rare forms of tumour associated with NF1 include pheochromocytomas, rhabdomyosarcomas, juvenile myeloid leukaemia and myelodysplastic syndrome. Several studies have demonstrated that it is only Schwann cells in the neurofibromas that exhibit ►somatic mutations (3).

Cellular and Molecular Regulation

The *NF1* Gene

The *NF1* gene, located at 17q11.2, spans 350 kb of genomic DNA, contains 60 exons and encodes a 12 kb mRNA transcript (Fig. 1). Introns 1 and 27b are both large, each being approximately 60 kb in size. Three genes (*EVI2A*, *EVI2B* and *OMGP*) are embedded in intron 27b, each comprises two exons. *EVI2A* is a small gene, encoding a 232 amino acid polypeptide, which is expressed in the brain and bone marrow. It encodes a putative transmembrane protein according to sequence analysis. The *EVI2B* gene is also a small gene that encodes a 448 amino acid protein; it is

expressed exclusively in the bone marrow. The *OMGP* gene encodes a 416 amino acid cell adhesion molecule that is expressed primarily in oligodendrocytes. These genes are transcribed in the opposite orientation to the *NF1* gene. The role of these genes (if any) in regulating the *NF1* gene is, however, not known.

The *NF1* gene promoter is located in a CpG island and exhibits a high degree of sequence conservation with other species. The 3' untranslated region (UTR) of the human *NF1* gene is 3.5 kb in length and has been highly conserved during evolution, suggesting that it may be important for mRNA stability or translational efficiency.

The *NF1* Gene Product (►Neurofibromin)

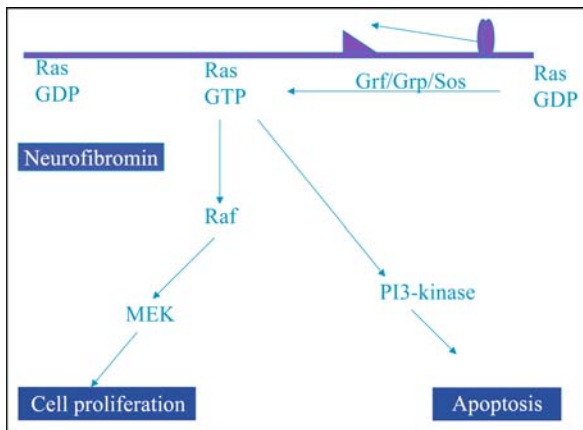

Neurofibromin, the *NF1* gene product, is ubiquitously expressed albeit at low levels. There are three alternatively spliced *NF1* exons (9a, 23a and 48a); 9a is specifically expressed in the brain whereas 48a is predominantly expressed in muscle. In most tissues, there appear to be equal amounts of mRNA with and without exon 23a. The functional significance of these three splice forms is however unclear. The expression of neurofibromin is highest in the central nervous system and it has been shown to be associated with tubulin.

Neurofibromin exhibits structural and sequence similarity to an evolutionarily conserved family of proteins, the mammalian GTPase activating protein (GAP)-related proteins. The most highly conserved region of the protein is the NF1 GAP-related domain (GRD), encoded by exons 20–27a. This is the only domain of neurofibromin to which a function has been ascribed. Activated p21-ras (ras with bound GTP) can transform fibroblasts and increases cell proliferation *in vitro*. Ras is anchored to the cell membrane through isoprenylation of its carboxyl CAAX box, which is mediated by farnesyl transferase. Neurofibromin has been shown to down-regulate cell growth by inactivating p21-ras (ras-GDP). Hence, inactivation of neurofibromin has been postulated to lead to up-regulation of ras activity and increased cellular proliferation. Co-localisation of neurofibromin with ras has however not been demonstrated. The role of activated ras in cell signalling is complex (Fig. 2). Activated ras sends signals along the Raf-mitogen-activated protein (MAP) kinase pathway thereby promoting cellular proliferation. Activated ras also sends signals through the PI3 (phosphatidylinositol 3) kinase and PKB (protein kinase B, also known as Akt) complexes and nuclear factor-kappa B (NF-kappa B), thereby exerting antiapoptotic influence. Activation of the ras pathway has been detected in a variety of human tumours. The inappropriate activation of these downstream effectors has also been reported in some NF1-deficient cells and tumours. It is still unclear whether Ras regulation is the primary and/or only function of neurofibromin.

Neurofibromatosis Type 1 (NF1), Genetics.

Figure 1 *NF1* gene spans approximately 300 kb of genomic DNA and comprises 60 exons. Three embedded genes *EVI2A*, *EVI2B* and *OMGP* located in intron 27b are transcribed in the opposite orientation to the *NF1* gene. The *NF1* transcript is 12 kb in size, of which 8.4 kb represents the coding region.

Neurofibromatosis Type 1 (NF1), Genetics.

Figure 2 Activated Ras sends signals along the Raf-mitogen-activated protein (MAP) kinase pathway thereby promoting cellular proliferation. Activated Ras also sends signals through the PI3 (phosphatidylinositol 3) kinase and PKB (protein kinase B, also known as Akt) complexes and nuclear factor-kappa B (NF-kappa B), thereby exerting antiapoptotic influence. Reduced levels of neurofibromin lead to increased signalling through *Raf* and PI3-kinase.

NF1 Gene Germline Mutations

The mutation rate for the *NF1* gene (~1 in 10,000 gametes/cell/generation) is approximately 10-fold higher than that found for most other inherited disease genes. The germline mutational spectrum of the *NF1* gene associated with disease expression in NF1 patients has been well characterised, with new mutations occurring in about one half of all NF1 individuals (4). Over 500 germline mutations have been identified so far and some 80% are truncating lesions (4). No clustering of mutations is apparent within the *NF1* gene. Recently, three separate mutations in the *NF1* gene have been identified in a Portuguese family. About 30% of mutations are associated with altered mRNA splicing.

The characterisation of mutations in the *NF1* gene has been a challenging task owing to the size of the gene, the absence of any obvious mutational clustering and the wide diversity of mutations (4).

The *NF1* gene promoter is highly conserved evolutionarily. No pathological mutation has so far been detected in this region. Similarly, only one mutation has been identified in the 3'UTR. Approximately 95% of all sporadic cases of NF1 result from mutation of the paternal chromosome. The paternally inherited mutations appear to be subtle lesions (<20 nucleotides) whereas the vast majority of *NF1* gene deletions are maternally derived.

NF1 ►Pseudogenes and ►Germline Mosaicism in the NF1 Gene

NF1-related sequences have been identified on a total of 7 human chromosomes viz. 2q12-q13, 12q11, 14p11-q11, 15p11.2, 18p11.2, 21p11-q11 and 22p11-q11. These *NF1* homologues represent non-processed pseudogenes, the result of a series of partial duplications of the functional 17q11.2-located *NF1* gene followed by translocation. The potential for such highly homologous sequences to interfere in the mutational analysis of the functional *NF1* gene should not be underestimated.

Two affected NF1 sibs with unaffected parents were shown to have an identical intragenic deletion in the paternal chromosome. 10% of the father's spermatozoa possessed the same constitutional mutation. ►**Mosaicism** for large deletions has been demonstrated in a number of typical NF1 patients using lymphocyte FISH analysis. Patients with segmental NF1 manifest NF1 features that are confined to a particular part of the body. It is believed that the molecular basis of this condition may be the somatic mutation of the *NF1* gene in an early stage of foetal development.

NF1 Gene Somatic Mutations

To date, specific somatic microlesions have only been reported in 42 NF1-associated tumours. Somatic *NF1* gene lesions have also been identified in several tumour types not usually associated with NF1, but it is not yet known just how *NF1* gene mutations contribute to the formation of either NF1-associated or unrelated sporadic tumours. Information on the somatic mutational spectrum of the *NF1* gene may help to identify other functional domains of neurofibromin, may improve our currently inadequate understanding of genotype/►**phenotype** relationships in NF1 and could also indicate whether the nature and location of germline mutations determines the type of "second hit", as has been reported in ►**familial adenomatous polyposis**.

NF1 – a ►Tumour Suppressor Gene

Genetic and biochemical evidence indicates that *NF1* is a tumour suppressor gene (TSG). Multiple neurofibromas from an individual NF1 patient harbour different somatic mutations indicating that the 'second hit' is an independent event in each neurofibroma. The somatic mutational spectrum of the *NF1* gene may thus be an important factor in the variable clinical expression of NF1. It follows that the factors that influence somatic mutation rates can in some sense be regarded as potential modifiers of NF1.

A number of different genetic mechanisms may give rise to the inactivation of the normal wild type *NF1* allele in an NF1-associated tumour, namely large or small DNA rearrangements, various subtler sequence

alterations, genomic instability at either nucleotide or chromosomal level or hyper-methylation of the gene promoter region. Whilst the acquisition of microsatellite instability may be a relatively late event in NF1-related malignancy, it may be comparatively infrequent in NF1 tumorigenesis.

It is still unclear if cells heterozygous for mutations at the *NF1* locus contribute to tumour formation or whether tumour development can only be initiated from cells with both *NF1* alleles inactivated. Mutations of the wild type allele are most likely to occur during cell division, but adult nerve sheath cells are known not to divide at a high rate. Whether the *NF1* second hit is acquired at an earlier developmental stage, with another subsequent event required to stimulate the growth of the tumour is unknown. Furthermore, the number of non-allelic gene lesions (subsequent to the initial *NF1* mutations) that are required for development of neurofibromas or for progression to MPNSTs is also unclear. Although dermal neurofibromas never become malignant, second hit mutations at the *NF1* locus have been detected. The nature of other non-genetic factors that might be involved in NF1 tumorigenesis is also unknown. Multiple sequential mutations of different genes involved in the progression towards a malignant phenotype have been demonstrated for colon cancer. Several studies have provided evidence that *TP53* and *NF1* mutations may exert a synergistic effect in some tumours both in humans and mice. In a panel of 11 MPNSTs, deletions of *TP53* and *CDKN2A* have been identified. Microsatellite instability (MSI) has been reported in NF1-associated neurofibromas and also intriguingly, the occurrence of NF1 in mismatch repair-deficient individuals with homozygous *MLH1* mutations.

Elucidation of the tumorigenic pathway is obviously a much more complex task than simply identifying a predisposing lesion in a given gene. Complete understanding will only come with the elucidation of the cellular consequences of those lesions in terms of the altered levels of expression of many other genes. Information on the gene expression patterns of cells in different developmental contexts and in response to different environmental conditions or disease states is now being obtained using microarray-based expression analysis.

Molecular Diagnosis

Owing to the extreme variability of clinical expression, NF1 disease progression cannot really be predicted. There has been little demand for prenatal diagnosis possibly because the majority of couples would want to know the clinical severity of the foetus's condition and this is something that cannot be predicted. There is nevertheless an urgent need for an inexpensive, accurate, DNA-based test for NF1. The development of a preimplantation test for NF1 has been initiated.

Animal Models of NF1

Neurofibromin is highly conserved at the amino acid sequence level in mouse, *Drosophila* and yeast. *Nf1* +/- heterozygous mice do not have an obvious phenotype; however, they are predisposed to develop leukaemia and pheochromocytomas. Although they manifest decreased learning ability, including poor performance in tests involving spatial learning and memory, these deficiencies can be overcome by extended training. Mice homozygous for *Nf1* mutations are embryonic lethals, having cardiac abnormalities and dying at approximately 12–14 days of gestation. Neurons harvested from the peripheral nervous systems of these animals show an ability to survive in culture without growth factor stimulation. Haematopoietic stem cells exhibit an increased proliferative ability and are more sensitive to granulocyte-macrophage colony-stimulating factor (GM-CSF) than either heterozygous or wild type cells. *Nf1* chimeric mice develop neurofibromas that are derived from *Nf1* -/- cells. Recent work has demonstrated that it is the interaction of Schwann cells carrying mutations on both the alleles of the *Nf1* gene with *Nf1* +/- mast cells that results in tumour formation, whereas the interaction with *Nf1* ++ mast cells does not result in the formation of tumours (5). Mouse models have further shown that NF1 malignancy is associated with homozygosity for mutations in the *TP53* gene.

The *Drosophila NF1* gene product is approximately 60% homologous with human neurofibromin. Homozygous *Nf1* null mutants are 20–25% smaller than wild type flies.

Further detailed studies on the interaction of neurofibromin with p21Ras, tubulin, growth factors or other proteins will also be important for the elucidation of the normal function of neurofibromin. By understanding the pathophysiology of NF1, effective therapies can be devised and targeted for the various features of NF1.

Clinical Relevance

Genotype/Phenotype Correlations

No clear relationship between genotype and clinical phenotype has yet been discerned for NF1. This may be due either to the influence of modifier loci or to the variable nature, location and developmental timing of the somatic mutations that determine the rate of progression and severity of disease in different tissues.

► **Genetic counselling** for NF1 patients is problematic, owing to the marked inter- and intra-familial variation in NF1 expression. Identical *NF1* gene mutations can occur in unrelated patients with very different phenotypes (4). The first genotype/phenotype studies demonstrated that NF1 patients with large deletions tended to have dysmorphic features and learning disability. NF1 patients with whole gene deletion are at higher risk of developing MPNSTs. In a recent study, we have also

found that NF1 individuals with missense mutations had a relatively lower risk of developing Lisch nodules when compared to people with nonsense or frameshift mutations. This tentative finding awaits confirmation in another NF1 patient population.

The exploration of genotype-phenotype correlations in NF1 is still however in its infancy due to the extensive mutational heterogeneity of the gene and because large-scale mutation screening is still laborious owing to the size and complexity of the gene. *NF1* mutations do not appear to be a major determinant of the common NF1 disease features. The corollary to this is that mutations in the *NF1* gene have been identified in families classified as rare variants of NF1 and these include Watson syndrome, neurofibromatosis-Noonan syndrome, familial café-au-lait spots, spinal neurofibromatosis and Leopard syndrome.

Definition

Neurons are the computational units of the central nervous system (CNS). The human ► [brain](#) contains about 10^{13} neurons. They represent individual elements and do not form a syncytial network as was originally proposed by Camillo Golgi and others. In contrast, Ramón y Cajal strongly supported the theory of neurons as individual elements that are connected via specialised contact sites.

Neurons are very heterogeneous with respect to both structure and function. In general, neurons fall into two groups. The majority (80%) are excitatory neurons, while the remainder are inhibitory ► [interneurons](#), which themselves represent a very heterogeneous class. In principle, neurons can be further characterised as local circuit or as projection neurons. Local circuit neurons are those within a given brain region, e.g. thalamus or ► [neocortex](#). Projection neurons connect various brain areas or regions, e.g. cortico-cortical, thalamocortical, sensory periphery with a higher brain region. In general, despite their heterogeneity all neurons consist of three basic structural compartments, the ► [soma](#) (cell body) of varying shape and size, a more or less elaborate dendritic tree that represents the input structure of the neurone and finally the ► [axon](#) resembling the output structure of the neurone that

always terminates in a highly specialized structure, the so-called ►**synapse** (from the Greek words for ‘together’ (syn) and ‘to clasp’ (haptein), introduced by Sir Charles Scott Sherrington). These synapses are the key elements of communication between individual neurons within a given neuronal network.

Characteristics

Development

The CNS is a derivative of the neuroectoderm, which develops very early during foetal development (third week *in utero*). It is generally accepted that the neurons of the CNS derive from various germinal zones. Among these are the so-called ►**ventricular zone**, where most of the excitatory neurons are generated and the ►**medial/lateral ganglionic eminence**, from where most of the inhibitory interneurons originate. The progenitor cells for excitatory neurons follow a vertical migration pathway along radial glial processes, while inhibitory interneurons migrate either horizontally or tangentially towards their final target region. In general, the migration of interneurons precedes that of excitatory neurons. In most mammalian species, the neocortex for example shows an inside first – outside last organisation of neuronal layers, meaning that early-generated neurons are located in deeper layers (1). Recently, evidence accumulated that both neurons and glial cells, the two major structural elements of the CNS, derive from common progenitor cells. During late prenatal and early postnatal development, transient neuronal populations appear to exist that may play important roles during neuronal migration and layer formation, axonal path-finding and synaptogenesis. After the establishment of the mature neuronal networks, these neurons may undergo selective cell death or they will be transformed into different neuronal cell types.

Structural Compartments of Neurons

Soma

Every neurone has a cell body (somatic region) of a different size and shape (3 µm in van G’huchten cells in the olfactory bulb up to 60 µm in a giant Betz pyramidal cell in the motor cortex). The largest element within the cell body is the nucleus, the largest biochemical compartment housing the genome of the neurone. The nucleus is constantly active, providing all the genetic information necessary for the protein biosynthesis required for information processing and storage (immediate early genes etc.). The neuronal cytoplasm contains all the structural elements found in a somatic cell that are indispensable to maintain neuronal metabolism and survival. In addition, the neuronal cell body produces and contains structural elements such as neurofilaments that are necessary for trafficking of membrane structures (vesicles) and receptor proteins (ion channels, G-proteins etc.) to the

other neuronal compartments (axon and ►**dendrites**). Furthermore, the neuronal soma is an input station for synaptic signals, but exclusively for synaptic terminals originating from inhibitory interneurons. This specific termination of inhibitory inputs is one of the major sources of inhibition within a given neuronal network.

Dendrites

The vast majority of neurons possess a dendritic tree that is more or less elaborate. However, a very small fraction of neurons (e.g. dorsal root and sympathetic ganglion cells in the peripheral nervous system, PNS) completely lack a dendritic compartment. Dendrites always emerge from the soma and serve as an enlargement of the surface area (i.e. the input area) of a neurone. The geometric organisation of the dendritic tree is shaped by the neuronal function and is therefore highly variable. Neurons may have unipolar, bipolar, multipolar, radially symmetric or asymmetric dendritic configurations (Fig. 1). Excitatory neurons, in particular those of higher brain areas, possess a highly structured compartment that is almost exclusively located on dendrites, the so-called dendritic ►**spines**. The structures form only excitatory synapses. The spine morphology is also extremely variable ranging from very short ‘stubby spines’ to elongated ‘spine-like protrusions’. In contrast, inhibitory interneurons have either smooth or sparsely spiny dendrites. Like the soma, dendrites contain neurofilaments for membrane and protein trafficking and occasionally internal stores for Ca^{2+} , an important intracellular messenger.

Dendrites represent the main input region of a neurone, integrating thousands of excitatory and inhibitory inputs arising from either local (within a brain region or area) or distant sources (thalamus, sensory periphery etc.). Generally excitatory inputs are located more distally making an integration of inputs necessary, while inhibitory inputs are found in more proximal segments on the dendrites.

It has long been thought that dendrites act like passive cables but it is now well established that they have a large ion channel complement that plays important roles in synaptic transmission, signalling between neuronal compartments and integration of synaptic inputs. In particular, active propagation of the Na^+ ►**action potential** generated in the axon back into the dendrite has been demonstrated to play a role in regulating the ►**synaptic efficacy**, one step thought to be involved in memory formation. Furthermore, a second action potential initiation zone exists in apical dendrites of pyramidal cells where Ca^{2+} spikes are generated (in contrast to Na^+ action potentials at the axon). These Ca^{2+} action potentials may be important for the intracellular integration of synaptic inputs from different sources (2).

Neurons. Figure 1 Morphologies of different types of neurons in the rat neocortex and cerebellum. (a) A Cajal-Retzius cell in layer 1 of the developing neocortex, a neurone that plays an important role in the layer formation of various brain regions. The soma and dendrites of Cajal-Retzius cells are oriented parallel to the pial surface. Note the long spine-like protrusions emanating from the primary dendrite. (b) Inhibitory layer 1 interneurone with a dense axonal domain that is almost exclusively located in layer 1 of the neocortex. The synaptic connectivity of local interneurons is extremely high. (c) Purkinje cell of the cerebellum with its prominent fan-like dendritic tree projecting throughout the molecular layer (ML); the spine density of the Purkinje cell is extremely high. Next to the Purkinje cell is an inhibitory cerebellar stellate cell that is located in the middle of the molecular layer. The stellate cell was stained simultaneously with the Purkinje neurone and was presynaptic to it. PCL, Purkinje cell layer; GCL granule cell layer. (d) Two synaptically coupled excitatory pyramidal cells in layer 2/3 of the neocortex. Both pyramidal cells have prominent apical dendrites that terminate in an elaborate tuft in layer 1. The shorter basal dendrites emerge at the bases of the pyramidal cell somata. Both apical and basal dendrites are densely covered with spines. The axons show a layer-specific projection pattern; collaterals are found in layer 2/3 and layer 5 but rarely in layer 4. These collaterals may project over several mm of the cortical surface. All staining was by biocytin/neurobiotin injections via patch-clamp micropipettes.

Axons

Axons are the main output structures of neurons and are structurally their most complex compartment. Axons can be categorised as local circuit axons (most interneurons, see Fig. 1b; Chandelier cells project

locally within the range of the dendritic tree; field span ~ 0.5 mm) and projection axons (pyramidal cells of the neocortex, see Fig. 1d; the axons of giant Betz pyramidal cell form the cortico-spinal tract; length ~ 0.7 – 0.8 m). The axon emerges either directly from the soma or from a

primary dendrite with a thick unmyelinated ►axon initial segment that is thought to be the action potential initiation zone. From there numerous axonal collaterals emerge; however each neuronal cell type shows a highly specific projection pattern that is regulated by the function of the neurone within the network in which it is embedded (e.g. a columnar projection as shown for spiny stellate neurons).

Axons differ widely with respect to their diameter (<1–20 µm). Furthermore, they display differences in their degree of myelination from a thick ►myelin sheath (as in motoneurone axons in the PNS or axons of the pyramidal tract) to no myelination. The myelin sheath is formed by the invagination of the axon into the cytoplasm of a Schwann cell (in the PNS) or a process of an oligodendrocyte (in the CNS), where it is suspended by two layers of plasma membrane (the ‘mesaxon’). The mesaxon elongates and spirals around the axon, each turn forming a lamella of myelin. The cytoplasm and extracellular space between each turn of mesaxon are reduced to a minimum and very closely packed. Unmyelinated axons have a very small diameter of 1 µm or less. In the CNS, unmyelinated axons are rare; in the PNS so-called C fibres involved in pain sensation, post-ganglionic neurons of the autonomic nervous system and olfactory nerves have unmyelinated axons. The myelin sheath is periodically interrupted by the so-called nodes of Ranvier. At these sites the axonal membrane contains Na⁺ and K⁺ ion channels at an extremely high density. The channel density is particularly high in the axon initial segment, which is supposed to be the action potential initiation zone on the axon. This is a prerequisite for reliable and fast signal propagation, as it enables a saltatory transmission of excitation (3). A thick axon diameter goes with a high degree of myelination and thus with a fast action potential propagation, i.e. signal transduction. A demyelination will lead to a slowing of action potential propagation and eventually to a complete failure of signal transmission. Along axons in higher sensory brain areas, presynaptic membrane specialisations (swellings), the so-called axonal boutons are formed. These constitute the presynaptic elements of neuronal signalling. Boutons form *en passant* synapses with different compartments of target neurons (soma, dendrites, dendritic spines and axon initial segments). Axonal boutons are highly specific with respect to their target structures.

Synapses

The central element for signalling between individual neurons is the synapse. At the synapse, incoming electrical signals (action potentials) are translated into a chemical signal (►neurotransmitter release), which in turn is transformed into a postsynaptic potential change, the excitatory or inhibitory postsynaptic potential (►EPSP/IPSP).

Structurally, a synapse always consists of a presynaptic terminal, a synaptic cleft and a postsynaptic target zone. Both the pre- and postsynaptic sites are highly specialized structures. The presynaptic site contains a pool of synaptic vesicles (containing the ►neurotransmitter) and a dense accumulation of various proteins involved in the neurotransmitter release process (e.g. the SNARE complex, Ca²⁺ channels etc.) and its metabolism (transporters etc.) (4). Once released the neurotransmitter molecules diffuse through the synaptic cleft (width 15–30 nm) to their target structures, the ligand-gated receptors (ion channels of G-proteins) that are embedded in a specialised area, the ►postsynaptic density (PSD), in the postsynaptic membrane. Apart from the signalling molecules, the PSD also contains various structural components that stabilise the synaptic complex and the arrangement and trafficking of the postsynaptic receptors. PSDs can be either continuous or perforated (periodic interruption of the PSD complex). Recently, it has been shown that synapses with perforated PSDs display a more efficient synaptic transmission (4).

These ‘chemical’ synapses fall into two major categories, inhibitory and excitatory synapses. Structurally, excitatory synapses are so-called ‘symmetric’ synapses because pre- and post-synaptic densities show a complete overlap while inhibitory synapses are ‘asymmetric’ (i.e. no overlap). In addition, synapses can be subdivided into those displaying ‘slow’ synaptic transmission (*via* G-proteins) and ‘fast’ transmission (*via* ligand-gated ion channels).

Neurotransmitter release at chemical synapses occurs *via* the Ca-dependent fusion of synaptic vesicles with the presynaptic membrane. However, it is currently not clear whether only one or several vesicles are released per action potential arriving at the presynaptic terminal. These two ►modes of release have been termed uni-vesicular and multi-vesicular, respectively. There is growing evidence that both mechanisms of neurotransmitter release exist at different synapses in the CNS (5).

Because of their structural and functional properties chemical synapses are subject to various regulatory mechanisms such as short- and long-term plasticity. The molecules responsible for the regulation of synaptic transmission are located both pre- and post-synaptically. Thus at ‘chemical’ synapses, both the probability of neurotransmitter release (which is Ca²⁺-dependent) and the postsynaptic receptor complement can be adapted to the state of activity in a given brain region.

Neurons may also communicate *via* a second type of synapse, the so-called ‘electrical’ synapse or ►gap junction. Gap junctions can be characterised as a specialised apposition zone of the somatic, dendritic or axonal membranes of two adjacent neurons that contain numerous hemi-channel proteins, the so-called

Neurons. Figure 2 (a) Electron microscopic image showing a cross-section through a myelinated (axm) and an unmyelinated axon (axum) in the peripheral nervous system. The myelin (m) sheath is formed by the invagination of the axon into the cytoplasm of a Schwann cell (glial cell), where it is suspended by two layers of plasma membrane (the 'mesaxon', mes). The mesaxon elongates and spirals around the axon, each turn forming a lamella of myelin. The cytoplasm and extracellular space between each turn of the mesaxon are reduced to a minimum, and very closely packed. Unmyelinated axons have a very small diameter of $1\mu\text{m}$ or less. They are only embedded in cytoplasm of a Schwann cell that forms a mesaxon but no myelin. (Photograph courtesy of A. Schardt/E. Niksch). (b) Electron micrograph of a synaptic contact between a presynaptic axonal bouton (b) and a postsynaptic dendritic spine (sp) that are separate by a narrow synaptic cleft (sc). A pool of neurotransmitter vesicles (ves) is clearly visible in the presynaptic bouton. The postsynaptic side is characterised by an electron dense structure, the postsynaptic density (psd), which contains structural proteins that anchor neurotransmitter receptors in the membrane opposite the neurotransmitter release site. Dendritic shaft, d. (c) Gap junction between two dendrites as seen in the transmission electron microscope. The opposing arrowheads indicate the gap junction coupling site between the two cells. The thin line in the middle represents the apposition of the gap junction hemi channels in the membranes of the two cells.

► **connexons.** Two connexons form a functional channel through which ions and small molecules can diffuse. Functionally, gap junctions serve to transmit electrical activity between connected neurons but also serve to interchange signalling molecules such as inositol triphosphate and Ca^{2+} . Signalling between gap-junction coupled neurons is always fast but undergoes heavy low-pass filtering, i.e. the signal waveform is slowed down and reduced in amplitude. Action potentials will appear as small 'spikelets' in the coupled neurone.

During early brain development, neurons communicate predominantly *via* gap junctions. This electrical communication is gradually replaced with communication *via* 'chemical' synapses during late postnatal development. However, it has been shown recently that even in the adult, distinct types of inhibitory interneurons in the neocortex and hippocampus form independent networks *via* gap junctions. These networks may play important roles in the oscillations of the electrical brain activity and rhythm generation that have been associated with arousal, sleep and attention (6).

Both types of synaptic transmission may occur in parallel at the same synaptic connection. Thus neuronal

communication within a network may occur *via* both signalling pathways indicating a high degree of complexity within the nervous system.

Neuropathy

Definition

Neuropathy is a general term used to describe disorders of the peripheral nervous system (peripheral neuropathy). Peripheral neuropathy can be associated with poor nutrition, a number of diseases, pressure or trauma, or can be caused by exposure to toxins and certain drugs.

- Diabetes Mellitus, Genetics
- Hereditary Neuropathies, Motor and/or Sensor

Neurotransmission

Definition

Neurotransmission designates a process where chemical substances called neurotransmitters (such as dopamine, serotonin and glutamate) are released at a nerve terminal as a result of the nerve impulse. Transmitters cross the synapse (gap between nerve cells) and bind to receptors on the second cell, thereby exciting it.

- Neurons
- Schizophrenia Genetics

Neurotransmitter

Definition

Neurotransmitters are signalling molecules (glutamate, γ -amino butyric acid (GABA), serotonin, noradrenalin, dopamine, neuropeptide Y etc.) released from the presynaptic terminal in order to bind to postsynaptic receptor proteins that may be either ligand-gated ion channels or ligand-gated G-proteins.

- Neurons

Neurotransmitter Release

Definition

Neurotransmitter release is a Ca^{2+} -dependent process by which the neurotransmitter (glutamate, GABA,

acetylcholine etc.) is released from synaptic vesicles after having docked to and fused with the presynaptic membrane.

- Neurons

Neurotrophic Factor Hypothesis

Definition

The neurotrophic factor hypothesis suggests that the target of innervation of a particular neuron produces a limited amount of a neurotrophin, i.e. a molecule that is essential for the survival of the neuron. Neurotrophic factors include the classic neurotrophins BDNF (brain derived neurotrophic factor), NT3 (Neurotrophic factor 3), NT4/5 and NGF (nerve growth factor) as well as other signalling molecules. Many of them signal through tyrosine kinase receptors.

Definition

The nerve growth factor (NGF) was the first neurotrophic factor to be discovered about 50 years ago. Its identification provided, among other things, the first support for the “neurotrophic factor hypothesis”, which holds that target cells secrete limited amounts of an essential trophic factor which is taken up by nerve endings *via* binding to specific cell surface receptors. Neurons that do not receive sufficient amounts of trophic factors will die by ►apoptosis. Today, NGF is only one of the numerous secreted factors discovered that have the ability to support the survival of neurons. These secreted trophic proteins have been grouped into different classes. The neurotrophins (NTs) are the best-studied class and thus far four neurotrophins have been identified in mammals, NGF, brain derived neurotrophic factor (BDNF), neurotrophin-3 (NT-3), and neurotrophin-4 (NT-4). Other classes of proteins able to

promote neuronal survival include members of the transforming growth factor β (TGF β) family, the interleukin 6-related cytokines, fibroblast growth factors (FGFs) and hepatocyte growth factor (HGF) (Table 1). Among these classes, the neurotrophin family is of significant importance because of its well-known physiological role in neuronal survival and the widespread expression of its family members both during development and in the adult nervous system. Here we will focus mainly on the characteristics, molecular interactions and regulatory mechanisms of this class of neurotrophic factors.

Characteristics

Structural Features

The neurotrophins together with transforming growth factor β belong to the “**cystine knot**” superfamily of polypeptide growth factors. The crystal structures of NGF and TGF β 2, have in fact revealed that although these proteins show very low sequence similarities, they share a common overall protomer topology which is based on three disulphide bonds (“cystine knot”) and four-stranded β sheets (1). All cystine knot growth factors acquire, upon dimerization, a well-defined hydrophobic core, which stabilizes the structure. In fact, their active forms exist only as **dimers**, homodimers or heterodimers. The interfaces used to form the dimers are in each case quite different, suggesting that dimerization is an important event and plays a fundamental role in regulating the binding of the different growth factors to their specific receptors and in modulating their biological activity.

Expression Patterns

In the peripheral nervous system (PNS), as the target-derived neurotrophic factor theory suggests, neurotrophins are expressed and secreted by the target tissues (which can be skin, muscle, glands or neurons) and regulate the survival and differentiation of the innervating neurons. The first NT expressed in the PNS during embryogenesis is NT-3, which supports the survival and differentiation of some sensory and sympathetic neurons, many of which become dependent on NGF during later stages of development. Likewise, BDNF promotes the survival of a subset of dorsal root ganglia (DRG) neurons, and other populations of sensory neurons like those of the vestibular organ (2). The expression of neurotrophins in the mammalian **brain** is regulated during development and by neuronal activity. During perinatal development, NT-3 shows the highest expression levels of all NTs, particularly in the **hippocampus**, neocortex and **cerebellum**, whereas BDNF expression levels in those same regions are low at birth and increase during the first weeks of postnatal development. NGF, on the other hand, behaves similarly to BDNF in the hippocampus, while in the other brain

structures NGF expression changes little during postnatal development. The NT-4 expression, on the other hand, is high in similar structures during postnatal development and continues thus into adulthood.

Functions: more than Survival Promoting Factors

The neurotrophins were originally identified as neuronal survival factors, and the analysis of mouse strains carrying mutations in the neurotrophin genes has extensively proved that sensory and sympathetic neurons require the trophic support of these factors secreted by the innervated targets (3). For instance, deletion of NGF causes loss of sympathetic neurons and specific populations of sensory neurons, confirming the pioneering studies of Levi-Montalcini in the early 1960s, where, using antibodies against NGF, it was first demonstrated that neurotrophic factors were essential mediators of sympathetic and sensory neuron survival. A more complex picture appears in the central nervous system (CNS), where the survival of neurons depends on multiple neurotrophic factors. Although originally identified as survival promoting factors, the biological effects of neurotrophins also include regulation of axonal and dendritic outgrowth, **cell migration**, **synapse** formation and synaptic modulation (3). The trophic activity of other families of neurotrophic factors are less well characterized, e.g., the TGF β subfamilies were identified more than twenty years ago as factors controlling diverse cellular processes, including cell proliferation, differentiation, cell-specification and apoptosis during development and in mature tissues in various species from flies to worms to mammals. It is only recently that TGF β has been recognized to also play unique roles in the developing and adult nervous system. Furthermore, the effect of TGF β as a survival-promoting factor has been shown mainly in **synergism** with established neurotrophic factors such as neurotrophins, fibroblast growth factor and particularly GDNF (4).

Molecular Interactions

In order to mediate their diverse biological functions, neurotrophins interact with **receptor tyrosine kinases** belonging to the Trk receptor family of which there are three members termed TrkA, TrkB, and TrkC. The binding of neurotrophins to Trk receptors is highly specific; NGF interacts selectively with TrkA, BDNF and NT-4 with TrkB, NT-3 with TrkC and, to a lesser extent, with TrkA and TrkB (Fig. 1a). The activation of Trk receptors, as for other receptor tyrosine kinases, occurs upon binding of neurotrophin ligand, which triggers receptor dimerization (homodimers for the Trk family) and autophosphorylation of tyrosine residues in the activation loop of the kinase domain. This is followed by phosphorylation of specific cytoplasmic tyrosines that act as docking sites for **adaptor**

Neurotrophic Factors. Table 1 Partial list of neurotrophic factors and their functions in the nervous system

Neurotrophic factors	Functions in the nervous system
Neurotrophin class:	
NGF	Survival of sympathetic neurons (SCG), and sensory neurons (DRG and trigeminal). Survival of basal forebrain cholinergic neurons.
BDNF	Survival of most neuronal populations in the PNS including vestibular, nodose, petrosal, geniculate, DRG and trigeminal neurons. Differentiation and plasticity function in the CNS
NT-4	Survival of nodose, petrosal, and geniculate sensory neurons. Plasticity function in the CNS.
NT-3	Survival of embryonic sympathetic, DRG and trigeminal sensory neuron precursor cells. Survival of adult sympathetic neurons that innervate the external ear and pineal gland and of cochlear sensory neurons that innervate the organ of Corti.
Transforming growth factor β class:	
TGF- β 2, β 3	Neuron and glial cell survival and differentiation cooperating with other neurotrophic factors.
Bone morphogenetic proteins and growth/differentiation factors:	
BMP2	Survival and differentiation of striatal GABAergic neurons, induction of cholinergic properties in CNS neurons.
OP-1	Enhances dendritic growth from cerebral cortical neurons.
BMP4/7	Induction of catecholaminergic properties in PNS and CNS.
GDF-5, GDF-15	Neurotrophic effects on midbrain dopaminergic neurons.
GDNF family:	
GDNF	Survival of sub-populations of peripheral autonomic and sensory as well as spinal motoneurons, dopaminergic and noradrenergic neurons.
Neurturin, Artemin	Survival of peripheral sympathetic and sensory neurons as well as midbrain dopamine neurons.
Persephin	Supports CNS dopamine and motor neurons.
Interleukin 6 class:	
IL6	Survival of cholinergic neurons.
IL11	Neuronal differentiation of hippocampal progenitors.
LIF	Cholinergic nerve differentiation, survival of motoneurons and sympathetic neurons.
OM	Cholinergic nerve differentiation.
CNTF	Cholinergic nerve differentiation, survival of cholinergic neurons and motoneurons, astrocyte differentiation.
CT-1	Cholinergic nerve differentiation, survival of cholinergic and dopaminergic neurons.
Fibroblast growth factor class	Survival of motoneurons and some subpopulations of DRG.
Hepatocyte growth factor	Survival of motoneurons, synergic activity with other neurotrophic factors for the survival of sensory and sympathetic neurons.

Neurotrophic Factors. Figure 1 Neurotrophic factors and their receptors. (a) Neurotrophins interact with two classes of receptors the Trk receptor tyrosine kinases and the receptor p75^{NTR}. The figure illustrates the interactions of each member of the neurotrophin family with the Trk proteins and with receptor p75^{NTR}. Strong interactions are indicated with solid arrows, weaker interactions with broken arrows. Abbreviations: NGF (nerve growth factor), NT (neurotrophin), BDNF (brain derived neurotrophic factor). (b) The TGFβ proteins, GDNF subfamily, activate the transmembrane Ret tyrosine kinase via different glycosyl phosphatidylinositol-linked GFRα receptors. Strong interactions are indicated with solid arrows, weaker interactions with broken arrows. Abbreviations: GDNF (glial-derived neurotrophic factor), NTN (neurturin), ART (artemin), PSP (persephin), GFRα (GDNF family receptor α).

molecules, leading to the activation of several downstream cascades, including the Ras/mitogen-activated protein kinase (Ras/MAPK) cascade, the phosphatidylinositol 3-kinase (PI3K) pathway, and the phospholipase Cγ (PLCγ) cascade, which mediate the diverse biological functions of neurotrophins. The NTs are also able to bind to another class of receptor called p75^{NTR}, but unlike Trk receptors, p75^{NTR} exhibits predominantly low affinity binding for all NTs. The p75^{NTR} receptor belongs to the family of tumor necrosis factor (TNF) receptors. Paradoxically, the activation of this receptor by neurotrophins has been shown to promote neuronal cell death rather than survival (5). Other classes of neurotrophic factors like the GDNF subfamily, whose members include neurturin, artemin, persephin and GDNF, transduce signals in a more complex manner, *via* a common receptor subunit, the c-Ret receptor and a distinct lipid-anchored subunit of the GDNF receptor (GRFα) (Fig. 1b).

Regulatory Mechanisms

Cleavage of Neurotrophins

The NTs are synthesized as pro-neurotrophins or precursors of about 270 amino acids (aa). The pro-region (N-terminal fragment of about 120 aa) is proteolytically removed in either the trans-Golgi by furin or in secretory granules by pro-protein convertases to produce the mature proteins of about 12 kD in size. It has also been shown that proNGF and proBDNF can be cleaved *in vitro* by extracellular proteases such as MMP7 and plasmin. Recently, it has been shown that pro-neurotrophins may preferentially bind p75^{NTR}, whereas mature neurotrophins preferentially bind Trk receptors. Moreover, this differential interaction elicits opposite functional effects in that proNGF-binding p75^{NTR} induces apoptosis, whereas

mature NGF binding Trk receptor usually enhances cell survival. Secretion of pro-neurotrophins at synapses could account for regulation of synaptic transmission and plasticity by different mechanisms. This may be particularly relevant at hippocampal synapses for BDNF/TrkB signaling, which is known to regulate **LTP**. Pro-neurotrophins in the pre- or post-synaptic compartment may act *via* p75^{NTR} and elicit effects distinct from those mediated by TrkB and mature BDNF, or they may be simply cleaved at synapses resulting in active ligands for Trk receptors. Plasmin is a good candidate protease for the cleavage of proBDNF not only because it has been shown *in vitro* to cleave proBDNF at the appropriate site, but also because it is expressed at synapses (Fig. 2a).

Secretion

Compared to other regulatory mechanisms little is still known about the modes and sites of neurotrophin secretion. It is known that upon synthesis NTs are packed into secretory vesicles. Two types of vesicle secretion have been described, constitutive or regulated, depending on whether their secretion occurs in absence or presence of specific triggering factors respectively. The vesicles of the regulated pathway fuse to the plasma membrane only in a Ca²⁺-dependent manner. However, due to the important role of BDNF in modulating synapse efficacy there is great interest in the identification of the sites and mode of BDNF secretion. Mainly for this reason most progress has been made recently concerning neuronal BDNF secretion at axonal and dendritic sites. Recent data suggest that BDNF secretion depends critically on high intracellular Ca²⁺-levels that can be triggered by electrical activity. For more details see reference (6).

Neurotrophic Factors. Figure 2 Regulatory mechanisms of neurotrophins. (a) Extrasynaptic cleavage of proBDNF. Uncleaved pro-neurotrophins may act on p75^{NTR} on pre and post-synaptic membranes and elicit effects distinct from those mediated by Trk receptors. ProBDNF could be cleaved extracellularly from protease like plasmin, implicated in learning and memory. (b) Neurotrophin signaling. Retrograde neurotrophin signaling, endosome-mediated model. Trk receptors on distal axons are activated upon binding to neurotrophins. The ligand-receptor complex internalizes through clathrin-mediated endocytosis. Some of the vesicles become specialized endosomes and are transported retrogradely to the cell body using a dynein-dependent and microtubule-dependent transport mechanism. The vesicle-associated Trk receptor remains autophosphorylated and capable of promoting a signal at nucleus level. Through the anterograde transport NT vesicles can also be transported from the cell soma to the axon terminals. After pre-synaptic secretion, NT actions can be autocrine or paracrine, depending on the site of receptor expression.

Retrograde/Anterograde Transport

Following secretion, constitutive or regulated, by the innervated target tissue, NTs bind to axonal neurotrophin receptors and are endocytosed in vesicles, so called "signaling endosomes". They are then retrogradely transported, according to the classical view, in the axon to the cell soma where they can

activate signaling cascades promoting survival (Fig. 2B). The retrograde transport was described first for NGF in sympathetic and sensory neurons of the PNS and in cholinergic neurons of the CNS. Subsequently, this mechanism was shown also for the other members of the NGF family, BDNF, NT-3 and NT-4, in the PNS as well as in the CNS neurons. However, recent studies

have shown that endogenous BDNF and NT-3 can also be transported anterogradely in the axon towards synaptic terminals where they are stored in vesicles, released and elicit postsynaptic effects. This mechanism, especially relevant for BDNF, contrasts with the traditional role of NGF as a retrogradely transported target-derived survival factor. BDNF, being anterogradely transported by central or peripheral neurons, can exert multiple roles, a neuron-transmitter like role for rapid postsynaptic functions, a trophic factor for postsynaptic targets such as skin and muscle, a source of BDNF for astrocytes, especially in injured brain etc. This alternative mechanism of trafficking described for these molecules has opened up many questions regarding the function of neurotrophins as well as of other neurotrophic factors in the biology and pathology of the nervous system (6).

Neurotrophins and Disease

Neurotrophin genes have been implicated in neurological or psychiatric disorders. A recent study has linked a ►[polymorphism](#) in the pro-domain of BDNF with depression, bipolar disorders and schizophrenia. This polymorphism is caused by a single amino-acid change, from valine (Val) to methionine (Met), at position 66 in the pro-domain of BDNF. In patients with bipolar disorder or depression, the Val ►[allele](#) seems to confer greater risk for the disease, whereas in patients with schizophrenia, the Met allele seems to be associated with impaired memory function. In animal models several lines of evidence have implicated neurotrophins in depression, for example restraint stress leads to decreased expression of BDNF in the hippocampus and administration of BDNF to the midbrain or hippocampus results in antidepressant effects. In ►[Huntington's disease](#) decreased production of BDNF has been shown; this could lead to insufficient neurotrophic support for striatal neurons, which then die. NGF has been implicated in the pathogenesis of ►[Alzheimer's Disease](#). Mutations in TrkA, the high affinity receptor for NGF, have been identified as the cause of a human syndrome, congenital insensitivity to pain and anhidrosis (CIPA). This disease is an ►[autosomal-recessive disorder](#) in which individuals exhibit defects in thermoregulation, anhidrosis (absence of sweating), mental retardation, unexplained fever and a failure to react to noxious stimuli (7).

Neutrophils

Definition

Neutrophils (also referred to as neutrophil granulocytes) form the biggest subpopulation of granulocytes, a population of white blood cells. The name results from the relatively neutral colour that their granules have when routinely stained. Neutrophils arise from the bone marrow, are released into the circulation and have an important function as the first line of cellular defense. Neutrophils are highly motile. They are attracted by cytokines expressed by activated endothelium, mast cells and macrophages during an infection. Neutrophils quickly gather at the site of an infection. When activated, they release reactive oxygen species and proteinases to defend invading bacteria. Furthermore, they can act as phagocytes to debride the wound.

NFκB

Definition

Nuclear factor kappa B (NFκB) proteins comprise of a family of structurally-related eukaryotic transcription factors, which are involved in a large number of normal cellular and organismal processes, such as immune and inflammatory responses, developmental processes, cellular growth, and apoptosis. They are also important during disease states, including cancer, arthritis, chronic inflammation, asthma, neurodegenerative diseases, and heart diseases.

Definition

The nuclear factor-kappaB (NF-κB, also called NF-κB/Rel) family consists of five evolutionarily conserved

mammalian ►[transcription factors](#), p50, p52, p65/RelA, c-Rel and RelB, which are widely expressed in human tissues. NF-κB family members form various dimeric complexes and the most prominent NF-κB species is a p50-p65 heterodimer. In resting cells, NF-κB is sequestered in the cytoplasm by inhibitory proteins (IκBs). A large number of immunological, inflammatory, morphological and mitogenic stimuli (Table 1) induce destruction of IκBs, which is followed by nuclear entry of transcriptionally active NF-κB. All known stimulatory pathways converge at the IκB kinase (IKK) complex, which is composed of two catalytic subunits (IKKα and IKKβ) and a regulatory (IKKγ, NEMO) subunit. Upon activation, the IKK complex phosphorylates IκBs, which are then targeted for rapid ubiquitination and for subsequent degradation by the 26S proteasome. Released NF-κB dimers are imported into the nucleus, where they induce gene expression through high affinity binding to DNA response elements related to a decameric consensus sequence (GGGRNYYCC), located in ►[promoter](#) or ►[enhancer](#) regions of target genes (Table 1). NF-κB-dependent gene regulation is involved in diverse cellular processes, including differentiation, apoptosis, proliferation and immune and inflammatory responses. Consequently, deregulation of the pathways that promote NF-κB activation is often found associated with tumor development and inflammation and diseases of the vascular system, the immune system and the epidermis.

Characteristics

NF-κB is a prototypic transcription factor whose activation involves serine/threonine phosphorylation, ubiquitin conjugation and proteasomal proteolysis of inhibitors (1, 2, 3, 4). A characteristic feature of the NF-κB regulatory system is the multiple steps at which activation, as well as post-inductive deactivation, can be tightly controlled. NF-κB pathway regulation can occur at the following levels: (i) the relative expression levels and dimerization of the various NF-κB/Rel family members, (ii) the binding to the family of inhibitory IκB molecules, (iii) the induced release from IκBs through their phosphorylation by IκB kinases (IKKs), the rate limiting step in the activation pathway, which triggers IκB proteolysis by the ►[ubiquitin-proteasome pathway](#), (iv) the autoregulatory termination of pathway activity by NF-κB-stimulated IκB expression, (v) the fate of precursor proteins, which are modified by proteasomal proteolysis and (vi) subunit-specific regulation of NF-κB transcriptional activity by phosphorylation and association with nuclear IκB family members and by interaction with histone acetylases or deacetylases.

Molecular Interactions

NF-κB Dimerization

All NF-κB family members share a conserved amino-terminal Rel homology domain (Rel domain) of approximately 300 amino acids (1) (Fig. 1). The Rel domain contains the dimerization interface, the DNA binding domain to recognize the decameric consensus sequences and the ►nuclear localization signal (NLS) for interaction with the nuclear import machinery. In addition, p65, cRel and RelB contain a carboxy-terminal transcription activation domain (TAD), which communicates with general factors of the transcription initiation complex. In contrast, p50 and p52 lack a TAD and require heterotypic association to act as transcriptional activators. p50 and p52 are synthesized as cytoplasmic precursor proteins (p105 and p100, respectively) and the generation of the mature transcription factors depends on a proteolytic processing reaction, that removes sequences C-terminal to the Rel domain (3, 4). The processing end-point is close to a glycine rich region (Fig. 1).

IκB Association

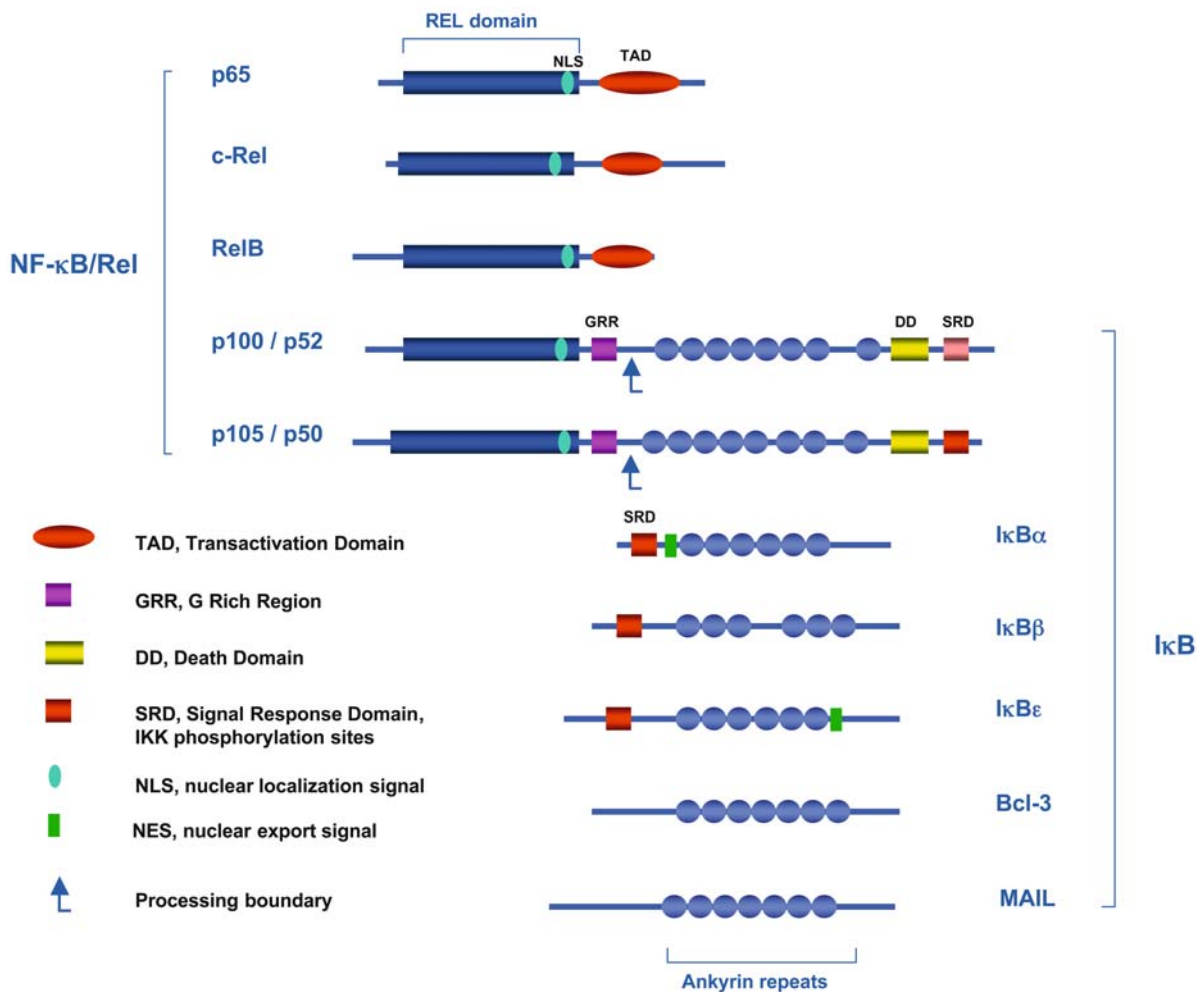

The activity of NF-κB is tightly controlled by its association with IκB proteins (Fig. 1). The IκB family is composed of the two cytoplasmic precursor molecules p105 and p100, the small cytoplasmic inhibitors IκBα, IκBβ and IκBε and the predominately nuclear IκB family members Bcl-3 and MAIL. The common structural motif of the IκBs is the ankyrin repeat domain (ARD), an interaction surface that mediates high affinity binding to the Rel domain of NF-κB dimers (3). While IκBα, IκBβ and IκBε preferentially interact with NF-κB heterodimers containing the p65 or c-Rel subunit, Bcl-3 and MAIL bind with highest affinity to p50 or p52 homodimers. p105 and p100 can bind to all NF-κB subunits, however p100 appears to be the only high affinity IκB for RelB.

In resting cells, cytoplasmic IκBs prevent nuclear entry of NF-κB by shielding the NLS at the carboxy-terminus of the Rel domain. Rapid IKK dependent proteasomal destruction of IκBs in response to activating agents produces accessibility and recognition of the NLS by importins, which drag NF-κB complexes to the nucleus. In contrast, Bcl-3 and MAIL associate with NF-κB-p50 or p52 dimers in the nucleus and function as co-regulators to affect expression of a subset of NF-κB regulated genes.

The genes coding for the inhibitory molecules *ikb*, *ikbe*, *p105/nfkb1* and *p100/nfkb2*, are primary NF-κB target genes (Table 1). Newly synthesized IκBα can enter the nucleus and dissociate NF-κB from DNA. A ►nuclear export signal (NES) on IκBα, which interacts with the nuclear export receptor Crm1, serves for export of IκB-NF-κB complexes. Thus, IκBα gene induction contributes to an auto-regulatory feedback mechanism and ensures that NF-κB activity is transient and ceases upon removal of the stimulus (3). Expression of the nuclear IκB homologue MAIL is strongly increased by a subset of NF-κB inducers (e.g. lipopolysaccharides and IL-1) and may positively modulate a secondary transcriptional response of NF-κB p50 or p52 homodimers, which escape the inhibitory action of *de novo* synthesized IκBα. Besides their inhibitory role in resting cells, the molecular interactions with IκBs establish a fine-tuning of the NF-κB transcriptional response in activated cells.

IκB Kinase Complex

Biochemical and genetic evidence identified the IKK complex as the central point of convergence of all known physiological NF-κB activating stimuli (2, 3, 4). The kinase complex is composed of three subunits: (i) the catalytic subunits IKKα and IKKβ, which hetero- or homodimerize through their ►leucine zippers and directly phosphorylate the SRD of the IκBs and (ii)

NF- κ B Pathway. Figure 1 The proteins encoded by the NF- κ B and I κ B multigene families of vertebrates. AR, ankyrin repeats; DB, DNA binding domain; DD, death domain; Dim, Dimerization domain; GRC, G rich region; NLS, nuclear localization sequence; RHD, Rel homology domain; SRD, signal response domain. The vertebrate NF- κ B proteins p105, p100, p50, p52, p65, c-Rel and RelB share a conserved DNA-binding and dimerization domain (Rel Domain) of about 350 amino acids which contains a nuclear translocation signal. Frequently used synonyms are RelA for p65, NFKB1 for p105, and NFKB2 or I κ B-10 for p100. p65, c-Rel and RelB contain C-terminal transcriptional activation domains (TAD). The p50 and p52 subunits are produced by processing of the precursor proteins p105 and p100. The C-terminal portions of the precursors contain repeated sequence motifs (*ankyrin repeats*), which are the characteristic conserved feature of the prevalently cytoplasmic group of I κ B proteins, I κ B α , I κ B β and I κ B ϵ and their predominantly nuclear homologues Bcl-3 and MAIL. Both precursors contain a conserved *death domain* (DD) a protein-protein interaction motif, which confers binding of I κ B kinases. Both precursors and the prevalently cytoplasmic I κ Bs carry a signal response domain (SRD), which upon phosphorylation by IKK attracts β ^{TRCP} ubiquitin ligases. Processing boundary, processive proteolysis limit close to a GRR. For conservation of NF- κ B and I κ B components in insects (1).

the functionally essential IKK γ /NEMO component, which has been proposed to recruit upstream activators into the complex (3). Dimeric IKK α / β molecules bind to IKK γ *via* a short peptide sequence in the very carboxy termini. IKK γ oligomerizes and a conserved **zinc-finger domain** at its carboxy terminal end is required for activation of the complex by a subset of

stimuli (3). Whereas IKK α and IKK β seem to be functionally redundant *in vitro*, studies in gene deficient mice reveal a prominent role of IKK β for rapid NF- κ B activation by pro-inflammatory stimuli and various other agents (2, 3). In contrast, IKK α contributes to an alternative NF- κ B pathway that induces processing of the precursor molecule p100

(see below) and whose function might be limited to prolonged processes, such as differentiation (3, 4). However, TNF α induces rapid translocation of IKK α to the nucleus, where it contributes to cytokine-induced chromatin-modification and gene activation (3, 4, 5). For IKK α , β and γ , the [▶chaperones](#), heat shock protein 90 (Hsp90) and Cdc37, are stoichiometric constituents of the IKK complex and are required for activation of the complex by TNF α , IL-1 or PMA. Hsp90 is bound *via* its co-chaperone Cdc37 to the kinase domain of IKK α and β (3).

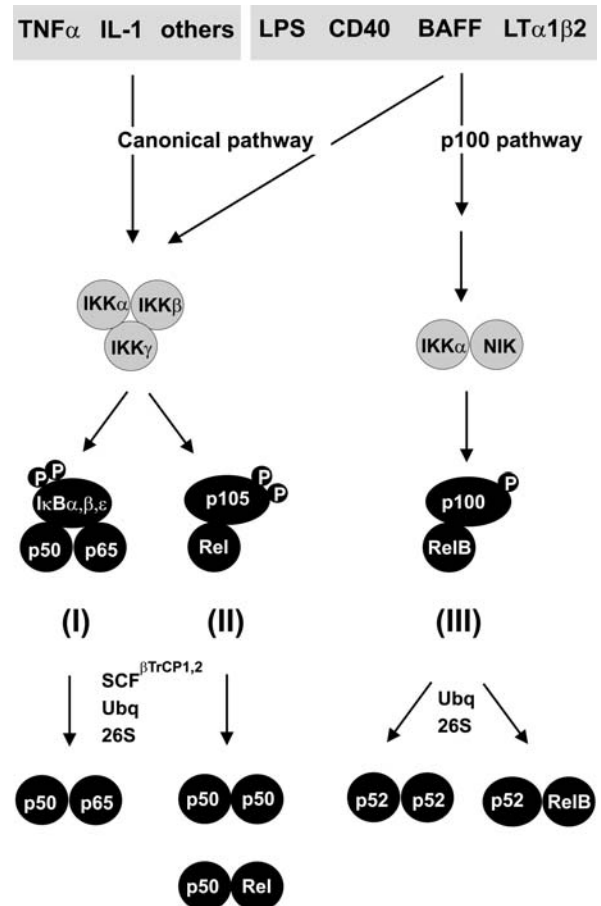

Regulatory Mechanisms

Molecular Mechanisms of NF- κ B Activation

The activation of NF- κ B activity by all known physiological stimuli depends on the activation of IKK. It is assumed that the activation of IKK kinase activity involves phosphorylation of IKK α and IKK β at serine residues in the activation loop in the conserved kinase domain. Several mitogen activated protein 3 (MAP3) kinase kinases, including NF- κ B-inducing kinase (NIK), mitogen-activated protein/ERK kinase kinases (MEKK1 and MEKK3), TGF- β -activated kinase 1 (TAK1) and mixed lineage kinase 3 (MLK3) have been suggested as upstream kinases and phosphorylate the IKK complex and activate NF- κ B when over-expressed or when analyzed *in vitro* (3, 4). Phosphorylation of the activation loop serines may also be achieved by trans-autophosphorylation of the kinases in an induced proximity mechanism. IKK α and IKK β are not biochemically equivalent and IKK α activation loop phosphorylation is not required for IKK activation by TNF α or IL-1 (3). Gene ablation experiments have established that IKK β and IKK γ are required for NF- κ B activation by proinflammatory stimuli, while IKK α is essential for morphogenic signals but also contributes to cytokine signaling (2, 3). For the TNF α pathway, recruitment of TNF receptor associated factors 2 or 5 (TRAF2, TRAF5) and receptor interacting protein 1 (RIP1) initiates downstream signaling. Furthermore, the IKK complex was shown to associate directly with the TNF receptor 1 complex and genetic evidence suggested that MEKK3 is needed for TNF induction (3).

The activated IKK complex phosphorylates I κ B α , β or ϵ at conserved serines in amino terminal sequences of the molecules. p105 contains a similar phosphorylation site in its carboxy terminus, which is phosphorylated by activated IKK as well. The phosphorylated sites in I κ B α , β , ϵ or p105 are bound by an SCF E3 ubiquitin ligase complex *via* F box containing substrate recognition molecules β TrCP1 and β TrCP2 (1, 2). The substrate I κ B molecules are then poly-ubiquitinated and completely degraded by the 26S proteasome (Fig. 2) canonical pathway (I). In contrast to the signal-induced destruction of the full-length p105

molecule, a basal processing reaction continuously converts a part of the cellular p105 pool to p50 by ubiquitin and proteasome dependent proteolysis of its C-terminal half. Depending on the relative expression levels of the NF- κ B subunits, p105 either binds its own processing product p50 or other Rel factors. Induced p105 degradation liberates these Rel factors (Fig. 2,

NF- κ B Pathway. Figure 2 General NF- κ B activation mechanisms. Most NF- κ B inducing agents rapidly activate the canonical pathway, which depends on the classical I κ B kinase complex; the IKK β and IKK γ subunits are essential. Small I κ B molecules (e.g. I κ B α) are phosphorylated, ubiquitinated after recognition by SCF $^{\beta$ TrCP E3 ubiquitin ligase complexes, degraded by the 26S proteasome (I) and release p50-p65 heterodimers. p105 complexes are phosphorylated as well, which results in SCF $^{\beta$ TrCP-dependent ubiquitination, proteasomal destruction of p105 and release of p105-bound Rel subunits (II). The p100-specific pathway ("novel pathway") is activated by a limited number of stimuli, which can also activate the canonical pathway. The p100 pathway specifically requires IKK α and NIK. Phosphorylation and ubiquitination of p100 results in its partial proteolysis by the proteasome, to generate the processing product p52, which associates with RelB (III).

(II)). The canonical pathway, which is induced by pro-inflammatory cytokines and various pathogenic agents is fast and results in degradation of I κ B α , β , ϵ and p105 within minutes to less than an hour and without requiring *de novo* protein synthesis. The vast number of rapidly activated NF- κ B target genes (Table 1) are activated by the canonical pathway and the predominant NF- κ B form, the p50-p65 heterodimer. A growing number of ligands, including lymphotoxins, B cell activating factor (BAFF) and CD40 ligand, which all activate the canonical cascade, also induce the p100 pathway. The latter, also known as the "novel pathway" results in induced proteolytic processing of p100 to p52 (3, 4). IKK α and NIK are required for phosphorylation of serines in a carboxy terminal signal response domain of p100, which in turn is essential for ubiquitination and degradation of the C-terminal half of p100 by the 26S proteasome. Induced p100 processing liberates p52-RelB heterodimers, since RelB is largely bound to p100 (Fig. 2, (III)). In contrast to the canonical pathway, induced p100 processing occurs only after hours of stimulation and requires the translation of unknown intermediates. It is assumed that the LT β receptor activated p100 pathway induces select target

genes, including the chemokines, B lymphocyte chemokine (BLC), secondary lymphoid tissue chemokine (SLC) and EB11-ligand chemokine (ELC) (3, 4).

Mechanisms of NF- κ B Dependent Transactivation

The release of NF- κ B proteins from cytoplasmic complexes with I κ B proteins and precursors allows nuclear import, but is not *per se* sufficient for full transcriptional activity of NF- κ B. A number of studies have highlighted the importance of p65 phosphorylation. p65 is the target of a variety of kinases and the sites of phosphorylation are both in the Rel domain and in the TAD (3, 5). One important site is serine 276, which is phosphorylated depending on the stimulus either by ►protein kinase A (PKA) or by mitogen- and stress-activated kinase-1 (MSK1). Phosphorylation at this site increases the association with transcriptional co-activators CBP and p300 and the transactivation potential (3, 5). Mice deficient in protein kinase C ζ (PKC ζ), glycogen-synthase kinase-3 β (GSK3 β) and TANK-binding kinase-1 (TBK1) all reveal impaired NF- κ B transcriptional activities, implying that phosphorylation of p65 or other subunits by these kinases may be functionally essential. Furthermore, p65 has

NF- κ B Pathway. Table 2 NF- κ B/Rel and IKK knockout phenotypes. An overview of the major physiological functions of NF- κ B and IKK gene products as revealed by homologous recombination in mice

Gene	Lethality	Affected Function
p50*		immune response (B cell function)
p52**		maintenance of peripheral B cell populations and normal spleen architecture
p65 (RelA)	embryonic lethality	anti-apoptotic function, liver
c-Rel		immune response (T and B cell function)
RelB	often premature death	normal function of hematopoietic system PP formation
p50*/p52**	premature death	osteoclast differentiation
p50*/ReB	as RelB, but stronger	immune response
IKK α	death at birth	normal limb formation, hyperproliferation of epidermal keratinocytes, embryonal PP formation
IKK β	death at E14.5	anti-apoptotic function, same as p65
IKK γ	male: death at E12.5-13.0 female: incontinentia pigmenti	same as p65 and IKK β
IKK α /IKK β	death at E12	neural tube closure, hepatocyte apoptosis, neuronal epithelium (hind brain), spinal cord and dorsal root ganglia formation

**NF κ B2 (p100/p52)

been shown to be acetylated by histone acetyltransferase (HAT) activities, including the p300/CBP and p300/CBP-associated factor (PCAF) co-activators in a signal-dependent manner (3, 5). Acetylated p65 can be deacetylated by histone deacetylase 3 (HDAC3). Deacetylation may be important for nuclear-cytoplasmic shuttling of p65-I κ B α complexes, because acetylated p65 interacts poorly with I κ B α (3, 5). Another requirement for the transcriptional induction of NF- κ B target genes is inducible chromatin modification exerted by IKK α (4, 5). In response to TNF α , a fraction of the cellular IKK α translocates to the nucleus, where it is recruited to promoters of responsive genes, as was shown for I κ B α and IL-6. IKK α contains a nuclear localization sequence. It is unknown how the nuclear import and recruitment of IKK α to promoters is regulated. It has been proposed that IKK α is required for histone H3 phosphorylation at serine 10 and subsequent acetylation of histone H3, which in turn is required for efficient transcription activity (4, 5).

Physiological and Pathological Regulatory Networks Which Depend on IKK and NF- κ B Activity

The biological responses to IKK and NF- κ B signaling largely depend on transcriptional up-regulation of a network of direct target genes that contain NF- κ B consensus sites in their promoter or enhancer regions. The functional groups of these genes (Table 1) underscore the range of cellular and physiological functions of IKK and NF- κ B, which include innate and adaptive immunity, inflammatory cytokine production, differentiation, programmed cell death and cell-cycle progression (3). A number of knockout studies have substantiated that individual NF- κ B genes are generally required for proper immune cell function (6) (Table 2). Protection against embryonic liver cell apoptosis is a further important function shared by p65, IKK β and IKK γ . Other functions include bone morphogenesis and skin proliferation and differentiation (Table 2). In the skin, IKK α regulates the differentiation of keratinocytes. However, recent studies have shown that IKK α does not require its kinase activity and does not activate NF- κ B to maintain its differentiation function (3). Thus, in addition to NF- κ B, IKK α also appears to regulate other as yet unknown effectors.

Since NF- κ B activates the expression of inflammatory cytokines and chemokines, it plays a key role in chronic inflammation. NF- κ B-associated pathological conditions include a wide spectrum of autoimmune and inflammatory diseases, such as rheumatoid arthritis, psoriasis and other skin conditions, asthma, Crohn's disease and atherosclerosis. Due to its anti-apoptotic and cell division activating effects, NF- κ B has been recognized to be of importance in the resistance of tumors to chemo- or radio-therapy (7). Constitutive

activation of IKK and NF- κ B is considered to be a critical step in the pathogenesis of certain lymphomas and leukemias (7).

Nicotine

Definition

Nicotine is the primary component found in smoke from tobacco products, which acts on the brain and induces addiction. Nicotine shares discrete neurochemical and functional properties with other addictive drugs. It accelerates the release of dopamine in the nucleus accumbens and the amygdala as well as other limbic structures. Addiction to nicotine is an enormous health, social, and financial burden.

Ni-NTA

Definition

Ni-NTA stands for Ni^{2+} -Ions bound to nitrilotriacetic acid. Ni-NTA resin is used to purify proteins containing a 6xHis tag (► [His-tag/6xHis](#)), since the tag binds to divalent cations; other cations such as Co^{2+} are also used. The bound protein is eluted from the resin using high concentrations of imidazole. Imidazole mimics the histidine side chain of the tag and thus competes for the binding sites on the resin.

NMR

Definition

NMR stands for Nuclear Magnetic Resonance. This spectroscopic technique enables the identification and characterization of molecular interactions. Other applications of biomolecular NMR are elucidation of protein structure and dynamics. Atomic nuclei containing a non-vanishing nuclear spin quantum number display separation of energy states in a static magnetic field (Zeeman splitting). Transitions between these energy states (resonance) can be induced by absorption of electromagnetic radiation of the appropriate frequency ($\Delta E = h \cdot \nu$).

- NMR-Based Screening
- Protein-Ligand-Interaction by NMR
- Protein Databases

Definition

►NMR-based screening refers to the identification of ligands for a pharmaceutically relevant target protein by the use of NMR spectroscopy (1, 2, 3, 4). NMR screening detects binding of ligands to a protein, rather than inhibition of protein function: NMR screening provides a binding assay, not a functional assay. NMR screening can be performed by protein observation, ligand observation or observation of a reporter ligand. A particular strength of NMR screening is its ability to robustly detect even weak protein-ligand interactions. This makes NMR screening particularly suitable for ►fragment-based ligand design (FBLD), a method for lead generation that is complementary to high-throughput screening. The lead compound can be further optimized with respect to potency, physico-chemical, pharmacological and pharmacokinetic properties and can, after successful optimization, be tested in clinical studies.

Description

Fragment-based Ligand Design

Like high-throughput screening (HTS), fragment-based ligand design is a method used to identify ligands for a target protein. Unlike HTS, which randomly screens available compounds for activity, FBLD attempts to design ligands based on structural knowledge and on knowledge of fragments with binding propensity to the target protein. FBLD can thus be considered a marriage of screening and ►structure-based drug design. FBLD comprises several steps: library design, fragment screening, structure elucidation and hit optimization (1, 5).

FBLD starts with the design and assembly of an appropriate compound library. This can be a general diverse library for use against a variety of target proteins, a targeted library, which is screened against a particular target class (e.g. kinases, proteases) and

NMR Spectroscopy

Definition

NMR spectroscopy is a method used to analyse the structure of molecules as large as proteins. When exposed to a magnetic field, the atomic nuclei in molecules can change their spin state in a resonance experiment. The resonance frequency depends on the local chemical environment. Furthermore, the information about the adopted spin states is transmitted to the neighboring nuclei via spin-spin coupling. This distance-dependent information can be used to learn about the spatial arrangement and thus the 3D structure of large molecules e.g. proteins.

which is biased to resemble known ligands for this target class, or can stem from a virtual library which is initially filtered by *in silico* screening. Whatever library is designed, care is taken to ensure that the compounds are “drug-like”, in the sense that they resemble fragments of marketed drugs or do at least not violate Lipinski’s “Rule of 5” and that they are readily amenable to chemical modification and linkage (6). Once the library is established, it is screened for compounds with binding affinity to the target protein. Due to their small size, which limits molecular interactions, the affinity of fragments to the target protein is generally weak, with dissociation constants often in the high micromolar or even millimolar range. Therefore, methods are needed which are sensitive enough to detect these weak interactions yet which are robust enough to avoid false positive detection. NMR spectroscopy is such a method, and NMR-based screening is particularly useful for this screening step. Other suitable screening methods include ►x-ray crystallography and ►mass spectroscopy. When binding fragments are identified, structural knowledge is sought to characterize the structure of the protein-fragment complex. This can be ideally done by x-ray crystallography if the complex crystallizes, or by NMR spectroscopy. Based on structural knowledge of the complex, an additional fragment that binds in the vicinity of the original fragment can be identified by second-site screening, so that both fragments can be subsequently linked to yield a high-affinity ligand, or the original fragment can be chemically modified and extended to yield a high-affinity ligand (1).

FBLD can be superior to HTS since the FBLD library is, as a virtual library, much larger than libraries used for HTS. If a protein binding site consists of three sub-sites, and each sub-site is probed by 1000 compounds, a virtual library of $1000 \cdot 1000 \cdot 1000 = 10^9$ (1 billion) compounds is screened, assuming that three independently identified fragments can eventually be linked to yield a single high-affinity ligand. However, actually only a thousand compounds need to be screened to gain access to the virtual library of a billion compounds. Libraries for HTS generally include only 10^5 – 10^6 compounds. NMR spectroscopy is an important component of fragment-based ligand design since it provides a sensitive and robust assay to identify weak binding affinity in fragments as well as the possibility of elucidating structural details on protein-fragment complexes.

NMR Screening Techniques

All NMR screening techniques described below perform binding assays rather than functional assays. This has the advantage that no functional assay has to be developed for screening and that in fact no knowledge about the biological function of a novel protein is

necessary. NMR provides a generic binding assay, which can be applied to all protein targets without the need for individual adjustment.

The NMR binding assay can be performed by monitoring either the protein resonances (“protein observation”), or the ligand resonances (“ligand observation”) or the resonances of a suitable reporter ligand (“reporter screening”) (1). The three variations are briefly described and illustrated below. The method of choice depends mainly on the nature and available quantities of the target protein, and the solubility of the test compounds.

Protein Observation

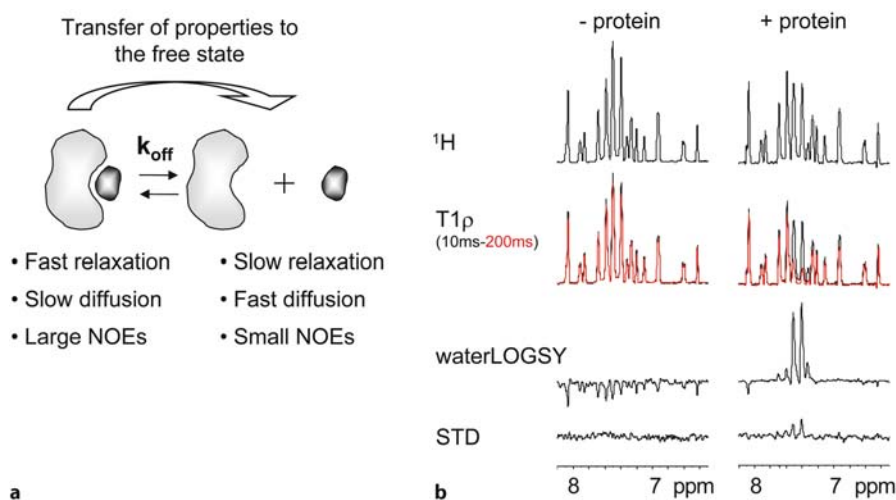

The chemical shifts of protein resonances depend sensitively on the local environment of the respective nuclei. When a protein is complexed by a ligand, the local environment changes and protein residues consequently experience chemical shift perturbations. These can be due to direct contact with the ligand or due to secondary effects such as conformational changes. Since one-dimensional protein NMR spectra are often too crowded, 2D spectra such as ►HSQC are often used to reduce spectral overlap. Chemical shift perturbations indicate the binding event, and also the ligand-binding site, assuming that chemical shift perturbations are mainly due to direct contact with the ligand and provided that the protein resonances have been assigned to their position in the amino acid sequence. An example of the protein observation technique is shown in Fig. 1, which also illustrates the identification of the binding site by this technique. The main advantage of the protein observation method is the high information content. By analysis of the ligand binding site, active-site ligands can be discriminated from non-active-site ligands, and ligands binding to one subsite can potentially be discriminated from ligands binding to another subsite. Disadvantages of the protein observation method are the need for large amounts of isotopically labeled protein (about 1 mg per sample), and the need for high ligand solubility. There is also an upper limit of about 30–50 kD for the target protein, since spectral overlap and peak broadening deteriorate the spectral quality for larger proteins.

Ligand Observation

An unbound ligand is a small molecule and behaves as such, i.e. it has sharp lines (relaxes slowly), small and positive ►NOEs and diffuses fast. A bound ligand, on the other hand, temporarily behaves like and adopts the properties of a large molecule. It shows broad resonances (fast relaxation), large negative NOEs and slow diffusion. Measurements of ligand relaxation, NOE or diffusion properties can therefore be used to detect protein-ligand interactions (1). Due to the high excess of ligand, ligand-observation techniques

NMR-based Screening. Figure 1 Protein observation: A ^{15}N - ^1H HSQC experiment on ^{15}N -labeled target protein is recorded in the absence (black) and presence (red) of compound (left). Chemical shift perturbations indicate binding of the compound and coloring of the residues that experience the greatest chemical shift perturbations indicate the ligand binding site (right).

NMR-based Screening. Figure 2 Ligand observation techniques: (a) Properties of the bound ligand are transferred and detected on the unbound ligand, if the ligand dissociates within the time scale of the NMR experiment, typically 100–1000 ms. (b) Several ligand observation techniques exist, measuring relaxation rates ($T1\rho$), water-ligand NOEs (waterLOGSY) or protein-ligand NOEs (STD).

observe only resonances of the unbound ligand, but they are able to detect the ligand history if the ligand dissociates within the time scale of the experiment. Any effects from a past binding event have been transferred to the unbound ligand and can be detected there (Fig. 2a).

Different ligand properties can be detected by different experiments. Representative spectra are displayed in Fig. 2b. A $T1\rho$ experiment measures ligand relaxation rates. If signal intensity after a 200 ms relaxation period (red spectrum) is not much weaker than signal intensity after a 10 ms relaxation period (black spectrum), the

compound relaxes slowly and is thus unbound. If signals decrease significantly at long relaxation periods, the compound is temporarily bound and is a ligand to the target protein. The waterLOGSY experiment (water-ligand observation with gradient spectroscopy) measures the sign and magnitude of NOEs between water and compound (2). This NOE is small and positive for unbound compounds (leading to negative signals in Fig. 2b), and is large and negative if the compound is bound to protein, provided the binding site also contains water molecules with high residence times. The STD experiment (saturation

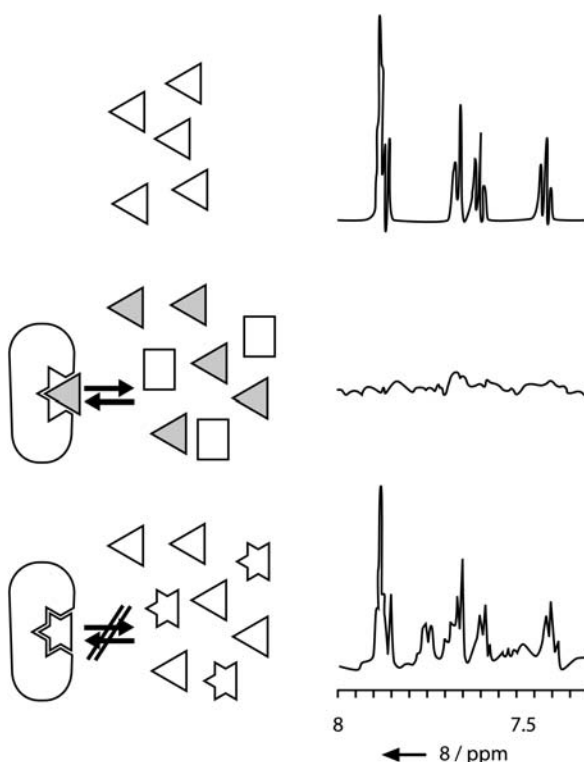

transfer difference) measures transferred NOEs between protein and ligands (4). In this experiment, compound signal intensities are compared with and without protein presaturation. When a compound is bound to the saturated target protein, the saturation is partially transferred from protein to ligand by protein-ligand NOE, so that the binding event can be detected. Literature reviews describe these experiments in more detail (1, 2, 3, 4, 7).

The main advantage of ligand-observation techniques is the significantly lower protein consumption (down to 10 µg per sample) and the lack of need for isotopic labeling. This allows the screening of poorly expressing proteins or of proteins expressed in organisms other than *E.coli*. Disadvantages are the lower information content of the spectra. The protein-binding site cannot be deduced and in fact non-specific binding is not directly discriminated. Hits from ligand-observed NMR techniques should therefore be checked by HSQC, if labeled protein is available, or by competition experiments as shown below. Another major drawback of ligand-observation techniques is the need for significant ligand dissociation during the NMR experiment. This essentially lets tightly binding ligands, or even medium binding affinity ligands with slow binding kinetics, appear non-binding (false negative). In order to alleviate this severe shortcoming, competition-based methods have been developed.

Reporter Screening

Competition assays (“NMR reporter screening”) have been developed to detect tightly binding ligands with small protein amounts (1, 2). For this method, a known, weakly binding ligand (the “spy molecule”, “probe” or “reporter ligand”) is added to the mixture of protein and test compounds. The binding of the reporter ligand is measured, not the binding of the test compounds. If the reporter ligand is bound even in the presence of test compounds, none of the test compounds has comparable or higher binding affinity. In contrast, if the reporter ligand is not bound any more, one or more test compounds must have displaced it and therefore must have comparable or higher binding affinity (Fig. 3). Even poorly soluble test compounds can be detected in this way, if their affinity is high enough.

Advantages of reporter screening are not only the ability to detect tightly binding ligands, but also the elimination of non-active site binders. If the reporter ligand binds to the active site, every compound displacing it should also bind to the active site. Additionally, the binding affinity of test compounds can be calculated based on the known affinity of the reporter ligand. If the reporter ligand is ^{13}C -labeled at one position or is chosen to contain a ^{19}F -atom, signal overlap with test compounds can be completely avoided (2).

NMR-based Screening. Figure 3 The principle of reporter screening. The reporter ligand (triangles) binds to the protein active site with moderate affinity. This leads to severely broadened lines in the presence of protein (middle panel), whereas the reporter ligand in the absence of protein has sharp lines (upper panel). In the presence of non-binding test compounds, the reporter ligand is still bound and shows broad lines (middle panel). If at least one of the test compounds has higher binding affinity, it can displace the reporter ligand; this is made visible by its sharpened lines (lower panel).

Hit Elaboration and Optimization

Primary hits from NMR-based screening have specific and validated, but generally only weak, binding affinity to the target protein and their binding affinities need to be increased. The NMR hit can be followed up by one of the following strategies (1, 7). In a linked-fragment approach, second-site screening is employed to identify a second ligand, which binds simultaneously and in the vicinity of the NMR hit (the “first ligand”). Linking both ligands then results in a significant increase in binding affinity if the linker has been well designed. In a merged-fragment approach, information on binding epitopes from several ligands is used to construct a merged ligand, which exploits binding interactions from two or more distinct ligands. These ligands cannot be linked since they bind at overlapping binding sites. Both the linked-fragment approach and the merged-fragment approach rely heavily on structural characterization of the binding of ligands to the target protein. In

a third strategy, hits from NMR-based screening are used as input to design directed libraries around these hits, perhaps using combinatorial chemistry. Structural information on the complex between the hit and the target protein is desirable, but not mandatory, since NMR screening is essentially used as a filter to select the most promising scaffold for combinatorial chemistry. In the elaboration strategy, hits from NMR-based screening are used to select analogous compounds, e.g. identified by a similarity search, for further follow-up studies such as computational docking and scoring or testing by NMR reporter screening or a biochemical assay. The follow-up strategy of choice depends on the nature of the NMR hits, the nature of the protein-binding site, available chemistry capacity and the amount of available experimental information. Several examples of successful NMR-based screening and subsequent optimization of the primary hits have been described and reviewed (1, 2, 3, 4, 7).

Clinical Applications

NMR-based screening is applied in pre-clinical or genomic research.

Therapeutic Consequences

Fragment-based ligand design including NMR techniques is expected to accelerate the drug discovery process, so that lead compounds as potential drug candidates are expected to be more rapidly identified.

Synonyms

Chromosomal nonhistone proteins; chromatin-remodeling enzymes; chromatin remodelers; architectural factors; nuclear matrix; nuclear acidic proteins

Definitions

The non-histone chromatin proteins are a heterogeneous group of proteins that act in the eukaryotic nucleus as part of large multisubunit complexes, playing important roles in regulating many processes such as nucleosome remodeling, DNA replication,

RNA synthesis and processing, nuclear transport, steroid hormone action and interphase/mitosis transition. The group includes proteins that regulate chromatin assembly, such as SWI/SNF; proteins that regulate enhanceosome and transcriptosome assembly, such as the high mobility group A proteins; modifying proteins, such as histone acetylase, deacetylase and methylase; proteins that help chromosomes to condense, such as topoisomerase II and many others generally involved in the establishment of functional and dynamic chromatin domains.

Characteristics

All genes are packaged into chromatin structures that can be modulated to generate transcriptionally active or repressed configurations in different cellular contexts and under changing environmental conditions. This remarkable plasticity is governed in part by multi-subunit protein complexes that enzymatically regulate chromosomal structure and activity. These complexes can either chemically modify the histone tails of nucleosomes or disrupt histone-DNA contacts through ATP hydrolysis. Specific combinations of modifying and remodeling complexes often act in a temporal manner to modulate the nucleosomal structure and expression of individual genes.

One important ► chromatin remodeling enzyme is SWI/SNF, which is a 2 MD multisubunit complex that is implicated in regulating critical cellular processes such as differentiation and cell-cycle arrest. Mammalian SWI/SNF complexes are present in biochemically diverse forms, indicating that they may have specialized nuclear functions. Each of these complexes contains one of two ATPases, BRG1 or BRM, and a variable subunit composition of BRG1-associated factors (BAFs). Association of specific protein domains with individual SWI/SNF subunits directs recruitment of the enzymatic complex to nucleosomal sites where stable remodeling occurs. Thus, the functional diversity of mammalian SWI/SNF can result from differential gene targeting of specific complexes by transcription factor interactions with individual SWI/SNF subunits. Another group of ATP-dependent chromatin-remodeling factors contains the nucleosome-dependent ATPase ISWI, which forms several functionally different complexes. ACF1 interacts with the SNF2H isoform of ISWI in the related complexes ACF, WCRF and CHRAC, all of which are conserved in *Drosophila melanogaster*, *Xenopus laevis* and human cells. ISWI is the primary motor of the nucleosome remodeling, whereas ACF1 enhances and directs the process. An interesting family of nonhistone proteins involved in changing the local conformation of DNA and/or nucleosomes and enhancing their accessibility and plasticity, is the high mobility group proteins (HMGs). They can be divided into three

groups that are completely dissimilar from each other as regards sequence and structure but are internally homogeneous, the HMGB (formerly HMG1/2), HMGN (formerly HMG14/17) and HMGA (formerly HMG1/Y) families. Each group is characterized by a distinct functional sequence motif; the "HMG box" for the HMGB proteins, the "nucleosomal binding domain (NDB)" for the HMGN proteins and the "AT-hook" for the HMGA proteins. The HMGA proteins include four members, HMGA1a, HMGA1b and HMGA1c generated by alternative splicing of the same gene, and HMGA2. Each of them contains three AT hook domains through which they bind AT rich sequences in the minor groove of the DNA and induce complex structural alterations. The "HMG-motif" proteins are a similar but distinct family of nonhistone chromatinic proteins. They contain one of the functional motifs of the HMG proteins, but the rest of the protein is different. The mixed lineage leukemia gene (MLL, ALL-1, HRX) is one of the "HMG-motif" proteins. It is homologous to the *Drosophila* protein Trithorax, and, like Trithorax, has been shown to be a positive regulator of homeobox gene expression. The main region of homology with Trithorax includes two small regions in the amino terminal half of the protein, a central zinc finger domain and a carboxy terminal SET domain (a motif that is also found in some mammalian Polycomb homologues, which are negative regulators of Hox gene expression).

Clinical Relevance

The chromatin remodeling complexes are involved in critical aspects of cellular growth and genomic stability. A variety of human malignancies are associated with mutations in BRG1 and INI1/SNF5, suggesting that loss of function of certain SWI/SNF complexes may contribute to tumorigenesis.

MLL and Human Leukemias

Rearrangements of MLL are common in infant acute lymphocytic leukemia, 5–10% of adult and pediatric acute leukemia cases, myelomonocytic leukemias and in leukemias that arise secondarily to DNA topoisomerase II inhibitor therapy. These rearrangements follow chromosomal translocations involving the chromosomal region 11q23. The fusion of MLL may occur with at least 20–30 different genes mapping to different chromosomal regions. The translocations delete the SET domain of MLL and replace it with one of many translocation different partners that in general share sequence homology. To date, two MLL motifs have been identified that are necessary for leukemic transformation. The first of these is the three AT-hook motif homologous to that in HMGA proteins and not present in *Drosophila* Trithorax. These motifs may be relevant to the function of MLL in leukemogenesis

because in all of these translocations the AT hook motifs are retained and are separated from the carboxy terminal portion of the protein. The second region important for transformation is that homologous to the noncatalytic region of DNA methyltransferase.

In some cases there are alterations in the MLL locus not associated with cytogenetic abnormalities; these were found to involve a direct tandem duplication of a portion of MLL spanning from exon 2 to exon 6 or from exons 8 or 4 to exon 6. This second type of alteration may be associated with trisomy of chromosome 11 and occurs in around 5–10% of AML patients.

The HMGA Proteins

HMGA expression is essentially restricted to embryonic development and is negligible in normal adult tissues. However, over-expression of HMGA proteins has been found to be a common feature of experimental and human malignant neoplasias, including thyroid, prostate, uterus, pancreas, breast, colorectal and ovarian carcinomas. Moreover, the expression level of the HMGA proteins is significantly correlated with parameters of a poor prognosis in patients with colorectal cancer. Therefore, an evaluation of the HMGA protein expression by immunohistochemistry can be very helpful in the diagnosis and prognosis of human neoplasias. Finally, several published papers demonstrate that HMGA over-expression is a necessary event in *in vivo* cell transformation and that the suppression of HMGA1 protein synthesis specifically kills malignant cells. In fact, an adenovirus carrying the *HMGA1* gene in an antisense orientation induces programmed cell death in carcinoma cell lines derived from human thyroid, lung, colon and breast cancers. This suggests the fascinating possibility of a new approach to the therapy of human malignant neoplasias based on the suppression of the HMGA protein function. The advantage of such an approach would be that:

- the low or null expression levels of HMGA gene expression in normal adult tissues would account for the specificity and low toxicity of such a kind of therapy.
- since HMGA gene over-expression appears to be a general feature of human malignant neoplasms, a therapy based on the inhibition of HMGA function might be applicable to diverse types of cancer.

HMGA proteins are also involved in the generation of benign tumors of mesenchymal origin, including lipomas, lung hamartomas, uterine leiomyomas, endometrial polyps, fibroadenomas and adenolipomas of the breast. In fact, rearrangements of the *HMGA1* and *HMGA2* gene have been detected in these neoplasias. Chromosomal translocations involving the regions 6p21 and 12q13-15, where the *HMGA1* and *HMGA2* genes respectively are located, account for these

rearrangements. In most of the cases of *HMGA2* rearrangements, breaks occur within the third intron of the gene, resulting in chimeric transcripts containing exons 1 to 3 of *HMGA2* (encoding the AT-hook domains) and ectopic sequences from other genes. The generation of transgenic mice over-expressing a truncated or a wild type *HMGA2* gene has confirmed the critical role of the *HMGA2* rearrangements in the development of human lipomas. From the most recent results, it seems that *HMGA2* expression may have an important role in obesity. In fact, the *HMGA2* gene seems to be necessary for physiological proliferation of adipocytes. Indeed, *HMGA2* knockout mice display a pygmy phenotype with a remarkable reduction in adipose tissue and disruption of the *HMGA2* gene prevents both diet- and gene-induced obesity. A possible therapy for human obesity by blocking of *HMGA2* function cannot be excluded.

Nonsense Mutation

Definition

Nonsense mutation describes single-base substitutions that change a sense codon coding for an amino acid into a termination codon, for instance UGG (tryptophan) to UGA (stop). Nonsense mutations are deleterious, as at such mutated positions the synthesis of the protein is terminated prematurely and full-length, functional protein is not made. Truncated proteins formed as a consequence of nonsense mutations may impair cell functions. In eukaryotic cells, mRNAs containing premature stop codons are subject to rapid, preferential nucleolytic degradation ► [nonsense-mediated RNA decay](#).

Nonsense-Mediated RNA Decay

Definition

mRNAs harbouring premature termination codons (PTC) in their sequence can be selectively degraded by nonsense mediated degradation, or nonsense-mediated RNA decay (NMD).

A termination codon is recognised as premature when it precedes an exon/exon splice junction. PTCs are generated following mutations, errors in fidelity of transcription, random gene rearrangement as occurring in immunoglobulin or T-cell receptor genes. This “quality control” process prevents the synthesis of truncated proteins that may be toxic. The NMD pathway has a direct impact on hundreds of genetic disorders in the human population, where about a quarter of all known mutations are predicted to trigger NMD.

Nonsyndromal/Nonsyndromic Deafness

Definition

Nonsyndromic/nonsyndromal deafness is a hereditary autosomal hearing loss that is not associated with other signs and symptoms. (In contrast, “syndromic deafness” includes forms of hearing loss that are part of genetic syndromes which also affect other parts of the body.) The different types of nonsyndromic deafness are named according to their inheritance patterns. More than 30 genes that, when mutated, can cause nonsyndromic deafness. One form is caused by mutations in the gene GJB2 that encodes for ► [connexin 26](#), which is expressed in the cochlear and vestibular regions of the ear.

Non-Uniform Sampling

Definition

Non-uniform sampling is a technique that is used in multi-dimensional NMR experiments, where the free induction decays with variable number of scans are collected as non-consecutive integers of fixed time increment in the indirect dimension. The data collected are typically processed with maximum entropy methods, since they cannot be processed using conventional Fast Fourier transform algorithms.

► [3D Structure by NMR](#)

Normalization

Definition

Normalization corrects for the different amounts of cDNA in the samples that are compared. Most often

this is achieved by measuring the signal intensity of so-called housekeeping genes, which are usually expressed at a stable level in all cells, independently of external factors. The expression level of genes that are compared between two samples is then mathematically corrected according to the differences found in the expression level of the housekeeping genes.

Notch Pathway

THOMAS KLEIN

Institute for Genetics, University of Cologne, Cologne, Germany

th.klein@uni-koeln.de

Definition

The *Notch* pathway is one of the fundamental signalling mechanisms that mediates cell communication in a wide range of developmental processes

throughout the animal kingdom (1, 2). It mediates communication between cells immediately adjacent to one another. The pathway was discovered and initially characterized in the fruit fly *Drosophila melanogaster*, but has been found in all other animal systems, including nematodes and vertebrates. In vertebrates, Notch signalling is required in many developmental processes, including limb development, segmentation of the mesoderm, vasculogenesis and haematopoiesis. Furthermore, it is involved in several heritable diseases, such as ►Alagille syndrome and ►Cadasil disease (3, 4). In many tissues it also seems to act to promote ►oncogenesis, in some cases as an important mediator of oncogenic Ras. On the other hand, recent work suggests that the pathway acts as a tumour suppressor in the skin (4).

Earlier work in *Drosophila* showed that loss of the function of the pathway during early embryogenesis led to the formation of excess neural tissue at the expense of epidermis. This led to the classification of all genes involved in the *Notch* pathway as ►neurogenic genes. The study of the role of the pathway during neurogenesis in vertebrates and invertebrates revealed that it mediates a binary cell choice among cells of an equivalence group. During this process, which is often termed lateral inhibition, a cell determined to become a neural precursor (e.g. a neuroblast) is thought to emit an inhibitory signal that forces its equipotent neighbours to adopt the epidermal fate (1, 2). This inhibitory signal is mediated through the *Notch*-pathway. Furthermore, the pathway is involved in a variety of inductive signalling events between non-equivalent cells in other developmental situations. One example of this type of signalling is the induction of the expression of genes along the dorsoventral compartment boundary of the *Drosophila* wing through Notch-mediated interactions between dorsal and ventral cells. Notch mediates a similar interaction between dorsal and ventral ectodermal cells during vertebrate limb development leading to the induction of the ►apical ectodermal ridge (AER).

Characteristics

Structure of the Core Components of the Notch Pathway

In *Drosophila*, the pathway has four core elements, two ►ligands, Serrate (►Ser) and Delta (►Dl), the Notch receptor and Suppressor of Hairless (Su(H)), which is a nuclear factor (1, 2). Notch is a large Type 1 transmembrane protein with several distinguishable motifs in its extra- and intracellular domains (Fig. 1). The extra-cellular domain contains a region containing 36 tandem repeats of the ►EGF-like motif, followed by a cysteine-rich region, termed the LNR (for Lin-12/Notch-related region). The intracellular domain contains a RAM 23 domain, adjacent to the transmembrane

domain, six repeats of an ankyrin/cdc10-like domain and a PEST sequence. The six ankyrin-like repeats are necessary and sufficient for the activity of the *Notch* receptor in *Drosophila*.

Both Dl and Ser belong to the DSL (Delta, Serrate, Lag-2) family, which are all ligands for Notch receptors (Fig. 1). They are transmembrane proteins that contain a DSL domain in the N-terminus of their extra-cellular domain and a stretch of EGF-like motifs. In Dl, the stretch comprises nine repeats, whilst Ser contains 14. Ser also has a cysteine-rich domain close to the membrane, which is absent in Dl (Fig. 1).

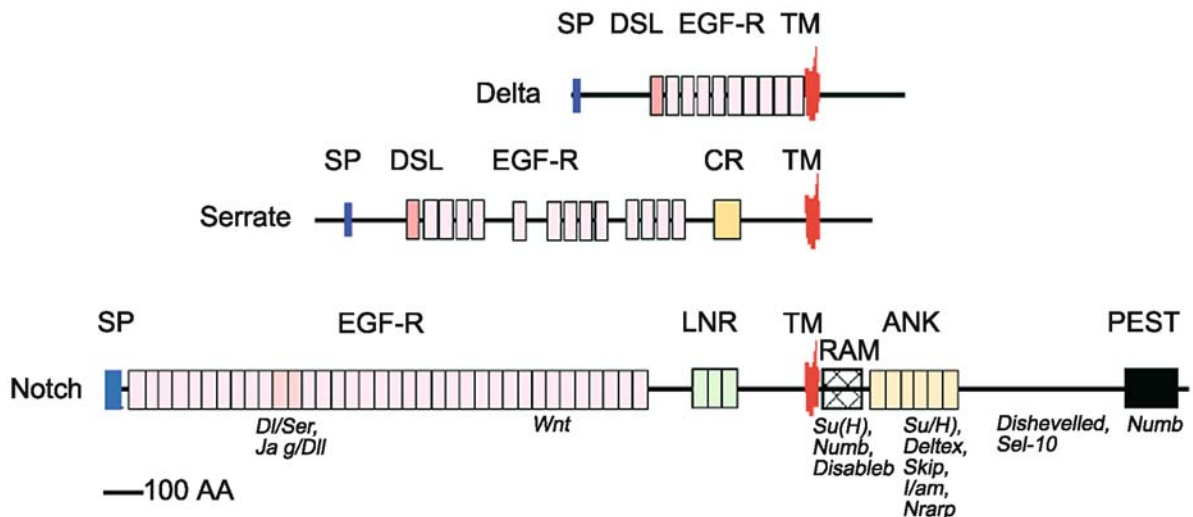

Orthologues in Vertebrates

Studies in various organisms revealed that all the components of the *Notch* pathway found in *Drosophila* are conserved throughout the animal kingdom (1, 2). In mouse and humans three ►orthologues of Dl exist, ►Delta-like (Dll) -1, -3 and -4 and two Ser-orthologues have been found and named ►Jagged (Jag 1 and 2). Four Notch receptors, have been isolated, Notch 1–4. While Notch 1 and 2 have similar overall structures to Notch, Notch 3 and 4 have only 34 and 29 EGF-repeats respectively and contain shorter intracellular domains. The vertebrate Notch receptors require proteolytic cleavage to become functional. A single precursor polypeptide is cleaved in a step referred to as S1 cleavage to produce a heterodimer consisting of a ligand-binding extra-cellular domain and a single pass transmembrane domain (Fig. 2; 1). Both domains associate through Ca^{2+} ion bridges and the LNR region plays an important part in this association. The S1 cleavage occurs in the Golgi apparatus and is performed by a furin protease. For *Drosophila* Notch receptor there is conflicting evidence as to whether S1 cleavage occurs.

Only one orthologue of the Su(H) transcription factor exists in mammals, which is referred to as CBF1 or RBPjk or CSL. In the absence of Notch activation, it seems to be a transcriptional repressor. Su(H)/CBF1 seems to form a complex that contains Hairless (H) in *Drosophila*, which recruits the co-repressors Groucho (Gro) and CtBP (c-terminal binding protein). In vertebrates there is evidence the repressor complex contains SMRT (silencing mediator of retinoid and thyroid hormone receptor), SKIP (ski-related protein) and histone deacetylase (HDAC) (2).

Signal Transduction

The intracellular domains of the Notch receptors are in fact membrane bound transcription factors, which are released through a sequence of two proteolytic cleavages induced by ligand binding (summarized in Fig. 2). Following cleavage the intracellular domain travels to the nucleus and associates with Su(H) to form a transcriptional activator complex. Signal transduction

Notch Pathway. Figure 1 The structure of the founding members of the *Notch*-receptor and DSL- families. All three depicted proteins are type 1 transmembrane proteins, with the N-terminus in the extra-cellular space and their primary amino acid sequence contains a typical signal sequence (SP) in their extreme N-termini. Delta and Serrate are ligands that contain the family specific DSL (Delta, Serrate, Lag-2) domain followed by a stretch of repeats homologous to the epidermal growth factor (EGF). The stretch comprises nine repeats for *Dl* and 14 for *Ser*. *Ser* has a cysteine-rich domain (CR) close to the membrane, which is absent in *Dl*. The intracellular domains of both ligands are relatively small and bear no significant motives.

Notch is the founder of the *Notch*-receptor family. The extracellular domain is large and contains a region of 36 EGF-like repeats followed by a cysteine-rich region, termed the LNR (for Lin-12/*Notch*-related region). In the intracellular domain, the RAM 23 domain is located immediately after the transmembrane domain (TM), followed by six repeats of an ankyrin/cdc10-like domain and a PEST sequence. Some of the factors that interact with different regions of the *Notch* receptor are listed below in italics.

in this pathway is in principle very simple, since it requires no intermediate factors or signal-amplification steps to mediate signal transduction from the receptor to the nucleus. However, the regulation of the release of the intracellular domain is complex and involves additional factors. The detailed events leading to the activation of the receptor are described below.

There is also evidence from several systems that a second, *Su(H)* independent signalling transduction mechanism exists. However, no details are known about this pathway (1, 2).

Molecular Interactions

Ligand Receptor Interactions

Several studies have revealed structural features of *Notch* and its ligands, which are crucial for their interaction. The ligands require the DSL domain to activate *Notch*, which seems to bind EGF-repeats 10–12 within *Notch*. Furthermore, EGF repeats 24–26 and 17–19 of *Notch* are required for the interaction of *Notch* with its ligands.

Cleavage of the Receptor

The binding of a ligand induces the first cleavage of *Notch*. This cleavage, called S2, is performed by a

protease of the TACE /ADAM metalloprotease family and occurs in the extra-cellular space, close to the membrane (Fig. 2; 4) (1, 2). In *Drosophila* the S2 cleavage is probably carried out by Kuzbanian (Kuz). However, it is unclear whether its orthologue ADAM 10 performs this cleavage in vertebrates (1, 2). The result of S2 cleavage is the shedding of the extra-cellular domain of *Notch*, which is endocytosed together with the ligand in the signal-emitting cell (Fig. 2; 3) (2). The remaining membrane-inserted intracellular domain referred to as **▶NEXT** (*Notch* extra-cellular truncation) is rapidly cleaved by an enzyme complex, the gamma-secretase complex that also cleaves the **▶amyloid precursor protein** (APP) (Fig. 2; 5) (2). This proteolytic complex contains one of the presenilin (Ps) proteases, Nicastrin, APH-1 and PEN-2 (5). **▶NEXT** is cleaved in the trans-membrane region to release the intracellular domain of *Notch* (**▶Nintra**) into the cytoplasm. This phenomenon is an example of regulated intra-membranous proteolysis (**▶RIP**) (2).

The activation of the *Notch* receptor also requires the functioning of the endocytic pathway on both the signal emitting and receiving sides of the pathway (Fig. 2; 3) (1). Recent studies in *Drosophila* revealed that the

Notch Pathway. Figure 2 Notch trafficking and signal transduction through the Notch pathway. After Notch is synthesized in the endoplasmic reticulum, the signal peptide is removed and the receptor is transported to the Golgi apparatus for further maturation. An important event is the cleavage by furin proteases (1) to produce the mature receptor, consisting of the extra-cellular domain connected to the membrane inserted intracellular domain through Ca^{2+} ion bridges. A further modification that occurs in some cells is the decoration of certain EGF-repeats in the

short intra-cellular domain of DI is important for endocytosis. It is probably ubiquitinated by the RING finger E3-ligase Neuralized (Neur), which regulates the endocytosis and functioning of DI. In vertebrates this function seems to be performed by the E3-ubiquitin ligase, Mindbomb (1, 2).

Although endocytosis is also required on the signal-receiving side of the pathway, its function is less clear. Studies in *Drosophila* suggest that endocytosis is not required for S3 cleavage, suggesting that S2 cleavage might be dependent on this process. One attractive hypothesis is that endocytosis is required when the ligand binds to the receptor in order to stretch the receptor and change its configuration. A conformational change could make the S2-cleavage side accessible to the Kuz/Tace-like protease.

Interactions in the Nucleus

Once Nintra is released into the cytoplasm, two nuclear localization signals direct it to the nucleus (Fig. 2; 6). In the nucleus Nintra seems to cause the dissociation of the Su(H)/CBF1 containing repressor complexes with high efficiency (1, 2). After dissociation of the repressor complex, an activator complex that contains SKIP, Mastermind (Mam) and histone acetylases is thought to assemble with the help of Nintra. Nintra has been shown to be able to assemble an activator complex in the absence of Su(H). Hence, Su(H) provides DNA binding specificity and Nintra is responsible for the assembly of the complex.

Studies in flies indicate that the Su(H)/Nintra activator complex alone is not sufficient to activate gene transcription. Additional transcription factors or complexes are also required to activate the transcription of target genes. These inputs also modulate the *Notch*-signal to provide the tissue specific transcriptional response.

Termination of Signalling

At the end of the signalling event, Nintra must be removed from the nucleus to terminate target gene transcription. This process is not very well understood, although recent evidence shows that in mammals and

nematodes Sel-10, a F-box protein, specifically targets nuclear Nintra for destruction by the [proteasome](#) (Fig. 2;) (1, 2).

Ligand Processing

A recent discovery is that during activation of the *Notch*-pathway not only the receptor but also the ligands seem to be cleaved in the same sequence and by the same proteases (6). The binding of at least some of the ligands (tested are Dll-1, Ser and DI) elicits their cleavage by Kuz and consequently by the γ -secretase complex and releases the intracellular domain into the cytoplasm. Interestingly, the intracellular domains travel to the nucleus as Nintra does. The significance of this nuclear translocation is at the moment not clear, but one work reports the interaction of the intracellular domain of Dll-1 with the AP-1 transcriptional complex. It is also possible that processing of the ligands is part of the degradation process of the ligand/receptor complex after termination of the signalling event.

Ligand Specificity

In vertebrates not only four Notch receptors, but also five different ligands have been discovered. These ligands and receptors are often expressed in strongly overlapping domains. This raises the interesting question as to whether specific interactions between certain ligands and receptors exist to perform specific functions. Whether such specific interactions exist is one of the most pressing questions.

Regulatory Mechanisms

Given the importance of the pathway and its involvement in so many processes, its activity must be regulated precisely. Several mechanisms have been discovered. One major mode of regulation is transcriptional regulation of the ligands and the Notch receptors. In *Drosophila*, Notch is ubiquitously expressed. Nevertheless, it is expressed at different levels, suggesting that transcriptional regulation is important. Overall, one major regulation of its activity occurs through the differential expression of the ligands.

extra-cellular domain with sugar chains by OFUT-1 and Fng (2, 8). The mature receptor is then transported to the cell membrane. The binding of a ligand such as DI activates the receptor. An important step in the activation of the receptor is endocytosis (3), which is required on the signal emitting side as well as the receiving side of the pathway. Dynamin and Neuralized are important for this process. The extracellular domain of Notch is endocytosed together with DI by the signal-emitting cell. This event is named ecto-domain shedding. The binding elicits the first cleavage of the receptor by a member of the ADAM/TACE family, which is encoded by *kuz* in *Drosophila* (4). The cleavage produces the intermediate NEXT (for *Notch* *Extra-cellular* *Truncation*), which is immediately subjected to RIP (for *regulated* *intra-membranous* *proteolysis* *release*) by the presenilin-containing gamma-secretase complex (5). RIP releases the intracellular domain (Nintra) from the membrane (6) and this travels into the nucleus (6) and combines with Su(H) to generate a transcriptional activator that controls the expression of the target genes. At the end of the signalling event the activator complex is targeted for protein degradation by the proteasome (7). Sel-10 is involved in this process.

In vertebrates, regulation of expression of the ligands and the receptors is much more complex, indicating a tight regulation. Although not tested, it is likely that this precise regulation of expression is used to tightly control the activity of the pathway.

► Glycosylation

In several situations certain EGF-repeats of Notch become modified by glycosylation (Fig. 2) (1, 2, 8). The sugar chain is added in the Golgi apparatus. Initially, a fucose residue is added by the *O*-fucosyltransferase (►OFUT1), encoded by the gene *neurotic (nti)* in *Drosophila*. The next step is the addition of N-acetylglucosamine to the fucose residue by the action of Fringe (Fng). The glycosylation of Notch enhances activation by D1 and suppresses activation through Ser. In several developmental situations, the modification leads to the activation of the *Notch*-pathway in a thin stripe along the boundary of Fng-expressing and non-expressing cells. Examples are the activation of Notch target genes along the dorsoventral boundary during *Drosophila* wing development or induction of the apical ectodermal ridge at the dorsoventral boundary during limb formation in vertebrates. Three variants of Fng have been found in vertebrates, named Radical fringe, Manic fringe and Lunatic fringe.

Ligand Concentration

Another means regulating Notch activity has been found by investigating the role of the *Notch*-pathway during *Drosophila* wing development: In cells that express high levels of ligands, the *Notch*-pathway cannot be activated. However, the cells with high levels of ligands can activate the pathway in the adjacent cells that express lower levels of the ligands (1). This cell-autonomous suppression occurs only if the levels of ligands increase above a certain threshold. The suppressive effect is used during wing development for regulation of the activity of Notch. The underlying mechanism of suppression of the activation of Notch is not understood. It is also not known, whether the vertebrate orthologues of the ligands have similar properties.

Numb and Asymmetric Cell Divisions

Evidence from *Drosophila* and more recently from mammals indicates that the *Notch* pathway plays an important role in promoting asymmetric cell division (7). In this process a cell divides to give rise to two different daughter cells. For example this occurs during neurogenesis to generate two different neurons from a single precursor cell. An important factor in this process is Numb, a protein that can prevent the activation of Notch in one of the two daughter cells. Numb is a membrane-associated cytoplasmic protein

that contains a phosphotyrosine-binding (PTB) domain and associates with the intracellular domain of Notch. During cell division Numb is asymmetrically distributed to one of the daughter cells and represses the activation of Notch in this cell. As a result the *Notch* pathway will be activated only in the sister cell, which adopts another developmental fate. Numb binds to alpha adaptin, a protein essential for the formation of clathrin coated endocytic vesicles (1), suggesting that Numb might target Notch for endocytosis and thereby remove the receptor from the cell surface. However, recently it was discovered that Notch requires the activity of the four pass transmembrane protein Sanpodo (Spdo) to promote cell asymmetry in *Drosophila* (7). Spdo associates with Notch and Numb and the interaction with Notch is required for the function of the receptor. It seems that Numb prevents the transport of Spdo to the membrane and thus prevents the activation of Notch in one of the daughter cells.

Suppressor of Deltex

The E3 ubiquitin ligase, named Suppressor of Deltex (Su(dx)) in flies and Itch in mammals, is a negative regulator of Notch when inserted in the plasma membrane. However, its function is so far not understood.

Notch Regulated Ankyrin Repeat Protein (Nrarp)

As in many other important signalling pathways, a feedback loop exists that counteracts the activity of the *Notch*-pathway. Activation of the *Notch*-pathway induces the expression of a small protein termed Nrarp (for Notch regulated ankyrin repeat protein) that contains two cdc10/ankyrin repeats (1). Nrarp can bind to the CBF/Nintra ternary complex and inhibit its activity. This feedback mechanism seems to be specific to vertebrates, since no equivalent gene exists in the genome of *Drosophila* or the nematode *C. elegans*.

Interactions with Other Signalling Pathways

Several important interactions with two other pathways have been reported. Various publications report negative interactions of the *Notch*- and Wnt- pathways at different levels (1, 2). For example the Wnt transducer Dishevelled (Dsh) can bind to the intracellular domain of Notch and prevent the activation of the receptor (Fig. 1). Furthermore, interactions are reported between Armadillo/ β -catenin, the major Wnt transducer, and Psn, which seem to promote the degradation of β -catenin.

Moreover, a strong antagonism between the EGF-pathway and Notch exists in several processes during *Drosophila* development. Whether this is also the case in the vertebrates remains to be determined.

Definition

The genome of every eukaryotic cell is packaged within the cell nucleus. Conceptually, the role of the nucleus is to provide an environment suitable for both expression and maintenance of the genome. These two functions can be sub-divided into a broad range of activities, including such diverse processes as transcription, RNA processing and export, DNA replication and DNA damage sensing and repair. In addition the genome must be tightly packaged, yet large parts of it nonetheless must be readily available as a transcriptional substrate either for basal metabolism or in response to specific stimuli.

The subdivision of biological processes into spatially and/or temporally discrete compartments confers numerous advantages. It permits the segregation of otherwise mutually exclusive processes, creates locally high concentrations of factors necessary for specific events/pathways and allows the coupling of energetically favourable and unfavourable reactions. Thus compartmentalisation allows for a much greater degree of complexity and efficiency than a simple system consisting of a homogenous mixture of its components. Unlike the compartments (organelles) found within the cytosol, those of the nucleus are not bounded by membranes. However, they are generally cytologically visible and can be defined by their constituent sub-units. While many of these compartments remain poorly described, they are the subject of intensive study and their roles in normal and aberrant nuclear function are slowly being understood.

Characteristics

Nuclear compartments can be divided into two categories, ►chromatin and the nuclear bodies that are found in the inter-chromatin space.

Chromatin

Unlike the compacted chromosomes seen in ►metaphase cells, which have a clear higher-order structure and exist distinct from one another, the conformation and position of decondensed chromatin in ►interphase nuclei is much less well defined. With the development of ►fluorescence in-situ hybridisation (FISH) methods, it has been shown that each chromosome occupies its own discrete territory in the nucleus (Fig. 1a,b). Between and even within these chromosome territories (CTs) is a chromatin-free space of varying width, termed the interchromatin domain (ICD). The ICD forms a network of channels extending to the nuclear pores, and contains nuclear bodies (see below) and smaller diffusible nuclear factors. It has been proposed that the interface between the surface of the CTs and the ICD is the major site of nuclear activity.

The subject of CT positioning in the interphase nucleus remains controversial. It has been suggested that smaller or more gene-dense chromosomes tend to be positioned more towards the nuclear interior. However it may be that differences in arrangements exist in different cell types, and indeed different species.

Within each CT the positions of specific genes and genomic regions also suggest some form of functional organisation. It has been shown that late-replicating, gene-poor regions are more likely to be located at the nuclear periphery and around the nucleolus than early-replicating, gene-rich regions (corresponding to R/T ►chromosome bands in metaphase chromosomes), which are found throughout the nuclear interior. It has been proposed therefore that chromosomes may be “polar”. Numerous studies have demonstrated the positioning of active genes on the CT surface, although the observation of transcription foci in the territory interior argues against such a straightforward relationship. This discrepancy may be explained by the fact that CTs have an irregular surface topology, with regions of invagination. In addition CTs may not form impenetrable barriers since diffusible molecules have been shown within them. Genes can also lie at the periphery of their chromosome territory, in extreme cases forming large-scale extensions or “loops”. In addition to the radial position of genes, studies have also shown that certain genes can associate, depending on their transcription status, with specific compartments, such as nucleoli, Cajal bodies, PML bodies, speckles and centromeric heterochromatin clusters (see below).

The studies thus far have largely been performed in fixed cells and so are uninformative about dynamic movements *in vivo*. Recently, live cell studies have shown that while CTs may have limited mobility, genes can also move up to 1–2 micrometres. It remains to be seen, however, if specific, directed movements exist.

Nuclear Bodies

The dynamic complexity of the nucleus, together with the small size and inherent difficulty of biochemical purification of nuclear sub-domains, have rendered the study of nuclear bodies problematic. To date only a few have been extensively characterised, the remainder having only a simple morphological or behavioural description (Table 1 and Fig. 1c,d).

The Nucleolus

This is the most prominent nuclear structure. It is dynamic, its size and organisation depending on cell type and status.

The chief function of the nucleolus is in ribosomal biogenesis. It is assembled around tandemly repeated clusters of **▶ribosomal RNA genes** (rDNA) found on human chromosomes 13, 14, 15, 21 and 22. These clusters are termed the “nucleolar-organising regions” (NORs). Although nucleolar integrity is dependent on ongoing rDNA transcription, only a fraction of rDNA genes are active. It is believed that heterochromatin at the NORs is important in nucleolar assembly, possibly *via* clustering of silent regions adjacent to active rDNA genes.

The nucleolus consists of three distinct morphological regions through which rRNA biogenesis occurs in a

Nuclear Compartments. Table 1 Nuclear bodies

Body	Appearance/behaviour	Postulated function(s)
Nucleolus	Large	rRNA biogenesis, RNA processing, nuclear regulation
Cajal body/ GEM	Small, multiple, dynamic	RNP maturation
PML body	Small, multiple, generally static	Multiple postulated functions
Splicing factor compartment	Multiple “speckles” of variable size, close to active genes	Splicing factor “depots”
OPT domain	Small, associate with chromosomes 6 and 7	Transcription of specific genes
Perinucleolar compartment	Touching the nucleolus	Transcription/RNA processing
Cleavage body	Small foci	RNA processing
GATA-1 body	Small foci	Transcription
PcG domain	Pericentromeric foci	Gene silencing

For further details see (6) and references therein.

vectorial manner: the “fibrillar centre” (*fc*), the surrounding “dense fibrillar component” (*dfc*), and the external “granular component” (*gc*). The *fc* consists of rDNA, active genes having a more peripheral localisation that extends into the *dfc*. rDNA primary transcripts transiently accumulate in the *dfc* and undergo a complex series of ►[rRNA processing events](#) as they radiate out into the *gc*. The final rRNA processing occurs here, following which the pre-ribosomal particles are translocated to the cytoplasm. In addition to rRNA synthesis and processing, the nucleolus is believed to be the site of assembly and action of other ►[RNP complexes](#), many of these having a role in protein synthesis. The nucleolus may also have a role in the processing of small transcripts generated by RNA polymerase III. Finally, aside from its role in RNA processing, there is increasing evidence that the nucleolus is important as a site of sequestration of regulatory complexes away from their target molecules. In particular it seems that confinement within and release from the nucleolus of cell-cycle and mitogenic growth factors has a critical role in the regulation of cell division and proliferation.

Cajal Bodies

Also known as “coiled bodies”, Cajal bodies (CBs) were initially described as “nucleolar accessory bodies”. A typical nucleus has 1–5 CBs although this number varies between cell types and within the cell cycle. They are spherical in shape, having a diameter of 0.1–1 µm, and are highly dynamic, most likely moving by simple diffusion.

By electron microscopy CBs appear as a tangle of coiled fibrillar strands. They are specifically detected by antibodies to the protein p80-coilin, although only a minor fraction of nuclear coilin is present in CBs at any given time. CBs have a large number of other components, being enriched in spliceosomal snRNPs, several nucleolar proteins and snoRNPs, RNA polymerase II transcription factors and a novel class of CB-specific small RNAs (scaRNAs).

The function of CBs remains unclear. They are frequently found associated with chromosomal loci encoding histones and several sn- and sno-RNAs. This association is apparently dependent on RNA polymerase, although CBs themselves are unlikely to be sites of transcription or splicing. Instead there is increasing evidence that they are functionally connected to the nucleolus and have a role in co-ordinating the assembly and maturation of RNPs.

PML Bodies

The existence of this class of nuclear body was first shown in 1991, when it was found to be targeted by autoantibodies against the Sp100 protein in patients with primary biliary cirrhosis. Its main clinical interest, however, came in the mid-1990s when one of its main constituents was found to be the promyelocytic leukaemia (PML) protein (see Clinical Relevance, below). In normal cells there are usually 5–30 PML bodies, depending on cell type and the stage in the cell-cycle. As with Cajal bodies, they are spherical, having a diameter of 0.25–1 µm. However, unlike CBs, they are relatively immobile.

Nuclear Compartments. Table 2 Components of PML bodies

Constitutive proteins	Conditionally present components
PML	HP1
Sp100	CBP
Daxx	Rb
BLM	GAPDH
SUMO	P53
NDP55, NDP65	HMG1/2
	Mutant ataxin
	BRCA1
	PA28
	RAD51
	RAD52
	ICPO (HSV-1)
	E4 ORF33 (Adenovirus-5)
	E1A (Adenovirus-5)

For a more comprehensive list see (6) and (7) and references therein.

The PML protein is the main structural component of PML bodies, being essential for the recruitment of other proteins. The proteins that have been detected in PML bodies form a diverse and (at present) expanding list (Table 2). These proteins have implicated PML bodies in gene transcription, repair, cell cycle control and apoptosis. In addition, PML bodies have been found to associate physically with indicators of transcription (including nascent RNA and transcription factors), sites of DNA repair and viral replication. It has also been proposed that PML bodies may simply be depot sites in which disparate proteins are sequestered. For example, the tumour suppressor protein, BRCA1, colocalizes with these bodies only when over-expressed. To elucidate the function(s) of these bodies, mutant PML models have been analysed. PML $-/-$ mouse embryonic fibroblasts (MEFs), were found to grow faster than PML $+/+$ cells. Conversely, HeLa cells over-expressing PML showed an accumulation of cells in G1 phase and a delay into S phase. PML $-/-$ knockout mice were also more likely to succumb to infections, as well as developing tumours when exposed to carcinogens or ionising radiation.

Other Nuclear Bodies

Less well-characterised nuclear structures include:

- The splicing factor compartment (SFC), found as numerous “speckles” enriched in pre-mRNA splicing factors that are not directly associated with sites of transcription. The SFC consists of perichromatin fibrils, thought to represent nascent transcripts, and interchromatin granule clusters. It is believed that the SFC represents sites of deposition and assembly of spliceosomal factors.
- GEMS (Gemini of coiled bodies) are closely related to/overlap with CBs. They contain the SMN (survival of motor neurones) protein involved in snRNP assembly.
- Oct1, PTF transcription (OPT) domains are found as one or few bodies with a diameter of up to 1.5 μ m that are only present during the G1 phase of the cell cycle. They are transcriptionally active, their preferential association with chromosomes 6 and 7 suggesting that they may have a role in transcription of specific genes from these chromosomes
- The perinucleolar compartment (PNC), an electron-dense region has multiple strands that directly contact the nucleolus. It contains several RNA polymerase III snRNAs and a high concentration of certain RNA binding proteins, suggesting a possible role in transcription and RNA processing.

Other Nuclear Compartments

Aside from the structures outlined above there are other nuclear regions that may also be considered as functional compartments. There is evidence that DNA replication and mRNA production may each occur in a large number of discrete immobilised foci through which the template DNA is postulated to pass. These are termed replication and transcription factories respectively. Structural nuclear elements may also play an important role in gene regulation. For example in some cell types chromatin recruitment to domains such as the nuclear periphery and centromeric clusters is an important mechanism of gene silencing. The nuclear lamina, lining the inner surface of the nuclear envelope serves several roles. It determines the size and shape of the nucleus, supports the nuclear pore complexes (NPCs) necessary for transport of macromolecules between the nucleus and cytoplasm and may have a role in tethering chromosome territories.

Clinical Relevance

Although the functions of many of the above bodies have not yet been defined, there is evidence that changes in the distribution and assembly of these structures, and in the interactions between them, are relevant in a variety of human diseases.

Of the non-chromatin bodies, PML bodies must arguably have the most diverse clinical links. Their role in an autoimmune disease has been mentioned above. Their link to malignant disease is well

established in acute promyelocytic ▶**leukemia** (APL), in which PML is found as a chimeric protein, fused with the retinoic acid receptor- α (RAR α). APL patients have an abnormal PML body distribution. Treatment with all-transretinoic acid causes PML body reformation, induces differentiation of the leukaemic cells and results in clinical remission. PML bodies also appear to be involved in cellular immunity against infections, although this function remains controversial. While interferon causes an increase in their number, suggesting an antiviral action, certain viruses such as cytomegalovirus (CMV) and herpes simplex virus type 1 (HSV-1) disrupt PML bodies. Finally, in spinocerebellar ataxia type I (SCA I), a neurodegenerative disease, the gene encoding ataxin-1 (a protein normally found in PML bodies) becomes mutated and disrupts the normal distribution of PML bodies. Changes in Cajal body distribution and/or function are found in a number of diseases, which may be linked by a failure to process RNAs correctly. Examples include the association of CBs with the neuronal nuclear inclusions characteristic of poly-glutamate expansion diseases such as Huntington's and the loss of functional SMN protein (involved in RNP assembly) from GEMs/CBs in patients with the severe neurodegenerative disorder spinal muscular atrophy (SMA).

As mentioned above, the nucleolus is thought to play a role in the regulation of cell proliferation. In particular, nucleolar compartmentalisation of the oncoprotein MDM2 and its antagonist, the tumour-suppressor protein ARF, are believed to be important in the control of cell growth arrest *via* MDM2-mediated degradation of the tumour suppressor p53. In addition, the presence of a perinucleolar compartment closely correlates with oncogenic transformation. Clues as to other nucleolar roles may come from the finding that the WRN protein, which normally accumulates in the nucleolus, is lost in patients with the accelerated ageing disease Werner syndrome. WRN is a DNA helicase and is postulated to have a role in the maintenance of nucleolar integrity.

Chromatin positioning too has been implicated in the pathogenesis of certain cancers. The specificity with which some malignancies have chromosomal translocations has prompted investigators to examine translocation breakpoints in interphase cells. The results suggest that genes are often found in proximity to their translocation partners. Examples include the *ABL* and *BCR* genes on chromosomes 9 and 22 (translocated in chronic myeloid leukaemia) and *MYC* and Ig-heavy and light chain genes on chromosomes 8 and 2, 14 or 22 (translocated in Burkitt's lymphoma and B-cell leukaemia).

In conclusion, the study of individual nuclear compartments has revealed much about the distinct processes occurring within the nucleus. The greater challenge

now, however, lies in understanding the regulatory networks that link these functional compartments so that we may derive an integrated model for how the nucleus functions as a whole.

Nuclear Envelope

N

Definition

Nuclear envelope defines a double bilayer membrane that encircles and encloses the genome, and regulates the movement of molecules into and out of the nucleus through special nuclear pores.

- ▶ Centromeres
- ▶ RNA Export

Nuclear Export Factor 1

- ▶ NXF1

Nuclear Export Signal

Definition

Nuclear export signal (NES) refers to a short hydrophobic stretch of amino acids that is rich in leucine

residues, and which is present on export adapter proteins that interact with ►[karyopherin/exportin receptors](#). For example, LR-NESs' are enriched in the amino acid leucine and recognized by the ►[exportin Crm1](#).

Nuclear Hormone Receptors: Regulators of Gene Transcription and Cellular Signaling

ANDREW C.B. CATO, LIUBOV SHATKINA
Forschungszentrum Karlsruhe, Institute of Toxicology and Genetics, Karlsruhe, Germany
andrew.cato@itg.fzk.de

Definition

Nuclear hormone receptors form a large class of ►[ligand](#)-activated proteins. In the activated state, they bind specifically to distinct DNA sequences to regulate the transcription of a number of genes that control cellular proliferation, differentiation, body homeostasis and reproduction. The ligands that activate the nuclear receptors are ►[steroids](#), ►[retinoic acids](#) (all-trans and 9-cis isoforms), vitamin D3, ►[ecdysone](#), oxysterols, ►[bile acids](#), thyroid hormones, fatty acids, leukotrienes and ►[prostaglandins](#). In addition, a number of receptors have been identified for which no ligands exist and these are referred to as orphan receptors.

Characteristics

The nuclear receptors share a common structural organization. They possess a centrally conserved DNA binding domain (DBD, also termed C-domain) with a short motif termed the P-box, which is responsible for DNA binding. In addition they contain an N-terminal domain (A/B domain) variable in length from 50 to 500 amino acids with a ►[transactivation function](#) (AF-1) and a carboxy-terminus moderately conserved ligand-binding domain (E-domain) (Fig. 1). Additionally, the E-domain contains a further transactivation domain (AF-2), a strong dimerisation interface, a nuclear localization sequence (NLS) and often a repression function. Between the C and E domains, is a non-conserved region (D-domain) that contains a ►[bipartite NLS](#). Some nuclear receptors contain a further domain at the C-terminus of the E-domain

(F-domain), whose structure and function are not yet known (Fig. 1).

Nuclear receptors are organized in a ►[phylogeny](#)-based nomenclature (Nuclear Receptor Nomenclature Committee 1999) of the NR_{xyz} where X is the subfamily, Y is the group and Z the genes of receptors that possess both DNA binding and ligand binding domains (1) (Table 1). Some of the nuclear receptor genes code for different isoforms originating from alternative splicing of the primary transcript or may originate from different genes at distinct chromosomal loci (Fig. 1).

Molecular Interactions Response Elements

Nuclear receptors regulate transcription of target genes by binding DNA as homo- or hetero-dimers to hormone ►[response elements](#), which may be formed by a repetition of the consensus sequence motif PuGGTCA. Two such core sequences separated by three nucleotides arranged as ►[palindromes](#) are recognized by most steroid receptors as homodimers. Androgen receptor (AR), a member of the steroid receptor family, can also bind as homodimer to direct repeats of this motif and retinoic acid receptors (RARs), thyroid receptors (TRs) and some orphan receptors heterodimerize with retinoid X receptors (RXRs) and bind to direct repeats of the core motif. The spacing between the two halves determines the type of heterodimer that will be formed. For example direct repeats separated by 5 nucleotides (DR5) will be recognized by RXR-RAR heterodimer whereas a DR4 will be bound by RXR-TR. Some orphan receptors such as steroidogenic factor 1 (SF1), RAR-related orphan receptor (ROR), Reverse-erb A (Rev-erb) or Nur77 can bind DNA as monomers through a single core sequence. In this case, an A/T-rich region 5' to the core element controls the binding specificity. The X-ray structure of sequence with which the nuclear receptor binds DNA has been solved. The DBD contains a ►[zinc finger](#) motif with two subdomains each containing a zinc ion coordinated by four cysteine residues, followed by an alpha helix of the general sequence -C-X₂-C-X₁₃-C-X₂-C- and -C-X₅-C-X₉-C-X₂-C-. The four cysteines of each finger chelate a Zn²⁺ ion.

Response elements for nuclear receptors for the activation of gene expression (also known as transactivation) and elements for negative regulation of gene expression (transrepression) have been described. There are at least three different types of response elements for transactivation using the glucocorticoid receptor as a classic example (although other receptors can also function in the same way). First, there are simple response elements that are usually of imperfect palindromic nature where the nuclear receptor is the sole sequence-specific DNA binding protein. Secondly,

Nuclear Hormone Receptors: Regulators of Gene Transcription and Cellular Signaling. Figure 1 Schematic diagram of the domain structure of several members in the superfamily of nuclear receptors showing the amino acid identity of the individual domains with reference to the human glucocorticoid receptor. Indicated are the molecular mass of the receptors, their chromosomal localization and the ligands they bind to. For simplification only human nuclear receptors are presented. In the case of CAR, ligand binding has only been described for the mouse receptor.

there are composite response elements that specify binding sites for the nuclear receptor and one or two non-receptor proteins. Thirdly, there are tethering response elements where the receptor is recruited through protein-protein interaction to another DNA-bound factor (2). In negative regulation of transcription, the receptors can bind negative response elements described for the glucocorticoid receptor as the negative glucocorticoid response element. The interaction of the receptor with this element leads to the

repression of gene expression possibly due to the replacement of or interference with binding of essential transcription factors required for the activity of the responsive gene. The most important mechanism for transrepression is through tethering response elements. In this case the activated receptor is tethered to already bound transcription factors, mostly the activator protein-1 (▶AP-1) or nuclear factor-κB (▶NF-κB) to inhibit their activity. As these transcription factors control the expression of a number of pro-inflammatory

** - present in the mouse only

genes, the negative regulation of their activity has become a paradigm for the anti-inflammatory action of a number of nuclear receptors, including glucocorticoid receptors. Transrepression by nuclear receptor (also described as cross-talk of nuclear receptors and AP-1 or NF- κ B) has been described not only for the glucocorticoid receptor but also for a number of family members including the estrogen, thyroid, vitamin D3 and retinoid receptors. Transrepression of AP-1 by nuclear receptors has also been described in *Drosophila*, indicating that the mechanism involved in this action is conserved in the fly as well.

The Ligand-Binding Domain

The ligand-binding domain (LBD) of nuclear receptors is structured as a three layered α -helical anti-parallel sandwich of 12 helices forming a ►hydrophobic

pocket. In the presence of ligand, contacts are established between the ligand and amino acid residues in the LBD, producing a conformational change that closes the lid (helix 12) of the hydrophobic pocket (3). This conformational change is important for transcriptional activation since it allows the AF2 that is situated on helix 12 to interact with coregulatory proteins (►coactivators). The recruitment of coactivators to helix 12 is usually mediated by a conserved short LXXLL helical motif present in the majority of coactivators. Intramolecular protein-protein contact of the nuclear receptors is also essential for transactivation. This is established between the AF1 at the N-terminus and the AF2 at the C-terminus and may be necessary as a platform for the recruitment of coactivators to the AF1 or for the stabilization of helix 12. Mutational studies have identified key features at

the N-terminus for intramolecular contact. In the androgen receptor a core sequence FXXLF binds the AF2 while another motif WXXLF binds to the LBD outside AF2 (where F, W and L are the single letter code for the amino acids phenylalanine, tryptophan and leucine, respectively, and X stands for any amino acid). In addition to coactivators, **corepressors** such as nuclear receptor corepressor (NCoR) and silencing mediator of retinoid and thyroid receptors (SMRT) interact with the nuclear receptors in the unliganded state. Their interaction is dependent on a conserved motif referred to as the CoRNR box or as LXXI/HXXXI/L.

Regulatory Mechanisms

Regulation of Gene Expression

In the absence of ligand, most nuclear receptors are present in the nucleus or cytoplasm or in complex with **molecular chaperones and cochaperones**, **immunophilins** or **cyclophilins**. Upon ligand binding, the receptor dissociates from the non-receptor proteins and acquires the ability to bind to its response elements. Those receptors that reside in the cytoplasm migrate to the nucleus to bind DNA. One of the primary changes that take place after ligand binding is **phosphorylation** of the receptor. Most phosphorylation occurs on serine and threonine residues but the estrogen receptor (ER) is additionally phosphorylated on tyrosine and this is used to bind to Src-homology domain 2 (SH2) of the oncoprotein c-Src in rapid non-genomic signaling by this receptor. Those receptors that are bound to molecular chaperones have basal phosphorylation that is increased upon ligand binding. Phosphorylation is quite essential for receptor action as it has been implicated in DNA binding, transcriptional activation and stability of the receptors.

Binding of ligand to the LBD of nuclear receptor also leads to the recruitment of coactivators. Among the most well characterized coactivators are the p160 steroid receptor coactivators (SRC), that serve as a platform for the recruitment of histone-modifying enzymes including CREB binding protein (CBP/p300) and methyltransferases that acetylate or methylate histones. These modifications are responsible for the decondensation of histones, **chromatin remodeling**, assembly of general transcription factors and transcription of target genes. The chromatin remodeling is carried out by complexes such as mating type switch/sucrose nonfermenting complex (SWI/SNF), polybromo- and brahma-related gene 1-associated factors (PBAF) or Mediator/thyroid hormone receptor-associated protein (TRAP)/Vitamin D receptor-interacting proteins (DRIP) (4). In the case of thyroid receptors, **corepressors** with histone deacetylase activity repress transcription in the absence of ligand. Binding of the ligand results in the dissociation of the

corepressors and recruitment of coactivators leading to the activation of **gene expression**. A number of the corepressor proteins such as NCoR, SMRT, receptor-interacting protein 140 (RIP140) and ligand-dependent nuclear receptor corepressor (LCoR) may be recruited to the surface of some nuclear receptors depending on the ligand bound to the LBD. They too function as platforms to recruit enzymes such as histone deacetylases or redox-sensing cofactors including C-terminal binding protein (CtBP) to repress transcription (5). A different type of regulation is demonstrated by the orphan receptor, constitutive androstane receptor β (CAR β) for which the steroid like compound (androstanol) represses transcription upon binding. In the unliganded conformation, CAR β interacts with coactivators such as SRC-1 whereas androstanol binding reverses this interaction.

Although ligands that bind some orphan receptors have been identified, not all the orphan receptors may bind ligand. An example of such a receptor is Nurr1 (NR4A2, Nur-related protein 1) that possesses a LBD with constitutive and cell-type specific activity. The crystal structure of its LBD shows that it adopts a canonical protein fold resembling that of the agonist-bound transcriptionally active LBD of nuclear receptors. Nurr1 LBD contains no cavity for ligand binding. The NGF1-B subfamily (NR4A1) and Nor1 (NR4A3, neuron-derived orphan receptor 1) as well as the Drosophila DHR 38 (NR4A4) have a similar LBD and are therefore predicted to be ligand-independent transcription factors.

Ligand Independent Activation of Nuclear Receptors

In general nuclear receptors are conventional transcription factors regulated by **allostery**. A signal that can trigger a conformational change in the receptor similar to that produced by the ligand should be able to activate the receptor (Table 2). Indeed epidermal growth factor-mediated phosphorylation at serine 118 of ER α leads to transcriptional activation of this receptor in the absence of ligand (6). Similarly progesterone receptor can be activated in a ligand independent manner by adrenocorticotrophic hormone (ACTH). Examples of other nuclear receptors whose activity can be controlled by phosphorylation include peroxisome proliferator activated receptor PPAR γ and orphan receptor NGFI-B where phosphorylation reduces their DNA binding activity. Another way of regulating nuclear receptor action in the absence of ligand is the interaction of the nuclear receptor with non-receptor proteins through its LBD. This converts the nuclear receptor into an appropriate conformation for its interaction with the transcriptional machinery in the absence of ligand. An example of this type of regulation is the activation of the orphan receptor SF-1 through an interaction with the bicoid-related homeobox transcription factor

Nuclear Hormone Receptors: Regulators of Gene Transcription and Cellular Signaling. Table 2 Ligand-independent regulation of the activity of selected members of nuclear receptors and the signaling pathways involved in this regulation

Receptor	Regulation	Activator/Repressor	Signaling pathway
ER (NR3A)	Activation	Epidermal growth factor	Phosphorylation of Ser118 (Mitogen-activated protein kinase pathway)
		Substitution of Tyr537 by Ala or Ser	
		Human X box-binding protein 1	Protein-protein interaction leads to alteration of LBD folding
		Cyclin D1	
		Cadmium	Metalloestrogen-Cd ²⁺ binds to the LBD
PR _β (NR3C3)	Activation	Dopamine	
		8-bromo cAMP	
		Gonadotropin-releasing hormone antagonist	
AR (NR3C4)	Activation	Phorbol ester	Growth factors: Phosphorylation of Ser515 (Mitogen-activated protein kinase pathway)
		Epidermal growth factor	
		Insulin-like growth factor-1	Akt phosphorylation of Ser213 and Ser791 (Phosphatidylinositol-3'-kinase pathway)
		Interleukin 6	JAK (Janus activated kinase) signaling through STAT3 (signal transducer and activator of transcription 3)
		Sphingosine-1-phosphate	Rho (ras homolog gene) family of proteins signaling pathway; FHL2 (four and a half Lim-domain protein 2)
		Protein Kinase A	
Nur77 (NR4A3)	Repression	Adrenocorticotrophic hormone (ACTH)	Alters phosphorylation at Ser354 and DNA binding activity
SF-1 (NR5A1)	Activation	Pituitary homeobox 1 (Ptx1)	Protein-protein interaction leading to alteration of LBD folding
		Phosphorylation	Phosphorylation of Ser203 (Mitogen-activated protein kinase pathway)

pituitary homeobox 1 (Ptx1). Similarly, cyclin D1 binds to the ER α LBD and activates this receptor in the absence of estrogen (Table 2).

Rapid Action of Nuclear Receptor

Nuclear receptors activate a number of signaling molecules within seconds and minutes. These effects are too rapid to arise from the genomic effects of the receptors that are usually manifested within minutes to hours. This rapid action of nuclear receptors is insensitive to inhibitors of transcription and translation and ranges from activation of **▶mitogen-activated protein kinases** (MAPKs) and phosphatidylinositol 3-kinase (**▶PI3K**) to activation of protein kinase C (Table 3) (7). The mechanism of activation of these pathways is not fully understood but it involves the interaction of the

receptors with Src-homology region 2 or 3 domains on a number of signaling molecules. Following these interactions, the kinase domains of the signaling molecules are activated leading to the transmission of signals that turn on a cascade of kinases finally resulting in activation of MAPK and PI3K and an increase in intracellular calcium. The proto-oncogene product c-Src has been identified as a key protein in this rapid action of nuclear receptors since most of the receptors analyzed so far interact with it and it is thought that binding of the receptor to this protein is essential for triggering the rapid action of the nuclear receptors. The physiological significance of the rapid action of nuclear receptors is diverse, ranging from bone protection, proliferation of mammary epithelial and prostate cancer cells and vasodilation to neuroprotection and oocyte maturation.

Nuclear Import and Export. Table 3 Different signaling pathways activated by the rapid action of steroid receptors

Rapid action	Receptor(s)
Ca ²⁺ mobilization	ER α
Activation of ERK1 and ERK2	ER α , ER β , PR, AR, GR
Activation of G proteins	ER α , ER β
Inositol phosphate production	ER α , ER β
Stimulation of adenylyl cyclase	ER α , ER β
Increase in intracellular cAMP level	MR
Activation of JNK	ER β , GR
Inhibition of JNK	ER α , GR
Activation of p38	GR
Activation of PI3K	ER α , PR, AR
Inhibition of PI3K	GR
Activation of PKC	GR, MR
Activation of Akt	ER α , AR
Inhibition of Akt	GR
Induction of Ca ²⁺ influx	PR, MR
Inhibition of EGF receptor signaling	GR
Activation of IGF-1	ER α
Activation of Na ⁺ -H ⁺ antiporter	MR
Activation of eNOS	ER α
Inhibition of Na ⁺ ,K ⁺ -ATPase channel	MR
Activation of Na ⁺ /K ⁺ /2Cl ⁻ cotransporter	MR

Nuclear Import and Export

ANJA PANNEK, KATRIN STADE

Berlin, Germany

kstade@mdc-berlin.de

Definition

In eukaryotic cells, DNA replication and RNA transcription occur in the cell nucleus, whereas protein synthesis occurs in the cytoplasm. This spatial separation of essential cellular processes can only be overcome by allowing macromolecules to traverse the nuclear membrane in both directions. Proteins as well as several classes of RNAs, which in the following will be collectively referred to as cargo, need to be imported into and exported from the nucleus, respectively. The most prominent cellular cargoes for nuclear import are transcription factors, ribosomal proteins and RNA binding proteins. In addition, in virally infected cells, whole viral genomes need to be imported into the nucleus. Cellular export cargo largely consists of proteins, messenger RNAs (mRNAs), transfer RNAs (tRNAs), ribosomal RNAs (rRNAs) and other small nuclear RNAs (snRNAs). All classes of RNAs are found in complexes with specific proteins and hence leave the nucleus as ribonucleoprotein particles (RNPs).

Characteristics

In general, nuclear transport relies on signals, receptors and energy (1). Viewed at the molecular level, nucleocytoplasmic trafficking can be described as follows. First, individual transport cargo is recognized by a specific transport receptor by virtue of either a ►nuclear localization signal (NLS) or a ►nuclear export signal (NES), respectively. Then, cargo-receptor complexes traverse the nuclear membrane through large proteinaceous structures called ►nuclear pore complexes (NPCs) that mediate all traffic between the nucleus and cytoplasm. Facilitated diffusion has been proposed to be responsible for this translocation step.

Finally, the release of individual transport cargo into the recipient compartment is achieved through interaction of the transport receptor with the guanine-nucleotide binding protein ►**Ran**. As a GTPase, Ran constantly switches between a GTP and a GDP bound form, although at a low intrinsic rate. *In vivo*, this reaction is enzymatically catalyzed by so-called effector proteins. The cytoplasmic localization of ►**RanGAP**, a protein that induces hydrolysis of RanGTP to RanGDP and the nuclear localization of ►**RanGEF**, which exchanges GDP for GTP on Ran, result in a low cytoplasmic concentration of RanGTP *versus* a high concentration of RanGTP in the nucleus. It is in fact this asymmetric distribution of RanGTP, also known as the Ran gradient, which defines compartment identity and confers directionality on transport processes by affecting the binding status of a transport receptor and its cargo.

Molecular Interactions Nuclear Import Pathways

Proteins destined for the nucleus contain a short amino acid motif generally termed a nuclear localization signal (NLS). Since NLSs can vary in amino acid composition and size, they are grouped into distinct classes. A particular NLS is recognized by a specific nuclear transport receptor or ►**karyopherin**. Karyopherins are a family of proteins of which the founding members were ►**importins** α and β . In Fig. 1, nuclear import is exemplified by the importin α/β route. In the cytoplasm, importin α binds to a cognate NLS on the cargo protein, associates with importin β and subsequently this trimeric complex docks at the nuclear pore complex. After NPC targeting is achieved, the complex travels through the nuclear pore, a process that is still not fully understood in its mechanistic details. Following translocation, the import complex dissociates in the

Nuclear Import and Export. Figure 1 Nuclear import. In the cytoplasm, the NLS-containing import cargo binds to the import receptor importin α which then associates with importin β . This trimeric complex translocates through the NPC into the cell nucleus, where importin β binds to RanGTP. This induces the release of NLS-cargo and importin α which binds to its own export receptor CAS in the presence of RanGTP. The importin subunits then travel back to the cytoplasm individually. On arrival in the cytoplasm, the two molecules of RanGTP utilized for importin export are converted to RanGDP by the RanGAP protein. This finally results in the release of the importins which are now free to engage in another round of import.

nucleoplasm releasing NLS-cargo and the two importin subunits. Release of cargo is achieved through binding of importin β to RanGTP whereas importin α is bound by its own export receptor, CAS, also in the presence of RanGTP. Both importins are then exported individually. Since two molecules of RanGTP are lost from the nucleus during importin subunit export, nuclear Ran needs to be constantly replenished. This goal is achieved by a specific Ran import pathway (1). Although the importin α/β route probably represents the best-studied example for nuclear protein import, additional import pathways exist. For example, nuclear import of the hnRNA binding protein A1 is mediated by an importin β -like transport receptor called transportin. In this case, a transportin-specific NLS is recognized on the A1 protein which is termed the M9 signal and which is different from the NLS recognized by importin α . Nuclear import of ribosomal proteins is mediated by several importins such as transportin, importin β , importin 5 and importin 7, which probably reflects the fact that such abundant cargo must enter the nucleus *via* parallel pathways to be effectively imported under conditions when ribosome production becomes a major cellular task. Again, the NLS signals used in this case differ from the so-called classical NLS recognized by importin α . Apart from nuclear protein import, nucleic acids are imported as well. For example, cellular uridine-rich small nuclear RNAs (UsnRNAs) are transcribed in the nucleoplasm but need to traverse the cytoplasm for maturation before returning to the nucleus. In addition, in virally infected cells, the viral genome needs to traverse the nuclear membrane to integrate into the host DNA for replication. However, in these cases it is not yet clear whether proteins with NLSs mediate nuclear import of these nucleic acids or whether alternative import pathways exist (2).

Nuclear Export Pathways

Nuclear export is fuelled by individual proteins as well as several classes of RNAs, which during their biogenesis in the nucleus are packaged into compact RNP particles by a diverse set of RNA binding proteins. As is the case for nuclear import, a specific signal on the cargo molecule is recognized by a nuclear export receptor or **▶exportin**, which in this complex travels through the NPC and releases its substrate into the cytoplasm (Fig. 2). However, unlike import complexes, export complexes can only be formed in the presence of RanGTP, i.e. in the nucleus and will dissociate in the absence of RanGTP, i.e. in the cytoplasm. Nuclear export signals of the so-called leucine-rich type (LR-NESs) have been identified on proteins such as protein kinase inhibitor (PKI) and are recognized by a karyopherin known as Crm1. Crm1 is also responsible for the nuclear export of other

important cellular regulators such as p53, I κ B α and cyclins. In addition, it mediates export of small nuclear RNAs, ribosomal RNAs and unprocessed viral messenger RNAs such as the precursor-mRNA of HIV. However in this case, additional adaptor proteins are needed since Crm1 does not bind directly to RNA. In addition to Crm1, several other exportins have been identified. For example, CAS is the exportin for the importin α subunit of the α/β import receptor (Fig. 1). It is noteworthy, that not all nuclear export is mediated by karyopherin family members. During their biogenesis in the nucleus, cellular mRNA transcripts become tightly packaged with specific sets of proteins. However, only after **▶mRNA processing** events such as 5'-capping, splicing and polyadenylation are complete, is an mRNA particle considered export competent and transported to the cytoplasm. Although some of the mRNA binding proteins have been proposed to contain NESs, no single karyopherin of the importin- β type has been shown to be responsible for bulk cellular mRNA export. Rather, an evolutionarily highly conserved complex of two proteins, TAP and p15, has been shown to mediate export of most cellular mRNAs. Since TAP/p15 can directly interact with the NPC, no additional adaptor protein is needed for nuclear export of cellular mRNAs.

Regulatory Mechanisms

Nucleocytoplasmic trafficking is a major cellular activity, in terms of both number of individual particles involved and energy consumption. Despite a high degree of complexity, nuclear transport pathways offer an exquisite opportunity for regulating gene expression and cell-cycle progression at various levels (3). There are at least three ways in which nuclear transport can be regulated. First, the cargo itself can be modified in a way that affects its ability to bind to a karyopherin. For example, masking and unmasking of nuclear import signals by phosphorylation has been shown to control transcription factors such as Pho4 and NF-AT. An interesting example of masking of a nuclear export signal was demonstrated recently for the transcription factor Yap1 in budding yeast. Yap1 is a shuttling protein, which constantly travels between the nucleus and the cytoplasm. However under steady state conditions, Yap1 is mainly found in the cytoplasm due to a LR-NES recognized by yeast Crm1. This specialized NES also contains cysteine residues, which are proposed to sense the redox state of the cell. In a situation of oxidative stress, the cysteines in the NES region are oxidized and Crm1 can no longer recognize the NES on nuclear Yap1. This lack of export in the presence of functional import finally leads to nuclear accumulation of Yap1 and results in increased transcription of anti-oxidative stress genes.

Nuclear Export

Cytoplasm

(low RanGTP)

Nucleus

(high RanGTP)

Nuclear Import and Export. Figure 2 Nuclear export. In the nucleus, an NES-containing export substrate binds to the export receptor Crm1 in the presence of RanGTP. This trimeric complex travels through the NPC into the cytoplasm, where RanGTP is converted to RanGDP by RanGAP. This induces the release of export cargo from Crm1. Crm1 then travels back to the nucleus to engage in another round of export. Since during export RanGTP is lost from the nucleus, nuclear Ran needs to be replenished. This is achieved by reimporting RanGDP into the nucleus where it is converted to RanGTP by RanGEF.

As a second possibility, the activity of the soluble transport machinery can be regulated. Some karyopherins are expressed only in certain tissues or cell types or at specific stages of the cell-cycle. For example, in the fruit fly *Drosophila*, the importin α subunit enters the nucleus at the onset of the mitotic phase of the cell-cycle. Finally, in a third scenario, the individual proteins of the NPC and their unique functions in protein import and RNA export may be utilized to control nuclear transport routes (4). Since all import and export pathways converge at the nuclear pore complex, the NPC can be considered as the central gate for all traffic across the nuclear membrane. Nuclear pore proteins have been shown to interact with karyopherins during translocation although the precise mode of their interaction is not yet fully understood. Very recently, it was shown that the diameter of the NPC could vary during the cell-cycle which allows regulated access of cargo-receptor complexes to the nuclear interior.

Nuclear Transport and Human Disease

It is clear from the study of nuclear transport pathways that perturbations at any of the regulatory levels involved could potentially lead to abnormal cellular function and ultimately cell death (5). As an example, it is well established that cytoplasmic mislocalization of the transcription factor p53 results in a failure to activate its nuclear target genes, which has a severe impact on a cell's ability to respond to stress situations. In the same line of thought, it can be easily imagined that over- or under-representation of any of the karyopherins involved in **p53** import or export could potentially have the same cellular effects. In addition, any mutations in the general transport machinery such as NPC proteins or the Ran GTPase system could severely affect multiple nuclear import and export pathways. Indeed, several proteins of the nuclear pore complex have been found to be mutated in different types of leukemia (5). Hopefully, in the near future the ongoing study of nuclear transport pathways will help

to shed some light on the development of human cancer.

Nuclear Poly(A) Binding Protein 1

Definition

Nuclear poly(A) binding protein 1 (PABPN1) designates a protein that binds to the growing poly(A) tails of mRNA precursors during nuclear processing. The protein is required for efficient poly(A) synthesis, and for limiting the length of the poly(A) tail in a mammalian cell to approximately 250 nucleotides. At some point during mRNA export, the protein is exchanged for the cytoplasmic poly(A) binding protein.

Definition

Nuclear pore complexes (NPCs) are large supramolecular assemblies that perforate the double-membraned

nuclear envelope (NE). Being composed of ~ 30 different proteins, termed **nucleoporins** (Nups), NPCs have an estimated molecular mass of ~ 125 MD in vertebrates and ~ 60 MD in the yeast *S. cerevisiae*. NPCs are the exclusive gateways for all traffic between the cell nucleus and the cytoplasm. Traffic through the NPC includes diffusion of ions and small molecules, as well as signal-dependent, receptor-mediated transport of proteins, RNAs and ribonucleotide protein (RNP) particles.

Characteristics

Electron microscopy studies, including 3D reconstructions, both in yeast and vertebrates, have led to a consensus model of the overall 3D NPC architecture (1, 2, 3, 4). Accordingly, the vertebrate NPC has a tripartite architecture with the central framework being embedded in the NE and the cytoplasmic filaments and the nuclear basket emanating towards the cytoplasm and the nucleus, respectively (Fig. 1). In the plane of the NE, the vertebrate NPC has a diameter of ~ 100 nm. The eight-fold symmetrical central framework is composed of eight spokes, each consisting of two approximately identical halves that are placed back to back in the midplane of the NE. The central framework therefore appears also roughly two-fold symmetrical in

the plane of the NE. The cytoplasmic ring moiety of the central framework is decorated by eight, ~ 50 nm-long kinky filaments, whereas the nuclear ring moiety is topped by the nuclear basket, an assembly of eight ~ 50 – 100 nm-long filaments that join into a distal ring (Fig. 1).

The central framework embraces the central pore, which has a length of ~ 90 nm and is narrowest in the midplane of the NE with a diameter of 45–50 nm widening towards the cytoplasmic and nuclear peripheries to ~ 70 nm (1, 2, 3, 4). It represents the sole gateway for all traffic through the NPC, allowing particles up to ~ 40 nm in diameter to traverse. In 2D projection images the central pore often appears obstructed by a particle, termed the central plug, which is highly variable both in size and shape. Based on 2D projection images and earlier 3D reconstructions (1, 2, 3), the central plug was thought to be a stationary component of the NPC. However, a more recent 3D reconstruction of native NPCs as well as nucleocytoplasmic transport studies using **atomic force microscopy** (AFM) suggest that the central plug most probably represents a major part the distal ring of the nuclear basket and, to a minor extent, cargo arrested in transit (3, 4).

3D reconstructions of the central framework have further unveiled eight peripheral channels or holes that

Nuclear Pore Complex. Figure 1 Nuclear pore complex architecture. The reconstructions of the central framework and the distal ring of the nuclear basket have been adapted from a tomographic reconstruction of native NPCs embedded in thick amorphous ice (3). The figure was modeled with a visual programming environment (ViPER) at the Scripps Research Institute (<http://www.scripps.edu>).

perforate the central framework (1, 2, 3). These peripheral channels have been proposed to mediate diffusion of ions and small molecules, to participate in the import of inner nuclear membrane proteins and/or to maintain the NE electrical conductance (1, 2). However, more recent data support the idea that the peripheral channels might act as voids or buffer zones to achieve the plasticity of the central framework needed for translocation of large cargoes, such as ►**Balbani ring mRNP** particles through the central pore or in response to chemical or physical effectors, such as Ca^{2+} or ATP, rather than as transport channels (1, 2, 3).

Molecular Interactions

The molecular building blocks of the NPC are a set of proteins called nucleoporins. Based on proteomic analyses in yeast and in vertebrates, the NPC is composed of ~30 different nucleoporins, each of which is present in 8 to 56 copies per NPC (1, 2). Based on immunolocalization studies by electron microscopy (EM), the majority of the nucleoporins are distributed fairly symmetrically on the cytoplasmic and the nuclear sides of the NPC, with only a few nucleoporins being located asymmetrically to either the cytoplasmic or the nuclear periphery (5, 6). Molecular interactions of nucleoporins involve intra-NPC interactions between distinct nucleoporins, as well as interaction of a subset of nucleoporins with soluble transport receptors that mediate nucleocytoplasmic transport of signal-bearing cargoes (1, 2, 7).

Interactions Between Nucleoporins

Based on biochemical and genetic interactions, nucleoporins are often organized in subcomplexes within the NPC (8, 9). The first identified and molecularly characterized NPC subcomplex was the vertebrate p62 complex, consisting of the nucleoporins p62, p58, p54 and p45 (Table 1). Based on immuno-EM data this complex localizes to the cytoplasmic and nuclear peripheries of the NPC's central pore and is involved in nuclear protein import (1, 2, 5, 8, 9). Additionally, p62 interacts with the nucleoporins CAN/Nup214 and Nup88, both located at the cytoplasmic ring moiety of the NPC. The example of p62 shows that nucleoporins can be organized in multiple subcomplexes. The Nsp1p complex represents the yeast homologue of the p62 complex. The Nsp1p complex is composed of the nucleoporins Nsp1p, Nup57p, Nup49p and Nic96p (Table 1). Like the p62 complex, the Nsp1p complex is implicated in nuclear protein import and is located at the cytoplasmic and nuclear peripheries of the central pore. Nsp1p and Nic96p are additionally found in a subcomplex that resides at the distal ring of the NPC's nuclear basket.

Another extensively studied subcomplex of the yeast NPC is the Nup84p complex, which consists of the

nucleoporins Nup84p, Nup85p, Nup120p, Nup145p, Seh1p and a fraction of Sec13p. Sec13 is also a subunit of the ►**COPII complex**, which is involved in vesicle transport from the ER to the Golgi apparatus. Based on immuno-EM data, the Nup84p complex is distributed symmetrically on both faces of the NPC and it participates exclusively in mRNA export. The vertebrate homolog of the Nup84p complex is the Nup107-160 complex, which is composed of the nucleoporins Nup107, Nup160, Nup96, Nup133, Nup37, Seh1 and Sec13 (1, 2, 8, 9). Besides having a role in mRNA export, this vertebrate NPC subcomplex is critical for nuclear pore assembly (1). The Nup107-160 complex has also been identified by its interaction with the vertebrate nucleoporin Nup153, a component of the nuclear basket, suggesting that Nup153 is also part of this subcomplex of the NPC. However, whereas the molecular composition of the distinct NPC subcomplexes is well described, how the individual nucleoporins interact with one another within as well as between subcomplexes has remained elusive.

Interactions Between Nucleoporins and Transport Receptors

A common feature of about one third of the nucleoporins is the presence of hydrophobic FG (phenylalanine-glycine) repeat motifs within their amino acid sequence (1, 2, 5, 6). ►**FG repeats** are often embedded in larger repeat motifs, such as FXFG (where X is any amino acid) or GLFG (where L is leucine). FG-nucleoporins predominantly line the cytoplasmic and the nuclear peripheries of the central pore and FG-repeat domains appear highly mobile – they can reach into and even through the central pore of the NPC (1, 2, 5, 6). FG-repeat nucleoporins might attract each other through weak hydrophobic interactions. Such weak hydrophobic interactions may give rise to a transient barrier within the central pore, which allows only the translocation of cargo that can penetrate into this hydrophobic meshwork (1, 2, 5, 6).

The interaction of FG nucleoporins with soluble transport receptors, which, in turn, associate strongly and specifically with signal-bearing cargo, is key for the translocation of cargo-receptor complexes through the NPC. Crystal structures of FG-repeat peptides in complex with different transport receptors, for example the protein import receptor ►**importin** β or the mRNA export receptor ►**TAP**, have unveiled that the interaction between the nucleoporin and the receptor primarily involves the phenylalanine ring of the FG core and hydrophobic residues on the surface of the receptor (1, 2). However, the strength and specificity of the interaction vary between different transport receptors and different nucleoporins.

Although the exact mechanism by which cargo-receptor complexes traverse the NPC has remained

elusive, different models for NPC translocation have been proposed based on the affinity and nature of the interactions between nucleoporins and transport receptors (1, 5, 7). However, there are nucleoporins, such as the yeast nucleoporin Nic96p, that exhibit no FG repeats within their amino acid sequence and yet are able to interact with transport receptors (1, 8),

indicating that other interactions between nucleoporins and transport receptors might play a role in nucleocytoplasmic transport.

Regulatory Mechanisms

The regulation of binding of cargo-receptor complexes to and their release from the NPC is best understood for

nucleocytoplasmic transport pathways that involve transport receptors of the importin family (also called ►**karyopherins**). Karyopherins collectively bind the small GTPase Ran, and can be either import receptors (importins) or export receptors (exportins) (7).

Ran, like all small GTPases, cycles between a GDP-bound and a GTP-bound state. The conversion between these two forms is achieved by two accessory factors, RanGAP, the GTPase-activating protein and RanGEF, the guanine-nucleotide exchange factor, termed RCC1. RanGAP is a cytoplasmic protein and catalyzes GTP hydrolysis by ►**Ran** with the help of two other cytoplasmic, Ran-binding proteins, RanBP1 and RanBP2. RanBP2, in turn, is a constituent of the cytoplasmic filaments of the NPC (Fig. 1), and is also referred to as Nup358 (Table 1). RCC1, the other Ran accessory factor, is, in contrast, a nuclear protein that catalyzes the loading of Ran with GTP. Due to this compartmentalization of the Ran accessory factors, a Ran gradient exists between the cytoplasmic and the nuclear NPC periphery, a high concentration of RanGTP within the nuclear nearfield of the NPC, and a high concentration of RanGDP in the cytoplasmic NPC nearfield. Ultimately, it is this RanGDP/GTP gradient between the cytoplasmic and the nuclear nearfield of the NPC, which determines the directionality of nucleocytoplasmic transport (6).

All karyopherins interact with RanGTP through a conserved amino-terminal domain. Importins bind their cargo in the cytoplasm in the absence of RanGTP. The binding of RanGTP to the importin causes a conformational switch within the importin molecule, so that its affinity for the cargo and the NPC is strongly reduced. As a consequence the cargo is released into the nucleus, whereas the importin-RanGTP complex is recycled back into the cytoplasm in a yet uncharacterized manner. In contrast, exportins can bind their nuclear export cargoes only in complex with RanGTP in the nucleus. Once on the cytoplasmic face of the NPC, the heterotrimeric cargo-exportin-RanGTP complex becomes dissociated upon RanGTP hydrolysis, which is induced by the orchestrated action of RanGAP, RanBP1 and RanBP2. RanGDP is imported back into the nucleus by its own import-receptor, called NFT2, which dissociates from Ran in the nucleus upon exchanging its bound GDP to GTP with the help of RCC1 (7).

Other regulatory mechanisms that might play a role in nucleocytoplasmic transport are, for example, phosphorylation of nucleoporins and/or the cargo, masking of ►**nuclear localization signals** or ►**nuclear export signals**, or the presence of nuclear retention signals on immature RNPs/RNAs. However, at the present time these latter mechanisms are not as well understood as the Ran cycle and its regulation of nucleocytoplasmic transport.

Nucleoporins

Definition

Nucleoporins are proteins that line the nuclear pore complex, and which contain phenylalanine-glycine (FG) dipeptide repeats.

- ▶ Nuclear Import and Export
- ▶ Nuclear Pore Complex
- ▶ RNA Export

Nucleoside, Nucleotide

Definition

Nucleotides are the subunits forming the DNA and RNA molecules. Nucleotides are composed of a nucleobase (purin- or pyrimidin base), which is linked via a glycosidic bond to a ribose or 2'-deoxyribose (together a nucleoside), with 1, 2, or 3 phosphate groups attached to the 5'-position of the ribose.

Definitions

In the nucleus of all eukaryotic cells the DNA molecules, which carry the genetic information, wrap around well conserved protein particles forming the nucleosomes (1). They represent the basic units of ▶ [chromatin](#), which constitutes the fundamental material of chromosomes. Chromatin structure is strongly linked to the function of the eukaryotic genome. Significant progress has been made in understanding the organization and the dynamics of nucleosomes and of chromatin fibers and how these structures influence nuclear processes.

Characteristics

The DNA of a single eukaryotic cell is packed in the nucleus, according to a hierarchical scheme of folding. At the first level of organization, almost two tight superhelical turns (▶ [Supercoiled DNA](#)) of DNA (146 base pairs) are wrapped around an octamer of two copies each of the four ▶ [histone proteins](#), H2A, H2B, H3 and H4. This unit, the nucleosome core particle (NCP), represents the basic repeating structure in chromatin and is invariant over the whole eukaryotic kingdom. Histones are characterized by their abundance, relatively small size and strongly basic charge due to their high content of lysine and arginine residues. The charged amino acids are localized on the N-terminal tails that extend from the histone molecules. Histones are easily extracted by exposing chromatin to acids or salts at elevated concentrations. This kind of removal demonstrates that histones are held in chromatin by electrostatic attraction (between their positively charged residues and the negatively charged phosphate groups present on the surface of DNA helix) rather than by covalent bonds.

According to analysis of the crystal structure of a single nucleosome, DNA lies on the surface of the ▶ [histone octamer](#) and makes about 1.67 left-hand superhelical turns around it (2, 3). Nucleosomes are connected to each other by 10–90 base pairs of ▶ [linker DNA](#) depending on cell type, organism and physiological status. This DNA tract interacts with the histone H1, also called the linker histone because it binds to the

exterior of nucleosomes and stabilizes the highly condensed states of chromatin fibers. The simple arrays of nucleosomes along the DNA molecule represent the first level of chromatin structure (the 10 nm fiber, also called “the beads-on-a-string” structure). Most of the chromatin in the nucleus is even more highly compacted. The next stage of packing involves folding the beaded structure into a 30 nm fiber. These fibers may be further folded on themselves to make the thicker fibers visible in both metaphase chromosomes and nuclei of non-dividing (interphase) cells. The highly condensed regions of chromosomes are called ►**heterochromatin**, the more open chromatin regions are called ►**euchromatin**; in these relaxed domains transcription may occur.

Histone Variants

Histone variants within any species are highly conserved specialized histones that co-exist with the major histone types in the nucleus and have the potential to alter chromatin structure locally. H2A and H3 variants have diversified to assume roles in ►**epigenetic** silencing, gene expression and centromere function (4).

One of the best-characterized variants is H2A.Z; it has been shown to be important for viability in many organisms. Its function is thought to be different from that of the major H2A protein; H2A.Z appears to alter nucleosome stability and is involved in gene regulation by maintaining a transcriptionally permissive “open” state and by protecting euchromatin from encroachment by “silent” heterochromatin. Another H2A variant is H2A.X, whose defining feature is a C-terminal extension containing a motif that is crucial for chromatin compaction and DNA repair.

Cse-4 and CENP-A are yeast and human, respectively, histone H3 variants that appear to be essential structural components of centromeric nucleosomes. Cse-4 can heterodimerize with H4 *in vivo*; CENP-A can be reconstituted into a *bona fide* nucleosome *in vitro*. H4 and H2B are invariant.

Histone Modifications

The structure and functions of nucleosomes are influenced by chemical alterations in the histone molecules. Covalent modifications of the core histones have important roles in gene regulation. In particular, the amino-terminal tails, which protrude out of the histone octamer, are subject to various covalent alterations, acetylation, phosphorylation, methylation and ubiquitination.

A histone modification affects chromosome function by two possible distinct mechanisms. Either it changes the electrostatic charge and as a consequence the structural properties of the histone or its binding to DNA, or it can create binding surfaces for protein

recognition modules, thus recruiting specific functional complexes to their proper sites of action (for instance, acetylated lysines are recognized by protein ►**bromodomains**, methylated lysines by protein ►**chromodomains**).

This multiplicity of modifications and their occurrence in defined patterns of combinations argues for the existence of a “histone code”(5).

Acetylation

This consists of the addition of acetyl groups to conserved lysine residues in histone tails. This process is catalyzed by ►**histone acetyltransferases** (HATs); the inverse process is catalyzed by ►**histone deacetylases** (HDACs). As a consequence of histone amino-terminal tail acetylation, a decrease in their overall positive charge occurs; as these tails are highly basic, it has long been postulated that acetylation decreases their affinity for the negatively charged DNA and facilitates the binding of proteins that regulate transcription to chromatin templates. HATs utilize acetyl-coenzyme A as a cofactor. Many of the HATs are components of large multisubunit complexes, recruited to promoters by interaction with DNA-bound activator proteins. Two major families have been discerned on the basis of structural similarities: GCN5-related N-acetyltransferases (GNAT) and MOZ, Ybf2/Sas3, Sas2, Tip60 (MYST). Although most nuclear acetyltransferases have been linked to transcriptional regulation there is evidence that they play a role in other chromatin-based processes. TAFII250 and Esa1 HATs regulate cell-cycle progression, Tip60 HAT complex is involved in DNA repair and apoptosis and Elp3 HAT activity helps the RNA polymerase II elongation complex. In addition, histone acetylation promotes cell differentiation and modulates cell survival, in fact MyoD, the key regulator of myogenesis, is associated with both p300/CBP and PCAF (human-HATs complexes).

Phosphorylation

This consists of the addition of phosphate groups to conserved serine residues in histone tails. The phosphorylation involving Ser-10 of histone H3 has emerged as an important modification, both in transcriptional activation and in chromosome condensation during mitosis. The identity of histone kinases (HKs) responsible for Ser-10 phosphorylation with previously known transcription-associated factors suggests that they may be recruited to specific promoters as coactivators just like the HATs.

Methylation

This consists of the addition of methyl groups. There are two types of histone methylation, targeting either arginine or lysine residues. In contrast to the previous modifications, methylation does not alter the overall

charge of the histone tails. By increasing methyl addition (mono, di or tri) the histone gets more and more basic and hydrophobic. These observations suggest a tight association between methylated histone tails and DNA and/or chromatin. Methylation of histones is catalyzed by histone methyltransferases (HMTs), which use S-adenosyl methionine (SAM) as a cofactor.

Unlike histone acetylation, which occurs throughout the cell-cycle, histone methylation peaks in the G2 phase, subsequent to DNA replication and histone synthesis and during heterochromatin assembly. Different histone methylations are associated with different chromatin functions, for example, H3 K4 methylation is linked to active genes, whereas H3 K9 methylation is linked to inactive genes.

Ubiquitination

Histone ubiquitination is still poorly understood. In the yeast *Saccharomyces cerevisiae* it has been shown that the ubiquitin-conjugating enzyme Rad6 (Ubc2) mediates methylation of histone H3 at lysine 4 through the ubiquitination of H2B at Lys 123. This modification is critical to mitotic and meiotic growth, although it is not yet clear whether it is involved in transcription.

► Chromatin Remodeling

Nucleosome structure is dynamic. This feature represents a fundamental requisite for all the processes taking place in the nucleus. In fact, transcription and replication, as well as DNA recombination and repair can occur only when specific protein complexes overcome the nucleosome barrier and reach the relevant DNA sites of action, e.g. promoters and replication origins. Nevertheless, nucleosomes do not only play a repressive role; they also contribute to the assembly of productive protein complexes on their surface.

The dynamic behavior of chromatin structure is largely due to enzymatic covalent modifications of the N-terminal amino acids of the core histones, but it is also due to the function of ATP-dependent chromatin remodeling complexes (6). These are able to alter the folding, fluidity and basic structure of chromatin by using the chemical energy of ATP hydrolysis. The results are mobilization and ►nucleosome repositioning.

Protein purification has revealed different classes of multi-component protein complexes that require ATP hydrolysis for their action, the *Drosophila* NURF, CHRAC and ACF, the yeast SWI/SNF, RSC, ISW1 and ISW2 complexes and the vertebrate SWI/SNF, ERC1, RSF and Mi-2/NRD/NURD complexes.

Although these complexes are compositionally and functionally different, they all share a motor subunit that belongs to the Snf2-like family of ATPases. The ATPase polypeptides of these complexes possess an

intrinsic chromatin-remodeling function, while the non-ATPase subunits may enhance or regulate the motor activity of the ATPase subunits. The non-ATPase subunits can mediate other specialized functions, for example both human SWI/SNF complex and its yeast counterpart can be recruited to target genes through direct interactions with gene-specific regulatory proteins.

As far as the remodeling mechanism is concerned, several models have been suggested. The first model for SWI/SNF-like enzyme activity is based on the idea that the energy coming from ATP hydrolysis is used to drive removal of one or both of the histone H2A-H2B dimers, resulting in DNA wrapping onto a tetramer of histones H3 and H4. A model was later proposed in which dimers are not lost but undergo dramatic rearrangements, giving rise to a novel nucleosome conformation and to its relocation to different positions relative to the DNA template. Most of the proposed mechanisms involve changes in the topology of nucleosomal DNA. ATP hydrolysis is used to generate superhelical torsion in nucleosomal DNA. Superhelical stress might then be relieved on the nucleosome surface by random dissociation (bulging) of small stretches of nucleosomal DNA. In these models the remodeling enzyme must continually inter-convert the distribution of bulged species, producing a window of opportunity for factor binding at essentially any position within the nucleosome. Although there are many data supporting these models, the molecular mechanisms of chromatin remodeling still remain to be determined.

Clinical Relevance

In the past few years the importance of chromatin structure in human disease has become increasingly clear; in fact, the mutation of genes whose products are predicted to regulate nucleosome structure and location is often the cause of complex multi-system disorders or neoplasias. Inherited diseases have been associated so far with mutations in several nucleosome remodeling ATPases, such as SWI/SNF, as well as in histone acetyltransferases (7).

The best example of a chromatin-remodeling disorder is the α -thalassemia/mental retardation syndrome (ATR-X, where the X indicates that it is linked to the X chromosome). It is due to mutations of the ATRX gene, coding for a nuclear protein that belongs to the family of SWI/SNF ATPases. Further examples of chromatin-remodeling disorders include mutations in other SWI/SNF related ATPases involved in nucleosome repositioning. Human diseases are also determined by mutations of genes coding for histone covalently modifying enzymes, as for example the Rubinstein Taybi syndrome caused by mutations in the CREB binding protein (CBP), a histone acetyltransferase. In addition, chromosomal translocations resulting

in the fusion of CBP or EP300, both involved in tumor suppression, with the ZNF220 gene, another histone acetyltransferase, are associated with aggressive human acute myeloid leukemia. A few diseases have been associated with aberrant histone deacetylases. The best example of this group is ►[Rett syndrome](#) caused by mutations in the MECP2 gene, encoding a protein that binds methyl-CpG in DNA. The current hypothesis is that the MECP2 protein recruits HDACs to methylated DNA and induces transcriptional silencing.

School of Molecular and Microbial Biosciences,
University of Sydney, Sydney, Australia
ric@mmb.usyd.edu.au

Synonyms

►[Nucleotides](#) are the building blocks of ►[DNA](#) and ►[RNA](#) and contain either a ►[pyrimidine](#) or a ►[purine](#) base. The pyrimidine bases found in DNA are cytosine and thymine; cytosine and uracil are found in RNA. The purine bases found in both DNA and RNA are adenine and guanine.

Definitions

Nucleotides consist of three chemical components, one of the 5 bases mentioned above, a ribose moiety in RNA and a deoxyribose in DNA and one to three phosphate groups linked together and to the ribose. There are two routes for nucleotide biosynthesis in living cells, the *de novo* and ►[salvage pathways](#).

The salvage synthesis of nucleotides may occur from a base such as uracil using a reaction catalyzed by a phosphoribosyltransferase enzyme.

All bases listed under Synonyms may participate in such a reaction. The alternative salvage reaction involves a ►[nucleoside](#) kinase enzyme.

Nucleosides that may participate in such a reaction are uridine, cytidine, (deoxy)thymidine, deoxycytidine, adenosine, guanosine, deoxyadenosine and deoxyguanosine.

The pathway for *de novo* biosynthesis of pyrimidine nucleotides consists of 9 enzyme-catalyzed reactions involving combination of the precursors, bicarbonate, glutamine, ATP, aspartate and P-Rib-PP to yield cytidine 5'-triphosphate (Fig. 1, 1). The pathway for *de novo* biosynthesis of purine nucleotides consists of 14 enzyme-catalyzed reactions from the precursors, P-Rib-PP, glutamine, ATP, glycine, N¹⁰-formyl tetrahydrofolate and aspartate (Fig. 2, 2).

Characteristics

De Novo Pyrimidine Nucleotide Biosynthesis

The pathway is shown in Fig. 1 with the reactions numbered in sequence. All of the reactions occur in the

Nucleotide Biosynthesis. Figure 1 The pathway for *de novo* biosynthesis of pyrimidine nucleotides.

►cytoplasm of human cells, except for dihydroorotate dehydrogenase (reaction 4), which is located on the outer side of the inner ►mitochondrial membrane (1). In mammals, the enzymes catalyzing the first three reactions of the pathway, carbamyl phosphatase, aspartate transcarbamylase and dihydroorotase,

are contained in a trifunctional protein called CAD (or DHO synthetase). The dihydroorotate produced must diffuse across the outer mitochondrial membrane to be oxidized by dihydroorotate dehydrogenase, which is coupled directly to the electron transport chain in mitochondria via ►coenzyme Q. The orotate formed

Nucleotide Biosynthesis. Figure 2 The pathway for *de novo* biosynthesis of purine nucleotides.

then diffuses back into the cytoplasm where it is further converted by UMP synthase. The enzymic activities catalyzing reactions 5 and 6, orotate phosphoribosyltransferase and OMP decarboxylase, are found in mammals as a bifunctional protein called UMP synthase. The uridine 5'-monophosphate (UMP) produced by reaction 6 is sequentially phosphorylated, $\text{UMP} \rightarrow \text{UDP} \rightarrow \text{UTP}$, the UTP is then converted to CTP by the enzyme, CTP synthetase. In mammals, the pyrimidine pathway is regulated at the first reaction, catalyzed by carbamyl phosphate synthetase II, by UTP, which is a feedback inhibitor and **►P-Rib-PP**, which is an activator. Thus when P-Rib-PP is available, pyrimidine biosynthesis proceeds (1).

De Novo Purine Nucleotide Biosynthesis

The pathway is shown in Fig. 2 with the reactions numbered in sequence. All of the reactions occur in the cytoplasm of human cells. The first reaction of the pathway is catalyzed by the enzyme, amido phosphoribosyltransferase, which is a very unstable enzyme with an iron-sulfur center. The unbranched portion of the pathway consists of 10 reactions yielding IMP; there is then a branch to AMP and another branch to GMP (Fig. 2). GMP and AMP are then phosphorylated ($\text{NMP} \rightarrow \text{NDP} \rightarrow \text{NTP}$). In mammals, purine biosynthesis is controlled by feedback inhibition of amido phosphoribosyltransferase by the end products, AMP, GMP and IMP (Fig. 2). This enzyme is also subject to inhibition by dihydrofolate (DHF) polyglutamates, which may regulate the pathway according to the state of reduction of metabolic cofactors (3). The enzymes catalyzing reactions 2, 3 and 5 of the pathway are contained in a trifunctional protein; those catalyzing reactions 6 and 7 and reactions 9 and 10 are contained in bifunctional proteins. There have been proposals that the intermediates of this pathway are "channeled", that is preferentially utilized by the next enzyme of the pathway without diffusing into the bulk solvent. There is some evidence for association of the **►multifunctional enzymes** of this pathway into a "**►pathway particle**" which could mediate substrate channeling and provide coordinate control of enzyme activity. However, more evidence is required to support these proposals.

Deoxynucleotide Biosynthesis

The deoxynucleoside 5'-triphosphates, dCTP, dTTP, dATP and dGTP, are formed in a series of reactions starting with a nucleoside 5'-diphosphate precursor (NDP).

For dCTP, dATP and dGTP, there is then a simple phosphorylation

For dTTP, the sequence of reactions is more complex

The 4 **►dNTPs** are then polymerized into a growing strand of DNA where the nucleotide (NMP) sequence is copied from an existing strand using the enzyme, **►DNA polymerase**.

Clinical Relevance

The *de novo* and salvage pathways described above for biosynthesis of pyrimidine and purine nucleotides may be considered universal, being found in organisms ranging from bacteria to humans. For cell division to occur, there must be two copies of each chromosome, for humans 92 chromosomes rather than the diploid number of 46. These chromosomes consist of DNA containing the genetic code or "blueprint for life". As stated above, DNA is synthesized from the 4 dNTPs and therefore active nucleotide biosynthesis is required for DNA synthesis to occur. Thus drugs for the treatment of cancer, bacterial or parasitic infections could selectively block nucleotide biosynthesis in the invading cells.

Cancer

There are a number of drugs that block pathways for nucleotide biosynthesis (4), the best known is probably methotrexate (MTX). MTX is a so-called antifolate drug, which inhibits the enzyme, **►dihydrofolate reductase**. The consequence of this inhibition is the accumulation of dihydrofolate polyglutamates in cells, which then block the pathway for *de novo* biosynthesis of purines (Fig. 2) and the synthesis of dTMP (Eq. 6). The result is major decreases in the cellular concentrations of dATP, dGTP and dTTP, while dCTP is unchanged. This imbalance in the pools of dNTPs results in genetic miscoding during replication of DNA and cell death. The basis of the selective toxicity of MTX on cancer cells is due to the more rapid growth of some cancers compared with normal cells of the body or to the slow but continuous growth of some cancers. It should be clear from this explanation that such cytotoxic drugs have side effects on the patient.

Bacterial and Parasitic Infections

While the differences between cancer and normal cells are subtle, there is considerable variation between the pathways and enzymes of pathogenic organisms and those of human cells. Thus, there is more scope for drugs with selective toxicity (4). For example, there are antifolate drugs that are more toxic to the pathogen than human cells and sulfa drugs block the synthesis of

folate in some bacteria, while humans must obtain it as a vitamin in the diet. The malarial parasite, *Plasmodium falciparum*, has the ►*de novo* pathway for biosynthesis of pyrimidine nucleotides (Fig. 1) but is unable to salvage pyrimidine nucleosides (Eq. 2). Conversely, the parasite lacks the *de novo* pathway for purine nucleotides (Fig. 2), but salvages the purine nucleosides, adenosine and guanosine (substitute these nucleosides into Eq. 2). This difference in pathways between malaria and the human host can be exploited in chemotherapy. Atovaquone is an antimalarial drug that blocks the electron transport chain, thus inhibiting dihydroorotate dehydrogenase (reaction 4) of the pyrimidine pathway (Fig. 1). The parasite cannot synthesize pyrimidine nucleotides required for DNA synthesis and cell division, while the patient can synthesize pyrimidine nucleotides *via* the alternative salvage pathway. Thus the malarial parasite dies and the patient survives. The basis for selective toxicity here is very strong, involving differences in pathways. Other enzymes of the pyrimidine pathway in *P. falciparum* are also potential targets for development of antimalarial drugs.

Nucleotide Excision Repair

JAMES E. CLEAVER

Auerback Melanoma Laboratory, UCSF Cancer Center, University of California, San Francisco, CA, USA
jcleaver@cc.ucsf.edu

Definitions

DNA repair encompasses a large and important set of cellular processes that maintain the integrity of the genome under onslaught from external and internal radiations, chemicals and oxidation. Every sequenced genome contains an extensive series of genes that

encode proteins for detection, modification, removal, replacement and bypass of damaged and non-informative DNA bases (1). These function in a number of different DNA repair mechanisms, each with a range of substrates and distinctive mechanisms. The mechanism by which large DNA adducts especially those produced by ultraviolet (UV) light are repaired is known as ►*nucleotide excision repair* (NER) (Fig. 1) (2).

Transcribed genes and their transcribed strands are more rapidly repaired by NER than other regions of DNA (3). A specific branch of NER has therefore been named “►*transcription coupled repair* (TCR)” to distinguish it from repair of the remainder of the genome, called “►*global genome repair*” (GGR). Many components of the basal transcription factor IIIH (TFIIH) are also involved in NER, contributing to its linkage to transcription.

Characteristics

Types of Damage Repaired by NER

The NER system recognizes and repairs DNA damage that consists of photoproducts produced by UV light and large DNA adducts produced by carcinogenic chemicals (Fig. 2). The most important wavelengths of UV are those in the UVC (240–280) and the UVB (280–320 nm) ranges that are strongly absorbed by nucleic acids. The photoproducts include the cyclobutane [5–5], [6–6] pyrimidine dimers (CPDs) and the [6–4] pyrimidine pyrimidinone dimers ([6–4]PDs) that involve both T and C pyrimidines (Fig. 1). The [6–4]PD can further photoisomerize to the Dewar photoproduct at longer UV wavelengths. Cytosine in dimers has an increased rate of deamination leading to cytosine to thymine (C to T) mutagenesis. Chemical adducts include those produced by N-acetoxy-N-acetyl amino-fluorene (AAAF), benzo(a)pyrene, aflatoxin, photo-activated psoralens, and cis-platinum. An oxidative purine product, 5',8-purine cyclodeoxynucleoside, that may accumulate in neurological tissue also requires the NER system for repair. The NER system can even recognize DNA triplexes formed by the binding of short oligonucleotides to double stranded DNA.

Other kinds of damage involving smaller modifications to DNA bases (alkylation) or DNA breakage require a different suite of enzymes, many of which are involved with immunoglobulin rearrangements and neurodegeneration. The distinctions between the various repair systems are not absolute, however, and there are overlaps in the substrate specificity of these various repair systems and variations in the efficiencies and sites of action on DNA in differing metabolic states.

Recognition of Damage in Non-Transcribing Regions of the Genome

The initial damage recognition factors uniquely required for GGR are the XPC and XPE DNA binding

Nucleotide Excision Repair. Figure 1 The sequence of steps involved in nucleotide excision repair from damage recognition by GGR or TCR mechanisms (I), DNA unwinding (II), verification (III), excision (III, IV), polymerization and ligation (V). (reproduced from Hoeijmakers JH (2001) *Genome maintenance mechanisms for preventing cancer*. Nature 411:366-374, with permission from Macmillan Publishers)

proteins (Table 1) (4). XPC is found in association with a cofactor HR23B, one of the two human homologs of the yeast Rad23 gene product. The XPC/HR23B complex is the earliest damage detector that initiates NER in nontranscribed DNA with highest affinity for the [6-4]PD. This complex stabilizes subsequent binding of the XPA-RPA proteins to the damaged site. In cells that lack the XPC/HR23B complex, repair is confined to small transcriptionally active islands of the genome, where repair occurs at normal rates, surrounded by oceans of unrepaired transcriptionally silent DNA. The constitutive level of expression of XPC is controlled by p53, and the protein can be induced further by UV irradiation. If a damaged site already contains a significant degree of unpaired bases the requirement for XPC/HR23B is relaxed.

The XPE protein is a ▶heterodimer having subunits of 127 kD (DNA Damage Binding Protein, DDB1) and 48 kD (DDB2) and mutations that are diagnostic for XP-E patients are located in the DDB2 subunit. The DDB1/2 heterodimer is involved in the recognition of damaged DNA but reconstitution of excision repair

using purified proteins and synthetic substrates lacking chromatin structure shows no requirement for DDB1/2 for damage removal and repair synthesis. The XPE protein is mainly involved in repair of mutagenic UV-induced photoproducts.

DDB1 (p127) is present in excess over its partner, and is predominantly cytoplasmic but translocates to the nucleus after UV irradiation. Mutations in DDB2 also prevent the accumulation of DDB1 in the nucleus. UV-induced expression of DDB2 involves p53 transactivation in human, but not rodent, cells. The consensus DNA-binding site for p53 is present in the human p48 promoter region but has mutated in the mouse homolog. These observations provide a partial explanation for early observations that excision repair can be low in some mouse cell strains.

By *in vitro* reconstruction using recombinant proteins, the complete excision process on metabolically inactive (nontranscribed) DNA can be carried out with a minimal set of components, replication protein A (RPA), XPA, TFIIH (6 sub-unit core of XPB, XPD, p44, p34, p52, p62 and 3 sub-unit kinase, CAK), XPC,

Nucleotide Excision Repair. (redrawn from Taylor, J. S., Cohrs, M. P. (1987). DNA, light. and Dewar pyrimidines: the structure and significance of TpT3. *J. Amer. Chem. Soc.* 109, 2834-2835, and reproduced from Ultraviolet radiation carcinogenesis, in *Cancer Medicine*, 6th edition, volume 1 edited by Kufe et al. 2003, with permission from B C Dekker, Hamilton, Canada)

HR23B, XPG, ERCC1 and XPF. CAK appears to act as a negative regulator and inhibition of phosphorylation stimulates repair. These individual factors of NER associate sequentially and independently on UV

photoproducts *in vivo*, without preassembly of a "repairosome" complex.

Recognition of Damage in Transcriptionally Active Regions of the Genome

CPDs are excised more rapidly from actively transcribed genes, especially from the DNA strand used as the template for transcription. Excision can be slow where binding proteins interact with the promoter but increases immediately after the ATG start site for transcription. The initial damage recognition mechanism for TCR may be the stalled RNA polymerase (Pol II) itself, although a potentially large number of proteins play a role in mediating the increased rate of repair in transcriptionally active genes. The blocked RNA Pol II masks damaged sites and must be removed, or backed off, to alleviate the arrested transcription and provide access for repair enzymes. The processes that alleviate the arrested RNA Pol II enhance the overall accessibility of the damaged site and permit more rapid repair than in non-transcribed regions of the genome. Persistently blocked RNA Pol II can be a signal for UV-induced apoptosis.

The Core Excision Process Common to GGR and TCR

DNA Unwinding

The damaged site is unwound by the 3'-5' (XPB) and 5'-3' (XPD) helicases of TFIID in concert with XPG, and then stabilized by the XPA-RPA binding complex. The basal transcription factor, TFIID that is involved in transcription initiation and elongation plays a major role in remodeling the damaged regions for excision to occur after initiation of damage recognition by TCR and GGR. The XPB and D components of TFIID and CSA interact with p53, suggesting a role for p53 in regulation of TCR. But this role is not as prominent as regulation of GGR by p53 in the overall repair reaction.

Damage Verification

After damage recognition, a process of damage verification occurs in which the initial proteins are replaced by another damage binding complex, the heterodimer of XPA/RPA. XPA binds to both the damaged and the undamaged strand, but RPA binds mainly to the undamaged strand. XPA acts as a foundation on which many of the other components of the NER process subsequently assemble. XPA binds to the p34 subunit of RPA through its N-terminal region and to the p70 subunit through a central portion in exon IV, as well as to many other NER components including ERCC1, TFIID, XPC, XPG, and DNA itself. The final stable complex that remains at the damaged site is unclear, but a subset of these components acts as an assembly point for the XPG and ERCC1/XPF nucleases that cut the damaged strand 3' and 5' to the damaged site.

Nucleotide Excision Repair. Table 1 The main genes and functions of the NER system

Gene	Chrom location ¹	Protein	Function	Partner(s)
XPA	9q34.1	273aa	DNA damage binding	RPA
XPB	2q21	782aa	3'-5' helicase	TFIIH

Excision of the Damaged Strand

The excision process involves removal of an oligonucleotide, 27–29 nucleotides long, containing the photoproduct as a result of cleavages 5 nucleotides on the 3' side of the photoproduct, and 24 nucleotides on the 5' side. The structure-specific cleavage pattern is determined by binding of RPA to the unwound damaged site, and the excised fragment is close in size to the footprint of RPA on DNA. Slight variations in the precise sites of cleavage result in the removal of variable fragments between 27 and 29 nucleotides. The XPG nuclease cleaves first on the 3' side of the damage and interacts with the XPC-HR23B complex and with TFIIH; the XPF-ERCC1 heterodimer cleaves subsequently on the 5' side of the damaged site. XPA serves as an anchor for the 5' nuclease through binding to ERCC1.

Synthesis of the Repair Patch

The excised region is replaced by the action of a complex similar to that involved in normal DNA replication. Proliferating cell nuclear antigen (PCNA) is loaded onto the DNA by the 5 subunit replication factor C (RFC) complex which then anchors the replicative DNA polymerases, Pol δ or Pol ϵ . The final closure of the repaired site occurs with DNA ligase I.

Replication of Damaged DNA

NER can remove DNA damage before DNA replication begins, and consequently plays a major role in reducing the amount of damage that becomes fixed as mutations during replication. DNA photoproducts,

however, are blocks to the replicative DNA polymerases, alpha, delta and epsilon (Pol α , δ , ϵ) that cannot accommodate large distortions such as DNA photoproducts or adducts in their active sites. Replicative bypass of these photoproducts is achieved instead by damage-specific polymerases with relaxed substrate specificity, known as class Y polymerases (5). These polymerases have larger active sites that allow them to read-through noninformative sequence information resulting from DNA damage. Consequently these polymerases have high error rates of the order of 1% when assayed *in vitro*, and this property must be controlled *in vivo* otherwise the results would be catastrophic to the cell.

Three class Y polymerase genes have been identified in the mammalian genome, Pol η , ι and κ . Pol η and ι are close homologs, unique to mammalian cells, only a single Pol η gene is found in yeast. Mutations in Pol η are found in one group of XP (Xeroderma pigmentosum) patients (XP variants) with clinical symptoms generally similar to those seen in the NER-defective patients. Pol η has the highest efficiency for replication of UV damage, followed by Pol ι with Pol κ having the poorest. Their relative efficiencies may differ for other kinds of chemical adducts. Pol η and Pol ι exhibit different base-specificities when replicating mis-coding lesions. Pol η preferentially inserts adenines, thus accurately replicating T-containing photoproducts. Pol ι preferentially inserts guanines, thus accurately replicating C-containing photoproducts. Pol η can therefore accurately replicate a T-T CPD. Pol ι can accurately replicate a T-C CPD or [6-4]PD. Pol η acts

distributively to extend nascent DNA chains by one or two bases across from CPDs, and the inserted bases may be edited by a separate exonuclease. Chain extension then requires the activity of Pol ζ or Pol κ that can extend the nascent chain from a terminal mis-paired base and then restore normal DNA replication. Pol η is uniformly distributed in the nucleus, and excluded from the replication fork until replication is stalled by UV damage. Pol η then traffics into the nucleus and accumulates with a large number of other proteins in microscopically visible foci at the replication fork. This requires specific sequence motifs at the C-terminal end of the protein for translocation and for binding to PCNA.

Clinical Relevance

► **Xeroderma pigmentosum** (XP) is a human, autosomally inherited, skin and neurodegenerative disease in which exposure to normal sunlight can result in a very high incidence of all kinds of skin cancer (6). XP is predominantly due to a failure of NER in cells that contain UV-induced photoproducts in their DNA. When these photoproducts are unrepaired, due to NER deficits, subsequent replication errors and cytosine deamination lead to characteristic C to T mutations, especially CC to TT mutations, that are found in the *p53* gene in sun- and UVB-induced skin cancers.

Mutations in NER genes are found in XP and in other cancer, developmental or neurodegenerative diseases such as Cockayne syndrome (CS), trichothiodystrophy (TTD), and Cerebro-Oculo-Facio-Skeletal (COFS) syndrome and have been summarized in the web-site ► www.xpmutations.org and in Table 1. Patients with mutations in those genes predominantly responsible for global genome repair, *XPC*, *XPE*, *XPF*, or replicative bypass, *XPV*, are at high risk for solar-induced skin cancer, but have few other complications. Patients with mutations in genes linked to transcription, *XPA*, *XPB*, *XPD*, *XPG* and the *CSA* and *CSB* genes, show high risks for neurodegenerative disease associated with diagnoses of CS or TTD.

Cells from CS patients are specifically defective in TCR. The excision of DNA photoproducts from total genomic DNA is normal in CS cells, but repair of transcriptionally active genes is reduced. Two CS genes, *CSA* & *CSB*, are involved specifically in TCR. *CSA* contains WD-repeat motifs that are important for protein-protein interactions. *CSB* contains an ATPase, helicase motifs and a nucleotide-binding domain, but only the last is essential for TCR and *CSB* does not function as a helicase. Cells lacking either *CSA* or *CSB* are unable to ► **ubiquitinate** the C-terminal domain (CTD) of RNA Pol II.

The XPG nuclease has a particularly complex range of activities, and mutations in XPG are associated with

both XP and CS diseases. XPG is an endonuclease in the FEN-1 family that is capable of strand-specific cleavage of a range of branched DNA substrates that may arise during DNA replication, repair and recombination. The XPG gene product also interacts with RNA pol II and facilitates efficient transcription elongation, thereby providing an explanation for the complex symptoms of some XPG patients who show both XP and CS symptoms. XPG is also a cofactor required for the activity of thymine glycosylase (*nth* gene) and is thereby linked to repair of oxidative damage that may also be important in maintaining neural functions that fail in CS.

Cancer risks are low or negligible in CS and TTD patients however. CS patients are photosensitive but do not show increased skin carcinogenesis, unlike mice with inactivated *Csa* or *Csb* genes that show increased skin carcinogenesis from UV light or chemical carcinogens (7). Mice however, also have inactive *XPE* genes, due to mutations in the *p53* response elements in the promoter region of the gene. Consequently the increased cancer rates in Cockayne mice might be due to their being double mutants in *Cs* and *Xpe*.

► **Polymorphisms** that are not directly associated with the high penetrance XP disease phenotype have been described for many of the NER and other repair genes. Polymorphisms have been found in the *XPA*, *XPC* and *D* genes, and others are listed in ► <http://greengenes.lbl.gov/dpublic/secure/reseq/>. Many of these polymorphisms result in non-conservative amino acid changes that could have an impact on NER function and disease. A large number of alleles present at low frequency individually could combine to create variation in disease frequency in the overall population.

Oncogene

MANFRED SCHWAB
DKFZ, Heidelberg, Germany
m.schwab@dkfz.de

Definition

An oncogene is a derivative of any gene that has the ability to stimulate cellular growth. In experimental assays, oncogene products can, alone or in cooperation with another gene, transform eukaryotic cells so that they grow in a way analogous to tumor cells. The definition was originally applied to the transforming genes acquired by RNA tumor viruses through the

transduction of cellular genes. Today, the term is used rather broadly. Oncogenes contribute to tumorigenesis by any positive modulation of cellular growth; they act by their presence (this in contrast to tumor suppressor genes), an activity that is often referred to as “dominant”. Tumorigenic activation of oncogenes can result from mutational/structural/numeric changes in a gene and possibly from regulatory enhancement of gene expression.

Characteristics

Oncogenes were originally isolated from RNA tumor viruses, where they are responsible for the rapid tumor induction after infection of an animal host. In the viral genome, the oncogene was referred to as a viral oncogene or *v-onc* (1, 2).

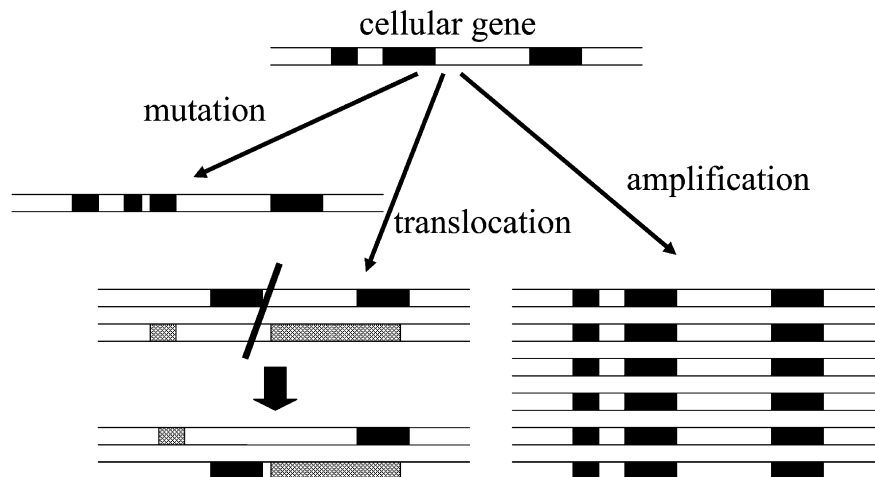

It was soon established that the *v-oncs* are actually derived from the genome of the host cell. They have been captured by the virus after infection of the cell by a process called transduction. Transduction appears in a range of animal species from chickens to monkeys; it has not been observed in humans. The cellular counterparts, from which the *v-oncs* are derived, are referred to as proto-oncogenes, or cellular oncogenes (*c-onc*). Proto-oncogenes are normal constituents of the cellular genome and are highly conserved among all eukaryotic organisms.

This original rigid definition has softened in subsequent years. Broadly speaking, the term oncogene now includes any gene that has a growth stimulatory effect on cells, by means of:

- conferring sustained cellular multiplication
- advancement of cell-cycle progression
- decreased requirement for growth factors
- focus formation under conditions of cell culture
- enabling cells to grow under more restricted experimental conditions, such as in soft agar
- tumorigenic conversion, such as in experimental animals
- conversion of cells to form tumors that undergo metastasis
- escape from apoptosis

The precursors of oncogenes (► [proto-oncogenes](#)) are present with their normal structures and expression activities in at least all higher animal cells. They represent what has been referred to as ‘enemies within’, but perform normal, usually vital, functions. Their oncogenic potential can be activated by any one of the following genetic changes (Fig. 1):

- Point mutation, resulting in an exchange of a base with the consequence of an amino acid change. The first example was the *RAS*^H oncogene from a human gastric cancer that can convert *in vitro* established cells to tumorigenicity.

Oncogene. Figure 1 Molecular pathways for activating the oncogenic potential of cellular oncogenes. Translocation is the exchange of genetic material between two non-homologous chromosomes.

- Translocation, in which DNA from two genes on two different chromosomes can recombine, resulting in a fusion gene and a fusion protein (e.g. *BCR/ABL* [*BCR-ABL1*]) in chronic myelogenous leukemia or deregulated gene expression, when normal gene expression signals are replaced by other DNA sequences, for example the juxtaposition of *MYC* and active *Ig* promoters in different types of lymphomas.
- Amplification, where the number of gene copies multiplies, with consequent enhanced gene expression; prototypic for this is the *MYCN* gene in neuroblastomas, which has emerged as the first molecular marker for patient prognosis and is a paradigm for the clinical usefulness of an oncogene alteration (3, 4).

Additionally, activation may be achieved through regulatory enhancement of gene expression, although such a type of activity is more difficult to establish, due to the lack of suitable counterpart cells for a faithful comparison of expression signatures.

Historically, the activity of point mutations was discovered through transfection assays, where total DNA from cancer cells was introduced into non-tumorigenic tester cells, either of murine or human origin. Cells that have incorporated the mutationally activated oncogene have acquired the ability to form tumors when transplanted into an animal host. Non-random translocations had been known for many years, particularly in lymphoblastoid cells. The availability of cloned retroviral oncogenes has allowed rapid determination of the molecular identity of the genetic information altered through the translocation event. The significance of oncogene amplification was

Oncogene. Figure 2 Early low-tech oncogene array for expression profiling of tumor cells. Retroviral oncogenes were spotted as a template onto a filter membrane (Ref.5; note that the cellular homologs had not been isolated at that time), poly-adenylated RNA was extracted from tumor cells, reverse transcribed into cDNA, which then was radioactively labeled and hybridized under conditions of reduced stringency to allow for interspecies cross-hybridization. These principles of array technology involving, as a hallmark, the reverse hybridization of a complex cDNA probe to a gene array, were first described in Ref.5, they are the same as those used in today's high volume arrays with thousands of genes (Ref.6).

established by the first application of array technology, using what in today's terminology is referred to as an "oncochip" (Fig. 2). Oncogene expression profiling of human and animal tumor cells carrying conspicuous cytogenetic manifestations of amplified DNA, "double minutes" (DMs) or "homogeneously staining chromosomal regions" (HSR) revealed the enhanced expression of an individual oncogene, such as *RAS*^K in a murine cell line or, more significantly, *MYCN* in human neuroblastoma. Subsequent analysis of the gene copy number showed that the enhanced expression is the consequence of the amplification (up to 500 additional gene copies) of the otherwise unchanged gene.

Oncogene Cooperation

Experimental approaches have shown that the expression of a single activated oncogene is insufficient to achieve full tumorigenic conversion of a normal cell. Only when at least two altered oncogenes or alternatively, a single altered oncogene under the control of a strong heterologous promoter are introduced can a normal cell assume a tumorigenic phenotype. Oncogene cooperation is well in line with the multiple genetic changes that a tumor acquires during its evolution to metastatic disease (multistep development). In the development of naturally developing tumors, oncogenes can also cooperate with tumor suppressor genes during cellular evolution towards the malignant phenotype.

Online Mendelian Inheritance in Man

Definition

OMIM™ (Online Mendelian Inheritance in Man) refers to the online knowledge base of human genes and genetic disorders authored and edited by Dr. Victor A. McKusick and his colleagues at John Hopkins University (Baltimore, MD) and elsewhere, and developed for the World Wide Web by the National Center for Biotechnology Information (NCBI). The database comprises over 14,000 inherited diseases and genetic traits in humans, with ample links to genomic and mutation databases and to the free MedLine data bank of scientific literature. The database at <http://www.ncbi.nlm.nih.gov/Omim/> is constantly updated and contains textual information and references.

DNA sequence, an open reading frame is characterized by the sequence of nucleotides, which when transcribed into mRNA, results in a series of triplet codons that is not interrupted by a stop codon. It begins with a start codon (ATG), terminates by a stop codons (TAA, TAG, TGA).

Origin Recognition Complex

Definition

Origin Recognition Complex (ORC) is a complex of six proteins, consisting of the subunits ORC1 to 6, that recognizes and binds to the replication origin. ORC was initially identified as binding specifically and ATP-dependently to Autonomously Replicating Sequences (ARSSs) in budding yeast. Further studies have demonstrated ORC to be conserved throughout eukaryotes. ATP-binding and -hydrolyzing activities of ORC depend on the ORC1 subunit. While DNA binding specificity of ORC is clear in budding yeast, it has yet to be clarified how mammalian ORC determines the DNA binding site.

Osteochondrodysplasias

Definition

Osteochondrodysplasias comprise of a group of disorders that primarily show abnormalities of bone and/or

cartilage. Dysplasias affect bone and/or cartilage as a tissue.

► Bone Disease and Skeletal Disorders, Genetics

Osteoclast(s)

Definition

Osteoclast(s) are large multinuclear cells, differentiated from the monocyte/macrophage lineage, which reabsorb old bone so that osteoblasts can replace it with new bone.

► Bone and Cartilage

► Bone Disease and Skeletal Disorders, Genetics

Osteoclastogenesis

Definition

Osteoclastogenesis refers to a process of osteoclast development that encompasses initiation, proliferation differentiation, and maturation.

► Bone and Cartilage

Osteocyte

Definition

Osteocyte is a mature (“retired”) osteoblast located within the bone matrix, which produces and resorbs bone matrix.

► Bone and Cartilage

Osteogenesis Imperfecta

Definition

Osteogenesis imperfecta is a dominant condition with decreased bone density, recurrent fractures and bowing, and other variable clinical characteristics. It is also called “brittle bone disease”. The disease results from mutations in either COL1A1 or COL1A2 genes, which code for the alpha1 and alpha2 chains of Type I collagen.

► Bone and Cartilage

► Bone Disease and Skeletal Disorders, Genetics

Osteoid

Definition

Osteoid designates a collagen 10A1 rich, weakly calcified bone matrix.

► Bone and Cartilage

Osteomalacia

Definition

Osteomalacia designates an abnormality (“soft bones”) of the mineralization of bone matrix in adults, caused by a vitamin D deficiency or problems in the metabolism of this vitamin. The effects of gravity and muscle tension are less than in the ► rickets of children, and may result in only bowing abnormalities of the weight-bearing long bones.

► Bone and Cartilage

► Hyper- and Hypoparathyroidism

Osteopenia

Definition

Osteopenia is characterized by a less than normal amount of bone, but not as severe as ► osteoporosis.

► Bone and Cartilage

Osteopetrosis

Definition

Osteopetrosis or “dense bone disease” is an inherited failure of bone formation, frequently caused by abnormal remodeling due to infunctional osteoclasts. Since the old bone tissue is not reabsorbed, the bones in the body overgrow. This results in sclerotic, thickened bones with poor mechanical properties. In the bones where bone marrow usually forms, the overgrowth expels the marrow. In the head and spine, this

overgrowth exerts pressure on nerves and causes neurological problems.

- ▶ [Bone and Cartilage](#)
- ▶ [Bone Disease and Skeletal Disorders, Genetics](#)

Osteoporosis

Definition

Osteoporosis is a degenerative bone disease that primarily affects post-menopausal women. It is characterized by a decrease in normal bone density due to the loss of calcium and collagen. As a consequence of decreased bone density, bones become brittle resulting in frequent fractures and other serious effects.

Overexpression/Misexpression

Definition

Overexpression/misexpression describes the expression of a gene product (RNA or protein) in greater-than-normal amounts (overexpression), or at a time or place different from that of wild-type expression

(misexpression). This may be achieved through the microinjection of mRNA, injection or transfection of an expression vector, through the generation of transgenic animals, etc. In classical genetic nomenclature, over-expression is analogous to a hypermorphic allele while misexpression is analogous to a neomorphic allele, although in fact overexpression may also produce a neomorphic phenotype.

Oxidative Stress

Definition

Oxidative stress comprises of a disturbance in the prooxidant-antioxidant balance of a cell in favor of the former. As a consequence, highly reactive molecules known as free radicals (reactive oxygen species; ROS) are produced, which can interact with other molecules in the cell and cause oxidative damage. Indicators of oxidative stress include damaged DNA bases, protein oxidation and lipid peroxidation products. This damage has been implicated in the cause of certain diseases and has an impact on aging processes.

Pal-CoA

Definition

Pal-CoA stands for Palmitoyl-Coenzyme A. Palmitic acid as well as other fatty acids must be activated before they can be transferred to proteins or lipids. Enzymes designated acyl-CoA synthetase link the carboxyl-group of the fatty acid to the – SH group of

coenzyme A. Synthesis of acyl-CoA requires ATP, and the energy of the ATP-hydrolysis is stored in the labile thioester-bond between the carbon chain and CoA. Pal-CoA is an amphipatic molecule with a hydrophilic head group, the CoA part, and a hydrophobic moiety, the acyl chain. The total concentration of long chain acyl-CoAs inside cells is in the range between 5 μ M and 150 μ M. However, the concentration of free Pal-CoA is very low (less than 200 nM), with most of it being bound to acyl-CoA binding proteins (ACBP). This helps to prevent possible damaging effects caused by the detergent-like properties of acyl-CoAs.

baptista@mail.nih.gov

Synonyms

Paralysis Agitans, Dopamine Responsive Parkinsonism

Definition

Parkinson's disease (PD) belongs to a group of conditions known as movement disorders. Clinically the disease is characterized by at least two of the cardinal features of bradykinesia (slowness of movement and a decrease in spontaneous movement), gait difficulty, postural instability, rigidity, resting tremor and asymmetry, as well as by a good response in the early stages to dopamine replacement therapy.

Characteristics

Clinical

Parkinsonism is a term used to apply to all disorders where at least two of the four cardinal features named above occur. Parkinson's disease is the most common cause of parkinsonism. Symmetric onset, lack of response to a reasonable trial of ►dopamine replacement therapy, prominent early dementia, eye movement difficulties, or severe, early ►dysautonomia (such as orthostatic hypotension), all argue in favor of an alternative cause of parkinsonism, such as progressive supranuclear palsy (PSP) or multiple system atrophy (MSA). James Parkinson first described Parkinson's disease in his essay on Shaking Palsy in 1817. Although classically a movement disorder as described above, the disease is systemic, and can cause problems with the skin (ruddiness and oiliness due to seborrheic keratosis), cognition (especially problems in executive function), mood (such as depression), and dysautonomia (cardiac sympathetic dysfunction, constipation,

and urinary difficulties). The pathological hallmarks of Parkinson's disease are the presence of Lewy bodies and a marked loss of dopamine-producing neurons in the ►**substantia nigra** (1). The neurotransmitter ►**dopamine** plays a crucial role in the initiation and maintenance of movement and thus its loss leads to a number of the above symptoms and signs. Hence dopamine replacement therapy is quite helpful in the early stages of this illness. However, not all symptoms are improved by dopamine replacement strategies, and there is currently no treatment known to slow the progression of the disease. Surgical treatment, including deep brain stimulation (DBS) in which a stimulating electrode is placed in deep brain structures (often the subthalamic nucleus), has been shown to be beneficial in some patients, but like dopamine replacement medication, is not curative. No therapies are known to slow the progression of this illness although neuroprotection trials are underway.

Genetic Causes of Parkinson's Disease

To date, several mutations have been identified as Mendelian causes of parkinsonism, and linkage has been made to several other regions, showing that in rare cases Parkinson's disease may be inherited as a ►**monogenic** trait (Fig. 1). (For more details see Hardy et al. 2003 (2), and Gwinn-Hardy 2002 (3)). Although

PD most often affects individuals over the age of 60 years, this illness may also affect younger people. Often, individuals with a younger age of onset of symptoms and a family history have a causative genetic mutation. Epidemiological surveys support the contention that the contribution of genetic compared to environmental factors is greater in younger patients. The role of susceptibility genes in PD is also supported by epidemiological studies that show a higher frequency of disease in patient relatives as compared to controls. It is often supposed that genetic variability plays a role in the development of later onset "typical" PD. Susceptibility genes may work in concert with environmental factors to influence disease incidence in the general population (see below).

The identification of multiple genes that produce a similar, if not identical, phenotype suggests that the gene products involved may have common cellular and molecular effects. As there are three genes unambiguously associated with PD (*α-synuclein*, *parkin* and *DJ-1*) plus a fourth (*UCHL1*) that is possibly causative in one family, there is a unique opportunity to delineate the pathway that leads to PD by understanding the molecular relationships between the gene products. The section below will deal with each of the gene products and the hypothesized cellular events that are thought to drive pathogenesis.

Parkinson's Disease: Insights from Genetic Causes. Figure 1 Regions of the human genome, encoding *PARK* loci, and regions with significant linkage to Parkinson's disease. Adapted from Riess et al., 2002.

Cellular and Molecular Regulation

α -Synuclein (PARK 1)

Alpha-synuclein was the first PD gene to be discovered in 1997 by Polymeropoulos and colleagues in an Italian family called the Contursi kindred. Affected individuals typically develop fulminant parkinsonism in the fourth or fifth decade, although the phenotype is variable. To date, in this and other families, two α -synuclein mutations have been identified (at position 30 alanine is substituted for proline [A30P] and at position 53 alanine is substituted for threonine [A53T]), both altering the amino acid composition of the protein. One of the oddities in this is that alanine at position 53 is poorly conserved throughout evolution. For example, rats and mice both have a threonine at the same position; the reason this is normal in rodents but causes disease in humans remains unclear. Alpha-synuclein has been shown to be a major component of Lewy bodies, including in familial and sporadic cases without any mutation in that gene, supporting the importance of this protein in general towards our understanding of Parkinson's disease.

The important function(s) of α -synuclein are still under investigation, as is the way that causal mutations affect these. Wild type α -synuclein appears to play an important role in synaptic function. It is associated with presynaptic vesicles; the protein binds to certain lipids in intracellular membranes. Knocking out α -synuclein in mice produces subtle changes in synaptic transmission, probably by reducing the number of vesicles that are normally present, which in turn may affect presynaptic protein amounts.

In Lewy bodies, α -synuclein is present in an insoluble, fibrillar form that can be recreated *in vitro* using purified protein. Events that promote fibrillation may include some oxidative modifications, high protein concentrations or the presence of some kinds of lipids. However, the role of mutations in this process is apparently complex. Several groups have shown that A30P does not promote the formation of mature fibrils, but instead creates a relatively soluble intermediate species referred to as oligomers or protofibrils.

Mutant forms of α -synuclein have a number of effects at the level of the whole cell. They can increase sensitivity of cells to various damaging events, including oxidative stress, dopamine toxicity, mitochondrial damage and proteasome inhibition. The precise mechanisms involved are likely to be multifactorial. Evidence suggests that the mutant forms have more extreme effects than wild type α -synuclein, consistent with their dominant cellular actions. However, at high levels of expression, wild type α -synuclein also has damaging effects. Several studies have shown that there is variability in the susceptibility of neurons to the damaging effects of mutant α -synuclein,

although it is notable that mouse models often show damage to spinal cord motor neurons rather than midbrain cells.

Parkin (PARK2)

Numerous mutations associated with parkinsonism have been identified in *parkin*. Originally described in Japanese teenagers and young adults as causal for autosomal recessive juvenile parkinsonism (ARJP), *parkin* has also been found to be important in other forms of parkinsonism. The original description was a disease characterized not only by an early age of onset as noted above, but also, by sleep benefit and foot dystonia. Subsequent reports in the non-Japanese literature, particularly in Caucasians, describe a later age of onset, no foot dystonia, and symptoms identical to "typical" PD, possibly with a slower than typical rate of progression. Patients with parkin mutations are not thought to generally have Lewy bodies although *post mortem* reports are limited to date. Parkin is one of several proteins that "tag" target intracellular proteins for degradation by adding chains of the small protein ubiquitin. The loss of functional parkin is hypothesized to compromise the ability of neurons to degrade potentially damaging proteins (for example, those that have an abnormal conformation) or proteins that may be toxic if allowed to accumulate in the cell. There is some evidence that one of the proteins that parkin acts upon is α -synuclein itself. Parkin has many other targets and it may be that these are also important in the pathogenesis of PD.

DJ-1 (PARK7)

Mutations in the gene encoding DJ-1 have been shown to cause PD in two European families and one from Venezuela. Mutations are inherited in an autosomal recessive fashion, and are postulated to result in disease due to a loss of function of the resulting protein. The precise function of the protein, and its relation to either α -synuclein or parkin is unclear at this time. No pathological evaluation of any affected members has been reported to date.

Ubiquitin C-Hydrolase-1 (UCHL1, PARK5)

A single mutation in this gene has been identified altering the amino acid at position 93, and leading to an abnormal enzyme, in a single sibling pair. Because it has only been described in that sibling pair to date, its importance in understanding Parkinson's disease remains to be confirmed. Nonetheless, further evidence for the involvement of this enzyme with PD comes from studies of a common genetic variant which appears to protect against the onset of PD. The function of UCHL1 is to recycle the ubiquitin "tag" added by enzymes such as parkin (see above), also supporting its role conceptually in the pathway which leads to

Parkinson's disease. The mutation identified reduces this activity. The way in which the mutation in *UCHL1* affects enzyme function is complex, and in fact there appear to be two distinct normal enzyme activities, one of which may affect α -synuclein processing, further supporting a potential importance of this enzyme.

Other Loci

The genes highlighted above were identified in families with apparent Mendelian parkinsonism. In the same way, five additional loci have been reported to date, for which the causative gene and mutation remain to be elucidated (Fig. 1).

A Comment on Possible Environmental Causes of Parkinson's Disease

There have been many proposed environmental insults that may lead to the onset and/or progression of Parkinson's disease, including pesticides and/or drugs. Exposure to the neurotoxin 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (►MPTP), a contaminant of the abused drug heroin, can reproduce many of the symptoms of PD; however Lewy bodies are not present in affected individuals. MPTP has become an important tool in the study of disease in animal models. A second model is the chemical used by exterminators, rotenone, which is an inhibitor of mitochondrial complex I activity (4).

Both of these toxins cause the loss of dopaminergic neurons. Outside of this observation, their relation to PD is unclear. However, accumulation of α -synuclein is seen in some models developed with both of these substances. Neither are known to cause Lewy bodies. Accumulation of ubiquitinated proteins has been reported for rotenone treatment but is not generally a feature of the MPTP model. It is not clear if the absence of Lewy bodies in these models represents a fundamental difference between the model systems and the genetic causes of PD, or, alternatively, if there is a peculiarity of PD in humans that promotes Lewy body formation not seen in animals. It is worth noting, however, that there are causes of parkinsonism in humans (such as PSP described above) which do not cause Lewy bodies. Parkinsonism has many causes, some of which lead to Lewy bodies, and those causes associated with Lewy bodies probably lead to the most common form of Parkinson's disease.

Clinical Relevance

The monogenic causes of Parkinson's disease described above are rare. In all likelihood, the risk of developing Parkinson's disease for individuals without a positive family history of disease will be due to a combination of genetic predisposition and environmental triggers. However, the study of the genetic

causes of Parkinson's disease is important for a number of reasons. Current treatment for Parkinson's disease is merely symptomatic; no interventions exist which interrupt the inexorable disease progression or which protect the nervous system from damage. Neuroprotective strategies in Parkinson's disease (PD) are being developed. Pre-symptomatic diagnosis is of extreme importance should such interventions be identified; it is thought that by the time a patient presents with motor manifestations, approximately 70% of the neurons in the substantia nigra have been lost and therefore the maximal desired impact of therapeutics is not possible. The families in which Parkinson's disease occurs in a Mendelian fashion will be key for the study and determination of such early diagnostic features. Therefore, the study of the genetic causes of Parkinson's disease remains of value, as it allows us to unravel the underlying biological mechanisms leading to Parkinson's disease, which in turn will allow development of better treatments and diagnostic methods.

Patch Clamping

CLAUDIA EDER

Institute of Physiology, Medical Faculty Charité,
Berlin, Germany

claudia.eder@charite.de

Definition

Patch clamping is a powerful method for studying ion currents in ► [biological membranes](#). In patch clamp experiments, charge movement caused by ion flux through ion channels or transporters is measured in a closed electrical circuit (1, 2). Patch clamping allows recordings of either single channel currents or of currents from entire cells or organelles. Single channel currents can be measured in patches of the membrane in intact cells or in excised patches. The sum of single channel currents produces the whole cell current of a cell. The patch clamp technique has made it possible to characterize the biophysical and pharmacological properties of ion channels and electrogenic ion transporters. Patch clamp recordings can be performed under *in vitro*, *in situ* or *in vivo* conditions.

Ion channels and ion transporters are membrane proteins that control the flow of ions across cellular membranes and therefore influence the behavior of all cells (3). By regulating intracellular ion concentrations and membrane potential, ion channels and transporters modulate cell volume, excitability, proliferation, migration, secretion and other cellular processes.

Description

Patch Clamp Set-up

The patch clamp set-up consists of at least a vibration-isolated table, a microscope, a micromanipulator, the patch clamp amplifier and a personal computer. The patch pipette filled with electrolyte solution is held in a pipette holder, which is mounted on a micromanipulator so that the patch pipette can be moved towards a cell. A silver-silver chloride wire connects the patch pipette solution and the patch clamp pre-amplifier (which is called the headstage). Another silver-silver chloride wire in the bath chamber is connected to the headstage and serves as the ground electrode. The headstage contains a current-to-voltage converter and is connected to the amplifier (Fig. 1a). Voltage- and current-clamp protocols are generated and controlled by a personal computer, which is also used for data storage. In some cases, additional micromanipulators are used to position stimulation pipettes, additional patch pipettes or superfusion systems.

Patch Clamping. Figure 1 (a) schematic representation of a patch-clamp setup. (b) Different patch-clamp configurations. The patch-pipette is brought into contact with the cell surface membrane, slight suction is applied to achieve a dense seal (giga-seal); cell-attached configuration. Whole cell configuration is reached when further suction is applied to break the membrane inside the tip. Excised patch configuration (inside-out and outside-out) is reached when the piece of membrane attached to the tip is excised from the cell. For further details see text.

Patch Clamp Configurations

In conventional patch clamp recordings, glass or fused quartz pipettes having a tip diameter of about 1 μm are used. Pipette tips are usually fire-polished immediately before using, because a very clean surface is required for these recordings. To carry out the patch clamp recording, the fire-polished pipette filled with electrolyte solution is brought into close contact with the surface of a cell (Fig. 1). Application of gentle suction to the inside of the pipette increases the resistance

between the glass pipette and the cell membrane reaching values of up to 100 gigaohms. The tight contact between the pipette tip and the membrane, which is called a **giga-seal**, prevents ion flux between pipette solution and bath solution. Thus, the small patch of membrane within the tip is electrically isolated, so that measurements of currents that are carried by ions flowing into or out of that cell patch through ion channels are possible. This configuration is called the cell-attached configuration. Depending on

the exact size of the membrane patch under the pipette and the density of ion channels in the membrane, activity of one or more ion channels can be detected. In the cell-attached configuration it is possible to alter the composition of the extracellular medium in the pipette, but there is no direct access to the inside of the patch, i.e. the intracellular milieu remains intact (Fig. 1).

Once the cell-attached configuration is obtained, other recording configurations can be produced (1, 2). Due to the mechanical strength of the giga-seal, the membrane patch at the pipette tip can be pulled away from the surrounding cell. Withdrawing the pipette will excise a patch with the internal membrane surface facing the bath solution and the external surface facing the pipette solution. This patch clamp configuration is called inside-out configuration. It is mainly used for the testing of various intracellular channel modulators, such as calcium, ATP, kinases and phosphatases, because these agents can easily be exposed to the intracellular side of the membrane by bath perfusion.

Alternatively, after reaching the cell-attached configuration, additional suction can be used to break the membrane within the tip, thus creating the whole-cell configuration. Whole-cell recordings permit diffusional exchange of the pipette solution with cytoplasmic constituents. After the establishment of the whole-cell configuration, pulling the pipette away from the cell will excise a patch with the extracellular side of the membrane facing the bath solution and the intracellular side facing the pipette filling solution. This patch clamp configuration is called outside-out configuration.

The disadvantage of outside-out and whole-cell recordings is that normal second messenger systems can be dialyzed out, which may result in current run-down. Therefore, the perforated patch-clamp method has been applied to achieve electrical access to the cell while minimizing cytoplasmic dialysis (4). This method involves briefly dipping the pipette tip in normal pipette solution and then backfilling with solution to which nystatin, amphotericin or gramicidin have been added. After giga-seal formation, these molecules form small pores in the membrane patch within the pipette. The pores lower the access resistance of the patch enough to allow voltage- or current-clamp of the whole cell membrane. These pores are exclusively selective for monovalent ions. They do not allow divalent ions and larger molecules such as proteins to pass. In ▶perforated-patch recordings normal intracellular Ca^{2+} buffering and second messenger mechanisms within the cell remain intact.

Patch Clamp Protocols

In general, the membrane currents of a cell are measured in the ▶voltage clamp mode of the patch clamp technique where the membrane potential is

controlled and the current activated at a certain potential is monitored (3). The holding potential is usually clamped near the resting membrane potential of the cell. Ion currents are studied using either voltage pulse or voltage ramp protocols. Voltage pulses are usually applied from a negative holding potential to a certain potential for a duration of a few milliseconds or seconds. This approach allows investigations of current kinetics, such as voltage- and time-dependent activation and inactivation behavior. Application of voltage ramps means that the membrane voltage is steadily increased from a negative to a positive potential (or in the opposite direction) within a few milliseconds or seconds. The advantage of voltage ramp protocols is that the activation threshold and reversal potential of currents can be easily estimated and changes in current amplitude can be visualized over the whole voltage range. The disadvantage is that time-dependent gating (opening and closing kinetics) will distort and complicate the data.

▶Current clamp recordings are used to monitor changes in the resting membrane potential of a cell (3). Furthermore, by application of various current pulses, electrical behavior, such as the pattern of action potentials, can be observed in excitable cells.

Combination of the Patch Clamp Technique and Single Cell PCR

The combination of the patch clamp technique and a molecular biological technique, namely single cell reverse transcription polymerase chain reaction (▶RT-PCR), permits correlation of the functional properties of individual cells with their specific gene expression profile. The patch clamp technique enables the harvesting of messenger RNAs (mRNAs) from a single living cell. During whole cell recording of ion channel activity, the cell interior is dialyzed with the internal solution contained in the patch pipette. After a sufficiently long recording, the electrode solution contains RNA. To obtain the remaining cytoplasmic RNA, suction is applied to the interior of the pipette before termination of the recording. The pipette contents are then expelled into a sterile reaction tube and used for subsequent RT-PCR experiments.

Clinical Applications

Ion channel dysfunction can lead to the appearance of clinical signs and symptoms. Such diseases are called ▶channelopathies. Three major types of channelopathy have been described so far: i) genetic, in which ion channels function abnormally or fail to function as a result of mutations, ii) autoimmune, in which antibodies perturb channel function and iii) transcriptional, which result from changes in the expression of non-mutated channel genes. Several efforts are currently

being made to develop new drugs that are capable of modulating ion channel activity, i.e. acting specifically either to restore ion channel functions or to inhibit ion channel activity. Although patch clamping remains the sole technique with the sufficiently high time resolution and sensitivity required for precise and direct characterization of ion channel properties, the conventional patch clamp technique is not practical for high throughput drug screening. The conventional patch clamp technique requires a skilled operator to manipulate the glass pipette onto the cell manually. It is a slow, labor intensive and thus expensive technique. This fact underlies current efforts directed towards improving the throughput of the conventional patch clamp technique in order to facilitate drug screening and to assay the function of genes that encode ion channel and transporter proteins directly. As an approach for high throughput screening for ion channel modulators, automated patch clamp systems have been developed (5, 6). These systems are often based on an array of planar chips. They allow multidrug and multiconcentration applications on a single cell and recordings can be performed in a great number of cells simultaneously.

Therapeutic Consequences

A number of common diseases, including epilepsy, cardiac arrhythmia, hypertension and type II diabetes, are primarily treated by drugs that modulate ion channels. Current studies aim at the development of more specifically acting drugs in order to minimize unwanted side effects. High throughput automated patch clamp systems will facilitate drug screening. The subsequent development of new drugs will lead to a better understanding and finally to a more efficient treatment of various channelopathies.

Patterson Function/Patterson Map

Definition

In X-Ray structure analysis, the Patterson function is defined as the convolution of the electron density with its own inverse, or equivalently, the Fourier transform of the diffraction intensities. The resulting map (Patterson map) calculated using this equation is essentially a map of all interatomic vectors of the crystal contents. The Patterson map can be used to locate anomalous scatterers (for instance heavy atoms) in the crystal.

PCR

Definition

A method for rapidly amplifying a small amount of DNA using a heat-stable polymerase and two oligonucleotide primers, one complementary to the (+) strand at one end of the sequence to be amplified, and one complementary to the (−) strand at the other end. In a series (typically 30) of temperature cycles, the DNA is repeatedly denatured, annealed to the primers and a daughter strand extended from the primers. As the daughter strands themselves act as templates for subsequent cycles, DNA fragments matching both primers are amplified exponentially. Thus, the original DNA need be neither pure nor abundant. PCR has become widely used not only in research, but in clinical diagnostics and forensic science.

Peptide Aptamers

PIERRE COLAS

Aptanomics, Lyon, France

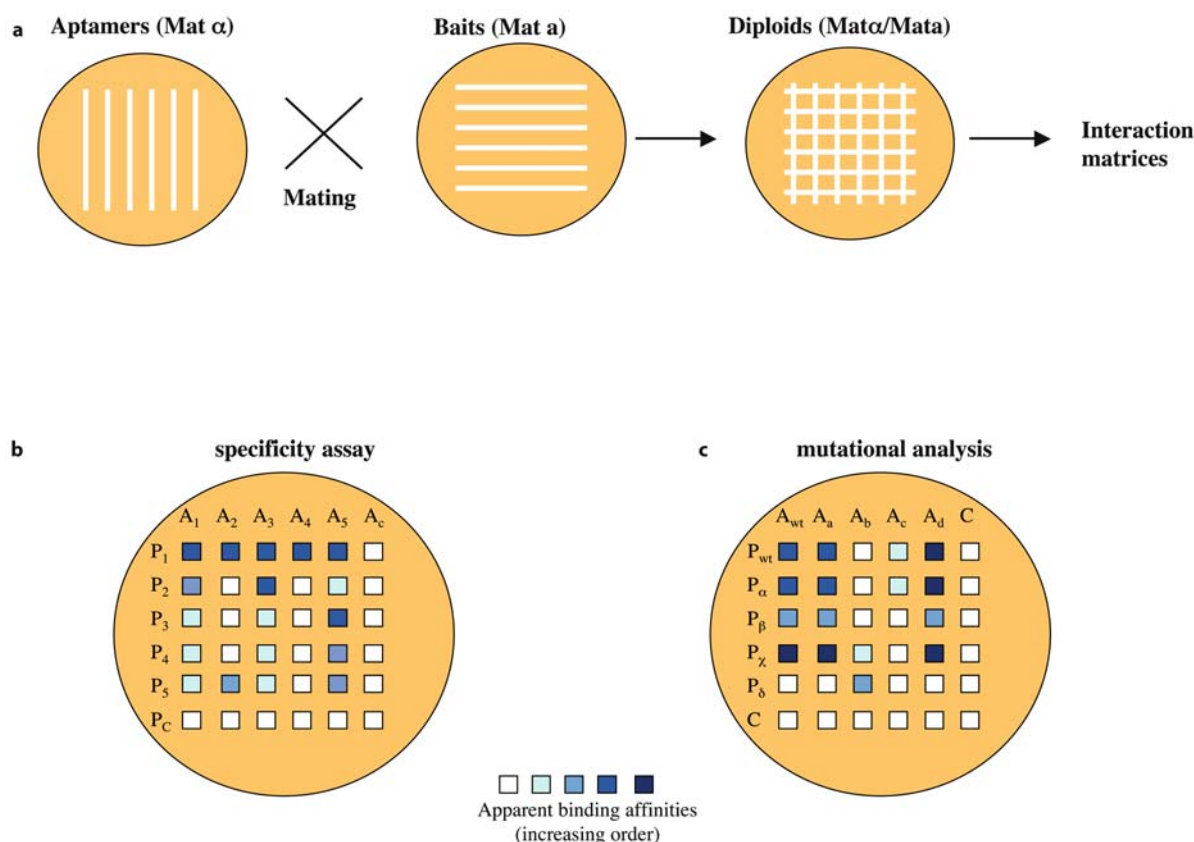

pierre.colas@aptanomics.com

Synonyms

Perturbagens, Peptamers

Definition

Peptide aptamers (from the Latin aptus: to fit) are an emerging class of recognition molecules that typically consist of a constant protein scaffold displaying a variable peptidic sequence inserted within the scaffold (1, 2). Two key features distinguish peptide aptamers from other combinatorial proteins (3). First, the variable region is inserted within the coding sequence of the protein scaffold in such a way that it is fused and thus constrained at both its amino- and carboxy-termini. This double constraint protects the aptamers from proteolysis and promotes increased binding affinity by reducing their conformational freedom. Second, peptide aptamers are generally isolated from combinatorial expression libraries through the use of intracellular selection methods. This contrasts with most combinatorial biology methods where ligands are selected *in vitro* and are thus often not suitable for intracellular targets. The ► yeast two-hybrid system is

Peptide Aptamers. Figure 1 Two-hybrid mating assays to determine peptide aptamer binding specificity and to map target binding site and aptamer pharmacophore. (a) Plasmids directing the expression of aptamers fused to an activation domain on the one hand, and of proteins fused to a DNA binding domain (baits) on the other hand, are transformed into yeast strains of opposite mating type. The transformants are streaked linearly on their respective selection media, as depicted. The streaks are then crossed on rich medium to allow yeast to mate at each intersection. The resulting diploid yeasts are then grown on selective medium. Different two-hybrid reporter genes can be used. They are typically carried by a plasmid that is co-transformed with the bait plasmids. Here, the *lacZ* gene is employed, conferring a blue phenotype on a X-gal-containing medium. The intensity of the blue color reflects the apparent binding affinity. Other reporter genes such as GFP or luciferases can be used to perform more quantitative binding assays. (b) specificity assay of a collection of peptide aptamers selected for their ability to bind a protein P_1 . P_{2-5} are proteins that belong to the same family as P_1 . P_c and A_c are an unrelated bait and aptamer, respectively. A typical result is schematized, where aptamer A_4 is highly specific for P_1 , aptamer A_2 exhibits a dual specificity for P_1 and P_5 , and the other aptamers show various specificity profiles against the protein family. (c) mutational analysis of a target-aptamer complex. P_{wt} and A_{wt} are the non-mutated protein and aptamer, respectively. $P_{\alpha-\delta}$ and A_{a-d} are different mutated variants (typically single aminoacid substitutions). A_a and P_a carry silent mutations. A_c and P_β carry loss-of-function mutations, whereas A_d and P_γ carry gain-of-function mutations (here, binding is assimilated to function). A_b and P_δ both carry loss-of-function mutations that compensate for each other and restore binding. Such mutational analyses greatly benefit from the use of reporter genes supporting a more accurate quantification of the binding affinities.

widely employed to select peptide aptamers for their ability to bind a given target protein. Peptide aptamers are also isolated for their ability to confer a selectable phenotype on a cell population, through a **transdominant genetic effect**. Fewer aptamers have been selected through extracellular display systems or have been designed from naturally occurring protein-binding surfaces. Peptide aptamers specifically bind target

proteins and modulate their function, often by inhibiting their interaction with other proteins. Hence, peptide aptamers are powerful tools for unraveling molecular regulatory networks and for identifying and fully validating new therapeutic targets. Moreover, peptide aptamers hold great promise in guiding the discovery of new therapeutic molecules that inhibit intracellular protein interactions.

Characteristics

Molecular Design

So far, the most frequently used peptide aptamer scaffold has been thioredoxin, a small ubiquitous disulfide reductase that maintains intracellular proteins in their reduced state. To construct combinatorial libraries, oligonucleotides of random sequence are cloned into the cDNA of thioredoxin, within its active site (2). Other scaffolds such as green fluorescent protein (GFP) or a catalytically inactive mutant of staphylococcal nuclease have also been used. Most libraries reported so far have featured variable peptidic loops of 20 amino acids, but this length can be adjusted as desired.

Specificity and Affinity

Peptide aptamers exhibit precise specificities for their target proteins. Typically, they can discriminate between different members of a protein family (e.g. the cyclin-dependent kinases) or even between different allelic variants of a given protein (e.g. Ras). The determination of their binding profile towards a protein family or a panel of mutants can be advantageously performed through two-hybrid interaction mating assays (Fig. 1a,b). The binding affinity of peptide aptamers can lie within the nanomolar range and can be further improved by random mutagenesis of the peptidic loop, followed by a more stringent selection (2). Semi-quantitative two-hybrid assays can accurately determine relative binding affinities between a target protein and a collection of peptide aptamers.

Inhibition of Protein Function

Most peptide aptamer collections selected for their ability to bind a target protein contain aptamers that inhibit the function of this protein and that produce compelling phenotypes when expressed in cellular models (1). Examples include aptamers targeting cell-cycle regulators (Cdk2, E2F, cyclin J), viral proteins (HPVE6 and E7, HBV core protein), a small G-protein (Ras), a small G-protein activator (Rho-GEF), a receptor tyrosine kinase (EGF-R) and a transcription factor (Stat3). Some of these aptamers have been shown to produce phenotypes when expressed in *Drosophila*. In all cases, it has been shown or strongly suggested that peptide aptamers interfered with their target protein by preventing it from interacting with one or more of its natural partners (Fig. 2). When aptamers are selected for their ability to produce a selectable phenotype, the challenge is to identify their target protein. This can be done by screening two-hybrid cDNA libraries against the selected aptamer, which is used as a bait protein. A complementary method consists of producing the selected aptamer in *E.coli*, coupling it to a solid

Peptide Aptamers. Figure 2 Peptide aptamers to manipulate regulatory networks. (a) a protein complex is depicted, where a target protein T interacts simultaneously with two partners A and B. (b) a peptide aptamer selected against T disrupts the T-A interaction without affecting the T-B interaction. (c) a similar protein complex formed between T' (closely related to T), A and B' (closely related to B) is not affected by the aptamer because it discriminates between T and T'. (d) a peptide aptamer derivative is built by fusing the catalytic domain of an enzyme to an aptamer selected against T, which is normally not a substrate of this enzyme. The aptamer derivative directs the specific modification of T by the enzyme (for example ubiquitination or phosphorylation).

phase and capturing the target protein from a cellular lysate. The captured proteins are identified by mass spectrometry.

Manipulations on Molecular Regulatory Networks

Peptide aptamer derivatives have been designed to enhance the range of manipulations that can be exerted on regulatory networks, beyond the disruption of protein interactions (1). Such derivatives consist of fusion proteins comprising a targeting domain (a peptide aptamer) and an effector domain (e.g. an enzyme catalytic domain or an addressing sequence). Peptide aptamer derivatives have been shown to direct the specific ubiquitination of their target protein in living cells or to modify its intracellular localization (Fig. 2d).

Clinical Relevance

Identification and Validation of Therapeutic Targets

The problem of validating therapeutic targets remains highly complex because it relates to fundamental biological questions and it suffers from the inadequate nature of many of the proposed methods. Biological processes are finely controlled by highly intricate protein interaction networks. Methods that inhibit or abolish gene expression (RNAi, antisense technology, gene knockout) often introduce severe molecular perturbations within such networks. In some cases,

no clear phenotype is obtained because compensatory or redundant mechanisms within protein families maintain homeostasis. In other cases, a strong phenotype is observed because of extensive secondary

deregulation within the network. Therefore, putative therapeutic targets may be either wrongly ruled out or wrongly validated if evaluated solely by such disruptive methods. Peptide aptamers introduce finer

Peptide Aptamers. Figure 3 Peptide-aptamer based discovery of small molecule drugs. A model of the interaction (not to scale) between a target protein and its peptide aptamer is obtained from structural studies and the mutational analysis depicted in Figure 1c. A simple case is presented, with no contribution of the aptamer scaffold (other than the double constraint imposed on the peptidic loop) to target binding. The model defines a binding site on the target protein, and a pharmacophore on the peptide loop of the aptamer. The colored symbols represent various physico-chemical descriptors that mediate binding (such as hydrogen bond donors and acceptors, hydrophobic and charged patches, defined spatial constraints, etc.). Computational chemistry software is then used to define small focused libraries enriched in small organic molecules that fit the target binding site and/or that conform to the aptamer pharmacophore. For a target-based or an aptamer-based pharmacophore search, the first step consists of defining the spatial distribution of a small set of descriptors from the structure of the target binding site (δ - χ - β) or from the structure of the binding determinant on the aptamer (b-c-d), respectively. The software then analyzes a virtual chemical library assembled from commercially available molecules and optionally from molecules that can be easily synthesized. Those molecules that do not comply with the defined sets are excluded. This low-resolution method is performed rather quickly with limited computational power. Virtual screening is a more accurate method that can be used whenever the target binding site is amenable to reliable molecular docking (typically deep pockets). Here, an exhaustive atomic representation of the pocket rather than a limited set of descriptors is defined. All molecules from the virtual library are screened against this pocket and are assigned a score that reflects the predicted fit. This method is much slower than pharmacophore search (one molecule per minute) and requires a higher computational power. The small focused libraries defined by these *in silico* approaches are then screened.

molecular perturbations that, like those exerted by small molecule drugs, are a direct consequence of the targeting of a specific binding site on the target. Hence, peptide aptamers validate therapeutic targets with higher confidence levels than other methods and they also provide a first indication of the druggability of the targets. Moreover, phenotypic selections of peptide aptamers allow the identification of new therapeutic targets, which are *de facto* validated prior to their identification.

Aptamers as Biotherapeutics

In view of the increasing therapeutic successes of ►monoclonal antibodies, it is conceivable to use peptide aptamers as biotherapeutic molecules. However, the usual issues of stability, toxicity and immunogenicity will probably require the exploration of various scaffold proteins. An additional difficulty will arise when targeting intracellular proteins, although it has been shown that peptide aptamers can penetrate living cells when fused to ►protein transduction domains (PTDs).

Aptamers as Guides to the Discovery of Therapeutic Molecules

Peptide aptamers are powerful guides to the discovery of small molecule drugs. Selected from combinatorial unbiased libraries, peptide aptamers “interrogate” protein surfaces to find new potential druggable sites. Various screening assays (such as yeast two-hybrid or fluorescence polarization) can be set up to discover small molecules that disrupt the interaction between a peptide aptamer and its target protein. Those hits that displace this interaction by targeting the protein are candidate mimics of the aptamer. To enhance the hit rates, a structure-based approach can be undertaken to circumscribe the chemical spaces to be screened. The structure of the aptamer bound to its target can be solved by NMR or the complex can be co-crystallized. The outcome of this approach is facilitated when the structures of the target protein and the aptamer scaffold are already known (as for thioredoxin). Besides these structural studies, the modeling of the interaction is greatly facilitated by performing quantitative two-hybrid assays with mutated variants of both target protein and peptide aptamer (Fig. 1a,c). A model of interaction defines a binding site on the target and a ►pharmacophore on the aptamer, which modern computational chemistry tools can convert into small molecule candidates to be screened (Fig. 3).

Peptide Aptamers to Exploit Protein Interactions for New Therapies

There is now mounting evidence that protein-protein interactions constitute a huge but still largely untapped pool of therapeutic targets. Although typical binding

interfaces are rather large, they contain “hot spots” that concentrate binding energy and can be targeted by small molecules. Moreover, many protein interactions can be inhibited through allosteric mechanisms, without the need for the aptamer or the therapeutic molecule to directly interfere with the binding interface.

Considerable resources have been invested collectively in establishing highly complex protein interaction maps in order to decipher molecular regulatory networks and to identify putative targets. The first challenge is now to identify which interactions are worth pursuing as therapeutic targets. The second major challenge is to discover small molecule drugs that disrupt these interactions. Peptide aptamers appear to be ideal tools to help achieve these two exciting endeavors.

Peptide Chips

RUDOLF VOLKMER-ENGERT

Molecular Libraries, Institute for Medical Immunology, Charité – University Clinical Center Berlin, Berlin, Germany
rve@charite.de

Definition

Peptide chips are miniaturized peptide arrays that are used as assay systems for large-scale and high-throughput biological analysis. In a peptide microarray format, peptides as capture molecules are immobilized in a small area on planar solid surfaces and probed for various biological or biochemical activities. Peptide arrays refer to a format of flat surfaces on which peptide sequences are organized in rows and columns which can be independently arranged. The array format uses a precise, spatially ordered arrangement of compounds that allows them to be examined side-by-side. This is in contrast to the library approach in which a huge set of related compounds are tested in batch followed by an additional selection step to isolate the candidate molecules with desired biological properties.

Peptide arrays can be generated on different planar solid surfaces by several methods, including deposition of pre-synthesized peptides with the aim of robots or by parallel peptide synthesis methodologies directly on a planar solid support. The density of the sequences on a peptide array ranges from 20 peptides per cm^2 (peptide macroarray) up to over a few thousands in a square cm area (arrays of minute size so called microchips). The typical peptide microarray is produced with densities of approximately 200 sequences per cm^2 on a glass slide and is called peptide chip.

Description Introduction

The examinations of protein activities and function have been carried out historically on the analysis of single molecules. However, the rapid pace of discovery of new gene products by genomic and proteomic initiatives have necessitated the design of alternative strategies for analyzing protein function. The possibility to determine thousands of different parameters in a single experiment perfectly fits the needs of so called “omic” approaches in biology. As demonstrated by DNA microarray experiments (“▶DNA chip”) the array format is a robust, reliable and established method for the global analysis of gene expression and allows a global view into the ▶transcriptome of a living cell or organism on the basis of a single experiment (1). But, it became obvious that the information obtained from DNA chips is not sufficient to understand life in general. The expression level of genes or mRNA does not close correlate with the abundance of functional protein molecules that are the principal components in organizing and mediating the physiological functions of any living cell. A proteome comprises not only sequence information about all the proteins in a cell, but also their quantity, localization, activity, modifications, interaction networks and regulation. In general, protein and peptide arrays are able to support proteomic research. Whereas protein arrays (reviewed in 2) are suited to investigate which protein interact with each other, peptide arrays enable one to precisely characterize molecular recognition events at the amino acid level (3). Peptides are chemically quite resistant compounds and, in contrast to proteins, usually have no folding requirements to achieve their active conformation. Beside their privileged role as biologically active molecules, peptides are accessible in a high degree of structural diversity through modern peptide synthesis approaches and molecular biology. Their chemistry is well established and routine. Chemical synthesis allows incorporation of non-natural building blocks, preparation of branched and cyclic structures and labeling with chromophores. Thus, peptides are perfect probe molecules for a robust screening assay.

Peptide Array production

Normally, two main principles are used for the preparation of peptide arrays. Firstly, the *in situ* peptide synthesis performed directly on the array surface. Secondly, the robotic supported immobilization of pre-synthesized peptide derivatives on modified array surfaces.

The direct peptide synthesis on a surface is seen as effective means of miniaturization of traditional chemical reactions. Peptides were prepared in parallel on the surface by a step by step solid phase peptide synthesis approaches. Two methods are reported in literature: (i) The light-directed, spatially addressable parallel chemical synthesis (reviewed in 4) and (ii) the SPOT synthesis concept (reviewed in 3 and 5).

The first one is a technology that permits extreme miniaturization of the peptide array formats. Addressable peptide arrays have been generated by this approach, using photomasks and photolability-protected amino acids. The synthesis involves multi-cycles with each cycle using light irradiation through a photomask followed by adding one type of amino acid to specific locations where the photo-labile protecting group on the terminal of the growing chain has been removed upon light irradiation. The amino acids used in the synthesis are not conventional but protected at the amino position with a photo-labile protecting group. Although promising for high-density microchips, the process has its limitations because production of photomasks is time consuming, expensive and requires a high-grade clean-room environment. Furthermore, most of the amino acids containing photolabile protecting groups are not commercial available and the photochemistry used is less efficient than conventional

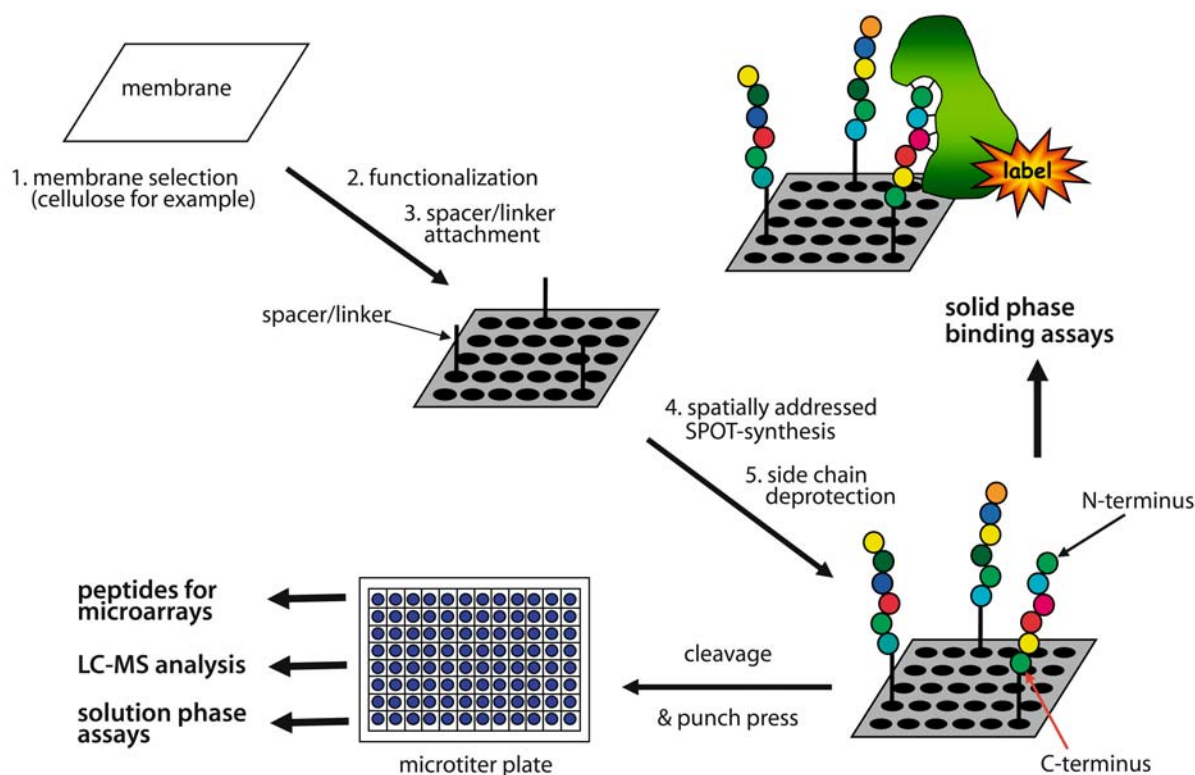

▶Boc chemistry or ▶Fmoc chemistry. That results in a poor stepwise yield and reduces the quality of the surface-bound peptides. As a consequence higher rates of false positive and false negative results are observed in the screening assay. An interesting alternative is the use of a novel photogenerated reagent chemistry combined with digital ▶photolithography and standard Boc chemistry (6). It based on an addressable photo-generated acid-formation using digital photolithography. Subsequently, the generated acid deprotects the t-Boc group of the growing peptide chain and releases the amino-terminus which is then amidated by an activated amino acid. Up to 4000 features in a 1.5 cm^2 area were synthesized on a microchip format (4).

The SPOT technique developed by Ronald Frank (7) consists of the stepwise synthesis of peptides on planar supports, such as amino-functionalized cellulose membranes or aminated polypropylene, applying standard Fmoc chemistry. The basic principle involved the positionally addressed delivery of small volumes of activated amino acid solutions directly onto a coherent

membrane sheet. The areas wet by the resulting droplets can be considered as micro-reactors provided that a non-volatile solvent system is used. The functional groups fixed on the membrane surface react with the pipetted reagents and conventional solid phase syntheses occur. The volumes dispensed as well as the physical properties of the membrane surface and the solvent system define the size of the resulting spots and together with the minimum distance between the spots the number of peptides which can be synthesized per membrane area. The SPOT technique is technically very simple and flexible and does not require any expensive laboratory automation or synthesis hardware. The degree of miniaturization using the SPOT synthesis concept is significant lower than the microchip format described above. In general up to 20 peptides can be prepared in a square cm area. Peptide arrays prepared by the SPOT technique became popular tools for studying numerous aspects of molecular recognition. Over the past decade ►B-cell epitope and ►paratope mapping, characterisation of numerous protein-protein interactions, enzyme-substrate recognition, inhibitory activity, peptide-metal ion interaction, peptide nucleic acid binding, ►T-cell

epitope mapping and the direct action of peptides *in vivo* have all been explored using synthetic peptide arrays on cellulose membranes prepared by the SPOT technique. Moreover, the SPOT technology has become a highly parallel and high throughput peptide synthesis tool. It enables the parallel synthesis of up to 2000 peptides in a very short time (one week) and at amount of approximately 50–100 nmol. Hence, SPOT synthesis is the prerequisite for the preparation of peptide microarrays (peptide chips). Figure 1 schematically shows the basics and applications of the SPOT technique.

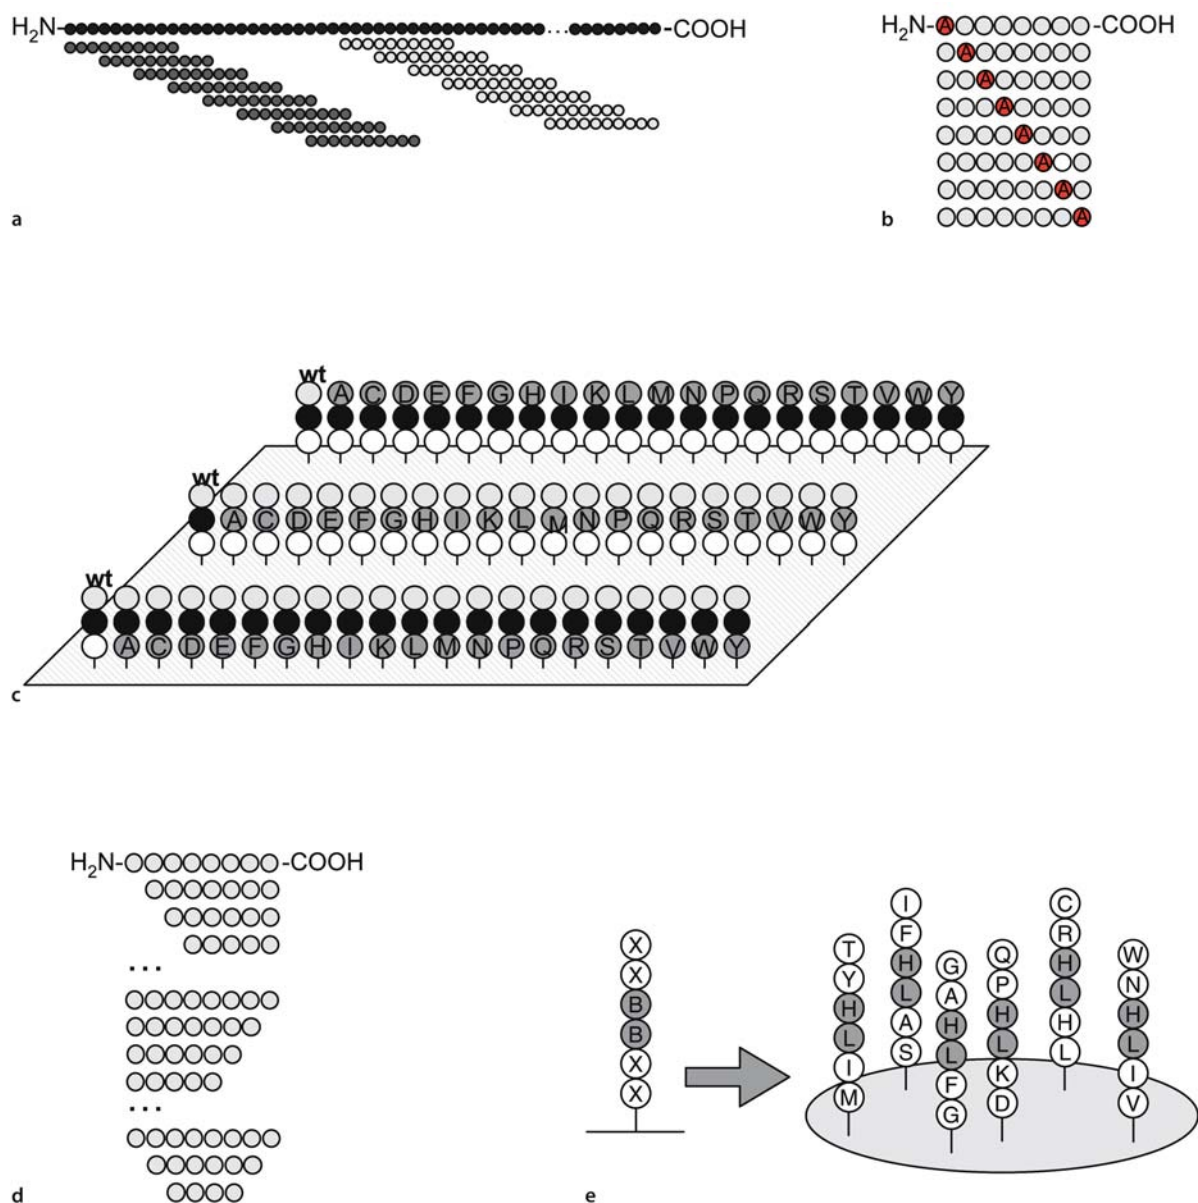

When large numbers of peptide arrays with the same sequences are required, immobilization of pre-synthesized peptides is more economical than *in situ* synthesis. In general long peptide sequences have to be purified to obtain high-quality products. Therefore immobilization is also the method of choice for that kind of peptides. Typically immobilization takes place on surface-functionalized glass slides, but self-assembled monolayers on gold surface have also been employed as a surface-modification tool. Chemoselective immobilization reactions are of particular interest in preparation of peptide arrays because they allow

Peptide Chips. Figure 1 Schematic view of the SPOT synthesis technique. Peptide arrays prepared by SPOT synthesis can be applied to solid phase binding assays as well as solution phase binding assays. With the possibility to cleave the compounds from the planar support peptide could be analyzed and applied to the fabrication of peptide chips.

control over both the orientation and the density of the attached peptide. Different chemoselective reactions were used for peptide microarray preparation. Only a few examples are given. An aldehyde function at the surface of a glass slide in combination with aminoxy-acetyl moieties in the peptide or cysteinyl residues was used for the preparation of peptide microarrays on glass slides. Also the native chemical ligation method is well suited for effective attachment of N-terminally

labelled peptides to thioester-modified glass slides. A more sophisticated reaction for an oriented immobilization of peptide derivatives is the Diels-Alder reaction between bezoquinone groups on self-assembled monolayers and cyclopentadiene-peptide conjugates. In the most cases of chemoselective peptide immobilization a spacer molecule is inserted between the peptide and the surface. This is done in respect to the accessibility of the surface-bound peptides to the proteins used in the

Peptide Chips. Figure 2 (a) The primary sequence of the protein to be examined is used to generate short linear overlapping 10mer peptides shifted by three amino acids (peptide scan). screening. Insertion of hydrophilic dextran structures between the surface and the presented peptide or incorporation of 1-amino-4,7,10-trioxa-13-tridecanamine succinimic acid as a spacer moiety have been described. Microarrays prepared by immobilization of pre-synthesized peptides on glass slides are predominantly used up to now for the identification and optimization of ►kinase substrates. They are produced typically with a peptide density of approximately 200 sequences per cm².

Peptide Library Types

A considerable number of different library types have been used for the investigation molecular recognition events. Two general types can be defined: knowledge-base libraries, comprising peptides with sequences that are derived from naturally occurring proteins, and libraries that are designed *de novo*, that is, either consisting of randomly generated single peptides or peptide mixtures based on combinatorial principles. The first knowledge based library is of particular interest for the mapping of protein-protein binding

sites, identification of the actual phosphor-acceptor residue of a known protein as a kinase's target and B-cell epitope or T-cell epitope mapping. Identification of the binding site of interests is achieved by a scan of overlapping peptides derived from the sequence of one or both interaction partners (Fig. 2a). The entire sequence of the protein whose epitope to another protein has to be determined is synthesized as a group of overlapping peptides usually between 8 and 15 amino acids in length which are shifted between one and five positions. Incubation of such a peptide scan with the binding partner and detection of peptide-bound protein by immunological methods, enzymatic reactions with chemoluminescent or chromogenic substrates, fluorescence or autoradiography reveals one (linear epitope) or more (discontinuous epitope) stretches of the protein which are part of the binding site. For closer characterization of the key residues of such binding regions i. e. amino acids with side chains which are effectively in contact with the receptor protein, substitution analyses are carried out by exchanging every position – but only one at a

Peptide Chips. Figure 3 Assay types and detection methods applied to peptide microarrays. (a,b,c) show the detection of protein binding to an immobilized peptide. (a) Detection of binding is mediated by the fluorescence or radioactive label directly incorporated at the protein. (b) In the case a fluorescently labelled non neutralization antibody is applied. In case b) binding is mediated by a secondary labelled antibody. (c) Protein-peptide interaction is mediated via a protein tag (here a GST tag) in combination with a fluorescently labelled antibody. (d) Detection of peptide phosphorylation on peptide microarrays. The array is incubated with the kinase of interest in the presence of [γ-³² or ³³P]ATP, and autoradiography is used for detection.

time – by either alanine (Fig. 2b) or by all other L-amino acids (Fig. 2c) resulting in all possible single site substitution analogs. Key residues may not be exchanged by any other or only by physicochemically similar amino acids without loss of binding. Truncation libraries (Fig. 2d) are used to determine the minimal length of the peptide sequence that is still recognized by the protein of interest. For *de novo* detection of B cell epitopes and kinase substrates both combinatorial approaches and randomly generated libraries of single peptides have proven to be useful. Combinatorial libraries have one or more defined amino position and a number of randomized or degenerated positions. Only one amino acid is introduced at the defined positions, while a mixture of amino acids is introduced at the randomized position. This results in a sublibrary of different sequences in each single spot (Fig. 2e).

Assays and detection

Detection methods in analyzing any array are required to offer high throughput, high signal-to-noise ratio, relatively low instrumentation costs, good resolution, and reproducible results. Many applications have used fluorescently labeled detection methods, because they are simple and stable to manipulate, they provide highly sensitive and resolved results and they are compatible with the standard array scanners developed for DNA microchips. Although radioactivity is also suitable for analyzing arrays, especially for enzymatic phosphorylation, due to sensitivity and specificity as well as the possibility of fluorescence detection, the use of isotope-labeled molecules raises safety concerns. Chemiluminescence is also highly sensitive however at present gives relatively lower resolution and relatively limited dynamic range. This detection method is mostly applied to the field of SPOT synthesis. Figure 3 shows assays as well as detection methods that are typically applied to peptide microarrays.

Peptide Mass Fingerprinting

Definition

Peptide Mass Fingerprinting (PMF) is a mass spectrometry based method for protein identification. The protein is cleaved by an enzyme with high specificity (trypsin, Lys-C, Arg-C, Asp-N, etc.) or chemically (CNBr). The generated peptide mixture is analyzed by ▶[Matrix-Assisted Laser Desorption/Ionisation \(MALDI\)](#) or electrospray ionisation (▶[ESI](#)) mass spectrometry. The determined set of masses (mass fingerprint) is characteristic for the protein present and is used to search peptide masses generated by theoretical fragmentation of protein sequences of databases.

▶[Mass Spectrometry: MALDI](#)

Peptide Mass Map

Definition

A protein can be digested by a protease (usually trypsin). The mass spectrum of the resulting peptides provides a peptide mass map. Because trypsin cleaves after Lys and Arg, the mass map is dependent on the sequence of the protein. Therefore, the peptide mass map can be used to identify the protein after database searching.

▶[Proteomics in Cancer](#)

Peptide Release Factor 2

Definition

Peptide release factor 2 is the enzyme that is responsible for recognizing the codons UAA and UGA in prokaryotes, and for causing termination of protein synthesis.

Peptidomimetic

Definition

Peptidomimetic molecules are molecules that mimic structural features of peptides, but lack some or all of

the amide bonds that link the amino acids in peptides together.

►Protein Prenylation

Peptidyl Prolyl *cis/trans* Isomerases

CORDELIA SCHIENE-FISCHER

Max Planck Research Unit for Enzymology of Protein Folding, Halle, Germany

schiene@enzyme-halle.mpg.de

Synonyms

A short term for peptidyl prolyl *cis/trans* isomerization is prolyl isomerization. According to the recommendations of the Nomenclature Committee of the IU/BMB, enzymes catalyzing prolyl isomerization were named peptidyl prolyl *cis/trans* isomerases in 1984. The colloquial terms prolyl isomerase and proline isomerase are frequently in use.

The alternative name rotamase, launched later on, does not fit the rules of IU/BMB, communicating an imprecise picture of the enzyme function. Also in use is the term immunophilin. Peptidyl prolyl *cis/trans* isomerase cannot be considered synonymous with immunophilins. An immunophilin is molecularly described in terms of high affinity for the immunosuppressant drugs cyclosporin A, FK506 or rapamycin characterizing some members of the cyclophilin and FKBP family. Regarding immunosuppressant affinity, many proteins not related to peptidyl prolyl *cis/trans* isomerases are immunophilic (ubiquitin, G-actin, interleukin 8, and many others), whereas many peptidyl prolyl *cis/trans* isomerases do not exhibit immunophilic properties. Alternative names for FK506 and rapamycin are tacrolimus and sirolimus, respectively.

Definitions

Peptidyl prolyl *cis/trans* isomerases (PPIases, E.C. 5.1.2.8) are enzymes evolved to accelerate the *cis/trans* isomerization of peptide bonds preceding prolyl residues in peptides and proteins. Due to the imidic structure, prolyl bonds have particular electron distribution and steric constraints resulting in both slow conformational interconversions and comparable equilibrium populations of the *cis* (dihedral angle $\omega \approx 0^\circ$) and the *trans* (dihedral angle $\omega \approx 180^\circ$) conformer in digopeptides and unfolded proteins (1). (Fig. 1)

At present, there are three families known, where the individual members can exhibit PPIase activity. They are termed ►cyclophilins (Cyp), ►FK506-binding proteins (►FK506 (Tacrolimus)) (FKBP) and parvulins, which are unrelated in their amino acid sequences,

have distinct substrate specificities and are sensitive to different types of inhibitors. The immunosuppressive drug ►cyclosporin A (CsA) and ►sanglifehrin avidly bind to and inhibit the enzyme activity of cyclophilins. FKBP are able to bind the immunosuppressive drugs ►FK506 or ►rapamycin. These compounds represent reversible tight-binding inhibitors for the majority of FKBP. Until now, a nonpeptidic reversible inhibitor of comparable affinity is not known for parvulins.

All three families comprise prototypic enzyme species consisting of a catalytic domain of 92 (parvulins), 109 (FKBP) or 163 (cyclophilins) amino acids. Many PPIases complement their catalytic domain with N- or C-terminal polypeptide segments of different chain lengths and functionality.

Regarding the substrate specificity, the PPIase families make use of a distinct set of amino acids flanking the proline residues. For cyclophilins, catalytic properties are relatively unaffected by the amino acid preceding proline. FKBP show a preference for substrates with a hydrophobic amino acid in the same position. The Ess1/Pin1 subfamily of the parvulins requires (PO₃H₂)-Ser/(PO₃H₂)-Thr-Pro moieties for high catalytic efficacy.

PPIases are abundant, ubiquitously expressed proteins. All genomes analyzed so far encode at least one PPIase but often far more. Among the 470 predicted coding regions in the bacterium *Mycoplasma genitalium*, which has the smallest known genome of any independently living organism, the FKBP-like trigger factor is the only PPIase present. In *Escherichia coli* there are 2 cyclophilins, 5 FKBP and 3 parvulins, in *Saccharomyces cerevisiae* there are 9 cyclophilins, 3 FKBP and a single parvulin. Presently, the SwissProt database (www.us.expasy.org/sprot/) annotates 16 cyclophilins, 18 FKBP and 2 parvulins for the human genome (2).

Characteristics

Assaying PPIase Activity

PPIases can be identified by their ability to accelerate the *cis* to *trans* isomerization of tetrapeptide substrates of the type Succinyl-Yaa-Xaa-Pro-Zaa-4-nitroanilide (Xaa, Yaa, Zaa are any natural amino acid) in an assay using the conformational specificity of proteases like chymotrypsin or trypsin as a kinetic probe. Practically,

Peptidyl Prolyl *cis/trans* Isomerases. Figure 1

the isomerization reaction is detected by means of the uv/visible absorbance of the released 4-nitroaniline. At high concentrations of the isomer-specific protease, the *trans* isomer of the substrate (~80–95%, dependent on Xaa) rapidly cleaves the anilide bond releasing the chromogenic 4-nitroaniline. Because the protease is not able to catalyze the cleavage of the remaining *cis* isomer (~5–20%) the *cis* to *trans* isomerization of inert conformer is the prerequisite for complete proteolytic cleavage, and thus forms the rate-limiting step for the remaining fraction of the reaction products produced. In the presence of PPIases the relaxation time of the uncatalyzed first-order isomerization reaction of about 125 s at 10°C can be decreased to the millisecond level. By dissolving substrates in dry LiCl/trifluoroethanol the content of *cis* isomer is occasionally increased allowing a higher signal to noise ratio of the assay. Other PPIase assays are based on the rapid disturbance of the *cis/trans* equilibrium of a proline-containing peptide followed by monitoring reequilibration kinetics in the presence of PPIases. As detection methods fluorescence, uv/visible and CD spectroscopy have been utilized. In favorable cases, dynamic NMR spectroscopy allows investigation of the kinetics of prolyl isomerization in peptides and proteins in an unperturbed equilibrium by magnetization transfer experiments. Prototypic PPIases are perfectly evolved enzymes in that they achieve relaxation times of the catalyzed reaction in the range of milliseconds concomitant with low substrate affinity. For oligopeptide substrates, both the Michaelis constant K_M and the turnover number k_{cat} are large, yielding k_{cat}/K_M values close to the diffusion-controlled limits for enzyme reactions ($k_{cat}/K_M > 10^7 \text{ M}^{-1} \text{ s}^{-1}$).

PPIases in ► Protein Folding

Prolyl isomerization often forms a late step in protein refolding because rapidly formed folding intermediates retain the prolyl bond in nonnative conformation and thus retard folding processes. The acceleration of slow folding events by PPIases may serve to avoid accumulation of aggregation-prone intermediates. Therefore, PPIases belong to the class of folding helper enzymes. In support of an *in vivo* role in protein folding, a PPIase of the cyclophilin family was shown to be involved in triple helix formation in type I procollagen in chick embryo fibroblasts. The trigger factors, a prokaryotic subfamily of FKBP, are localized to the large subunit of ribosomes, and can bind to nascent chains suggesting a crucial role in *de novo* protein folding in bacteria.

Several PPIases are able to accelerate the rate of prolyl bond limited kinetic phases in the *in vitro* refolding of ribonuclease T1 (RNase T1). This enzyme has two prolyl bonds (Tyr38-Pro39; Ser54-Pro55) in *cis* conformation in the native state. The site-directed

mutagenized, reduced and carboxymethylated variant Ser54Gly/Pro55Asn is used as standard protein substrate for PPIases. With $k_{cat}/K_M = 1.1 \times 10^6 \text{ M}^{-1} \text{ s}^{-1}$ the *E. coli* trigger factor catalyzed refolding of denatured RNase T1 variant Ser54Gly/Pro55Asn exemplifies a particularly efficient PPIase effect on protein folding *in vitro* (3). The efficacy of trigger factors results from presenting extended secondary binding sites for the unfolded protein substrate. The link between acquisition of biological activity and molecular details of the folding process was shown for the CH3 domain of the heavy chains of IgG. The formation of the essential *cis* isomer of the Phe34-Pro35 bond precedes protein dimerization constituting the rate-limiting step of this reaction. PPIase catalysis shifts the rate-limiting step from prolyl isomerization to fast chain collapse.

The identification of PPIases as crucial proteins in a variety of biological processes shows that these enzymes may play a biological role that is more general than just affecting *de novo* protein folding.

PPIases in Cell Signaling

Beside unfolded polypeptides, PPIases are able to make use of native protein substrates. This property allows them to influence those proteinaceous ligands that express biological activity only in one of the isomeric forms of a particular prolyl bond (2). Proline-directed protein kinases and phosphatases exhibit such a kind of isomer specificity in phosphate transfer reactions on oligopeptides and proteins. PPIases are able to affect the kinetics of phosphate transfer reactions thereby influencing the dynamics of subsequent phosphorylation-dependent chain rearrangements in the targeted proteins.

Definite identification of natural PPIase substrates has been reported as an exception. A large number of binding proteins, which may include the putative cellular substrates, were identified by chemical cross-linking, affinity chromatography, the yeast two-hybrid system or co-purification experiments for many PPIases. Because the detection of a catalyzed prolyl isomerization *in situ* proved to be very difficult, the role of PPIase catalysis *in vivo* has to be analyzed by the generation of PPIase variants with reduced enzymatic activity or by the use of specific cell-permeable PPIase inhibitors.

For example Cyp40 inhibits the DNA binding activity of the transcription factor c-Myb. This effect could be abrogated by the inhibitor CsA. The parvulin-like PPIase Pin1 with its preference to catalyze $(\text{PO}_3\text{H}_2)\text{-Ser}/(\text{PO}_3\text{H}_2)\text{-Thr-Pro}$ moieties interacts with a series of mitotic phosphoproteins, including Polo-like kinase-1, Cdc25C and Cdc27, and its catalytic activity is involved in cell division control in eukaryotes. This human parvulin also interacts with the C-terminal domain of RNA polymerase II; thereby altering the

interaction with proteins required for transcription of essential cell cycle genes. Inactivation of Pin1 induces mitotic arrest and ▶apoptosis.

A mitochondrial complex comprising the adenine nucleotide translocase of the inner membrane and matrix Cyp22 forms the permeability transition pore, which can open transiently allowing free permeation of low molecular weight molecules playing a central role in apoptosis. Immunosuppressive and nonimmunosuppressive cyclophilin inhibitors antagonize mitochondrial-mediated apoptosis by inhibition of the opening of the ▶mitochondrial permeability transition pore.

PPIases are found to form heterooligomeric complexes with different receptors. The intracellular ▶calcium release channels on the endoplasmic or sarcoplasmic reticulum, the ryanodine receptor and the inositol 1,4,5 triphosphate receptor were found to be associated with either cytosolic FKBP12 or FKBP12.6 acting as modulatory proteins to stabilize the channel gating functions. FKBP and cyclophilins with additional ▶tetratricopeptide repeat (TPR) motifs are found to be associated with ▶hsp90 as components of nuclear receptor heterocomplexes like unactivated steroid receptor complexes or the unliganded aryl hydrocarbon receptor. Prototypic PPIases contribute to the control of receptor and non-receptor protein kinases. For example, the phosphorylation of TGF β family type I receptor by the type II receptor chain is inhibited by FKBP12. Similarly, the interaction of Cyp18 with the SH2 domain of the interleukin-2 tyrosine kinase as a substrate controls the catalytic activity of the neighboring protein tyrosine kinase domain.

The enzymatic activity of PPIases is probably involved in many processes of pathophysiological relevance.

▶Familial amyotrophic lateral sclerosis associated mutant Cu/Zn superoxide dismutase-1 (SOD) induces apoptosis of neuronal cells associated with high levels of reactive oxygen species. Over-expression of wild type Cyp18, but not of Cyp18 variant Arg55Ala with a reduced enzymatic activity of about 0.1% of wild type Cyp18, protected cells from death after SOD Val148Gly expression, underlining the importance of PPIase activity in mutant SOD-mediated apoptosis. The FKBP-type PPIase macrophage infectivity potentiator (Mip) protein of *Legionella pneumophila*, the causative agent of Legionnaires' disease, represents a PPIase activity dependent virulence factor necessary for optimal intracellular survival of the pathogen.

Clinical Relevance

The prototypic PPIases Cyp18 and FKBP12 are thought to be important as presenter proteins for the immunosuppressive drugs CsA, FK506 and rapamycin in human (4, 5). A composite surface created by the drug and the surrounding amino acid residues of the respective PPIase enables PPIase/drug complexes to

recruit other cellular proteins involved in signal transduction. Both the Cyp18/CsA and the FKBP12/FK506 complexes interact with the protein phosphatase 2B (calcineurin) in an inhibitory manner, thereby inactivating the nuclear factor of activated T cells (NFAT) followed by the blockage of interleukin-2 transcription and suppression of T cell expansion. However lymphocytes of patients treated with CsA do not show dramatic effects on calcineurin activity. For the FKBP12/rapamycin complex, the mammalian target of rapamycin (mTOR), a phosphatidylinositol kinase-related protein kinase was identified as an interaction partner, resulting in the inhibition of the interleukin-2 stimulated transition from G1 to S phase in T cell replication. By the down-regulation of the T cell activation program, the drugs can prevent allograft rejection, and are prophylactic for the prevention of graft-versus-host disease following bone marrow transplantation.

Whereas rapamycin has a potential as an antitumor agent, the drugs CsA and FK506 have been shown to induce increased incidence of malignancy. CsA induces phenotypic changes, including invasiveness of non-transformed cells by a cell-autonomous mechanism. Apparently, alterations in the expression pattern of many PPIases coincide with malignant transformation. Pin1 is highly over-expressed in breast cancer. Deletions in the region of the *Cyp40* gene might be a late event in breast tumor progression. The prototypic cyclophilin COAS2, which has 83.6% sequence identity to the constitutively expressed Cyp18 was found to be over-expressed almost exclusively in aggressive metastatic or chemotherapy resistant tumors.

Incorporation of Cyp18 from the host cells into nascent human immunodeficiency virus type 1 (HIV-1) virions *via* direct interaction with the HIV-1 Gag polyprotein p55gag is required for virion infectivity. HIV-1-associated Cyp18 mediates HIV-1 entry into host cells *via* interaction with the surface receptor ▶CD147 of the targeted cell. (Me-Ile-4)cyclosporin (SDZ NIM 811) is a 4-substituted cyclosporin derivative that is devoid of immunosuppressive activity but retains full capacity for binding to Cyp18 and exhibits potent anti-HIV-1 activity.

Peripheral Nervous System

The peripheral nervous system (PNS) is a part of the nervous system and consists of the nerves (spinal nerves, cranial nerves) and neurons that reside or extend outside the central nervous system (CNS). The PNS can be divided into two major parts: the somatic nervous system and the autonomic nervous system. The somatic nervous system consists of sensory neurons that send sensory information running from stimulus receptors via the peripheral nerve fibers to the central nervous system, and of motor neurons running from the CNS to the muscles and glands - called effectors - that take action.

The autonomic nervous system is divided into three parts: the sympathetic nervous system, the parasympathetic nervous system and the enteric nervous system. The autonomic nervous system controls smooth muscle of the viscera (internal organs) and glands. Diseases of the PNS can affect the nerve roots, ganglia, plexi, autonomic nerves, sensory nerves, and motor nerves.

Peroxisomal Disorders

RONALD J.A. WANDERS

Pediatrics and Clinical Chemistry, University of Amsterdam, Academic Medical Centre, Amsterdam, The Netherlands
r.j.wanders@amc.uva.nl

Definition

Peroxisomal disorders are relative newcomers in the arena of genetic diseases in man in which there is an impairment in one or more peroxisomal functions, either caused by a defect in peroxisome biogenesis or a single peroxisomal enzyme deficiency. They include a range of different diseases with the ► [cerebro-hepato-renal](#) syndrome, usually called ► [Zellweger syndrome](#), as prototype. Zellweger patients show a great number of abnormalities and the clinical picture is dominated by the typical craniofacial features and by neurological aberrations. Facial features include a large anterior fontanel with widely spaced sutures, a broad/full forehead, micrognathia, external ear deformity, low/broad nasal bridge, shallow orbital ridges and redundant skin folds in the neck. The neurological picture is dominated by the profound hypotonia, resulting in poor sucking requiring gavage feeding, depressed neonatal and deep tendon reflexes and a flat occiput. Other neurological abnormalities include an abnormal Moro response, hypo/areflexia and epileptic seizures (1).

Studies in Zellweger syndrome patients have been instrumental in the identification of additional peroxisomal disorders, which now comprise some twenty different diseases. All peroxisomal disorders identified today are autosomal recessive disorders with one exception, which is ► [X-linked adrenoleukodystrophy](#).

Characteristics

Functions and Biogenesis of Peroxisomes

Functions of Peroxisomes

►**Peroxisomes** are subcellular organelles just like mitochondria (►**Mitochondria – Biogenesis and Structural Organization**) and ►**lysosomes**, and are now known to catalyse a variety of different functions in the eukaryotic cell. These functions include (1):

1. Fatty acid beta-oxidation

Peroxisomes are able to degrade fatty acids just as mitochondria do. The mitochondrial and peroxisomal ►**beta-oxidation** systems are different however, one major important difference being that mitochondria and peroxisomes oxidize different fatty acids. Indeed, whereas mitochondria oxidize the bulk of the long chain fatty acids derived from dietary sources and lipolysis, peroxisomes oxidize only a few fatty acids, notably 1) ►**very long chain fatty acids** with chain lengths of 24 carbon atoms or more, 2) ►**pristanic acid** and 3) ►**di- and trihydroxycholestanic acids**. The latter are intermediates in the synthesis of the primary bile acids, ►**cholic acid** and ►**chenodeoxycholic acid** from cholesterol in the liver.

2. Ether phospholipid biosynthesis

Peroxisomes play an indispensable role in the synthesis of a specific set of phospholipids called ►**ether phospholipids**; plasmalogens are the main type of ether phospholipid. Ether phospholipids resemble the normal di-acyl phospholipids in many respects, the only difference being the presence of an ether bond rather than an ester bond at the *sn*-1 position of the glycerol backbone.

3. Fatty acid alpha-oxidation

Some fatty acids cannot undergo beta-oxidation but can only be broken down by an alternative mechanism, called ►**alpha-oxidation**, in which the terminal carboxyl group is released as CO₂. ►**Phytanic acid** is the prototype fatty acid undergoing alpha-oxidation, which occurs in peroxisomes only.

4. Glyoxylate detoxification

Peroxisomes catalyse the detoxification of ►**glyoxylate** to ►**glycine**. This reaction is catalysed by the peroxisomal enzyme alanine glyoxylate aminotransferase (AGT).

Peroxisome Biogenesis

In addition to the improved knowledge about the metabolic functions of peroxisomes, much has been learned recently about ►**peroxisome biogenesis**. First of all, it is now firmly established that peroxisomal matrix and membrane proteins are synthesized on free polyribosomes in the cytosol. Matrix proteins contain one of two different targeting signals called ►**PTS1** and ►**PTS2** that allow specific recognition by the

peroxisome. Two soluble receptors, named ►**PTS1** and ►**PTS2** receptor encoded by the ►**PEX5** (►**PEX Gene**) and ►**PEX7 genes**, respectively, recognise these signals and carry the proteins involved to the peroxisome, followed by transfer of the proteins across the peroxisomal membrane and recycling of the receptors. Many of the proteins involved in this complicated process have been identified in recent years. These proteins are called ►**peroxins** and are encoded by their respective, so-called, ►**PEX genes** (2).

Peroxisomal Disorders

The peroxisomal disorders are usually subdivided into two groups 1) the peroxisome biogenesis disorders (PBDs) and 2) the single peroxisomal enzyme deficiencies.

Peroxisomal Biogenesis Disorders

Apart from Zellweger syndrome, a number of different peroxisomal disorders have been identified as belonging to this category. These include ►**neonatal adrenoleukodystrophy** (NALD), ►**infantile Refsum disease** (IRD) and ►**rhizomelic chondrodysplasia punctata** (RCDP). ZS, NALD and IRD show overlapping signs and symptoms, ZS being the most severe, NALD intermediate and IRD the least severe. Together, ZS, NALD and IRD, are referred to as the “Zellweger spectrum”. In ZS, NALD and IRD, peroxisome biogenesis is completely deficient, resulting in the lack of morphologically identifiable peroxisomes and as a consequence, the complete loss of peroxisomal functions. This explains why ZS, NALD and IRD patients have elevated very long chain fatty acid levels, deficient plasmalogens and elevated phytanic acid levels.

►**Complementation studies** have shown that there is profound genetic heterogeneity within the ZS/NALD/IRD group, with eleven different complementation groups identified so far. The different genes mutated in each of these groups have all been identified in recent years (Table 1).

Rhizomelic chondrodysplasia punctata (RCDP) is different from ZS, NALD and IRD, not only in clinical terms but also in its biological and molecular basis. Patients who are suffering from RCDP show a disproportionally short stature primarily affecting the proximal parts of the extremities, a typical facial appearance, including a broad nasal bridge, epicanthus, high arched palate, dysplastic external ears and micrognathia, congenital contractures, characteristic ocular involvement, dwarfism and severe mental retardation with spasticity. Roentgenological studies have shown a series of abnormalities including symmetrical shortening of the femur and humerus with irregular and broad metaphyses, calcific stippling mainly of the epiphyses, absent femoral head nucleus,

Peroxisomal Disorders. Table 1 Peroxisomal disorders and the genes involved

Peroxisomal Disorders	Gene Name	Exons	Chromosome	Protein (AAs)
Peroxisome biogenesis disorders				
PBD Type 1: Zellweger spectrum	PEX1	24	7q21-q22	1283
ZS/NALD/IRD	(PXMP) PEX2	4	8q21.1	626
	PEX3	12	6q23-q24	373
	(PXR1) PEX5	15	12p13.3	602&639
	PEX6	17	6p21.1	980
	PEX10	6	1p36.32	326
	PEX12	3	17q21.1	359
	PEX13	4	2p15	403
	PEX16	11	11p12-p11.2	346
	(PXF) PEX19	8	1q22	299
	PEX26	5	22q11.2	305
PBD Type 2: Rhizomelic Chondrodysplasia Punctata (RCDP) 1	PEX7	10	6q21-q22.2	323
Single peroxisomal enzyme deficiencies				
X-linked adrenoleukodystrophy	ABCD1	10	Xq28	745
AcylCoA oxidase deficiency	ACOX1	14	17q25.1	660

RCDP3 (alkylDHAP synthase deficiency)	AGPS	20	2q33	658
Refsum disease (phytanoylCoA hydroxylase deficiency)	PHYH	9	10p15-p14	338
Hyperoxaluria Type 1 (alanine glyoxylate aminotransferase deficiency)	AGXT	11	2q37.3	392
Acatalsasaemia	CAT	13	11p13	526

coronal clefts of vertebrae, increased intravertebral disc spaces, cupping of dorsal ribs and a barrel-shaped thorax. In RCDP, peroxisomal biogenesis is only partially deficient as a consequence of mutations in the ►*PEX7*-gene coding for the PTS2 receptor. The normal routing of PTS1 proteins explains why peroxisomal beta-oxidation is completely normal in RCDP whereas plasmalogen biosynthesis and phytanic acid alpha-oxidation are deficient.

Single Peroxisomal Enzyme Deficiencies

The different single peroxisomal enzyme deficiencies can be classified according to the pathway involved. These are:

a) Peroxisomal fatty acid beta-oxidation disorders

X-linked adrenoleukodystrophy (XALD) is the prototypical peroxisomal fatty acid beta-oxidation disorder with a variety of different phenotypes. ►**Childhood cerebral ALD (CCALD)** and ►**adrenomyeloneuropathy (AMN)** are the most frequent phenotypes, together accounting for > 80% of all cases. CCALD presents in young boys in the middle of the first decade, starting with behavioural abnormalities, decline in school performance and deterioration of vision and hearing. CCALD is relentlessly progressive with death occurring within two years. AMN presents much later in life with neurological deficits. Patients gradually develop

spastic paraparesis often in combination with disturbed vibration sense in the legs and sphincter dysfunction. The sensorimotor neuropathy in AMN is predominantly axonal. In all XALD phenotypes, very long chain fatty acids accumulate as a result of their defective beta-oxidation in the peroxisome. The gene involved in XALD codes for a peroxisomal half-ABC transporter, which is involved in the transmembrane transport of very long chain fatty acids from the cytosol into the peroxisome (3).

D-bifunctional protein deficiency is another peroxisomal beta-oxidation disorder and ranks among the more frequent peroxisomal disorders. Interestingly, the clinical presentation of affected patients is very different from XALD, being very severe and resembling Zellweger syndrome in many respects, including the craniofacial dysmorphism and neurological abnormalities.

Acyl-CoA oxidase deficiency is much less frequent and has been described in some fifteen patients in the literature only. All patients show severe neurological abnormalities, resembling those observed in the peroxisome biogenesis disorder NALD. The last beta-oxidation disorder is 2-methyl-acylCoA racemase (AMACR) deficiency, described in only a few patients. Patients with this deficiency show a slowly progressive polyneuropathy resembling that observed in classical Refsum disease.

b) Disorders of ether phospholipid biosynthesis

The two single enzyme deficiencies in this category are dihydroxyacetonephosphate acyl transferase (DHAPAT) deficiency, and alkyl-dihydroxyacetonephosphate (alkyl-DHAP) synthase deficiency. The clinical signs and symptoms of these two disorders closely mimic those described in rhizomelic chondrodysplasia punctata with the characteristic rhizomelic shortening, especially of the upper extremities.

c) Peroxisomal fatty acid alpha-oxidation disorders

Refsum disease is the only peroxisomal disorder in which peroxisomal fatty acid oxidation is deficient. Cardinal manifestations include retinitis pigmentosa, cerebellar ataxia, chronic polyneuropathy and an elevated protein level in CSF with normal cell count. Less constant features include sensory neural hearing loss, anosmia, ichthyosis, skeletal malformations and cardiac abnormalities. The clinical picture is often that of a slowly developing, progressive peripheral neuropathy manifested by severe motor weakness and muscular wasting especially of the lower extremities. Patients with Refsum disease are unable to alpha-oxidize phytanic acid as a consequence of the deficiency in the peroxisomal enzyme ►phytanoyl-CoA hydroxylase.

d) Disorders of Glyoxylate Detoxification

Primary hyperoxaluria Type 1 (PH1) is the only peroxisomal disorder belonging to this group. Patients show recurrent calcium oxalate nephrolithiasis and nephrocalcinosis frequently leading to progressive renal insufficiency and death before the age of twenty. In primary hyperoxaluria Type 1, alanine glyoxylate aminotransferase, a peroxisomal enzyme, is deficient, leading to the production of excessive amounts of oxalic, glyoxylic and glycolic acids which are excreted in urine.

Cellular and Molecular Regulation

As described above, the peroxisomal disorders are clinically and genetically heterogeneous with the involvement of a large variety of different genes which either code for proteins involved in peroxisome biogenesis or for proteins involved in different metabolic functions, be it an enzyme or a transporter protein. Peroxisomes are generally regarded as highly flexible organelles playing different roles in different organs. Furthermore, peroxisomes are highly inducible, at least in rodents, by 1) hypolipidaemic agents such as clofibrate, 2) plasticizers but also 3) high-fat diets. Apart from the increase in the number of peroxisomes, these agents also produce a profound induction of the fatty acid oxidation enzymes in peroxisomes. The nuclear hormone ►peroxisome-proliferator-activator-receptor alpha (PPAR-alpha) plays a crucial role in this induction process. Activated PPAR-alpha forms a heterodimer with the retinoic X-receptor (RXR) and binds to response elements present in a variety of different genes, including the ones coding for some of the peroxisomal beta-oxidation enzymes, thus causing enhanced transcription (4).

Clinical Relevance

The group of peroxisomal disorders is diverse with some twenty different diseases. In most of these there is neurological involvement, which is usually quite severe. Current estimates suggest that the group of peroxisomal disorders as a whole has a combined incidence of about one in 5000. Thanks to the improvement in clinical recognition of patients and the development of adequate laboratory methods, patients can be classified and the underlying molecular defect can be established. Furthermore, prenatal diagnosis of all peroxisomal disorders can now be done using either biochemical or molecular methods.

Peroxisome

Definition

Peroxisomes are subcellular organelles present in all body cells, except in the mature erythrocyte catalysing a range of important metabolic functions. One of the most important metabolic processes of the peroxisome is the β -oxidation of long and very long chain fatty acids. The peroxisome is also involved in bile acid synthesis, cholesterol synthesis, amino acid and purine metabolism. The importance of the peroxisome and these processes is underscored by the existence of numerous genetic disorders associated with defects in the peroxisome.

Peutz-Jeghers Syndrome

DIETER E. JENNE

Max Planck Institute of Neurobiology, Martinsried,
Germany
djenne@neuro.mpg.de

Synonyms

Polyps-and-spots syndrome; pigment spot polyposis

Definition

Peutz-Jeghers Syndrome first described in 1921 by a Dutch physician named Peutz (1) and further studied by Jeghers in 1949 (2) is characterized by the occurrence of gastrointestinal hamartomatous polyps and abnormal melanocytic pigmentation of the lips, buccal mucosa and hands in an individual, who may have inherited this syndrome in an autosomal dominant fashion. Inactivating mutations in the *STK11* (*LKB1*) gene (3, 4), a serine threonine ►kinase of the nucleus and cytoplasm, have been identified in the majority of patients. Carriers of a dysfunctional *STK11* allele often suffer from

multiple benign tumors and polyp-induced gastrointestinal complications, but also bear an increased lifetime risk of developing various cancers within and outside the gastrointestinal tract (5, 6). Surveillance and screening protocols for PJS patients and their relatives have been developed.

Characteristics

Epidemiology

The disease incidence is uncertain. Estimates fall between 1:8,300 and 1:120,000 per live birth. All races and both genders are equally affected. An incidence of 1:30,000 is calculated for the UK on the basis of 2,000 known individuals with PJS. *De novo* mutations in the *STK11* gene on 19p13.3 account for about 10–40% of all PJS cases. The syndrome shows high penetrance during life, although onset, clinical severity, relapse of symptoms and clinical course are highly variable.

Clinical Features

The predominant symptoms are caused by the formation and growth of multiple polyps in the gastrointestinal tract (Fig. 1). Rectal bleeding, recurrent colicky abdominal pains, in particular after meals and

Peutz-Jeghers Syndrome. Figure 1 Schematic drawing (cross section) of an early-stage Peutz-Jeghers polyp. Smooth muscle cells (dark-grey) from the tunica muscularis mucosae and from the inner circular layer of the tunica muscularis propria proliferate and expand into the tela submucosa. Once fused they form a continuous smooth muscle bundle, which connects the head of the polyp with the tunica muscularis propria. Thin ramifications (arborization) originating from the muscularis mucosae divide the head of the polyp into several sectors (not shown). The tree-like branching of smooth muscle cells connects the inner circular layer of the tunica muscularis propria with the tunica muscularis mucosae and occupies the connective tissue space (tela submucosa) (courtesy of Robert Schorner, Photolab, Max-Planck-Institute of Neurobiology).

in the morning, and increased peristalsis of the small intestine are the most common symptoms which patients report. Pain attacks are caused by invaginations of small polyps (intussusception), whereas bowel obstructions are rare complications of larger polyps, which may manifest as acute abdomen. Invaginations of polyps that develop in the sigma or rectum can lead to anal prolapse. Chronic blood loss as a result of erosions and ulcerations on the surface of polyps can cause the general symptoms of anemia (achrocythemia), like fatigue, adynamia, syncopes and growth retardation in children. In two-thirds of all cases this gastrointestinal bleeding is not visible. One third of patients will experience the first gastrointestinal symptoms before the age of 10, another third during the second decade of life. After the age of 30 the growth of polyps decreases and new polyps are rare. Extraintestinal polyps of the gallbladder and nasopharynx have been reported in a few cases.

The second cardinal feature is abnormal mucocutaneous pigmentation (1–6 mm macules) around the mouth and the nasolabial folds, on the lips (Fig. 2) crossing the vermilion border and affecting the buccal mucosa. This clinical sign is very helpful in the demarcation of PJS from other inherited hamartomatous polyposis syndromes. Uncommon sites of pigmentation are the dorsal and volar aspects of the hands and feet, the perianal and genital region and the rectal mucosa. With advancing age, in particular after puberty, pigmentation often fades and sometimes disappears completely. Buccal pigmentation tends to persist in PJS and is rarely mimicked by ordinary freckles.

Additional clinical signs and symptoms can originate from hormone producing benign gonadal tumors resulting in precocious puberty and menstrual irregularities in females. Ovarian sex cord tumors with annular

tubules (►SCTAT) sometimes produce excessive estrogens. Sertoli cell tumors can trigger gynecomastia and growth acceleration in male patients.

Individuals with PJS bear a significantly higher relative and absolute risk for all types of cancer at all stages of life. The lifelong cumulative risk of dying from intestinal or extraintestinal malignancies is 48% by the age of 57 and 93% by the age of 65. The site with the highest relative risk for cancer is the small intestine, followed by the stomach, pancreas, colon, esophagus, ovary, lung, uterus and breast in decreasing order. Counting all cancers in PJS patients between the age of 15 and 64, cancer most frequently develops in the breast (54%), colon, (39%), pancreas (36%), stomach (29%), ovary (21%), lung (15%) and small intestine (13%).

Histopathology

Peutz-Jeghers polyps have a non-neoplastic hamartomatous appearance (Fig. 1). They consist of a branching framework of connective tissue and smooth muscle cells lined by normal intestinal epithelium with numerous goblet cells. Epithelial and goblet cells are sometimes surrounded by smooth muscle cells (pseudoinvasion), which may be mistaken for an invasion of the tela muscularis mucosae and submucosa and the beginning of an adenocarcinoma. The muscular and fibrous framework of the stalk and head adds high mechanical stability to Peutz-Jeghers polyps. This explains the relatively frequent complications induced by these hamartomatous polyps.

In contrast to adenomatous polyps, dysplasia, specifically of the epithelial cell layer, and aneuploidy are absent. A direct malignant transformation of a benign hamartomatous polyp into cancer is unlikely. Secondary erosions and inflammatory infiltrates, however, occur frequently in larger polyps and may contribute to the occasional formation of adenomatous as well as carcinomatous foci. The most common location of Peutz-Jeghers polyps is the small intestine (jejunum, ileum, duodenum in that order), followed by the large intestine and stomach. Population differences in the distribution of polyps along the gastrointestinal tract may exist.

Pigment spots of the facial skin and buccal mucosa develop in most individuals with PJS before the fifth year of life, but are rarely present at birth. The margins of macules are irregular and fuzzy. Histologically, hyperplasia of melanocytes is found at the epidermal-dermal junction. Transport to and deposition of melanosomes in the basal layer of keratinocytes is disturbed. The number of melanosomes is increased in the dendrites of melanocytes and thus abnormal extracellular deposition of melanin and melanin-containing macrophages are seen in the basal layer of the epidermis. Pigment spots from PJS patients

Peutz-Jeghers Syndrome. Figure 2 Typical pigment spots on the lips and periorally in a Peutz-Jeghers patient (courtesy of Dr. W. Back and Dr. S. Löff, Mannheim Clinics, University of Heidelberg).

display the typical histopathological and electron microscopical features of lentigo simplex.

Cellular and Molecular Regulation

Structure of the *STK11* Gene

To date, 75 different germ line mutations have been identified in *STK11* (LKB1). *STK11* encodes a highly conserved serine threonine kinase (STK), which is present in vertebrates, *Drosophila* and *Caenorhabditis elegans* (Par4). The human gene consists of 10 exons which span about 23 kb on 19p13.3 and is transcribed in telomere-centromere direction in many tissues and cell types. Exons 1 and 2 are separated by an extremely rare intron type with unusual splice junction sequences. Intron 2 is removed in an U12 snRNA-dependent manner. The open reading frame codes for a polypeptide chain of 433 amino acid residues, which can be divided into three segments, a kinase domain (residues 46 to 314) and two regulatory domains at the N- and C-termini.

Functional Features of the *STK11* Protein

The kinase domain is most closely related to the yeast SNF1/cyclic AMP-activated protein kinase subfamily. Its catalytic activity is regulated by a number of cellular proteins, which determine its subcellular localization, catalytic activity and phosphorylation state. Endogenous *STK11* is mainly localized in the nucleus, but a significant fraction is retained in the cytoplasm. Mutation of the nuclear localization signal at position 38–43 prevents its accumulation in the nucleus. A cofactor protein called STRAD (ste20 related adapter) binds to *STK11*, activates it and re-directs *STK11* to the cytoplasm. As a consequence both *STK11* and STRAD become phosphorylated. An in-frame deletion of the four residues 303–306 (Ile-Arg-Gln-His) found in a PJS family abolishes STRAD interactions and cytoplasmic retention. A number of threonine and serine residues of *STK11* can be modified by phosphorylation, but only Thr336 and Ser431 in over-expressed *STK11* were shown to be required for suppression of cell growth in certain *STK11* deficient cell lines. Thr336 is phosphorylated in cells exposed to ionizing radiation. The C-terminus, furthermore, displays a typical consensus site (Arg-Arg-Leu-Ser) for phosphorylation by the cyclic AMP-activated protein kinase A (PKA) and a **►prenylation** site (Cys-Lys-Gln-Gln). Ser428 (equivalent to Ser431 in the mouse sequence) is indeed phosphorylated by PKA and the p90 ribosomal S6 protein kinase (RSK) in endogenously expressed *STK11*. Cys430 is farnesylated in cultured cells. These two sites are of functional significance since truncation of the terminal 20 residues by a *STK11* mutation has triggered the full-blown PJS syndrome. Both functional sites are conserved and essential to properly regulate cell polarity in

Drosophila. As observed in *C. elegans* and *Drosophila*, *STK11* functions in establishing tissue polarity and ventral-dorsal tissue patterning. Reduction of its activity may, therefore, facilitate the local overgrowth and disorganization of differentiated cells.

Cellular Functions

Defects in **►apoptosis** regulation have been inferred to explain benign **►hamartoma** formation in accordance with the reduced number of apoptotic epithelial cells in PJS polyps. Apoptotic epithelial cells on the tip of intestinal villi and at the base of crypts contain higher cytoplasmic levels of *STK11* than those in PJS polyps. Besides this *in situ* correlation between elevated cytoplasmic *STK11* levels and apoptosis in epithelial cells, *STK11* associates with the tumor suppressor p53 and translocates to mitochondrial membranes during apoptosis, a process that appears to amplify the apoptotic cascade.

Mouse embryonic fibroblasts can be immortalized by *STK11* inactivation. These cells then become resistant to culture stress-induced senescence. On the other hand these cells cannot be transformed by activated RAS and SV40 large T antigen. The complete inactivation of *STK11* prevents the hamartoma-to-adenocarcinoma transition, but unblocks cellular proliferation of local stromal and epithelial cells.

Multiple rationales have been proposed for the growth suppressive effect of *STK11*. Its ability to mediate a G1 cell-cycle arrest only in certain *STK11* deficient cell types on one hand and its presence in many normal

Peutz-Jeghers Syndrome. Figure 3 The activity of *STK11* is regulated by phosphorylation (indicated by the P) at multiple serine and threonine sites through the actions of multiple upstream kinases, which have been poorly characterized. Ser428 e.g. can be phosphorylated via different signaling pathways, either by the cAMP dependent kinase A (PKA) or the p90 ribosomal S6 protein kinase (RSK) which in turn is activated by the epidermal growth factor (EGF) receptor, a receptor tyrosine kinase (RTK). cAMP is generated by adenyl cyclase (AC) whose activity is regulated by G-proteins coupled to various seven transmembrane domain receptors (GPCRs).

proliferating cell types on the other hand, however, illustrates the complex mechanisms that control the activity and multiple functions of STK11 with regard to cellular proliferation. The complex crosstalk between the stroma and the epithelial cell compartment in the small intestine probably involves membrane receptors and secretory signaling molecules from different cell types. Several observations support this suggestion. Phosphorylation of STK11 at Ser428 by PKA is triggered by elevated cAMP levels as well as by epidermal growth factor (EGF) *via* p90 ribosomal S6 protein kinase (RSK). Moreover, signal processing *via* certain G-proteins may also be altered by STK11 depending on its phosphorylation state. Recently, STK11 was shown to interact with activator of G-protein signaling 3 (AGS3). The more STK11 functions and interacting proteins are disclosed, the slighter the hope that either STK11 or any interacting partner will be a suitable target for drugs with predictable effects in tumor patients.

Mouse Models for Peutz-Jeghers Syndrome

An essential role of STK11 in early embryonic development was demonstrated by targeted disruption of both gene copies in mice. Development was normal until day 8 (E8.0) and thereafter heavily disturbed, so

that all embryos died by day 11 (E11.0). Obvious problems were the defects in tissue vascularization, neural tube closure and placenta development. Heterozygous mice with one inactivated and one normal copy of the gene were viable at birth and grew normally until they developed numerous polyps, predominantly in the glandular stomach between 20 and 45 weeks of age. Unfortunately the mechanism of hamartoma formation in heterozygous animals has so far remained unclear. At present, all theoretical possibilities, allelic loss (loss of heterozygosity) by mitotic recombination or interstitial chromosomal deletions, acquired second hit of the normal allele, epigenetic inactivation by promoter methylation and ▶**haploinsufficiency** are still being considered.

Clinical Relevance

Diagnosis and Genetic Testing

Clinical and histopathological findings are still crucial for the diagnosis of Peutz-Jeghers syndrome although molecular genetic testing of the *STK11* gene is widely available. In patients without a known family history, either two histologically confirmed PJS polyps from the gastrointestinal tract or any PJS polyp in combination with characteristic mucocutaneous pigmentation are sufficient diagnostic criteria. For patients with a

Peutz-Jeghers Syndrome. Table 1 Differential diagnosis of familial hamartomatous polyposis syndromes

Syndrome	Polyp characteristics	Inheritance & etiology
Peutz-Jeghers	hamartomatous polyps with smooth muscle core mainly in small intestine	STK11 (LKB1), 19p13.3 autosomal dominant
Juvenile polyposis	juvenile polyps, primarily in colon with cystic dilatations	SMAD4, 10q23.31 BMPR1A, 10q23.31 autosomal dominant
Cowden's disease	hamartomas in various tissues including gut (colon & stomach)	PTEN, 10q22-23 autosomal dominant

Peutz-Jeghers Syndrome. Table 2 Differential diagnosis of familial facial lentiginosis syndromes

Syndrome	Major Findings	Inheritance (autosomal dominant)
Peutz-Jeghers	facial pigment spots, polyps	STK11 (LKB1), 19p13.3
Carney complex	multiple myxoma, endocrine tumors	PRKAR1A, 17q22-24 second locus at 2p16?
Bannayan-Riley-Ruvalcaba	perigenital pigment spots juvenile polyps	PTEN, 10q22-23
Laugier-Hunziker	oral and cutaneous spots subungual pigmentation	unknown
LEOPARD	lentiginosis, electrocardiographic abnorm., ocular hypertelorism, pulmonary stenosis, abnormalities of genitalia, retardation of growth, deafness	PTPN11, 12q24.1

first-degree relative with Peutz-Jeghers syndrome, either typical pigment spots or any number of PJS polyps are the minimum criteria for diagnosis. If these clinical criteria are met or a *STK11* mutation is already known among a first-degree relative, genetic testing can be considered.

Sequence analysis of the nine coding exons of *STK11* reveals disease-causing mutations in more than 70% of all familial cases. *STK11* mutations in sporadic cases are found with lower frequencies. ►Nonsense mutations that cause the truncation of the polypeptide chain are of conclusive significance for the diagnosis, but ►missense mutations are more difficult to assess. Natural amino acid variations for *STK11* have not been found in the healthy human population. Any substitution of residues that are shared by the various mammals and higher vertebrates are highly suspicious. In dubious cases bioinformatic tools can predict the possible functional impact of an amino acid substitution on the structure and function of *STK11*, using 3D-structural and comparative models.

Other genes that cause Peutz-Jeghers syndrome have so far not been identified. Linkage to the *STK11* locus on 19p13.3 was excluded in some PJS families. In one large Indian family the gene defect appears to be linked to 19q13.3. Failure to identify *STK11* mutations can have many reasons. The widely used exon scanning strategies are not suited to discovering promoter mutations, splicing enhancer defects, polyadenylation anomalies, intronic mutations generating new splice sites, intragenic insertions or exon deletions, intragenic inversions and other long range rearrangements of the *STK11* locus. Mutation screening at the transcript level using blood cell mRNA is recommended when coding exons are found to be normal. Since *de novo* mutations account for a significant number of PJS cases, somatic mosaicism and segmental forms of *STK11* mutation must be considered as well.

Management of PJS Families

The clinical diagnosis and final proof of *STK11* mutations in a PJS patient has serious consequences for the patient and his relatives. Clinical evaluation, ►genetic counseling and genetic testing should be offered to the parents and at-risk relatives. The type of mutation, however, is not useful in predicting onset, severity, clinical course and various complications of the disease in asymptomatic individuals.

An extensive medical surveillance programme is recommended irrespective of *STK11* mutations to all patients who meet the clinical criteria for PJS and to asymptomatic, at-risk relatives in familial PJS. In cases of sporadic PJS without *STK11* mutations, it is not possible to assess the risk to relatives. In sporadic cases with *de novo* mutations in *STK11*, the parents should be carefully examined for subtle signs of the disorder

and gonadosomal mosaicism of one parent should be considered. *STK11* testing can be performed prenatally and before embryo implantation if an *STK11* mutation is known in one parent. The ethical problems and legal situation associated with such requests should be clarified with a genetics professional.

Adequate follow-up care and cancer surveillance must be offered to affected individuals and asymptomatic at-risk family members in early life (at the age of 10). Physical examination of breasts, abdomen, pelvis and testes and a complete blood count should be performed every year and complemented by ultrasound investigations of the pelvis (women), testes (men), abdomen and pancreas. Every other year, esophagogastro-duodenoscopy and colonoscopy and in the case of abdominal complaints a small bowel follow-through (contrast enema) are recommended. All polyps larger than 10 mm should be removed by electrocautery snare either during endoscopy or surgically after laparotomy. The need for repeated bowel resections and emergency interventions should be minimized. Mammography should be started later at the age of 25 and repeated initially at intervals of 5 years, after the age of 38 every second year and after the age of 50 annually. The beneficial effects of special medical care and surveillance on the morbidity and mortality of PJS patients have not yet been assessed in prospective studies.

Phage Display

Definition

The phage display is a technology that displays protein or peptide libraries on the surface of a multitude of

phages which also contain the encoding gene (each phage contains the gene for its encoded protein or peptide). Proteins or peptides reactive with a specific molecule can therefore be isolated by a binding reaction (which eliminates the non-binders) and multiplied because of the association of the binding protein and the corresponding encoding gene in the same particle.

Synonyms

► [Pharmacogenomics/Pharmacogenetics](#)

Definition

Pharmacogenetics, a term coined by Vogel in 1959 (1), deals with the interindividual differences in response to drugs caused by mutations of proteins leading to alteration of pharmacokinetics and pharmacodynamics of drugs. It uses genetic information to predict an individual's drug response. The term pharmacogenomics has been introduced in recent years to describe the progressive transition from genetics to genomics, acknowledging that the genome is more than the sum of its genes. It is a genome-wide approach to identify genes that contribute to a specific disease, to identify new drug targets, design new drugs and target drugs to specific patient populations.

Characteristics

There are in principle three mechanisms by which
► [genetic polymorphisms](#) or ► [rare mutations](#) in proteins that are involved in the metabolism, transport

and action of drugs lead to interindividual differences in response to and toxicity of drugs (Fig. 1).

The rate at which drugs are eliminated from the body is a major determinant of both the intensity and duration of drug action and toxicity. Drug metabolizing enzymes, in particular ►cytochrome P450 enzymes, play a pivotal role in the elimination of most drugs. Variability of drug metabolism is responsible for the pronounced interindividual differences in plasma concentrations when patients receive the same dose of a drug. As a consequence, variability in drug action and side effects/toxicity ensues. During the last 30 years, mutations have been identified for many phase 1 and phase 2 enzymes catalyzing the biotransformation of drugs. These mutations affect either the expression or catalytic properties of the enzymes. In the case of mutations leading to a loss of function, administration

of a standard dose of a drug will lead to very high plasma concentrations resulting in an exaggerated response, side effects or toxicity. At the other end of the spectrum, gene amplifications of enzymes resulting in ultra rapid metabolism of drugs have been identified as a mechanism for poor response. In the case of prodrugs, which require bioactivation for therapeutic efficacy, loss of enzyme function due to polymorphism of the enzyme is associated with a loss in efficacy (Table 1).

But even if the drug dose is individualized by therapeutic drug monitoring in order to achieve the same plasma concentrations substantially, variability in therapeutic response and side effects will still be observed because concentrations at the site of action vary substantially. It is increasingly recognized that transfer of drugs in and out of cells is not a passive

Pharmacogenomics. Figure 1 Different pharmacogenetic mechanisms responsible for interindividual drug response. Drug metabolism: Mutations in cytochrome P450 genes lead to decreased or deficient enzyme expression in human liver. Patients carrying these mutations given the same dose of a drug as wild type individuals will accumulate drug concentrations in their plasma that lead to a higher risk of developing adverse drug reactions. Drug transport: Absorption and elimination of drugs as well as transfer of a drug from the blood into different tissues depend on active transport processes via membrane transporters. P-glycoprotein, the product of the MDR1 gene, is located in the blood brain barrier (BBB) and mutations in this gene associated with decreased expression of P-glycoprotein will lead to an enhanced transfer of drugs and/or metabolites into the brain. Thus, despite the same plasma concentrations, different concentrations may be achieved at the site of action. Drug action: Generally, drugs act via their interaction with specific receptor proteins such as β -adrenoceptors. Despite the same target concentration at the site of action, mutations in the receptor gene may cause alterations in receptor activity, leading to differences in drug response.

Pharmacogenomics. Table 1 Examples of genetic polymorphisms influencing drug response in humans

Gene	Drug
Drug-metabolizing enzymes	
CYP2C9	losartan, NSAID, phenytoin, tolbutamide, S-warfarin
CYP2C19	diazepam, mephenytoin, proguanil, proton pump inhibitors
CYP2D6	antiarrhythmics, antidepressants, β -blocker, codeine, 5-HT ₃ antagonists, neuroleptics
Dihydropyrimidine dehydrogenase	5-fluorouracil
Glutathione transferases	various cytotoxic agents
Thiopurine S-methyltransferase	azathioprine, 6-mercaptopurine
UGT1A1	irinotecan
Drug transporters	
ABCB1 (MDR1)	antiepileptics, cyclosporine, digoxin, HIV protease inhibitor
OATP1B1 (OATP-C)	methotrexate, statins
Serotonin transporter (5-HTT)	antidepressants
Drug targets	
β_2 adrenoceptor	β_2 agonists
Gs protein α	β -blocker
ALOX5	leukotriene receptor antagonists
APO E	statins

process depending on physicochemical properties, lipophilicity and protein binding but also involves active transfer by transport proteins.

Transporters are membrane proteins that maintain cellular homeostasis through import and export of endogenous compounds. Because of their localization in intestinal, hepatic and renal epithelial cells, these transport proteins are important for the absorption, bioavailability and elimination of drugs. Moreover, they play an important role in targeting drugs to organs because they are localized in blood-organ barriers such as the blood-brain and blood-placenta barrier. Thus, mutations either affecting the expression or changing the affinity of the transporter can alter the absorption and elimination of drugs. Due to their localization in blood-organ barriers, polymorphism in drug transporters can lead to different concentrations at the site of action although blood concentrations are similar. Among the many transporters identified MDR1, MRPs, OATPs, OCTs, OATs and nucleoside transporters are of particular interest since they transport not only endogenous compounds but also exogenous substrates including drugs. For all these transporters mutations have been identified which modify either their expression or function.

Finally, the same concentration of a drug at the site of action does not necessarily mean an identical response, because mutations at drug targets (receptors, neurotransmitter transporters, signaling pathways) can profoundly alter response. In the case of β_2 adrenoceptor polymorphisms, marked differences in the bronchodilatory response to β_2 agonists such as albuterol have been described. Moreover, the effectiveness of generally ineffective drugs such as gefitinib in patients with lung cancer can be explained by sensitizing mutations of the epidermal growth factor receptor in the tumor.

With the complete sequence of the human genome available, it is hoped that individualized medicine will soon become a reality. The expectations are that with the use of genomic information we can determine an individual's drug response and select the appropriate dose of the drug. This would allow achievement of the optimal therapeutic response, avoid therapeutic failure and minimize side effects and toxicity. Although many genes responsible for inherited differences in the metabolism, transport and action of drugs have been identified, this new knowledge has not been translated into clinical practice. With the exception of a very few examples of drug metabolizing enzymes, the

contribution of genetic polymorphisms to individual differences in drug effects and toxicity are not well understood. Moreover, most of these studies have focused on the consequences of a single gene polymorphism for altered drug response. This approach, however, neglects the fact that the drug response phenotype like most disease phenotypes is a complex polygenic trait with nongenetic factors contributing to the manifestation of the phenotype. The extent to which genetic factors contribute to the drug response/toxicity phenotype will depend on whether the candidate gene is a gene of major, moderate or minor effect. There are also misconceptions with respect to the information provided by a pharmacogenetic test. Even in the case of a gene with maximum effect, the presence or absence of a mutation will not provide a straight forward yes or no answer, but rather the likelihood that in a subject with a given mutation an event will occur or not. The highest positive predictive value of a genetic test will be observed for genes with a major effect. In the case of drug metabolizing enzymes, mutations leading to a loss of function will result in higher drug concentrations. If these higher drug concentrations are associated with toxicity, the likelihood that a patient with this genotype will develop toxicity is very high if he is exposed to the same dose as the patients who carry the wild type of the gene. However, the negative predictive value (likelihood that a patient without the mutation will not have toxicity) can be rather poor if non-genetic factors leading to high drug concentrations, which are associated with drug toxicity, are neglected. If a patient who carries a wild type gene is concomitantly treated with a drug that inhibits the enzyme, the patient will develop the phenotypic high concentration that is usually associated with the presence of two mutant alleles, a phenomenon called phenocopying.

Clinical Relevance

For all major classes of drugs, a substantial proportion of patients will not respond or respond only partially when standard doses of a particular drug are administered. Possible mechanisms underlying the marked interindividual variability in drug response and toxicity include heterogeneity of the disease and such clinical variables as age, gender, diet, co-administration of drugs and renal and hepatic functions. In addition it has become apparent during the last three decades that genetic factors can be responsible for significant heterogeneity in the efficacy and toxicity of therapeutic agents.

It has been suggested that, depending on the drug, genetic factors account for 20–95% of the variability in drug disposition and effects (2, 3). In a recent systematic review by Philipps and co-workers (4), among 27 drugs frequently cited in adverse drug reaction (ADR) studies, 59% were metabolized by at

least one enzyme with a variant allele known to cause poor metabolism. Conversely, only 7–20% of randomly selected drugs were metabolized by enzymes known to be polymorphically expressed. This analysis suggests that genetic variability in drug metabolizing enzymes is a contributor to the incidence of ADR. Altogether, the effects of most drugs are determined by many proteins and it will be the composite of genetic polymorphisms in multiple genes that determine drug response, along with non-genetic factors.

To date the best-characterized genetic polymorphisms influencing variability of drug response are mutations in drug metabolizing enzymes. They have a profound effect on the pharmacokinetics and pharmacodynamics of drugs.

Cytochrome P450 2C9

Cytochrome P450 2C9 (CYP2C9) is a major enzyme involved the metabolism of the more potent S-enantiomer of the oral anticoagulant warfarin. Two mutations (*CYP2C9**2 and *3), which have only 20% and 5% respectively of the wild type enzyme activity, have been identified as major risk factors for severe bleeding complications on the initiation of anticoagulant therapy, if patients receive the standard dosage.

Cytochrome P450 2C19

Cytochrome P450 2C19 (CYP2C19) exhibits a genetic polymorphism that produces three distinct phenotypes in the population, the poor metabolizer (PM), the heterozygous (hetEM) and the extensive metabolizer (EM). Following administration of the same dose of proton pump inhibitors, which are mainly metabolized by CYP2C19, PM have a 3–12× higher drug exposure than EM. In view of the close relationship between drug concentration and inhibition of acid secretion, with up to 12 fold difference among patients it is becoming apparent that, with the current practice of administering the same dose to all patients, Hp (*Helicobacter Pylori*) eradication and ulcer healing will be affected by the CYP2C19 genotype. Apart from antibiotic resistance, multivariate analysis showed that CYP2C19 polymorphism was the most important factor influencing Hp eradication success.

Cytochrome P450 2D6

Approximately 25% of all drugs in clinical use are metabolized by cytochrome P450 2D6 (CYP2D6). Case reports and case control and observational studies clearly indicate that PM are at a much higher risk of developing concentration related ADR. On the other hand, ultra rapid metabolism, which is partly explained by *CYP2D6* gene amplification, has been identified as a factor responsible for lack of drug response.

Moreover, in the case of drugs where efficacy depends solely on the formation of an active metabolite, such as the analgesic effect of codeine mediated by the formation of morphine, loss of analgesia has been demonstrated in PMs (5).

Thiopurine S-Methyltransferase

Thiopurine S-methyltransferase (TPMT) catalyzes the S-methylation of thiopurines (6-mercaptopurine and azathioprine). TPMT enzyme activity is controlled by a genetic polymorphism. Approximately 1 in 200 individuals has a very low TPMT activity, 10% have intermediate activity and 89% show normal/high activity. Numerous clinical studies in childhood ALL, rheumatic diseases and IBD have demonstrated that TPMT-deficient patients are at high risk of severe and sometimes fatal hematotoxicity due to the accumulation of cytotoxic metabolites after treatment with standard doses of thiopurines unless a dose-adjusted administration of AZA is used. Prospective determination of erythrocyte TPMT activity or *TPMT* genotype is advocated as a routine procedure prior to therapy in order to avoid drug toxicity.

Dihydropyrimidine Dehydrogenase

5-Fluorouracil (5FU) is widely prescribed for the treatment of solid tumors (e.g. colorectal cancer) and is metabolized to a major extent by dihydropyrimidine dehydrogenase (DPD) to inactive dihydrofluorouracil. DPD exhibits genetic polymorphism in humans. G > A transition at the exon 14 5'-splice consensus sequence characterizes about 50% of non-functional DPD alleles, leading to skipping of exon 14. Total DPD deficiency causes an inherited deficiency in pyrimidine metabolism and is usually associated with thymidine-uraciluria and potentially neurological disorders, whereas heterozygotes appear less likely to exhibit a phenotype in the absence of 5FU treatment. There is currently no strong consensus as to the optimal panel of DPD genotypes that should be determined to provide adequate sensitivity and specificity of DPD genotyping for guiding 5FU therapy.

UDP-Glucuronosyl Transferase

Reduced expression of the UDP-glucuronosyl transferase 1A1 (UGT1A1), which has been associated with increased blood concentrations of unconjugated bilirubin, has been linked to polymorphisms in the *UGT1A* coding region (Crigler-Najjar syndromes) or differences in the number of TA repeats in the *UGT1A1* promoter region (Gilbert's syndrome). Irinotecan is used to treat several human cancers and dose-limiting toxicities of irinotecan (e.g. diarrhea, leucopenia) have been associated with higher levels of the SN-38 metabolite, which is conjugated by UGT1A1. A 7-fold higher likelihood of diarrhea and/or leukopenia was

found in patients with UGT1A1 polymorphisms when compared to patients inheriting the wild type genotype.

Phase

Definition

In the context of circadian rhythms, the term 'phase' describes the momentary state of an oscillation within a period. Phase relation refers to the distance between the phases of defined variables of two oscillatory processes.

- ▶ [Circadian Clocks](#)

Phase Problem

Definition

The central problem in crystallography arises from the fact that the electron density distribution can be

calculated from the amplitudes and phases of diffracted X-rays, but only the amplitudes can be measured. Solving the phase problem means estimating phases well enough to produce a useful electron density function.

► [3D Structure Determination by X-Ray](#)

Phases of the Cell Cycle

Definition

Cell growth and division is divided into 4 phases. In G1-phase (gap 1 phase) the cell grows and prepares for duplication of its DNA in S-phase (synthesis phase). After DNA synthesis is complete, the cell enters G2-phase (gap 2 phase), during which further growth occurs and the DNA is checked for integrity and if necessary repaired. In M-Phase (mitosis), the DNA is condensed into the characteristic mitotic chromosomes and the two copies (chromatids) are separated into two daughter cells. The cell cycle can last from between 10 to 30 hours. Cells that are no longer dividing leave the cell cycle and go into the resting G0-phase (gap zero phase).

Phenotyping; phenotypical characterization; phenotypic screening; phenotypical profiling

Definition

Phenomics is an emerging scientific field focused on phenotypical characterization of ► [mutation](#)-induced changes. It will integrate multidisciplinary biological and genetics research as well as technological advancements and will help organize and mine complex phenotypical data, thereby facilitating multifactorial understanding of complex biological phenomena.

The ease with which genetic mutations can be induced or introduced with targeted mutagenesis (e.g. ► [gene targeting](#) with the use of ► [homologous recombination](#) in ► [embryonic stem cells](#)) or random mutagenesis (e.g. with the use of ► [chemical mutagens](#) such as ENU (ethyl nitroso urea) in mammalian organisms, such as the mouse (► [Large-Scale ENU Mutagenesis Approach in Mice](#)) has created a significant need for phenotypical analysis. Developments in computer technology, instrumentation and ► [bioinformatics](#), as well as in numerous biological disciplines including neuroscience will help to meet the demand set by the molecular revolution. A new field, phenomics, is being born that will integrate multidisciplinary research with the goal of understanding the complex phenotypical consequences of genetic mutations at the organismal level. Although this essay will use examples of behavioral phenotyping to illuminate the role of phenomics in neuroscience, the general conclusions drawn should be valid for all fields of biological investigation.

Characteristics

Genetics has become a major driving force in biology. With the development of ever more powerful recombinant DNA technologies has come the need for sophisticated phenotypical screening tools. Understanding the function of genes even in such a complicated organ as the mammalian brain or studying brain diseases of our own species is now becoming possible.

For most biomedical research the preferred model organism has become the house mouse (*Mus musculus domesticus*) partly because the genome of this species has high sequence homology with that of the human. The recognition that phenotypical characterization of this species is crucial has led to the Mouse Phenome Project (3). Grant funding agencies, e.g. the National Institutes of Health (NIH, USA), have also issued requests for applications to stimulate phenotyping of genetically engineered mice (► http://www.nih.gov/science/models/mouse/genomics/priority_setting_genomics.pdf). It is forecast that the demand for sophisticated and fast phenotyping tools will broaden

the perspective of these analyses both conceptually and technologically.

An Example of Phenotyping Tools: New Ways to Probe Brain Function with Behavioral Analysis

The ultimate output of the brain is behavior and behavioral analysis has the potential to reveal functional alterations of any circuit or any neurobiological process of the brain. However, there have been serious practical issues that limited the utility of behavioral phenotyping. Behavioral tests were time consuming and thus investigators could perform only a limited number of them. The danger of too narrow a focus was that the consequences of the mutation could not be revealed properly. By now it has been widely accepted that broad-spectrum test batteries should be conducted. The questions of how many tests are needed and what should be included in a test battery are debated. It is probable, however, that novel mutations induce unexpected functional changes that may not be captured by a limited number of tests. Furthermore, the ►phenotype, including behavioral traits, is influenced not only by the effects of a large number of genes that interact with each other and modify each other's effects (►epistasis) but also by an almost certainly even larger number of environmental factors that also interact with the genetic effects and lead to the phenomenon termed genotype environment interaction. In summary, the number of "phenes" (or traits) and the number of tests needed to properly quantify them is likely to be enormous.

In the behavioral phenotyping of rodents including the mouse, some test batteries have already gained recognition [for review see (1)]. For example, the SHIRPA protocol is a conglomeration of previously characterized and individually developed tests. CANTAB (►<http://www.camcog.com>) is a system that has some ingenious computerized behavioral paradigms that allow the user to compare behavioral functions across multiple species, from rodent to man. The question of how to organize and design test batteries has been debated. The issue of whether one needs standard or custom designed tests is also not trivial (4, 5, 6). One argument for standardization is clearly the ability to compare results from lab to lab (4). However, the issue of rigidity in standardization leading to the inability to properly evaluate potentially unique genetic effects has been pitted against the advantages of cross-lab comparability (6). The emerging consensus appears to be a compromise; one needs to have a set of standard tests, a sort of reference point, but the need for creative thinking and custom made phenotypical test applications is also recognized (5). Numerous other questions have also been considered. For example, investigations as to how the order of tests in a battery may influence the outcome of the study and whether one test may

interfere with another have been started. The problems associated with lab-specific environmental factors and their interaction with the genotype of the studied subjects, i.e. genotype environment interaction, has been brought to attention and false positive and negative findings due to inappropriate control of the environment and/or the ►genetic background (2) have also been pointed out [for review see (1)]. Finally, the importance of better understanding of the ecology of the mouse and utilization of biologically/ethologically relevant paradigms has been extensively discussed [for review see (1)].

Often, the rationale behind test batteries is that they are organized hierarchically; the investigator starts from broader, less specific, tests that are sensitive to numerous factors and subsequently employs more and more specialized tests that finally tease out the details of the functional alterations of the brain. The question, however, of what the organizing principle should be has not been explicitly addressed. Pharmaceutical and biotechnology research companies may benefit from test batteries that are primarily organized according to disease target. For example, a test battery aimed at ►Alzheimer's disease research may need to cover major domains of cognition, e.g. attention, short- and long-term memory and executive function, in a manner similar to the way these behavioral phenomena are examined in the human clinic. Others may prefer organizing the test battery in a way that would allow one to tap into different neurobiological mechanisms or the function of neuroanatomical areas of the brain. For example, in the analysis of memory, one may be interested in whether acquisition, consolidation, retention or recall is affected by the mutation. One may also be interested in what brain area is affected, e.g. whether procedural learning (perhaps cerebellar function), relational learning (perhaps the hippocampus), elemental learning (perhaps the cortex) or emotional learning (perhaps the amygdala) is altered. While test batteries based upon these different organizing principles are clearly not orthogonal or mutually exclusive, they may yield different answers when employed. However, irrespective of the organization of the test battery, it has been generally appreciated that multiple tests tapping into the same phenotype (behavioral trait in this case) while employing idiosyncratic procedures and representing unique performance demands must be conducted to avoid false findings.

Speed Versus Quality

From the above it is clear that a test battery represents a significant challenge. Optimizing a battery is not trivial. The primary problem is practical; phenotyping is space and time intensive. The danger is that speed may be increased at the expense of quality. Steps have been taken to address this problem. One solution is

scalability, i.e. the increase of the number of pieces of apparatus (and thus experimental subjects) one runs in parallel. The second solution is to increase the information density of the test, i.e. the number of phenotypical measures that one can obtain from a single test. The third is to increase the flexibility of the test apparatus to enable it to tap into a broader spectrum of domains of gene function. Increased processing speed and memory capacity now allow computers to control several pieces of apparatus in which, e.g. animal behavior is monitored. Computerization also makes it possible to record numerous phenotypical measures at the same time. For example, detection of motor patterns is now possible using force transducer technology or 3D computer vision (1). The latter pioneered by PsychoGenics Inc. (Tarrytown, NY, USA) and Noldus Info. Tech. B.V. (Wageningen, The Netherlands) is particularly sophisticated and will allow quantification of a large number of behavior elements, motor and posture patterns in an automated manner. The “SmartCube” of PsychoGenics can also be equipped with numerous instruments including food receptacles, shock grids and conditioned stimulus delivery devices, thus facilitating both complex behavioral quantification and stimulus presentation. Thus, one can design and conduct countless types of behavioral paradigms in a precisely controlled manner and without the interference of a human experimenter. Another device based on the principles of scalability, increased information density and flexibility is the Intellicage developed by NewBehavior Inc. (Zurich, Switzerland, <http://www.newbehavior.com>). This system employs transponder-based technology to monitor the whereabouts of several mice in the same (intelli)cage. As the device can differentiate the individual mice by means of implanted commercially available microchips, the computer based monitoring system can tell which mouse is working to obtain reward from a receptacle, which one is running in the middle of the cage and which one is sitting in the corner frustrated by all this technological sophistication. The Intellicage is not only sophisticated but also mimics the natural habitat, a mouse community. It has been developed on the basis of information gathered in field studies and the semi-natural enriched environment it provides may facilitate the high-throughput analysis of several behavioral phenomena ranging from learning or anxiety to numerous aspects of social interaction.

Bioinformatics to the Rescue

The amount of phenotypical data gathered using such devices can be staggering. Bioinformatics tools and multivariate statistical methods may be required to properly and concisely extract information from phenotypical tests. Furthermore, phenotyping may

include a large number of different disciplines. For example, in addition to behavioral tests, *in vivo* multielectrode recording from individual neurons can be performed and the behavioral and electrophysiological quantification of brain function may be conducted *in vivo* in the same, freely moving, mouse, further increasing the demand for complex mathematical procedures in data analysis and data mining. Emergent patterns based on phenotypical “mosaic pictures” may be discovered that reflect certain neurobiological mechanisms or disease states better than individual measures. In summary, investigation of complex phenotypes will require new analytical procedures. Comprehensive databases will help the investigator. The seeds of such databases already exist. For example, the Internet accessible public domain ‘Induced Mutant Resource’ (or IMR) database (<http://www.jax.org/resources/documents/imr/>) together with another database called TBASE (<http://tbase.jax.org/>) from The Jackson Laboratory (Bar Harbor, ME, USA) provides comprehensive listing of mutant mice along with their phenotypical profiles. Open discussion forums where scientists can share data and ideas beyond the details usually provided in peer-reviewed journals have also been suggested. Bioinformatics tools that were developed to cope with the large amount of genetic information coming out from sequencing of genomes or gene expression analyses will be also crucial for organizing and interpreting phenotypical data.

Clinical Relevance

Phenomics will be defined not only by the sophistication of the experimental paradigms but also by technological complexity. Hardware and software engineers as well as biologists, bioinformaticians and statisticians will co-develop test paradigms and equipment that will enable the investigator to characterize the phenotype of genetically altered organisms in a detailed manner. Phenomics will be a crucial approach in both academic as well as industrial research and may lead to a significant paradigm shift in the genetic modeling and analysis of human diseases. These phenotyping tools will also be useful for the analysis of the effects of pharmaceutical agents, the so called small molecules, and thus the development of drug therapies.

Phenotype

Definition

Phenotype is the physical appearance of an organism, a tissue or a cell, determined by the genetic make-up (“genotype”) together with the environment. The term is also used to define the consequences of a particular mutation, or to describe certain cellular or molecular characteristics. Phenotypic traits are not necessarily genetic.

Synonyms

PKU; phenylalanine hydroxylase deficiency;
Fölling disease

Definition

PKU (► OMIM *261600, ► <http://www.ncbi.nlm.nih.gov/Omim/>) is an inborn error of metabolism with a deficient or absent activity of the enzyme phenylalanine hydroxylase (PAH, phenylalanine 4-monooxygenase, ► EC 1.14.16.1, ► <http://www.chem.qmw.ac.uk/iubmb/>). The enzyme defect is due to mutations in the PAH gene on human chromosome 12q24.1 and is inherited as an autosomal recessive Mendelian trait. Almost 500 different mutations are now known. The most severe PAH defects render tyrosine, the product of the enzymic reaction, an essential amino acid. With such defects, the PAH substrate phenylalanine (phe) can only be cleared through protein synthesis and, less efficiently, through minor alternate metabolic routes and urinary excretion. The clinical chemical results are elevated blood levels of phe (i.e. hyperphenylalaninemia) and of acidic phe metabolites. Without strictly

managed dietary treatment this will lead to an irreversible state of mental retardation.

Excluded from this definition are the various types of atypical severe phenylketonuria with genetic defects of PAH cofactor (tetrahydrobiopterin) recycling or synthesis, e.g. dihydropteridine reductase deficiency (OMIM *261630) and GTP cyclohydrolase deficiency (OMIM #233910, *600225). They make up only about 1 per cent of all cases of hyperphenylalaninemia.

Characteristics

PKU deserves interest from a multitude of points of view. It has become the textbook example of a classic inborn error of metabolism which covers almost all aspects of modern biochemical genetics of man, including biochemical pathogenesis, diet therapy, population-wide newborn screening and maternal disease. PKU also contributes to the study of population history because the distribution of different mutations may serve as a tracer of ancient population movements. And, research in PKU contributed one of the first disease models in mice (1, 2)

Clinical Characteristics

The clinical phenotype of untreated PKU is characterized by severe mental retardation, a seizure disorder, microcephaly, fair complexion of skin and hair, eczema and, sometimes, a peculiar 'mousy' odor. None of these signs would allow a specific diagnosis. It was Föllings discovery in 1936 of a highly specific sign (the urine of some mentally retarded patients turns green on addition of an acid solution of ferric chloride) that made possible the delineation of PKU as a clinical entity. The next step, also done by Fölling, was the identification of phenylpyruvic acid (PPA) as the agent involved in the color reaction.

PPA, the transamination product of phe, is chemically unstable and its excretion may be low. Furthermore, the ferric chloride reaction is rather insensitive. It therefore was Fölling's discovery of increased blood levels of phe that finally established a diagnostic criterion with 100% sensitivity. Testing for hyperphenylalaninemia enabled the diagnosis of PKU in all suspected cases, e.g. among the residents of institutions for the mentally retarded where about 1% of the elderly are afflicted with severe types of PKU.

In the young population, the unfavorable and irreversible course of the disease has almost disappeared in the industrial nations due to newborn screening and subsequent initiation of diet therapy. Nevertheless, reversible cognitive features may be observed when, at times, the rules of diet therapy are not obeyed. Such signs of temporarily elevated blood levels of phe are headache and the inability to work with concentration. If the diet was discontinued early, e.g. at the age of 6, adults may manifestly reduced intelligence scores.

Those with normal intelligence seem to possess, as a protective mechanism, a reduced capacity for phe transport from blood to brain.

With regular monitoring of blood phe and with firm adherence to the low-phe diet therapy well into adulthood, the regular outcome is a PKU person with a normal mental phenotype and successful social adaptation.

As a phe-dependent embryo-fetopathy, maternal PKU has emerged as a second clinical manifestation of PKU, this time in the heterozygous offspring of homozygous mothers who never knew of their disease or who forgot about their metabolic disease after treatment was discontinued at an earlier age. If maternal blood levels exceed 20 mg per dl, offspring will be mentally retarded in over 90%, will be microcephalic in about 75% and will have heart malformations in about 12% of cases. Birth weight will be reduced.

Therapeutic Management

The dietary treatment of PKU commenced in 1953 when Bickel, Gerrard and Hickmans documented improved mental development of PKU children on a low-phe diet. This early success made any controlled study unethical. It therefore remained unknown in the beginning that 2–5% of people with classic PKU will more or less escape mental retardation without dietary treatment and the mild non-PKU hyperphenylalaninemia (MHPA) has only recently been established as an entity that does not require a PKU diet. Diet therapy must start within the first weeks of life in order to avoid the irreversible cognitive sequels of hyperphenylalaninemia.

The rules of dietary treatment concern (i) the level of phe that should be attained and (ii) the question of whether or when the treatment could cease. Presently, treatment centers aim at 300 micromoles phe per liter (i.e. 5 mg/dl) and life-long dietary surveillance is now uniformly recommended.

To prevent the maternal PKU embryo-fetopathy, pregnant PKU women must be treated as strictly as PKU children and optimal treatment will start pre-conceptionally.

Additional therapeutic options are (i) a supplementation with the cofactor tetrahydrobiopterin which stabilizes a number of different enzyme mutants, thus acting as a 'pharmacological chaperone' and (ii) supplementation with large neutral amino acids which inhibit the transport of phe from blood to brain (see above). (iii) A still experimental option is dialysis with phe ammonia-lyase (PAL, EC 4.3.1.5) containing cartridges. PAL converts phe into ammonia and *trans*-cinnamic acid. The latter product becomes metabolized to hippuric acid, which is finally excreted into urine. (iv) Gene therapy is presently being investigated with genetically engineered keratinocytes as one of the possible future methods.

Newborn Screening

During pregnancy, the metabolic defect of the fetus with PKU is corrected through transplacental outflow of phe into the maternal circulation. Thus it is only after birth that hyperphenylalaninemia ensues. In classic cases, then, blood levels may exceed 40 mg/dl, the normal level being about 1 mg/dl.

The semi-quantitative bacterial inhibition test invented by Guthrie and Susi measures the outgrowth in agar plates of *Bacillus subtilis* spores in the presence of the phe analog β -thienylalanine. Quantitative data are obtained by enzymatic screening with phe dehydrogenase, E.C. 1.4.1.20. Tandem mass-spectrometry has emerged as a general and highly specific method for screening for a larger number of inborn errors of metabolism, including PKU.

PKU screening has become paradigmatic in a number of ways. To be socially and economically acceptable, any screening procedure must fulfill all of the following three criteria. (i) It must be robust, sensitive, and specific. (ii) The disease to be screened for must have an appreciable incidence at birth and (iii) the disease must be treatable. It therefore would make no sense to screen for PKU in Finland where the disease is almost absent and it is highly controversial to screen for ►Duchenne muscular dystrophy as long as its lethal course cannot be averted by therapeutic measures.

Population Genetics of PKU Mutations

Population history (bottlenecks and migration), population structure (degree of inbreeding, religious and geographic isolates) and chance (so-called genetic drift) determine the frequency of given mutant PKU alleles and of PKU incidence in general. Countries with a high PKU incidence are Turkey (1/2,600), Ireland (1/4,500), and Scotland (1/5,300). The incidence in Poland and Germany is about 1 in 7 to 8,000, whereas in UK, France and Switzerland it is comparatively low (about 1/15,000). In countries with high PKU incidence, pediatricians must recall the possibility of maternal PKU when caring for a child with unexplained microcephaly and congenital heart disease.

Of special interest is the geographical distribution of mutations and the regional changes (clines) of their frequencies. It shows, for example, that the mutation R408W (arginine in position 408 changed to tryptophan) originated once in Ireland and once in Eastern Europe. The distribution of other mutations allows estimates of their age and may give hints as to the peopling of countries.

Mouse Models of PKU

Artificially created mouse mutants have become indispensable objects in the study of the pathogenesis and therapy of human inherited diseases.

In the 1970s, experimental PKU models were created by treating mice with high doses of phe together with the PAH inhibitor *para*-chlor-phenylalanine. Since 1990, real mouse PAH mutants are available. They are created by male germline mutagenesis with N-ethyl-N-nitrosourea (ENU). The second of these mutants, the *Pahenu2* mouse, is due to a phe → serine substitution in exon 7 of the PAH gene and has a severe metabolic phenotype.

Cellular and Molecular Regulation

Research in PKU also set the stage for genotype-phenotype correlations in inborn errors of metabolism. In the beginning, the mutant enzymes were studied in patient liver biopsies. With the advent of molecular techniques, it became possible to analyze enzymes with defined mutations in transfected cell lines and relate these data to the clinical outcome.

Now, that the 3D-structure of the PAH enzyme has been elucidated, it has become possible to deduce the mechanism of action of a given mutant, as it was possible to do with the hemoglobinopathies when the 3D-structure of the adult hemoglobin tetramer had been defined in the 1960s. Despite the power of the modern approaches, it has become increasingly evident that predictions may fail. Although the PAH enzyme defect obeys the rules of Mendelian inheritance, PKU turns out to be a multifactorial disorder with environmental and (still unknown) genetic factors contributing to clinical variability, even within families (3).

Types of Mutations

The PAH gene was cloned in 1983 and the first PAH mutation, a deletion, was identified in 1985. At present, almost 500 mutations are known, and most of them were discovered between 1990 and 1995. With 63%, missense mutations are the most frequent type, followed by 13% small deletions, 11% splice mutations and 5% nonsense mutations. There are 7% putative silent mutations, e.g. V399V, where a DNA base change A → T in codon 399 changes the valine codon CAA to the valine codon CAT. Some of the putatively silent mutations and also some missense mutations turned out to be splice mutations, because they had created a new splice site.

With increasing age and wider geographical distribution of a mutation, there is a growing probability that a second mutation will be acquired 'in *cis*' by one of the mutant alleles, either by a mutational event or by homologous crossing-over in a compound heterozygote. The beta hemoglobin sickle cell (HbS; HBB glu 6 val) mutations Hb C Harlem / Georgetown (HBB glu 6 val + asp 73 asn), and Hb C Ziguinchor (HBB glu 6 val + pro 58 arg), provided the first examples of *cis*-mutations, six being known by now for Hb S alone. There are 12 known *cis* mutant alleles of the

PAH gene. The ancient R408W mutation, for example, has acquired a *cis* mutation in each of two different alleles, E183Q in one and D315Y in another. Undetected *cis*-mutations may mislead the interpretation of disease alleles and of innocuous DNA polymorphisms. In the cell, the PAH enzyme exists in an equilibrium state of homo-dimers and homo-tetramers. Each subunit is composed of 452 amino acids (aa) and structured into three functional domains, the N-terminal regulatory domain (aa 1-142), the middle catalytic domain (aa 143-410) and the C-terminal tetramerization domain (aa 411-452). With regard to this structural basis, PKU mutations may be classified as active site mutations, dimer interface mutations and domain structure mutations (4). Somewhat unexpectedly, not all active site mutations lead to classic PKU, e.g. Y277D that concerns an evolutionarily highly conserved position. Domain structure mutations cause a broad spectrum of PKU phenotypes. They are pathogenic mostly by interfering with the overall protein stability, e.g., when a large hydrophobic aa is replaced by a smaller one (leucine by valine) or *vice versa* (valine replaced by methionine) or when a hydrophobic aa is replaced by a polar one (phe by serine).

Biochemical Parameters of Mutant Enzymes

Enzymatic parameters that can be altered or nullified by a mutation are substrate and cofactor affinities, maximum catalytic velocity, protein stability at different temperatures and amount of immunoreactive material. If an enzyme is easily available, like erythrocyte glucose-6-phosphate dehydrogenase, all these parameters can be estimated for characterizing its mutants. However, because PAH is primarily a liver enzyme, only a few early studies were made on native liver biopsy samples. They established a clear relationship between residual PAH activity and severity of PKU phenotype. MHPA patients were found to have $\geq 5\%$ of normal PAH activity. Modern *in vitro* expression analysis (IVE) uses transfected cell lines (COS, human kidney), yeast and *E. coli* to analyze enzyme activity, immunoreactive protein, specific activity and amount of mRNA, all expressed as % of wild type. Most of these data do more or less correlate with the clinical phenotype. An interesting exception is the catalytic domain mutant A309V with high activity *in vitro* and a severe phenotype *in vivo*. Although the mutation density is 2–3 \times higher in the catalytic domain sequence than in the two other domains, IVE data indicate that most PAH mutations cause PKU by interfering with normal folding and by destabilizing the enzyme protein with consequent formation of inactive protein aggregates. PKU has therefore been called a 'protein folding disorder'.

Mild mutations and most recently also more severe ones have been shown to be tetrahydrobiopterin-responsive. Their different mutant sites are found all over the protein, pointing to a general stabilizing effect. This effect is now therapeutically exploited.

Classification of PKU and the Prediction of Metabolic Phenotype

A reliable prediction of the metabolic phenotype early in life is important for two reasons; management of diet therapy can then be individualized and informing parents about the disease will be based on validated prognostic features. In the pre-genomic era, Blaskovitz had devised a three days protein-loading test for evaluating the phe tolerance of six months old babies. In the severe types of PKU, very high phe blood concentrations could ensue during this test. Alternative measures to define disease severity were the initial phe levels in newborns, loadings with tritiated phe or unlabelled phe and, in older patients (5 years), the daily amount of ingested phe that was tolerated while keeping phe blood levels at 5 mg/dl. For classical, moderate, mild PKU and MHPA, these amounts were set at ≤ 20 , 20–25, 25–50 and ≥ 120 ('normal diet') mg phe per kg body weight per day.

A classification system for adults is based on phe blood levels during 'normal diet', classical PKU 20, moderate PKU 10 and MHPA 4 mg/dl, respectively. A metabolic model has been published (5) which enables translation of such values into kinetic parameters of phe disposal. These clinical classifications of metabolic phenotype can now be related to the different PKU mutations, so that predictions have become possible in newborns (6). The system is based on the observation that in compound heterozygotes the metabolic phenotype is determined in an additive fashion. Homozygotes for a null mutation and compound heterozygotes for two different null mutations will have classic PKU, e.g. R408W/R408W and R408W/R158Q. Compound heterozygotes of a null and a mild mutation ('functional hemizygotes') display a mild metabolic phenotype; two moderate or mild mutations act additively. Classic, mild, moderate and MHPA mutation are scored in a geometric series as 1, 2, 4, and 8 respectively and the sum of the two scores predicts the metabolic phenotype: 2 \rightarrow classic; 3 \rightarrow moderate; 4 \rightarrow moderate/mild; 5 and 6 \rightarrow mild; 8 \rightarrow mild/MHPA; 9, 10, 12, and 16 \rightarrow MHPA.

Pathogenesis of Metabolic and Cognitive Phenotype

The above predictive system (6) was evaluated in 184 patients, and discrepancies were found in about 20% of cases. This indicates that individuals may differ with regard to the 'handling' of their mutations. This

postulate is corroborated by observations of siblings with identical genotype but different phenotypes and it receives further support from the finding that the mutations I65T and R261Q are overrepresented in patients with discordant phenotypes. It can, at present, only be surmised which factors modulate the metabolic effect of mutations. They may act at the level of the PAH enzyme (e.g. capacity of chaperones and proteases), at the level of intermediary metabolism (capacity of secondary metabolite pathways) or at the level of renal physiology (urinary excretion).

A great number of hypotheses have been formulated to explain the finding of varying cognitive capacities in untreated or 6 years only treated PKU patients. Beside the surmised influence of neurotransmitters, the only validated relation is the blood-brain barrier phe transport and the corresponding intra-cerebral concentration of phe. The latter, as measured with magnetic resonance spectroscopy, correlates inversely with the cognitive capabilities and is in the range seen in heterozygotes when intelligence in the patients has remained normal. This points to phe itself as the major pathogenic factor in the cognitive outcome of PKU.

Phosphatidyl Serine

Definition

Phosphatidyl serine (PS) is a membrane phospholipid that is located in the inner cytoplasmic leaflet of the cell membrane. In apoptotic cells, PS is translocated within the cell membrane so that it appears on both the inner and the outer surface. PS represents an important surface molecule that helps to recognize the cell as an apoptotic one for phagocytes.

Phospholamban

Definition

Phospholamban (PLB) is a 52 amino acid, homopentameric protein that regulates the cardiac Sarco-plasmic Reticulum Ca^{2+} -ATPase (SERCA2).

Photobleaching

Definition

Photobleaching denotes the light induced irreversible destruction of a fluorophore's fluorescence properties. This can occur during the course of exposing a fluorophore to a light source, or it can be regulated by controlled exposure of a discrete ROI (►[region of interest](#)) to intense laser light. After ca. 10^5 excitation-emission cycles, most common fluorophores tend to undergo photodeconstruction, i.e. an irreversible transition to a non-fluorescent state.

Definition

Living cells react to external stimuli, in order to perform their functions in organisms or to adapt to their environment. Stimuli are realized in physical or chemical signals which are often detected by specialized membrane receptor proteins. For the perception of light Nature has developed exceedingly diverse solutions, which are in many – if not all – cases driven to the physical limit of single photon detection. Beyond every day's experience, light controls much more than 'sees the eye'; almost every organism monitors and reacts towards illumination. In physical terms, photoreceptors serve to capture the short lived excited state caused by photon absorption, in order to channel the energy of the excited state into a conformationally or chemically altered ►[chromophore-protein interaction](#).

A high percentage of the photonic energy is thereby stored in the chromoprotein. Examples include *cis/trans* isomerization in ►**rhodopsins** or phytochromes and cysteinyl adduct formation in phototropins. By extending the local alterations near the chromophore to functionally defined domains, the receptor protein becomes competent to form a long lived signaling state. This is recognized by specialized coupling components of a downstream regulatory network. Biological outputs include neuronal signaling, behavioral responses, circadian adjustment, DNA gene regulation or protein expression.

Characteristics

Absorption of light serves many biological functions. The free energy of visible light can be fed into energy transduction and photosynthesis in plants and microorganisms or provide a signal for information flow as in vision or be used for the entrainment of a circadian clock. Typically, each family of ►**chromoproteins** performs more than one of these purposes by one or several of its members (1). The archetype in signal transduction is the visual pigment rhodopsin, the “visual purple” in the retinal rods and cones (2). It has numerous cousins in the still expanding family of ►**retinal proteins**. Vertebrate proteins include those serving circadian entrainment, a role most likely played by the melanopsins located in the photosensory ganglions of the retina and also by pinopsin which is expressed in the avian pineal (3). Photoisomerases (►**RGR**) located in retinal pigment epithelium use photonic energy for the backisomerisation of photolysed all-*trans*-retinal into the 11-*cis* form needed for visual pigment regeneration. Bacterial rhodopsins which display some structural similarities with vertebrate rhodopsins are found throughout all three kingdoms of life and serve sensory as well as energy needs of the cell. A new class of retinylidene proteins, channelopsins, are light activated proton and/or cation channels. Another family of photoreceptors, ►**cryptochromes** encompass flavoproteins which are sensitive to blue light. These receptors, which share sequence homology with light dependent DNA repair photolyases, have been detected in plants and as circadian clock components in animals (4). Finally, phytochromes with phytochromobilin as chromophore, absorbing predominantly the red and far-red region of the spectrum are involved in plant growth and development.

Photoreceptors are found not only in cell membranes but also as soluble proteins or as a part of larger multidomain proteins in the interior of the cell. Intracellular photoreceptors often appear as domains of larger polypeptides. In this way, ►**LOV domains** harboring the flavin chromophore can be directly connected to histidine kinase effectors. Such an

arrangement may guarantee the most efficient transmission of the light signal from receptor to effector. Receptors that bind diffusible extracellular ligands have to connect to both sides of the plasma membrane to carry the signal to the cell interior. Although there is no such requirement for photoreceptors, the membrane bound proteins are in their general topology strikingly similar to “normal” receptors not carrying a chromophore. This may reflect a common evolutionary origin and/or the same signal processing principle. Examples include visual signal transduction, where rhodopsin shares the seven transmembrane structure of other G-protein coupled receptors (►**GPCRs**). Another well-characterized representative is bacterial ►**phototaxis**. In this latter example the receptor comprises a seven transmembrane protein (SR I and II) and a tightly bound transducer (►**Htr** I and II), which in turn displays homology to the cytoplasmic domain of eubacterial ►**chemotaxis** receptors. Interaction partners are G-proteins like transducin (Gt) or histidine kinases like CheA, activating the visual cascade in rods and cones or the two component system in eubacterial photo- and chemotaxis, respectively. These two receptor systems are currently the best understood and reveal instructive similarities and differences (2, 5, 6). Their elucidation may help to understand common principles in photoreceptor signaling and even signal transfer for stimuli other than light.

Molecular Interactions

Topology

The extracellular (intradiscal) and intracellular regions of seven helix receptors (Fig. 1) each consist of three interhelical loops (E(xtracellular) and C(ytoplasmic), respectively), and terminal (COOH- or NH₂-) tail regions. The cytoplasmic domain of the transducer protein in bacterial phototaxis displays short connecting loops of transmembrane helices and is highly homologous to the corresponding section of chemotaxis receptors. It has been shown that chimeric proteins convey the ability for phototaxis to *E. coli*, demonstrating the functional identity of chemo- and photo-taxis signaling pathways. The complex between sensory rhodopsin and the transducer forms in a 2:2 stoichiometry. In the rhodopsin of vertebrate rods, a fourth cytoplasmic loop is introduced by anchoring the C-terminal tail to the membrane *via* two Cys residues which carry palmitates in the native structure. It also contains the short helix H-VIII, adjacent to H-VII, which runs parallel to the cytoplasmic surface. Rhodopsin is contained in the flat disc vesicles, which fill the outer segment of the rod cell like a stack of coins. Rod cells share with all sensory cells a bipartite outer/inner segment structure with a thin connecting cilium. Transducin (Gt) is bound to the cytoplasmic surface of the discs and, by interaction

Photoreceptors. Figure 1 Crystal structure of rhodopsin (lower panel) and the sensory rhodopsin II-transducer complex (upper panel) as viewed from the cytoplasm. Corresponding helices display the same color. Helix VIII (rhodopsin) and TM1, TM2 are depicted in grey.

with light-activated rhodopsin, catalytically converts into the active GTP-bound form which in turn activates a cyclic GMP phosphodiesterase. This effector hydrolyses the second messenger cyclic GMP. Its low concentration results in the closure of cyclic GMP dependent ion channels.

Receptor Activation and Regeneration

The absorption of a photon causes isomerization of the retinal chromophore between *cis* and *trans* configurations, followed by thermal relaxations which ultimately lead into the signaling state. The covalent retinylidene linkage between chromophore and apoprotein is

provided by a ►Schiff base. In the dark ground state, the nitrogen of the Schiff base is protonated and stabilized by a counter ion, provided by the negatively charged carboxylic group on a Glu or Asp residue in the third helix. After light excitation the retinal chromophore undergoes fast initial motions on the excited-state potential surface. Eventually, retinal reaches a region in the configurational space, where the transition to the product state can take place. The subsequent reactions leading to the signaling state were in both systems initially characterized by colored intermediates (such as K, L, M in the case of sensory rhodopsin II or Batho, Lumi, Meta I, Meta II in the case of rhodopsin, denoted according to the respective UV/Vis absorption spectra). The conversion into the activating conformation is marked by a UV absorbing “bleached” product (M or Meta II), in which the Schiff base is still intact but deprotonated (Fig. 2).

The decisive difference between vertebrate and bacterial rhodopsins concerns the reversibility of the light induced pathway (Fig. 2). In bacteria, thermal reactions restore the original all-*trans* ground state. Contrarily, after light excitation of the 11-*cis* retinal-opsin ground state complex, vertebrate rhodopsins follow a unidirectional mechanism which finally leads to the hydrolysis of the retinylidene Schiff-base and the export of all-*trans* retinal. This is enzymatically reisolomerized into 11-*cis*-retinal in neighboring pigment epithelium cells. In addition, the back transport of 11-*cis* retinal to opsin requires several enzymatic and transport steps. This retinoid cycle takes minutes to be completed. The question arises as to why nature has chosen such an elaborate cycle to regenerate the light sensitive receptor. Not even the absorption of blue light allows the restoration of the original 11-*cis*-retinal-opsin complex. This is likely to be the price to be paid for the exceedingly stable ground state provided by this form of retinal (6 and citations therein). Apparently, this specific 11-*cis* retinal-protein configuration is necessary for the complete inhibition of thermal receptor activation in the dark on the one hand and single quantum excitation on the other hand.

Properties of the Signaling State

Properties of the ►signaling state are best understood when considering the dark ground state first. A major stabilizing element is the salt bridge from the Schiff base nitrogen to its counter ion (Asp⁷⁵ in SR/Htr, Glu¹¹³ in rhodopsin). The X-ray structure of the SR II/Htr II complex revealed a tight interaction between helix F_{SRII} and TM2_{HtrII}. Vertebrate rhodopsin displays special interactions between helices, including the tripeptide Glu¹³⁴-Arg¹³⁵-Tyr¹³⁶, highly conserved throughout GPCRs, which contributes to stabilizing the hydrogen bond network between helices III and VI. Met²⁵⁷ in H-VI is surrounded by a Leu cluster

Photoreceptors. Figure 2 The photoreaction cycle of (a) rhodopsin and (b) sensory rhodopsin II. Only the intermediates involved in the direct formation and sustenance of the signaling state are depicted.

extending to H-II and H-III. The NPxxY(x)_{5,6}F motif extends over H-VII and H-VIII causing a rectangular kink by hydrophobic interaction between Tyr³⁰⁶ and Phe³¹³. Certain interactions must persist to reach the

signaling state. They comprise the hydrophobic interaction between Tyr³⁰⁶ and Phe³¹³ in rhodopsin and may include a strong hydrogen bridge between Tyr¹⁹⁹ in SR with Asn⁷⁴ in Htr.

The transition into the signaling state is enabled in both systems by a breakage of the Schiff base stabilizing salt bridge. It is brought about by proton transfer from the Schiff base to the counter ion and thus defines the M or Meta II photointermediate. A second step reveals itself as a spectrally silent conversion, termed M1 \rightarrow M2 or MetaIIa \rightarrow MetaIIb. It is found either by kinetic analysis of the photocycle in SR or by proton uptake to Glu¹³⁴, which breaks interactions around Glu¹³⁴-Arg¹³⁵-Tyr¹³⁶. Light-induced helix motion, which has been demonstrated for both receptors, is in SR/Htr definitely linked to M1 \rightarrow M2. Helix F/ VI tilts out of the helix bundle, with the hinge probably located at Pro 175 or a Gly-Gly tandem in SR and H-VI, respectively. Helix F motion in SR would tangentially collide with TM2, thus inducing its rotation (Fig. 1).

Regulatory Mechanisms

Once the signaling state of the receptor is reached, the signal has to be processed by the downstream components of signaling pathways. Although mechanistic details of the signaling machineries in living cells are quite diverse they do exhibit a number of operating principles in common. To meet the cell's need, the incoming signal has to be amplified and must be switched off on demand. In bacterial signal transduction, the signaling cascades usually belong to regulatory systems which integrate over different extracellular inputs and which may additionally incorporate information from the physiological state of the cell. The cells also have to control the effector activity over several orders of magnitude. Unlike bacterial signal transduction, the rod cell is highly specialized serving like the olfactory cells only one purpose. In vision the system has to cope with light intensities ranging from single quanta to brilliant sun light as encountered in snow, i.e. 11 orders of magnitude. Depending on the species, a substantial part of the adaptation utilizes the transduction machinery in the sensory cell itself.

Amplification of the Light Signal

The ►**amplification** of the incoming signal is different for the rhodopsin signal transduction chain from that of the bacterial photoreceptors. The activation of a G-protein, as a catalytic process, has the capacity for "particle amplification" in the first step of signal relay. Amplification is thereby driven by the GTPase cycle of the G-protein. Signal transfer from SR/Htr to the His-kinase CheA however follows a stoichiometric signal transfer. This receptor family and its circuit elements show high homology to the chemotaxis system. For the latter it has been shown that the receptors form patches

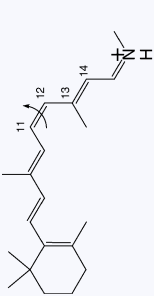

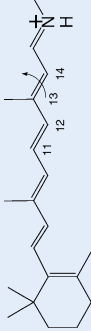

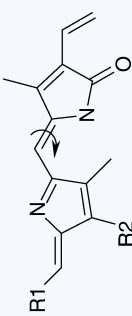

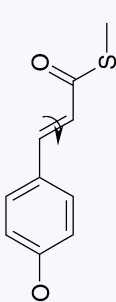

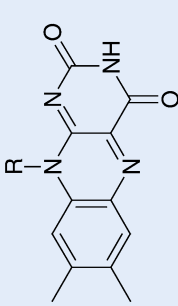

and higher order receptor assemblies. Amplification based on the idea that the activation of one receptor may affect numerous neighboring receptors would be fundamentally different from that involving G-proteins, because there is no energy fed into the system except the photo- or chemo-activation.

For vertebrate rhodopsin, a supramolecular arrangement (rows of dimers) was also reported. Although a constitutive dimerisation of rhodopsin has been challenged, based on the diffusional freedom of rhodopsin in dark-kept intact rod cells, a "functional" dimerisation of GPCRs may well play a role in different stages of their activation/ deactivation. The actual amplification at the G-protein stage, more than hundred in the rod cell, is much lower in the microvillar photoreceptors of insects. Their transduction chain *via* Gq/phospholipase C, feeds into a heteromultimeric signaling complex ("transducisome") of ►**trp channels**. Subcellular translocation of such channels has been shown to be involved in long term adaptation. Less clear is the role of a rod transducisome, which forms through an unusual set of glutamic-acid-rich proteins of unknown function. While a translocation of components of this complex has never been observed, Gt and arrestin undergo translocation between the inner and outer segment and through the thin connecting cilium. Extended illumination depletes the outer segment of Gt but enriches it with arrestin.

Deactivating Interactions and Adaptation

Light activation must be reset on a subsecond time scale, to allow repeated activation of the transduction system. In the case of the bacterial photo- and chemoreceptors, the deactivation and adaptation of sensor kinase activity is an intricate interplay of two proteins which methylate and demethylate specific residues located in the cytoplasmic domain of the transducer (or chemoreceptor). In this way the phosphate flow is regulated by integral feedback control. In the rod, the dark level of cyclic GMP is restored by a feedback loop activating a guanylate cyclase *via* calcium-binding protein(s). A complete reset also implies the deactivation of the cascade at all its stages, namely, receptor, G-protein and effector. The Gt-phosphodiesterase complex is deactivated by the intrinsic GTPase activity of the G-protein, up-regulated by RGS-9, a member of the "regulators of G-protein signaling" family. Rhodopsin is deactivated by interaction with rhodopsin kinase, phosphorylation and subsequent binding of arrestin. Ultimate deactivation in the dark requires regeneration of rhodopsin with fresh, metabolically supplied 11-*cis*-retinal. This closes the rhodopsin cycle and makes the receptor available for renewed light activation.

Photoreceptors. Table 1 Brief compilation of various photoreceptor classes

Chromophore	Primary reaction	Photosensor	Cellular location	Signaling cascade (components)	Physiological response
	11-cis → all-trans	Rhodopsin	Specialized photoreceptor membrane Plasma membrane	G-protein Second messenger	Neural response Circadian synchronization
	all-trans → 13-cis	Bacterial Rhodopsin	Bacterial plasma membrane	Two component system His kinase	Phototactic response
	cis → trans	Phytochrome	Cytoplasm Nucleus	Two component system His kinase (prokaryotes) Ser/Thr kinase Transcription factors (plants)	Photomorphogenesis Phototactic response Circadian synchronization
	trans → cis	Xanthopsin	Cytoplasm	Not known	Phototactic response
	Electron transfer? Covalent adduct formation	Cryptochrome Phototropin LOV domain	Cytoplasm Cytoplasm	Kinase activation DNA-binding In the dark: ubiquitination Two component system His kinase (prokaryotes) Light regulated Ser/Thr kinase activity (plants)	Photomorphogenesis Circadian synchronization Photomorphogenesis

PI3K

Definition

Phosphatidylinositol 3-kinase (PI3K) is a heterodimeric enzyme, comprising of a 110 kDa catalytic subunit (p110) and an 85 kDa regulatory subunit (p85). In addition to its p110 binding site, the p85 subunit contains SH2 and SH3 domains, which mediate its interactions with other cellular proteins. Phosphoinositide 3-kinase (PI3K) family enzymes phosphorylate the phosphoinositide class of lipids at the 3-OH position of the inositol ring. Upon activation, PI3Ks phosphorylate phosphatidylinositol (4,5)-bisphosphate (PtdIns(4,5)P₂), a constitutive membrane component, to create the lipid second messenger phosphatidylinositol (3,4,5)-trisphosphate (PtdIns(3,4,5)P₃) (and its immediate metabolic product PtdIns(3,4)P₂). PtdIns(3,4,5)P₃ induces the membrane translocation and/or conformational changes of target proteins, such as a variety of enzyme classes, e.g. protein kinases, phospholipases and guanine nucleotide exchange factors.

Synonyms

Genome analysis in plants; plant functional genomics

Definition

Plant genomics refers to the analysis of plant genomes, which includes physical mapping of the genome, genome sequencing and annotation (prediction and identification of genes), the elucidation of the (biochemical) functions of the identified genes and gene products and their roles in determining the characteristics of the organisms.

Characteristics

The major/ultimate goal of plant genomics is to provide detailed and comprehensive knowledge of the molecular processes underlying plant life. As for any other organism, the central aims of plant genome analysis are the identification of all the genes of a plant, the determination of the biochemical function of the corresponding gene products and the elucidation of the roles these genes play in plant metabolism, growth and development and in interaction with the environment. Thus, the major principles of plant genomics are

nearly identical to those of human, animal or microbial genomics, but several features distinguish the characteristics of plant genome analysis. These include the broad range of different important plant species to be studied, the enormous size and complexity of many plant genomes, the opportunities to establish (large) experimental populations including immortalized segregating populations and the ease of genetic transformation (at least for a number of model plant species).

Justification of Plant Genomics

Plants are the dominant form of life on our planet, representing more than 99% of the total terrestrial biomass. They grow in all regions of the earth, occur with an enormous diversity of properties including their (biochemical) composition and constitute the basis and essential component of any ecosystem. Plants represent the essential prerequisite for all human and animal life and welfare. As naturally growing renewable resources with an adjusted ecological balance, plants are not only absolutely indispensable for the production of bulk nutrients for human food and animal feed but they also provide us with essential vitamins and medicine, with fibers for clothing and many raw materials for industrial use and for building and construction. As a result of these various different uses of plants and plant products, a wide range of plant species are in the focus of plant genome analysis. These range from model organisms used to rapidly advance our understanding of the principles of plant life to major crops, trees and medicinal plants. Thus, plant genome analysis reaches far beyond understanding the molecular mechanisms which permit plants to function and interact with the environment. The results of plant genomics are expected to support very strongly plant improvement for human and animal needs and plant use in a better, sustainable and more efficient way. These considerations and expectations triggered initiation and conductance of significant plant genome analysis programs worldwide. In addition to the importance of plant genome analysis for human society, plants exhibit a number of properties that make them ideally suited to serve as model systems and to advance our basic understanding of life. Regardless of the particular aim of the work, either basic scientific investigations or studies on applied aspects, the advances in plant genomics make plant research one of the most exciting research branches of all.

Front-Runners in Plant Genomics

A special feature of plant genomics is the variety of the species examined, ranging from model species serving as front-runners to crops with highly complex genomes. Due to its favorable properties, the most widely used plant model species is *Arabidopsis thaliana*, a member of the *Brassicaceae* family related to oilseed

rape and cabbage (8). Its small size, numerous seeds produced by a single individual *via* self-pollination and the ease of chemical mutagenesis made it an ideal object for genetic studies in plants. The very small size of *ca.* 135 million (Mbp) base pairs distributed among the five chromosomes and the low complexity of its genome made it the first choice for plant genome analysis. The achievements of the international *Arabidopsis* Genome Initiative (AGI) include the first complete BAC-based physical map established for any organism and the first complete plant genome sequence at the end of the year 2000 (9). As the second multi-cellular organism (after the nematode *Caenorhabditis elegans*) with its genome fully sequenced, *Arabidopsis* represents one of the central biological model systems for basic research. With the genome sequenced and a comprehensive inventory of the genes of this model species at hand, the *Arabidopsis* (genome) research community has now taken the challenge to decipher the function of all the genes. This includes for every gene the determination of the site, condition and level of activity (expression), the (sub-cellular) localization and the biochemical function of the gene product, its position in regulatory or metabolic networks and its interaction with other factors and its role in plant growth and development, metabolism and interaction with the environment (functional genome analysis) (1). The worldwide *Arabidopsis* functional genome analysis projects are coordinated by the multinational *Arabidopsis* steering committee (MASC; ►http://www.Arabidopsis.org/info/2010_projects/MASC_Info.jsp), which has been founded according to the excellent experience of the predecessor committee that coordinated the international *Arabidopsis* genome-sequencing project. This work is strongly supported *via* a wide range of important resources and novel techniques, which include very comprehensive sequence-indexed gene k.o. populations (see: ►<http://signal.salk.edu/cgi-bin/tdnaexpress>, ►<http://www.mpiz-koeln.mpg.de/GABI-Kat>, ►<http://flagdb-genoplante-info.infobiogen.fr/projects/fst>, ►<http://www.Arabidopsis.org/abrc>), full-length cDNA collections (see: ►<http://pfgweb.gsc.riken.go.jp/projects/raflcdna.html>, ►http://www.Arabidopsis.org/abrc/ssp_clone.jsp), gene-chips for genome-wide expression analyses (see: ►<http://www.affymetrix.com/products/arrays/specific/arab.affx>, ►<http://www.catma.org>) and other novel techniques such as proteome analysis and metabolic profiling, the latter having been originally developed in *Arabidopsis* and now adopted for many other organisms (3). Supported by a comprehensive database, which serves as the major information resource (TAIR, ►<http://www.Arabidopsis.org>), *Arabidopsis* research continues to accumulate the most extensive information on plant gene/genome function.

As mentioned earlier, *Arabidopsis* is “only” the front-runner of plant genomics and several crop species’ genomes are under very extensive analysis. The example of *Arabidopsis thaliana* genome sequencing has shown how well the tremendous workload can be distributed and the high financial expenses can be shared among various national genome programs. This led to the formation of new international sequencing consortia, concentrating on sequencing of the rice genome as a model for grasses (►<http://rgp.dna.affrc.go.jp/IRGSP/index.html>) and of the poplar genome, as a model for trees (►<http://www.ornl.gov/sci/ipgc>). Like the situation in the dicots, where *Arabidopsis* was selected for sequencing, rice was chosen for sequencing according to its relatively compact genome as the first monocot plant species and as a representative of the grasses, which include as other important crops wheat, maize and sorghum. While the rice genome has a size of *ca.* 430 Mbp distributed among 12 chromosomes, the evolutionarily related genomes of the other cereal crops are much larger: sorghum (750 Mbp), maize (2,400 Mbp), barley (5,000 Mbp) and wheat (16,000 Mbp). In contrast to *Arabidopsis*, however, rice does not only serve as a model for monocots / grasses but is a very important crop itself. It feeds half of the world’s population with a production area of more than 150 million hectares and more than 580 million metric tonnes in yield (FAO statistics). Rice is the predominant staple for many countries in Asia and the Pacific, in Latin America and the Caribbean and in Africa. In developing countries, rice accounts for 715 kcal/capita/day, 27% of dietary energy supply, 20% of dietary protein and 3% of dietary fat (6). In spring 2002, a draft version of the almost complete genome sequence of “Japonica-variety” rice was assembled by Researchers of Syngenta (4). At the same time a draft sequence of an “Indica-variety” was generated by researchers from China (10). The completely finished high quality genomic sequence of the rice genome, established by the International Rice Genome Initiative was available at the end of 2004. This will boost rice research as much as the availability of the genome sequence in *Arabidopsis* did and similar resources for functional analysis (including sequence indexed k.o. populations are currently being established by the International Functional Genomics Consortium (►<http://www.iris.irri.org/IRFGC>). The third plant genome sequence soon to be finished will be that of the poplar tree. The *Populus* genus includes poplars, cottonwoods, and aspens – fast-growing trees widely used in forestry research. These fast growing trees produce seeds prolifically, and can be genetically modified in the laboratory. The tree to be sequenced is a female *Populus balsamifera* (black cottonwood or balsam poplar). With a size of 550 Mbp organized in 19 chromosomes, the genome of this model tree is only

4 times as big as that of *Arabidopsis thaliana*. The complete sequencing and annotation data are available on the consortium web site (►<http://genome.jgi-psf.org/poplar0/poplar0.info.html>).

The moss *Physcomitrella patens* is being developed as a model system for plant biological studies and will support plant functional genomics. Bryophytes are the oldest living branch of land plant evolution. They are separated by approx. 450 million years of evolution from seed bearing plants. To fully understand and employ land plant evolution and plant diversity, mosses are to be added to the current list of model plants. The dominance of the haploid gametophyte in the life cycle of this moss facilitates genetic analysis. To date, this moss is the only known terrestrial plant with an efficient system for homologous recombination in its nuclear DNA, making gene-targeting strategies as easy as in yeast. In contrast to seed bearing plants, the dominating generation in the moss life cycle is the haploid gametophyte. Therefore *Physcomitrella* is an ideal model for gene-function analyses. Loss-of-function mutants created by a targeted gene knockout approach (homologous recombination) can be analyzed immediately without complex back-crosses (5). The *Physcomitrella* genome is about 3.5× as big (~480 Mbp) as the *Arabidopsis* genome and is distributed among 27 chromosomes. Today more than 100,000 EST entries exist in databases and represent approximately 25,000 genes. Preliminary analysis of genes and ESTs strongly indicate that these sequences are highly similar to those of the corresponding genes of seed bearing plants.

With the availability of the genome sequences, the multi-parallel analysis techniques (“x-omics” such as transcriptomics, proteomics and metabolomics) can be applied as efficiently in these plant species as in the model plant *Arabidopsis* (2). The functional genome analysis thus performed will further enhance the massively increasing amount of available data to be stored, analyzed and interpreted. As a consequence, bioinformatics developed in parallel to the analytical techniques will play the same essential role in plant genomics as in human, animal or microbial genomics. As does the research in these other kingdoms, plant biology becomes more and more an information and computable science research and has moved into plant systems biology.

Beside this shift of paradigms and the broad increase in basic knowledge, plant genomics influences the way in which our staple crops are produced and will be produced in future.

Genomics of Other Plant Species

As mentioned above, humans depend on a wide range of crop plants that provide bulk nutrients such as carbohydrates (cereals), starch (potato, cassava or

yams) and proteins (legumes). Plants provide fat, oil, wax and fiber (cotton, soy or rapeseed). Furthermore, we cultivate plants as fruits or vegetables and as fodder plants for our livestock. But plants also contain natural stimulants (cacao, coffee) and provide wood, cork, rubber, dyes and tanning agents (indigo, henna, eucalyptus). They supply insecticides (neem tree, Dalmatian pyrethrum or tobacco). Many plants have a positive influence on our health; many substances from medicinal plants are either directly used or served as lead compounds for the development of new drugs. Ten of the world’s 25 top-selling drugs in the late nineties derived from natural sources. The number of plant species with very large genomes that have to be subjected to genomes analysis is therefore far greater than that of animals (including models such as mouse, rat and primates and our farm animals). This challenge is being met in several ways.

General and basic gene functions will mainly be clarified in the principal plant model systems such as *Arabidopsis* and rice. Many of the corresponding genes in crops and other important plant species will carry out the same or very similar functions and the knowledge gained through the functional genomics/systems biology approaches in the principal models will be highly useful to direct targeted analyses in the other plants species. This “bridging concept” requires a good sequence information basis for the crops that is being provided by comprehensive expressed sequence tag (EST) libraries. They represent snapshots of the genes expressed in a given tissue and/or at a given developmental stage and provide a good representation of the expressed regions of the genome if a sufficient number of different libraries are analyzed from a range of tissues, developmental stages and after various environmental challenges. As only genic sequences are analyzed independent of the genome size, this approach is highly cost efficient, especially for species with very large genomes. Up to the present, more than 20 million ESTs (from all kind of species) are in public databases. Platforms for comparative plant genomics are being developed at different places in the world including the “reconstructomics” platform using the SPUTNIK program (►<http://mips.gsf.de/proj/sputnik/>). SPUTNIK is a tool to analyze “genomeless genomes”, i.e. to estimate the gene content represented by the ESTs and to establish unigene sets for plant species for which no genome sequence information is available. A further highly important tool for the verification of the proposed gene function in crops is TILLING (targeted identification of local lesions in genomes) (7). This refers to a procedure for the targeted identification of mutant alleles that was first developed in *Arabidopsis* and is now applied to many other species including animals and other plants. Thus, genes selected for detailed analysis on the basis of the

information provided by the model system will be tested for their functions in the crop plant through the identification of corresponding mutants and their characterization.

However, the gene functions specific to certain plant families will remain largely undiscovered and the basis of model species will be broadened stepwise to representatives from other families. These will include tomato for the *Solanaceae* and *Lotus japonicus* or *Medicago truncatula* for legumes. The latter play an important role in providing protein and are able to fertilize themselves by fixation of atmospheric nitrogen through symbiosis with soil bacteria. Genome sequencing programs on tomato, soybean, *Medicago*, maize etc. have been initiated or will soon be initiated. However, they are not currently directed towards the same level of completion as the *Arabidopsis* or rice genome sequences. Instead, so-called draft sequence versions will be established (low coverage) or sequencing will be concentrated on gene-rich regions. Methods developed for these purposes, such as the enrichment of weakly methylated DNA or the separation from repetitive sequences based on re-association kinetics, lead to cost savings and first insights into crop species genomes. Both methods have just proven their functionality in the sequencing of gene-rich regions in the maize genome. The sequences thus obtained for a wider range of plant species will be anchored to the genomes of the principal models, *Arabidopsis* and rice and great emphasis will be put on comparative genomics in plants in the future.

Application of Plant Genomics to Crop Improvement

One aspect of plant genomics that is radically different from genome analysis in humans and model animals and which is closely related to genome analysis in farm animals is its direct connection to practical application. Crop genome analysis provides breeders with a wealth of information and novel tools to enhance and speed up the breeding process. Molecular markers such as microsatellites (simple sequence length polymorphisms, SSLPs) or single nucleotide polymorphisms (SNPs) provide the means to identify favorable genome segments as quantitative trait loci (QTL) in experimental populations or breeding populations. Marker-assisted selection (MAS) is increasingly applied, e.g. in backcrossing programs used to introduce favorable genes/alleles from exotic germplasm.

These procedures provide the means to increase the efficiency of the (classical) breeding process by addition of the new knowledge gained through plant genome research *via* genetic engineering to achieve the necessary boost in high quality food production for the global human population. All this is happening against the background of a world population still growing and a reduction of available resources like water, arable

land and energy *per capita*. Plant genome research is a basic element to support the development of a sustainable and ecologically balanced agriculture. Moreover, it also supports the production of new and improved products. The diversity of the uses of plants mentioned above shows the potential of the uses of plant genomics to benefit humans and the environment. Through the possible use of exotic breeding material and the efficient use of such germplasm *via* MAS assisted backcrossing, it also becomes clear that plant genomics research provides the means to enhance the use of natural genetic diversity and to support its preservation. These natural resources offer great potential for further crop improvement and the information gained through plant genome analysis will strongly support their protection.

Considering this potential and the need to enhance crop improvement procedures, several plant genome programs have been initiated that have a major focus on crops. In the year 1998 the “National Plant Genome Initiative” was founded in the USA (► http://www.nsf.gov/bio/dbi/dbi_pgr.htm). In January 2003 this initiative presented the strategy plan for the second program stage (2003–2008). In contrast to the first period, which mainly focused on building up resources and establishing technologies, these tools will now be used to address a wide range of important biological questions in plant science. The second phase will involve a continued elucidation of the genome structure and organization of crops like rice, maize, tomato and *Medicago* as key plant species. Furthermore, the transfer of knowledge about gene functions from key plants to other crops will help to understand complex processes like tuber or bulb development, wood formation, fruit development and nutrient uptake and use in plants. Plant genomics will expand into the analysis of biodiversity, studies of ecology and ecosystems and the development of sustainable production systems, renewable resources and novel biomaterials. It will greatly benefit from advances in bioinformatics, the integration and interaction of plant genome databases, the development of standard operating principles and the development of new algorithms to analyze plant genomics data. Furthermore, education and training of students and young researchers will be important aspects of plant genomics, as will the outreach to broaden the recognition in our society of the importance of plant genomics. National plant genomics research programs also exist in Canada, Brazil, China, Japan and Australia, with major foci on rice, maize, wheat, soybean, rapeseed and sugarcane. In Europe, several larger national plant genomics programs with major emphasis on model and crop plants, including *Arabidopsis*, rice, wheat, barley, maize, rapeseed, grapes, tomato, potato, *Medicago*, sugar beet etc. have been started in the UK (GARNET,

2000, ►<http://www.york.ac.uk/res/garnet/garnet.htm>), France (Génoplante, 1999, ►<http://www.genoplante.org>), Germany (GABI, 1999, www.gabi.de), the Netherlands (BioSystems Genomics, 2002, ►<http://www.biosystemsgenomics.nl>), Sweden (SCTFG, 1999, ►<http://www.upsc.nu>) and Spain, 2003, (<http://www.mcyt.es>). In addition, efforts are being made to concentrate national activities in Denmark, Finland, Hungary and Italy and others will follow. To enhance the output of these various initiatives, further increase in co-operation across programs and setting cross-links between programs will be necessary to make developed resources, technologies and information freely available and thus enhance the efficiency of plant genome research and increase the output achieved with the limited available financial resources. The European Research Area Net Plant Genomics (►<http://www.erapg.org>) is a European wide activity directed towards these goals.

A Vision of Plant Genomics

Plant genomics represents the bridge between classical molecular biology and the holistic view into complex systems. The term “plant system biology” thus emerged during the last few years as it did for several other groups of species. As in the general concepts of genomics, many commonalities exist at this level also among the studies of various species. The use of systematic genomics, transcriptomics, proteomics and metabolomic technologies and the increasing use of bioinformatics to construct models of complex biological systems are shared between the different kingdoms. However, plant systems biology may broaden much faster from the analysis of the properties and mechanisms of the organisms themselves to the incorporation of the interaction of the organisms with their environment (both biotic and abiotic influences). Plant performance, that of our field crops in particular, is very strongly affected and limited by environmental conditions. Tolerance or resistance to adverse conditions thus offers the greatest potential to increase and secure yields in sustainable production systems. Thus, while plant systems biology as a logical expansion from plant functional genomics will probably develop similarly to that of other systems (from analysis of simple cellular processes to studies at the organ and whole plant level), the long term vision may be an extension into the study of plants as interacting partners within ecological systems.

Plasmid/Plasmid Vector

Definition

Plasmid is a small circular DNA molecule that replicates independently of the genome, and is used extensively as a vector for DNA cloning. Plasmid vectors for cloning generally contain a replication origin, an antibiotic-resistance gene, and other varying sites. Expression vectors, for instance, also contain a ribosomal binding site, a promoter and often a

transcription terminator. In the context of clinical gene transfer, an expression construct is usually inserted in the plasmid, and the bacterium *E. coli* is used for plasmid propagation.

Pleiotropic/Pleiotropic Gene Effect

Definition

A gene is referred to as pleiotropic when it leads to many different phenotypic expressions. Affected individuals can have one or more of a range of signs and symptoms. For example, the Marfan gene is pleiotropic with widespread effects and can cause long fingers and toes, dislocation of the ▶ lens of the eye, and dissecting aneurysm of the ▶ aorta.

- ▶ Manic Depression
- ▶ Marfan Syndrome

Plexiform Neurofibromas

Definition

Plexiform neurofibromas refers to benign tumors originating from cells of the Schwann cells or endoneural mesenchym of peripheral nerve fibers. Plexiform characterises local infiltrating growth causing pain and neurological failures. These are benign tumours associated with major nerve trunks and are usually found in young children.

Pluri-/Multipotent

Definition

The terms define the property of a stem cell that enables it to differentiate into all (pluripotent) or several (multipotent) cell types of the ca. 200 different tissues in the body. Pluripotentiality (pluripotency) is a property of embryonic stem cells. However, pluri/multipotent cells are not able to form a complete organism in a morphological manner, which is only possible for totipotent stem cells.

PML Nuclear Bodies

Definition

Promyelocytic leukemia protein (PML) is a tumor suppressor protein, whose function is disrupted by the translocation t(15;17) in acute promyelocytic leukaemia (APL). PML has a wide range of functions *in vivo*, and is involved in suppression of cell growth, multiple pathways of apoptosis, transcriptional regulation, and genome stability. PML proteins contain zinc finger motifs, and are typically concentrated within discrete speckled multiprotein subnuclear domains, designated as PML nuclear bodies. PML nuclear bodies are also targeted by many DNA viruses in early infection, and are the site of viral transcription initiation. Subsequently, the viral early proteins localize to, and eventually disrupt, PML nuclear bodies.

Definition

Peptide nucleic acid (PNA) is an artificial mimic of nucleic acid, which was invented more than a decade ago (7). The molecule combines many features that are similar to those of natural nucleic acids with characteristics that are rather different or even unique to PNA. First and foremost, N-(2-aminoethyl)-glycine units linked by ►amide bonds substitute the (deoxy)ribose-phosphate backbone and the nucleobases are attached via a methylene carbonyl link to the glycine moiety. Nevertheless, the distances and angles within PNA oligomers much resemble the conformation of nucleic acids (Fig. 1). One format of application is the microarrays that are made for a highly parallel analysis of nucleic acids. To this end, very many different PNA molecules are attached onto a small planar surface,

PNA Chips. Figure 1 Structures of PNA and DNA.

e.g. a microscope slide. Upon addition of a DNA or RNA sample, hybridisation occurs on the chip at PNA-oligomers that are of complementary sequence to molecules in the sample. Recorded by detecting a label that is attached to the DNA or RNA, various forms of information can be deduced from such studies, such as for example, sequence variations or changes in the amount of an individual RNA molecule within a complex mixture.

Description

PNA binds to complementary single-stranded DNA or RNA in a sequence-specific manner. Because of the PNA's uncharged nature, the duplexes are substantially more stable than the equivalent double-strand molecules formed by DNA and RNA alone. The neutral amide backbone also allows PNA to hybridise to nucleic acids in the absence of salt, since no positive ions are required for counteracting the interstrand repulsion that occurs between two negatively charged nucleic acid molecules. As a result, the target DNA has fewer secondary structures and is therefore more accessible to a PNA probe than it would be to a DNA oligonucleotide. Being an artificial molecule, PNA is not degraded by nucleases or proteases. This makes it a versatile tool in assays that are subjected to environmental constraints.

Applications of PNA in biotechnology divide into reactions that occur in homogenous solution and analyses that take place on a solid support. Important examples of the former assay format are the use of PNA as an antisense reagent, as a DNA-opener and as a tool for PCR-clamping or the detection of single nucleotide polymorphisms. A comprehensive and up-to-date overview on the various applications of PNA is provided by Nielsen et al. (12). For all its advantages, however, PNA has not had quite the impact that was initially predicted. The limited solubility of PNA molecules is especially an obstacle that hampers many applications in solution. For the analysis of nucleic acids on microarrays, however, this limitation is not so restricting, since the PNA concentration is low and the molecules are constrained by their physical attachment to the solid support. ►DNA-microarrays, also named DNA chips, are an assay format that is widely used in biotechnology and biomedical research, since they permit molecular analyses of complex samples, such as genome-wide ►transcriptional profiling, typing of ►single nucleotide polymorphisms or epigenetic studies. Moreover, microarrays will become even more important in future, once the various types of analysis are established to a quality standard that will, for example, allow their use in routine medical diagnostics or food-processing control. Substituting PNA for DNA oligomers as the chip-bound capture molecules could

contribute substantially to achieving higher sensitivity and improved assay robustness. Also, taking advantage of the chemical differences between the PNA probe and the nucleic acid analyte, their interaction can be detected directly, with neither molecule carrying a label. In consequence, the processing is much simplified, facilitating automation. Simultaneously, the degree of bias caused by introduction of a label is avoided and the effort in sample preparation is reduced significantly.

Synthesis

As with DNA microarrays, the probes for PNA chips can either be pre-fabricated and attached to the chip surface by means of robotic devices or synthesised directly *in situ*. With respect to synthesis chemistry, PNA does not differ from ►peptides. Therefore, most procedures developed for the synthesis of peptides can be used for the production of PNA-oligomers and *vice versa*.

Parallel synthesis in 384-well filter-bottom microtiter plates has been established. This releases adequate numbers of PNA-molecules that are of good quality and in sufficient yield for the production of microarrays. In this process, the consumption of reagents per individual oligomer is reduced significantly compared to standard column-based synthesis protocols. Furthermore, procedures for the attachment to the chip surface exist, which select for the binding of full-length molecules (1). In the analysis of biological samples, this leads not only to better reproducibility but also to a higher dynamic range of detection and thus an improved accuracy.

Alternatively, *in situ* synthesis on the array by the SPOT method (8), in which the individual monomers are placed sequentially at the relevant positions of the chip in small volumes of liquid, has been described. Unfortunately, following this protocol, throughput is limited with current liquid handling systems. Also, only a very limited number of array copies can be produced simultaneously. However, drawing on expertise from ink jet technology, for example, handling of small volumes is improving and should soon allow the quick synthesis of many different molecules in many copies. In addition, the control of synthesis by ►photolithography was described for peptide arrays even before the technique was used for the production of DNA chips (3). In combination with PNA monomers that can be deprotected by light, procedures could be established that are equal in throughput to current production processes for DNA microarrays. All *in situ* synthesis formats, however, have the disadvantage that not only full-length molecules but also shorter derivatives that result from the incomplete yield during each synthesis step will be on the arrays.

Basic Hybridisation Characteristics

Overall, hybridisation to PNA chips is performed similarly to hybridisation to DNA microarrays. The main difference is the stability of the duplex formed. Comparable to results on PNA-DNA interaction in solution, the stability on a solid support of a duplex formed by a DNA molecule and a surface-attached PNA oligomer of mixed base composition is in general 1–1.5°C higher per base pair than that of the corresponding DNA-DNA hybrid. Therefore, both higher hybridisation and washing temperatures are used on PNA chips or the length of the PNA oligomers is reduced. The dissociation temperature of PNAs can be predicted from their sequence with reasonable accuracy and the sequence specificity of binding is high. In addition, PNAs that contain a ‘chiral box’ at their centre exhibited even higher mismatch recognition than normal molecules. ►Chirality can be introduced into PNA-monomers by substituting D-lysine for the usual N-aminoethylglycine backbone (6). ►Hybridisation to complementary molecules in a parallel rather than anti-parallel fashion, potentially possible because of the PNA’s achiral nature, is strongly disfavoured on PNA chips.

Label-Free Diagnostics

Especially for routine applications in a clinical setting, it would be advantageous to avoid labelling of the probes and the target molecules altogether. Besides speeding up the analysis process and reducing cost, all labelling steps introduce an additional degree of variation. In addition, such procedures should assist in the integration of the assays into automated analysis systems, which are eventually required for the analysis of patient samples. From its hybrid nature – being chemically rather different from nucleic acids while nevertheless behaving very similarly – PNA offers some unique opportunities to achieve such ends.

►Surface Plasmon Resonance

One means for the direct detection of DNA-binding to microarrays is surface plasmon resonance, although it is not unique to PNA arrays. The microarray surface is illuminated with polarised light. Reflection of the light occurs at a conductive film at the interface between the chip and the fluid containing the sample. Upon hybridisation of DNA molecules to the chip-bound PNA oligomers, the refractive index changes, resulting in a resonance signal that can be detected. The refractive index is directly proportional to the mass change at the particular position. This allows a real-time monitoring of the hybridisation process. The variation in signal intensities for a single C to T conversion was found to be as high as 300-fold (2). To date, however, the sensitivity of the procedure is still

inadequate for the analysis of complex mixtures of analyte molecules.

Electrochemical and Direct Electronic Detection

Beside the obvious benefit of avoiding extra labelling steps, a direct electrical detection of binding events would have the additional advantage that the connection to the electronic data analysis could be simplified even further. In addition, the read-out could be much faster than with other systems and real-time measurement during the hybridisation process would be possible. Conductance measurement (4) or **▶ impedance-based detection** (5) have been used for signal recording. As above, there are still limits in the sensitivity of the assay. In order to circumvent this dilemma, various electrochemical detection methods based on electrochemically active substances such as methylene blue or Hoechst 33258 are being investigated. Micro-fabricated PNA arrays were equipped with electrodes made of gold. Different PNA molecules that had a cysteine at their N-termini were bound to the electrodes *via* the thiol groups. The advantage of using PNAs is the smaller adhesion of the positively charged electrochemical compound to the neutral backbone, thereby reducing the background signal. Subsequent to the hybridisation of a DNA-fragment and appropriate washing steps for the removal of unspecific binding, the array is incubated in a solution that contains the electrochemical substance. Hoechst 33258, for example, binds to the minor groove of PNA-DNA duplexes. This produces an anodic peak current that is measured by linear sweep voltammetry. In all systems based on electrical measurements, the complexity of the array is still limited at present, thereby turning the advantage of continuous and parallel measurement at all array features into a handicap as far as arrays with very many spots are concerned. However, the number of array features required for many routine assays in the microarray format will anyway be relatively small.

Secondary Ion Mass Spectrometry

A third process seems sensitive enough to circumvent the above-mentioned limitation on sample complexity. In addition, the hardware required for the detection process could be adapted to deal with large feature numbers on the chip, although detection is performed sequentially rather than in parallel as with electrical measurement. A combination of PNA microarrays and detection of bound nucleic acids by time-of-flight secondary ion **▶ mass spectrometry** (TOF-SIMS) could permit a direct analysis of genomic DNA (1). SIMS is very sensitive in detecting fragments (PO_2^- and PO_3^-) of the phosphate ions, which are an integral part of nucleic acids but missing entirely in PNA. In addition, a DNA fragment contains very many phosphates. Since both the detectable marker and signal amplification are

therefore intrinsic to the target molecule, analyses could be performed without any prior amplification by means such as PCR and without labelling. In this respect, it is also of advantage that relatively long fragments can be hybridised to PNA-oligomers under low salt or no salt conditions and that the duplex stability is high.

Subsequent to a hybridisation of nucleic acids to a PNA microarray and the removal of non-specifically bound molecules by appropriate washing steps, the binding of nucleic acids is identified by mass spectrometry. A primary ion beam is directed at the microarray surface, causing the fragmentation and release of molecule fragments present at this position. However, just a monolayer of molecules is actually affected. Concurrently with fragmentation, the released molecules are ionised by the primary ion beam. Negatively charged ions are accelerated into the flight tube of the mass spectrometer, in which they are separated according to their mass-to-charge ratios. Phosphates and therefore the respective signals should only be present when nucleic acid has hybridised to the complementary PNA molecule at a given position.

From the difference in backbone structure of PNA and nucleic acids, other fragments, such as parts of the sugar molecules, could also be used as an indicator for the binding of nucleic acids. Since the sugar molecules of RNA and DNA are different at the 2'-position, the procedure could even distinguish between the two molecular classes. This process could even allow discrimination of living cells or organisms, producing a signal from both DNA and RNA, from dead ones, which should exhibit a signal that only represents the relatively long-lived DNA.

Point Spread Function

Definition

An optical system produces a complex three-dimensional light distribution of an ideal point light source in the image space in and near the image plane. This light distribution represents the point spread function of the optical system. For an aberration-free, diffraction-limited optical system, the slice of the diffraction pattern in the image plane is designated as Airy function, which is the mathematical description of the diffraction pattern of a circular aperture. Above and below the image plane, the diffraction pattern changes periodically along the optical axis, so that bright and dark Airy-disk-like patterns appear alternately with diameters increasing proportional to the distance from the image plane.

Definition

► Poly(ADP-ribosyl)ation is a posttranslational protein modification in eukaryotic cells (1-3). This modification is carried out by members of the family of poly(ADP-ribose) polymerases (PARPs), which catalyse the covalent transfer of ADP-ribosyl moieties from NAD⁺ to “acceptor” proteins (initiation reaction) as well as repeated cycles of ADP-ribosyl transfer to previously transferred ADP-ribosyl moieties (“elongation”) and also branching of the growing chains, thus creating highly complex polymers of protein-linked ADP-ribose (Fig. 1). Poly(ADP-ribosyl)ation was originally discovered as a biochemical reaction dependent on DNA strand breaks, but among the presently known PARPs, activation by DNA strand breaks could only be detected for PARP-1 and PARP-2, which both localise to the cell nucleus. In the context of living cells PARP-1 is the major catalyst of poly(ADP-ribose) formation under conditions of DNA damage induced by ionising radiation, alkylating agents and oxidants. The enzyme catalysing the catabolism of poly(ADP-ribose) by hydrolysis of the ribose-ribose linkages in the polymer is termed poly(ADP-ribose) glycohydrolase (PARG) (Fig. 1). The enzymes involved in poly(ADP-ribose) metabolism and their genes are listed in Table 1.

Characteristics

Catalytic Activity of PARP-1 and Life Cycle of Poly(ADP-ribose)

PARP-1 is the best-characterised member of the PARP family. While its gene (termed *ADPRT* in man and *Adprt1* in mouse according to official nomenclature)

Poly(ADP-Ribosyl)ation, Pathophysiology. Figure 1 Schematic representation of the structure of poly(ADP-ribose). Ade, Adenine; Nam, Nicotinamide; PARG, poly(ADP-ribose) glycohydrolase; PARPs, poly(ADP-ribose) polymerases; Rib, Ribose; grey arrows, sites of poly(ADP-ribose) cleavage by PARG.

is constitutively and abundantly expressed in proliferative tissues, its catalytic activity is stimulated dramatically by double-stranded DNA with interruptions in the sugar-phosphate backbone (i.e., single-strand or double-strand breaks), thus making poly(ADP-ribose) a cellular immediate early response to DNA strand breakage. PARP-1 has been detected in all eukaryotic species studied except yeasts and displays a highly conserved domain structure. Its N-terminal DNA-binding domain binds to DNA strand breaks *via* two zinc fingers, which causes an immediate and dramatic activation of the catalytic centre within the C-terminal NAD⁺-binding domain. In intact cells PARP-1 itself is the major acceptor protein to be modified with poly(ADP-ribose), this automodification occurring in a specific centrally located domain. However, additional acceptor proteins have been found in living cells, e.g. histones and topoisomerases. The existence of poly(ADP-ribose) in living cells is transitory and depends on the presence of DNA strand breaks, due to rapid turnover of the ADP-ribose polymer.

Cellular Functions of PARP-1

Cytoprotection and Maintenance of Genomic Stability

Various strategies have been employed to abrogate poly(ADP-ribose)ation, including competitive low-molecular-weight PARP inhibitors, expression of dominant negative PARP-1 versions, PARP-1 antisense RNA, or *Adprt1* knockout mice. The results have demonstrated that poly(ADP-ribose)ation contributes to the recovery of proliferating cells from low-level DNA damage as induced, e.g. by alkylating agents, oxidants or ionising radiation. This effect has been linked mechanistically with an involvement of PARP-1 in DNA base-excision repair. Furthermore, poly(ADP-ribose)ation counteracts the induction of genomic instability by DNA damage (2).

Cell Death by Energy Depletion

In contrast to the above cytoprotective function, PARP-1 overactivation may lead to cell suicide, due to severe depletion of its substrate, NAD⁺, and consequently of ATP. This cytotoxicity mechanism has most prominently been identified in various non-proliferative cell types *in vivo* and *in vitro*, by comparing *Adprt1*-knockout with wild-type mice and derived cells, or by using PARP inhibitors (see below, "Clinical Relevance").

Transcriptional Regulation

Over the last few years numerous physical and functional interactions of PARP-1 with transcription factors have been described, including AP-2, B-MYB, DF1-4, E47, NF-κB, p53, PC1, Oct-1, RXR, HTLV-1 tax, TBP, TEF-1 and YY1. Their interaction with PARP-1 has either positive or negative effects on the specific transactivation process, depending on the interaction partner. An involvement of PARP-1 was also reported in the control of the E2F-1 promoter. Consistent with the above, primary *Adprt1*-knockout fibroblasts displayed down-regulation of genes involved in regulation of cell-cycle progression, mitosis, DNA replication or chromosomal processing or assembly, while some genes encoding extracellular matrix or cytoskeletal proteins, implicated in cancer or ageing, were up-regulated.

Of great functional relevance is the finding that PARP-1 acts as a cofactor for ►NF-κB transactivation, a signalling pathway playing a key role in immune and inflammatory responses. This was shown by the lack of the lipopolysaccharide (LPS)-induced increases in tumour necrosis factor-α (TNF-α) production, inducible nitric oxide synthase (iNOS) expression and nitric oxide (NO) production in *Adprt1*-knockout mice and by the dramatic protection of such mice from endotoxic shock. The co-transactivator function of PARP-1 apparently depends on the presence of PARP-1 protein,

with NF- κ B and PARP-1 forming a stable nuclear complex independent of DNA binding. Primary cells from *Adprt1*-knockout mice are also impaired in NF- κ B transactivation induced by various stimuli involved in inflammatory and genotoxic stress signalling. PARP inhibitors, however, did not block the transcriptional activation of a NF- κ B-dependent reporter gene in wild type cells. Neither the enzymatic activity nor the DNA binding activity of PARP-1 was required for NF- κ B-dependent transcriptional activation in *Adprt1*-knockout cells complemented with different PARP-1 mutants. PARP-1 interacted *in vitro* directly with both NF- κ B subunits (p50 and p65), each subunit binding to a different PARP-1 region. In cells, PARP-1 was shown to activate the promoters of the iNOS and P-selectin genes in a NF- κ B-dependent manner upon stimulation of the cells with inflammatory stimuli or co-transfection of p65 (4).

Recently, a loss of several stress-activated transcription factors as well as decreased expression of genes for cytokines and cellular adhesion molecules was observed in glial cells from *Adprt1* knockout mice. In this system it was shown that augmented expression of some but not all of these genes is dependent of PARP-1 catalytic activity (5). This might explain why PARP inhibitors can lead to functional improvement in

in vivo models of inflammation or ischemia-reperfusion damage (see below).

Role in Apoptosis

Apoptosis is associated with dramatic changes in the poly(ADP-ribosyl)ation system. There is proteolytic cleavage of PARP-1 into two fragments by caspase-3 during the execution phase of apoptosis, which serves as a biochemical marker for apoptosis. This cleavage is thought to abrogate the responsiveness of PARP-1 to DNA strand breaks. On the other hand, despite PARP-1 cleavage, there is evidence from several different cell systems for massive accumulation of poly(ADP-ribose) (i.e., the product of PARP activity) in apoptotic cells. Furthermore, PARP-1 activation is required for translocation of apoptosis-inducing factor (AIF) from the mitochondria to the nucleus and AIF is necessary for PARP-1-dependent but caspase-independent cell death (6). This may represent an additional mechanism by which PARP-1 can kill cells, perhaps independent of NAD⁺ depletion and transcriptional regulation of inflammation-related genes.

Clinical Relevance

In contrast to the physiological, “cytoprotective” functions discussed above, PARP-1 over-activation

can lead to cell death and dysfunction or degeneration of tissues. Many experiments have been reported in animal models of a wide variety of common, debilitating or even lethal human disorders over the last few years that all provide evidence for a pathogenic role of PARP(-1) activity. Typical experimental strategies were (i) to demonstrate PARP activation in the target tissue under conditions of induction of pathology, and (ii) to analyse the phenotype of *Adprt1* knockout mice or normal animals treated with PARP inhibitors. The various paradigms are discussed below, but it must be noted that very little, if anything, is known as yet about the role of PARP activity in human patients. Likewise no clinical trials of PARP-inhibitory compounds have been reported to date. Therefore it is impossible to predict exactly what clinical relevance PARP inhibitors are going to have.

Ischemia-Reperfusion Damage

Ischemia of tissues followed by reperfusion is known to induce massive release of ROS and NO in the affected area. The resulting DNA damage and PARP(-1) over-activation appears to be crucial for the ensuing acute cell death, which at the macroscopic level is typically manifested as an infarct. Apart from acting as a drain for cellular NAD⁺ in the target cells, PARP-1 may also be involved in this context as a co-transactivator for NF- κ B (see above) and perhaps of other stress-induced transcription factors in macrophages or microglia, thus mediating the inflammatory component of tissue damage. The critical role of PARP(-1) in ischemia-reperfusion damage was demonstrated in a variety of organs.

Adprt1 gene knockout or PARP inhibitors can reduce the volume of brain infarct and attenuate the associated neurological dysfunction. PARP inhibitors seem to be effective even when administered after the onset of ischemia. An important pathogenic component is the excessive release of glutamate and the resulting excitotoxicity. It is interesting to note that a selective role of PARP-1 in excitotoxicity induced by NMDA but not AMPA (two glutamate agonists interacting with distinct receptors) has been observed in *Adprt1*-knockout mouse brain. Protective effects by PARP inhibition have also been reported in rat brain cortex under global cerebral ischemia without reperfusion. Protection was also afforded to the inner retinal elements under conditions of retinal ischemia-reperfusion damage.

In *Adprt1*-knockout mice cognitive and motor deficits after traumatic brain injury are attenuated.

The size of myocardial infarcts after ischemia-reperfusion can be significantly reduced by abrogating PARP(-1) activity. Myocardial contractility and relaxation, coronary blood flow, and endothelial function were all significantly improved and myocardial

high energy phosphate content was preserved in the PARP inhibitor-treated animals, whereas activation of P-selectin and the adhesion molecule ICAM-1 was suppressed.

Ischemia-reperfusion damage in liver or in the kidney is attenuated by PARP inhibitors.

Increased mucosal PARP activity has been seen after occlusion-reperfusion of the superior mesenteric artery of rat and mouse, followed by mucosal damage and hyper-permeability of the intestine. There was attenuation of such alterations and reduction of neutrophil infiltration of the ileum by PARP inhibitors or in *Adprt1*-knockout mice subjected to the same ischemia-reperfusion protocol.

Toxin-Induced Parkinson Syndrome

A common model for Parkinson's disease is the administration of 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) to animals. Its metabolite is known to provoke formation of ROS in the dopaminergic neurones of the substantia nigra, thus leading to selective neuronal death and Parkinson's syndrome. Dopaminergic neurones from *Adprt1* knockout mice were protected against MPTP-induced cell death, mirrored by increased resistance to clinical disease.

Chronic Heart Failure

Chronic heart failure induced in rats by chronic coronary artery ligation led to increased nitrotyrosine formation and PARP activation in the myocardium and intramural vasculature, depressed left ventricular performance and impaired vascular relaxation of aortic rings. The PARP inhibitor N-(6-oxo-5,6-dihydro-phenanthridin-2-yl)-N,N-dimethylacetamide (PJ34) improved both cardiac dysfunction and vascular relaxation (7).

Septic or Haemorrhagic Shock

Adprt1-knockout mice are resistant to lethal septic shock induced by injection of LPS or by caecal ligation and puncture. This seems to be mediated by a deficiency of NF- κ B transactivation, thus reducing the typical LPS-induced increases in serum levels of TNF- α , IL-6 and IL-10, and of iNOS expression and NO production. *Adprt1*-knockout mice further exhibited a lower degree of inflammation in the gut and lung. The contribution of PARP to bacterial LPS-induced acute lung injury and vascular failure was assessed in pigs. LPS infusion evoked a decline in systemic arterial pressure and a biphasic elevation of pulmonary arterial pressure, while lung compliance declined and respiratory resistance increased. Pre-treatment with the PARP inhibitor 3-aminobenzamide (3-AB) eliminated the rise in pulmonary and total respiratory resistance but did not alter the systemic and pulmonary hemodynamic responses to LPS infusion, suggesting a role for PARP

activation in the changes of lung mechanics after LPS-induced acute lung injury.

Adprt1-knockout mice are also resistant to haemorrhagic shock and the rapid decrease in blood pressure after resuscitation, displaying an increased survival time and reduced lung neutrophil sequestration. In rats undergoing haemorrhage and resuscitation, the PARP inhibitor 5-aminoisoquinolinone (5-AIQ) reduced multi-organ injury and dysfunction but did not prevent circulatory failure.

Diabetes Mellitus and Diabetes-Related Endothelial Dysfunction

Type-1 (juvenile) diabetes results from selective destruction of insulin-producing pancreatic β -cells during islet inflammation. Cytokines, ROS and NO, which are all released during this process, contribute to β -cell death. *Adprt1*-knockout mice are completely resistant to diabetes induction by streptozotocin. Furthermore, knockout mouse derived β -cells in culture or wild type cells treated with PARP inhibitors are also protected from cell death induced by exposure to ROS, NO or streptozotocin.

Many diabetic patients suffer from retinopathy, nephropathy, neuropathy and accelerated atherosclerosis, all of which are preceded by dysfunction of endothelial cells. PARP activation seems to play a role in the pathogenesis of endothelial dysfunction in diabetes. Treatment of diabetic mice with a PARP inhibitor allowed maintenance of normal vascular responsiveness despite persisting severe hyperglycaemia.

Other Acute and Chronic Inflammatory Disorders

P selectin and circulating xanthine oxidase are involved in neutrophil infiltration of the lung associated with acute pancreatitis. Up-regulation of P-selectin, generation of platelet-activating factor and neutrophil recruitment were all prevented by PARP inhibition or by scavenging of H_2O_2 .

Crohn's disease is a chronic inflammatory bowel disease characterised by oxidant-induced tissue injury and increased intestinal permeability. *I110*-knockout mice are used as a model for Crohn's disease, as they display increased intestinal permeability, pro-inflammatory cytokine release and nitrosative stress. Here the PARP inhibitor 3-AB normalised colonic permeability, attenuated inflammation, and reduced secretion of TNF- α and IFN- γ , expression of iNOS, and nitrotyrosine levels. Recently a chemically modified antisense oligonucleotide (ISIS 110251) blocking expression of PARP-2 was tested for efficacy in *I110*-knockout mice. This oligonucleotide reduced PARP-2 mRNA levels in liver by up to 80%. In *I110*-knockout mice with established colitis, treatment with ISIS 110251 normalised the colonic epithelial barrier and transport function, reduced pro-inflammatory cytokine secretion

and iNOS activity and attenuated inflammation. These data indicate a significant role for PARP-2 in mediating colonic inflammatory disease.

The PARP inhibitors 6(5H)-phenanthridinone and benzamide attenuated experimental allergic encephalomyelitis (EAE) in rats, reducing clinical score, neuroimmune infiltration and expression of inflammatory mediators such as iNOS, IL-1 β and IL-2, cyclooxygenase-2, TNF- α and INF- γ in the spinal cord of myelin-immunised rats. This effect seemed to be due to a reduction of NF- κ B and AP-1-mediated production of pro-inflammatory cytokines.

Excitotoxic brain lesions initially result in the primary destruction of brain parenchyma, followed by microglial cell migration towards the sites of injury and release of large quantities of ROS, which causes secondary damage that accounts for most of the loss of brain function. Microglial migration was found to be controlled by expression of the integrin CD11a, which in turn is regulated by PARP-1/NF- κ B. Antisense-mediated down-regulation of PARP-1 or CD11a abrogated microglial migration almost completely and protected neurones from secondary damage.

Intra-thoracic administration of zymosan-activated plasma leads to an increase in lung infiltration by neutrophils and serves as a model for acute inflammation. The PARP inhibitor 5-AIQ reduced the degree of lung injury and attenuated the expression of P selectin and ICAM-1 as well as the recruitment of neutrophils into the injured lung. The up-regulation of P selectin and ICAM-1 in human endothelial cells exposed to oxidative stress or to TNF α was also attenuated by 5-AIQ.

Adprt1-knockout mice were protected against bacterial meningitis-associated central nervous system complications including blood-brain barrier breaching and increase in intracranial pressure. This was accompanied by a reduction in meningeal inflammation and improved clinical status. A similar effect was achieved by PARP inhibition using 3-AB.

Outlook: ADP-Ribosylation Inhibitors as Therapeutic Drugs for Humans

It is obvious that PARP-inhibitory substances with appropriate pharmacokinetic profiles possess a significant potential as drugs for a "cell-rescue therapy", in view of the above prominent role of PARP-1 overactivation in a wide range of highly prevalent disabling and even lethal conditions (7). Improved PARP inhibitors, which ideally should target specific cell types, could turn out to be very useful tools for therapy and/or prevention.

With regard to inhibitor specificity, it should be noted that, by definition, all existing PARP inhibitors inhibit PARP-1, but the first-generation inhibitors at least, interfered also with other ADP-ribosyl transfer

reactions, such as mono-ADP-ribosylation of proteins, cyclic ADP-ribose formation or NAD⁺ glycohydrolysis, albeit at different IC₅₀ levels. In addition, the novel PARPs are likely to be inhibited as well, probably at similar IC₅₀ levels as PARP-1. It will be desirable to further increase inhibitor selectivity, so as to minimise possible side effects arising from collateral inhibition of enzymes other than PARP-1.

Definition

The 3' ends of all eukaryotic mRNAs are generated by post-transcriptional processing of a precursor RNA generated by ► [RNA polymerase II](#). As part of these processing reactions, which take place in the cell nucleus, the 5' end receives a 7-methyl guanosine ► [cap](#), whereas the 3' end receives a ► [poly\(A\) tail](#) – a string of adenylate residues not encoded in the genome. These two end modifications are characteristic for all mRNAs and only for mRNAs, and thus define an mRNA molecule as such. By means of specific binding proteins, cap and poly(A) tail function synergistically in translation, and during ► [mRNA decay](#) they are the first targets to be attacked by hydrolytic enzymes before the coding sequence is degraded. 3' end processing leading to polyadenylated RNA consists of two partial reactions. The RNA is first cleaved endonucleolytically, then the upstream cleavage fragment receives the poly(A) tail by polymerization from ATP, whereas the downstream fragment is degraded (Fig. 1). The efficiency of 3' processing can be regulated so that the output of mature mRNA and therefore of the encoded protein is adjusted to physiological needs. Genes frequently have two or more potential cleavage/polyadenylation sites and, in some mRNA precursors, the choice among these sites can also be regulated and determine the kind of protein made.

The only mRNAs that do not receive a poly(A) tail are those encoding the histone mRNAs synthesized during the S phase of the cell-cycle. Their 3' ends are generated by a different type of cleavage reaction that leaves a conserved stem-loop structure at the end of the

Polyadenylation. Figure 1 An outline of the 3' end processing reaction. The primary transcript containing the cap and the polyadenylation signal sequences is first cleaved between the AAUAAA polyadenylation signal and the downstream element. Cleavage generates a 3' hydroxyl and a 5' phosphate. The downstream fragment is degraded, whereas the upstream fragment, containing the coding sequence, is polyadenylated.

message; no poly(A) is added. The stem-loop structure, associated with a specific protein, plays the same role for the histone message as the poly(A) tails for all other messages.

Characteristics

RNA Sequences Directing Polyadenylation

In mammals, two sequence elements are sufficient to direct 3' end processing and polyadenylation of a messenger RNA. The highly conserved AAUAAA hexanucleotide sequence (poly(A) signal) is located between 10 and 30 nucleotides upstream of the cleavage site. Therefore, this signal remains in the upstream cleavage fragment, destined to become the mature mRNA and is required not only for cleavage but also for subsequent polyadenylation. In contrast, a less conserved GU- or U-rich element (downstream sequence element) is found downstream of the cleavage site; it is thus removed from the mRNA by cleavage. The phosphodiester bond to be cleaved is defined by the spacing between the AAUAAA sequence and the downstream sequence element. The cleavage reaction preferentially occurs after an adenosine residue, usually at a CA dinucleotide sequence. Sequences upstream of AAUAAA have been shown to increase the efficiency of some poly(A) signals and are commonly found in the poly(A) sites of viral genes. Nonetheless, these upstream sequence elements do not appear to be essential for general 3' end processing and have been identified in only a small number of cellular mRNAs.

Factors and Mechanisms

3' processing can be carried out in a cell-free system derived from HeLa cell nuclear extract. Proteins involved in the reaction have been identified by the biochemical fractionation of such extracts and reconstitution of cleavage and polyadenylation. ▶ **Cleavage and polyadenylation specificity factor** (CPSF) contains at least four subunits and is required for both partial reactions. This complex specifically binds the AAUAAA polyadenylation signal. The downstream sequence element is recognized by ▶ **cleavage stimulation factor** (CstF), a heterotrimer. RNA binding of the two proteins is cooperative. ▶ **Cleavage factor I** (CF I), probably a heterodimer, is also believed to be involved in substrate RNA binding at an early stage of the reaction, but no details are known. ▶ **Cleavage factor II** (CF II) contains at least two subunits. One of the CF II subunits is likely to bind ATP, as predicted from its sequence, and the cleavage reaction is ATP-dependent. Beyond this, the role of CF II is unknown. ▶ **Poly(A) polymerase**, the enzyme carrying out poly(A) tail synthesis in the second step, is also required or at least stimulatory for the cleavage reaction. Most if not all of these proteins assemble in a large complex on the substrate RNA before any reaction takes place. It is

unknown which of the many polypeptides catalyzes hydrolysis of the phosphodiester bond. Fig. 2 shows a largely hypothetical view of the cleavage complex. Based on a comparison to the 3' processing system of *S. cerevisiae*, one can expect that additional polypeptides involved in the reaction remain to be discovered. The second step of 3' processing, polyadenylation, is tightly coupled to cleavage *in vivo* and under normal reaction conditions *in vitro*, but can be uncoupled easily *in vitro* by the use of 'pre-cleaved' RNA substrates ending at or close to the normal cleavage site. CstF, CF I and CF II are only required for the cleavage reaction and are dispensable for polyadenylation uncoupled from cleavage. Under these conditions, poly(A) synthesis requires both CPSF and poly(A) polymerase and, in addition, the ▶ **nuclear poly(A) binding protein 1** (PABPN1). Poly(A) polymerase can synthesize poly(A) from ATP by elongation of a primer RNA, but has only marginal catalytic activity on its own and no sequence specificity. The enzyme is stimulated synergistically by CPSF and PABPN1. During the reaction, CPSF remains bound to the AAUAAA sequence and PABPN1 covers the growing poly(A) tail. Cooperative recruitment of poly(A) polymerase by these two proteins thus depends on the presence of appropriate binding sites in the RNA and results in processive poly(A) tail synthesis, which stops at a length of approximately 250 nucleotides. A cartoon of the polyadenylation complex is presented in Fig. 3. According to sequence database information and a limited number of experimental studies, there are multiple versions (splice variants and/or different genes) of many of the polypeptides mentioned above.

Polyadenylation. Figure 2 A hypothetical view of the cleavage complex. CPSF is shown as a heterotetramer binding the AAUAAA sequence, and CstF is shown as a heterotrimer recognizing the downstream sequence. The two complexes interact as indicated. The arrangement of the other proteins is hypothetical. The 70 kD subunit of CPSF is shown touching the CA cleavage dinucleotide based on a suggestion that it might be the endonuclease of the complex. Experimentally verified RNA binding polypeptides are CPSF 30K and 160K, CstF 64K and both subunits of CF I. PAP, poly(A) polymerase.

Polyadenylation. Figure 3 A hypothetical view of the processive polyadenylation complex. CPSF remains bound to the AAUAAA sequence and contacts PAP through its 160 kD subunit. PABPN1 covers the growing tail with monomers touching each other; RNA binding is slightly cooperative. PABPN1 also touches poly(A) polymerase, increasing the enzyme's affinity for RNA. An additional contact shown between PABPN1 and CPSF 30K has been experimentally proven for the isolated polypeptides, but its significance in the context of the polyadenylation reaction is unknown.

The biological relevance of this diversity remains largely unexplored. In addition to the poly(A) polymerase involved in nuclear mRNA polyadenylation, a second type of such enzymes exists in the cytoplasm. These are only remotely related in sequence to the nuclear enzymes and appear to function in post-transcriptional regulation by regulated poly(A) tail extension on certain mRNAs.

Polyadenylation in the Context of mRNA Production

A number of observations suggest that the 3' processing reaction as outlined above does not take place as an isolated event *in vivo*. Instead, 3' processing is coupled to other aspects of mRNA synthesis. The substrate on which the cleavage complex assembles is the nascent RNA. In living cells, cleavage and polyadenylation are efficient only when the precursor RNA is made by RNA polymerase II – transcripts of RNA polymerase I or III are processed poorly. Similarly, processing *in vitro* is more rapid with precursor RNAs made by RNA polymerase II in the extract as compared to synthetic substrates. While some of the dependence on RNA polymerase II *in vivo* may be explained by the fact that the cleavage reaction is stimulated by the 5' cap, which in turn is only added to RNA polymerase II transcripts, it is believed that there is also a more direct involvement of the polymerase. Some of the 3' processing factors bind the C-terminal domain of the largest subunit of the enzyme. Consequently, these proteins are thought to be delivered to the nascent RNA through their transient association with the polymerase rather than from

solution. Transcription termination of RNA polymerase II also depends on the assembly of the processing complex on the polyadenylation signal in the growing RNA chain, although probably not on the processing reaction itself. It is currently unknown how the signal of polyadenylation site recognition is transmitted to the elongating RNA polymerase.

In addition, cleavage/polyadenylation is known to be stimulated by the presence of an upstream intron and, in turn, splicing of the 3' terminal exon of an mRNA is stimulated by cleavage and polyadenylation.

Clinical Relevance

Mutations in polyadenylation signals can cause a variety of diseases by reducing the expression of the affected gene.

The **thalassemias** are characterized by a defective synthesis of either the α - or the β -globin chain. A large number of mutations in the polyadenylation signals of both the α - and the β -globin gene that usually lead to a mild clinical manifestation of thalassemia have been described and are commonly detected in compound with more severe thalassemia mutations. This indicates that the poly(A) site mutations by themselves lead only to a partial inactivation of the affected gene and thus do not cause a strong phenotype. This is probably due to the presence of extended transcripts arising from failure to process the mutated polyadenylation signal and processing at a cryptic downstream signal. The resulting mRNA species can be translated into normal polypeptides and thus contribute to the formation of functional $\alpha_2\beta_2$ hemoglobin. Furthermore, at least some normally polyadenylated mRNAs are produced, although their expression is markedly reduced.

Clinical studies have revealed an association between the risk of venous **thrombosis** and the presence of a G \rightarrow A mutation at position 20210 of the **prothrombin** gene (coagulation factor II). This mutation affects approximately 1–2% of the Northwest European population and represents one of the most common genetic risk factors for the occurrence of thromboembolism. Elevated prothrombin plasma concentrations in the carriers of the mutation are thought to play the key role in the pathogenesis of thrombosis. The 20210 G \rightarrow A mutation affects the 3' terminal nucleotide of the prothrombin mRNA 3' untranslated region and changes the CG dinucleotide at the cleavage site into a CA dinucleotide. The CG dinucleotide presumably constitutes an unfavorable cleavage site, which is responsible for a relatively inefficient 3' end processing of the prothrombin pre-mRNA. Mutation to a CA causes an increase of cleavage site recognition and an elevation of correctly 3' end processed mRNA. This leads to increased protein synthesis and thus links the prothrombin 3' end processing efficiency to the hemostasis of the blood-clotting cascade.

An inborn deficiency of ►**arylsulfatase A** (ASA) causes the lysosomal accumulation of cerebroside sulfate within nervous tissue and the characteristic symptoms of ►**metachromatic leukodystrophy** (MLD). However, an ASA deficiency is also commonly found in apparently healthy individuals and has been termed arylsulfatase A pseudodeficiency. The ASA pseudodeficiency allele may be clinically relevant in compound heterozygotes with an MLD allele. Pseudodeficiency is caused by a mutation changing the major polyadenylation signal from AAUAAC to AGUAAC, which severely diminishes ASA-mRNA levels.

Connections have also been made between 3' processing of mRNA and cell-cycle progression and cancer. Nuclear extracts from cells treated with DNA damaging agents have a defect in 3' processing. This may be caused by an inhibitory interaction between cleavage stimulation factor (CstF, see above) and the protein BARD1, which, in turn, associates with the tumor suppressor BRCA1. BRCA1 and BARD1 are thought to be involved in DNA repair. It has been suggested that this mechanism may serve to inhibit inappropriate cleavage and polyadenylation of nascent transcripts associated with RNA polymerase stalled at sites of DNA damage. Many tumors show enhanced activity of poly(A) polymerase and increased levels of transcription of two different poly(A) polymerase genes. On the other hand, modest over-expression of poly(A) polymerase is deleterious for growth of tissue culture cells. The enzyme is down-regulated by phosphorylation of its serine- and threonine-rich C-terminal domain during mitosis. This may contribute to the general shutdown of gene expression at this phase of the cell-cycle.

The inherited disease ►**oculopharyngeal muscular dystrophy** (OPMD) is caused by moderate and genetically stable trinucleotide expansions in the PABPN1 gene, which lead to corresponding expansions of a naturally occurring tract of ten consecutive alanine residues at the very N-terminus of the protein. Addition of a single alanine results in a recessive phenotype, whereas additions of up to seven alanines are dominant. The mutations cause the aggregation of PABPN1 in the form of regular fibrils in the nuclei of muscle cells. The mechanism leading to cell damage is unknown but is unlikely to involve a defect in mRNA polyadenylation.

Adult onset polycystic kidney disease

Definition

Disease Characteristics

Autosomal dominant polycystic kidney disease (►ADPKD) is the commonest inherited disease of humans, has a prevalence of 1:1000 and shows no racial or geographic predilections. In patients with ADPKD, multiple renal cysts develop throughout adult life, causing the loss of renal function that is the principal source of morbidity. Although cysts are also observed in the liver and pancreas, patients with ADPKD rarely develop dysfunction of these organs. In the majority of affected individuals, progressive renal failure typically leads to the requirement for renal replacement therapy by mid to late adulthood, but disease progression is very variable, even within families, raising the possibility that environmental factors and modifying genes have an important influence on the ADPKD phenotype. In addition to cyst formation, a range of other features has been associated with this disease, including hypertension, cerebral aneurysms, heart valve abnormalities, colonic diverticuli and hernia formation.

Molecular Genetics

ADPKD arises as a consequence of mutations in one or other of two genes, ►PKD1 and ►PKD2, which were identified in 1994 and 1996 (1, 2). Disease characteristics in patients with mutations in the PKD1 gene (ADPKD type 1) are identical to those of patients with mutations in the PKD2 gene (ADPKD type 2) with the exception that disease progression is generally less rapid in the latter. It is therefore likely that the PKD1 and PKD2 gene products, named ►polycystin-1 and ►polycystin-2, function in the same pathway. Many of the disease-specific mutations of these two genes encode truncated or nonsense polypeptides, suggesting that ADPKD arises as a consequence of loss of function of polycystin-1 or polycystin-2. The loss of function model has gained support from studies in transgenic mice. Renal cyst formation was observed in homozygous PKD1 or PKD2 knockout embryos (neither transgenic model survived beyond 16 to 18 days post-conception) but not in heterozygous animals, which lived into adulthood and displayed delayed and rather rare cyst formation. Hence, the pattern of cyst formation characteristic of human disease appeared to require loss of both PKD alleles. More recently, evidence that cyst formation requires inactivation of both PKD alleles has emerged from a human study, which also provided an explanation for the sporadic and focal nature of cyst formation in ADPKD. In this study, human cyst epithelia were found to be ►monoclonally derived, and exhibited ►loss of heterozygosity for the PKD1 gene (3). Hence, in ADPKD, each cyst probably arises from a single renal tubule cell, not because of the ubiquitous germline mutation, but as a

consequence of a somatic mutation or “second hit” to the sole remaining normal PKD allele in that cell. Subsequent clonal proliferation of the affected cell would then give rise to the cyst epithelium. This model accounted for the observation that, despite the universal presence of the germline mutation in ADPKD, the kidneys appear not to exhibit a generalized abnormality. The second hit hypothesis for pathogenesis in ADPKD was subsequently confirmed in the currently most convincing animal model for the disease. This model arose from the fortuitous development of a transgenic mouse with an unstable PKD2 allele (4). In this mouse, an early germline inactivation of one PKD2 allele gave rise to a heterozygote background upon which subsequent sporadic inactivation of the remaining intact PKD2 allele created a phenotype closely resembling human disease.

Characteristics

Polycystin-1

Polycystin-1 is a 4302 amino acid protein with a large extracellular domain, 11 transmembrane passes and a smaller cytoplasmic carboxyl terminus. The extracellular domain displays a range of motifs indicating the capacity for interactions with extracellular proteins and carbohydrates. In particular, a series of so-called ►PKD domains suggest the potential for ligand binding, raising the possibility that polycystin-1 acts as a transmembrane receptor. This view gains further support from the presence of a ►heterotrimeric G protein binding and activation domain in the cytoplasmic carboxyl terminus. A ►G protein-coupled receptor proteolytic site (GPS) lies close to the cell membrane in the extracellular amino terminus of polycystin-1. Polycystin-1 is physiologically cleaved at this position and this cleavage event appears to be functionally important. However, the way in which cleavage modulates the function of polycystin-1 remains unknown. A lipoxxygenase homology (LH) domain lies within the first intracytoplasmic loop and probably mediates interactions with lipid or lipoprotein. The combination of a GPS and an ►LH domain appears to be the hallmark of all polycystin-1-like proteins, which are forming an expanding family with diverse tissue distribution and, probably, diverse functions. A motif resembling a sea urchin protein named “►receptor for egg jelly” (the REJ protein is found in the cell membrane of sea urchin sperm) lies in a region of the extracellular domain of polycystin-1, proximate to the cell membrane. In sea urchin fertilization, binding of the REJ protein to a component of the egg jelly activates cation channels in the sperm cell membrane. The resultant cation influx triggers the acrosome reaction. The presence of the REJ motif raises the possibility that polycystin-1 might similarly modulate membrane cation flux in response to extracellular

Polycystic Kidney Disease, Autosomal Dominant. Figure 1 Polycystins 1 and 2 are transmembrane proteins. The coiled coil domain in the cytoplasmic carboxyl terminus of polycystin-1 mediates binding with the cytoplasmic carboxyl terminus of polycystin-2. The extracellular amino terminus of polycystin-1 probably interacts with other proteins (via leucine rich repeats, PKD domains and the LDL-A region) and/or with carbohydrate (via the WSC domain and the C-type lectin region). Conformational changes induced by such interactions might be transduced to modulate intracellular signal transduction pathways (via the carboxyl cytoplasmic terminus G protein binding and activation site or coiled coil domain) or to influence the channel properties or membrane localization of polycystin-2.

signals. In fact, this seems rather likely since polycystin-1 is known to interact with polycystin-2 (via a [coiled-coil domain](#) in the polycystin-1 cytoplasmic carboxyl terminus) and polycystin-2 is a cation channel.

Polycystin-2

Polycystin-2 is a six transmembrane domain protein with overall homology to voltage activated calcium channels. This protein has been characterized as a calcium permeable non-selective cation channel (5) and has been identified as the founder member of a novel sub-class of so-called transient receptor potential proteins ([TRP Channel](#)). Members of the TRP family are thought to function as the pathway for [store-operated calcium entry](#) following a calcium release stimulus. The polycystin-2 carboxyl terminus exhibits an endoplasmic reticulum (ER) retention signal, a coiled coil domain and an [EF hand](#) motif typical of voltage gated calcium channels. The EF hand is a calcium-binding domain that might account for the sensitivity of polycystin-2 to inhibition by calcium. The polycystin-2 coiled-coil domain, located in the carboxyl terminus, is required for homotypic interactions between polycystin-2 molecules; interactions with polycystin-1 appear to require a domain in the carboxyl terminus of polycystin-2 that lies outside this coiled coil region.

Cellular and Molecular Regulation

Polycystins 1 and 2 Function in the Same Pathway

The precise roles of polycystins 1 and 2 remain uncertain. Polycystin-1 is probably resident at the plasma membrane with a basolateral distribution and

within junctional complexes, but polycystin-1 immunoreactivity has also been identified in the central apical cilia of renal epithelial cells. Debate continues over whether polycystin-2 is confined to the ER or if this protein might also function in the plasma membrane. More recent studies indicate that polycystin-2 co-localizes with polycystin-1 in the apical [cilia](#). As discussed above, observations of human disease and knockout-mouse phenotypes indicate that the two proteins almost certainly act in the same pathway with respect to the generation of cysts. Direct genetic evidence that polycystins 1 and 2 are indeed functional in one pathway arose from studies in [C. elegans](#), where the polycystin-1 homologue [Lov-1](#) colocalized with the polycystin-2 homologue in the cilia and cell bodies of male sensory neurons (6). Mutations in either protein lead to loss of the male ability to locate the hermaphrodite vulva; double mutations (inactivating Lov-1 and polycystin-2) produced no additive effect. Subsequent studies have confirmed that polycystins 1 and 2 are functionally inter-dependent in a number of other pathways as listed below.

1. The effect of exogenously over-expressed polycystin-1 to induce G0/G1 cell cycle arrest in MDCK cells is mediated by activation of the [JAK-STAT](#) pathway and is dependent upon polycystin-2.
2. Polycystin-2 appeared to antagonize polycystin-1 activation of Gi/o-type G-proteins.
3. Channel activity attributable to polycystin-2, exogenously over-expressed in Chinese hamster ovary cells, was dependent upon co-expression of a

polycystin-1 cDNA with an intact coiled-coil domain.

4. In a reconstituted membrane system, the non-selective cation channel activity of polycystin-2 was subject to spontaneous run-down that was reversed by addition of the polycystin-1 cytoplasmic carboxyl terminus.

Are All Polycystin Functions Relevant to the ADPKD Phenotype?

The polycystins appear to be involved in numerous processes, but no predominant function has yet emerged. In view of this apparent diversity, it is possible that some of the functions attributed to the polycystins are not related to cystogenesis, and perhaps not to any of the features of the ADPKD phenotype. A number of observations give support to this possibility. It is apparent from transgenic mouse studies that the polycystins play developmental roles, influencing cardiac (polycystins 1 and 2) and blood vessel development (polycystin-1), skeletal configuration (polycystin-1) and even left-right axis determination (polycystin-2). However, in the light of the double hit hypothesis, which suggests that *de novo* cyst formation could take place throughout adult life, it seems reasonable to propose that it is the polycystin functions expressed in renal epithelial cells in the terminally differentiated stage of development that are important in the pathogenesis of ADPKD. It is more difficult to envisage how the ADPKD phenotype could emerge as a delayed consequence (manifesting in adulthood) of some developmental dysregulation. These questions will be resolved when a conditional polycystin knock-out mouse is developed. Polycystin functions might be arranged along a developmental, time-based axis, but there is also evidence for a spatial separation suggested by the observation that polycystin-2 does not always co-localize with polycystin-1. Since it is very likely that ADPKD arises from disruption of a single pathway involving both proteins, the involvement of polycystins 1 and 2 in divergent pathways could indicate that such pathways are not relevant to ADPKD.

One way of organizing the large amount of information that is accumulating is to focus on those functions of the polycystins that are plausibly related to cyst formation. These functions could be considered the clinically relevant functions of the polycystins and might be expected to operate in the single (putative) pathway whose disruption in terminally differentiated renal epithelial cells leads to the cyst forming phenotype.

Clinical Relevance Polycystins and Cyst Formation

The initiator of cyst formation is a sporadic “second hit” to the single normal PKD allele in an individual

renal tubule cell (the first hit being the germ line mutation affecting all cells). According to a plausible model for cystogenesis, the single affected cell proliferates and gives rise to an epithelium deficient in the contextual responses that maintain normal tubular architecture. As a consequence, small evaginations develop from the tubule lumen, which separate from the tubule to form a small cyst rather than a tubule-like structure. Cyst expansion proceeds as a consequence of continued cyst epithelial cell proliferation accompanied by fluid accumulation within the cyst lumen. Hence, three basic processes probably underlie cystogenesis, 1) the transition from stable epithelial population to proliferation, 2) loss of the morphological constraints determining normal tubule architecture and 3) a shift in the balance of transepithelial transport from reabsorption to secretion. Each of these could arise as a consequence of the failure of affected cells to maintain a terminally differentiated phenotype. The evidence that polycystin pathways are involved in these three processes is discussed below.

Proliferation

As described above, polycystin-1 is known to inhibit cell proliferation in concert with polycystin-2 through activation of the JAK-STAT pathway. Therefore, loss of polycystin-1 or 2 would be predicted to result in increased cell proliferation.

Loss of the Morphological Constraints Determining Normal Tubule Architecture

Little is known of the processes maintaining tubule architecture in mature renal epithelial cells. Even when cell division occurs, after acute renal injury for example, the regenerating epithelium in normal individuals reconstitutes within the tubular basement membrane rather than budding out to form cysts. Perhaps the co-localization of the polycystins to the apical cilia in renal tubule epithelial cells provides a clue to cystogenesis. It has been proposed that the cilia function as a mechano- or chemo-sensory organ. If, in ADPKD, renal epithelial cells should lose information from the cilia, they may fail to detect environmental cues required for the maintenance of the tubular configuration of the epithelial sheet; for instance chemical gradients or direction of flow of luminal fluid. An increasing number of murine models for cystic kidney disease have been demonstrated to arise from mutations in proteins involved in cilia formation and function including ►polaris, ►cystine and ►inversin. Furthermore, there is evidence that the polycystins are required for one normal function of the cilia, namely the mediation of flow-dependent cell calcium responses in which ciliary deflection triggers alterations in membrane calcium channel activity. The dependence of this ciliary function upon polycystin-1

was demonstrated in renal epithelial cell lines derived from homozygous polycystin-1 knockout mice (isolated at E15.5) that exhibited loss of the normal cell calcium response to flow (7).

A Shift in the Balance of Transepithelial Transport from Reabsorption to Secretion

The proximal and distal renal tubular epithelia, from which cyst lining epithelia are derived, are predominantly reabsorptive, transporting ions and water from the apical (luminal) to the basolateral (blood) compartments. In cysts as in tubules, the apical membrane of the epithelial cells faces the lumen. These cyst epithelial cells become progressively flattened and de-differentiated in appearance as disease progresses, and lose the capacity for avid sodium reabsorption. In addition to diminished reabsorption, aberrant secretion across the cyst epithelium is probably required for fluid accumulation within the cyst lumen. In classical secretory tissues, such as colon and lung, transepithelial chloride secretion is driven by the opening of apical chloride channels. Two chloride conductance pathways that mediate secretion have been identified, the ►cAMP activated cystic fibrosis transmembrane conductance regulator (►CFTR) and the calcium activated chloride channel ►Cl_{Ca}. If sodium reabsorption is down-regulated in the cyst epithelium, then constitutive basal activity of either chloride channel might play a permissive role in the gradual accumulation of cyst fluid. However, since interruption of polycystin pathways might promote dysregulation of heterotrimeric G protein signal transduction and/or intracellular calcium homeostasis, it is conceivable that these chloride channels might be pathologically activated by up-regulation of ligand-induced stimulation of cAMP or intracellular calcium concentration in ADPKD.

Definition

Polyglutamine Disease

The polyglutamine diseases are a group of nine hereditary neurological disorders caused by pathological expansion of a CAG trinucleotide repeat in the disease gene. These include Huntington's disease (►HD), Kennedy's disease (►KD), dentatorubral pallidoluysian atrophy (►DRPLA), and six forms of dominantly inherited spinocerebellar ataxia (►SCA1–3, 6, 7 and 17) (1). They are all late-onset neurodegenerative disorders for which there is currently no treatment. The expanded CAG repeat in the disease genes results in elongated stretches of polyglutamine in the disease proteins, making them toxic to neurons. Thus, the polyglutamine diseases appear to share a common molecular basis determined by the toxic gain of function associated with expanded polyglutamine. The phenotypes of the different polyglutamine diseases vary considerably. HD is characterized by degeneration of cortical and subcortical grey matter and the clinical picture is dominated by dementia, psychiatric disturbances and profound movement disorders. DRPLA patients experience dementia and movement disorders similar to HD, but also frequently develop a progressive ataxia. The SCAs are dominated by degeneration of cerebellar nuclei leading to progressive ataxia, although involvement of other systems is frequent. KD is characterized by slowly progressive motor neuron degeneration leading to muscle atrophy and weakness. The distinctive clinical picture seen in each of these diseases is a reflection of the selective vulnerability of different populations of neurons in each of these diseases despite widespread and overlapping expression of some of the disease proteins. The selective neurodegeneration in these diseases has long been enigmatic, since each disease protein shares the same gain-of-function mutation. Recent evidence strongly suggests that the context of the polyglutamine expansion is a strong determinant of this selectivity, causing the polyglutamine toxicity to be influenced by the normal interacting partners of the disease protein and, perhaps, partial loss-of-function of the disease protein.

Cellular and Molecular Regulation

Polyglutamine Aggregation

An important advance in understanding the toxicity of expanded polyglutamine was the recognition of

ubiquitinated neuronal inclusions in degenerating regions of the brain and spinal cord tissue from patients with these diseases (2). These inclusions consist of large accumulations of insoluble aggregates of the disease proteins (or polyglutamine-containing fragments) in association with a host of additional proteins. This insight was in agreement with known biochemical features of long polyglutamine tracts, the propensity to aggregate *in vitro* as anti-parallel β -strands termed 'polar zippers'. When the genetic basis for the polyglutamine diseases was established, it became apparent that there is a close correlation between the threshold CAG repeat length that leads to disease and the polyglutamine length that leads to aggregation in experimental systems. This observation formed the initial basis of the argument that aggregation of expanded polyglutamine is the acquired property underlying the toxic gain-of-function. While the primacy of aggregation in initiating the toxicity of the polyglutamine-containing proteins is now supported by substantial evidence, the nature of this toxicity and its target has remained elusive. Agents that prevent polyglutamine aggregation, such as Congo red or trehalose, have shown some effectiveness in ameliorating polyglutamine toxicity in mice. These results underscore the relationship of aggregation to toxicity and show the potential therapeutic value of preventing aggregation.

The Importance of Nuclear Localization in Polyglutamine Pathogenesis

Substantial evidence indicates that the nucleus is an important site of polyglutamine toxicity for at least some polyglutamine diseases. The first insight into this came from recognition that accumulation of mutant protein in the nucleus correlates with disease (Table 1). In some cases, disease-associated proteins are normally located in the nucleus. Others are normally located in the cytoplasm, but are redistributed to the nucleus where they accumulate and form inclusions during the disease process. Mutant forms of huntingtin, ataxin-3 and the androgen receptor all show this nuclear redistribution in disease. In addition to this circumstantial evidence, the importance of nuclear localization as a requisite step in polyglutamine pathogenesis is now supported by substantial experimental evidence from cell culture and animal models of HD, KD, DRPLA and SCAs 1, 3 and 7 where nuclear localization is required to initiate toxicity. It should be noted, however, that nuclear localization of mutant protein has not been observed in SCA2 and SCA6 (Table 1). In these diseases, mutant forms of ataxin-2 and ataxin-6 are found to accumulate in the cytoplasm and cell membrane, respectively. Any

Polyglutamine Disease, the Emerging Role of Transcription Interference. Table 1

Disease	Protein	Normal Location	Disease Location	Normal Function
Huntington's Disease	Huntingtin	cytoplasm and nucleus	cytoplasm and nucleus	unknown; implicated in regulation of transcription and vesicular transport
Kennedy's Disease	Androgen receptor	cytoplasm and nucleus	cytoplasm and nucleus	ligand-responsive transcription factor
Dentatorubro-pallidoluysian atrophy	Atrophin-1	nucleus	nucleus	unknown; <i>Drosophila</i> ortholog shown to be a corepressor of transcription
Spinocerebellar ataxia 1	Ataxin-1	cytoplasm	cytoplasm and nucleus	unknown; evidence of RNA-binding
Spinocerebellar ataxia 2	Ataxin-2	cytoplasm	cytoplasm	unknown
Spinocerebellar ataxia 3	Ataxin-3	cytoplasm	cytoplasm and nucleus	unknown; implicated in repression of transcription and proteolysis of polyubiquitinated proteins
Spinocerebellar ataxia 6	CACNA1A	plasma membrane	Cytoplasm and membrane	voltage-dependent calcium channel
Spinocerebellar ataxia 7	Ataxin-7	nucleus	nucleus	transcription factor; component of STAGA complex
Spinocerebellar ataxia 17	TATA-binding protein	nucleus	nucleus	transcription factor; component of basal transcription machinery

unifying hypothesis of polyglutamine pathogenesis will need to account for this difference in subcellular localization.

A Primary Role for Transcription Interference?

A wide array of altered biological processes have been described in model systems of polyglutamine disease and proposed as mechanisms to account for polyglutamine toxicity including impairment of the ►ubiquitin-proteasome system (UPS), altered synaptic function, disrupted axonal transport and induction of programmed cell death. While abnormalities in these systems may contribute to neuronal dysfunction or loss, evidence is scant that any of these pathways serve as primary targets for expanded polyglutamine. In contrast, a growing body of evidence suggests that interference with regulators of transcription may be a primary mechanism in polyglutamine disease, perhaps initiating a cascade of subsequent abnormalities. Among the early indications that transcription might be a proximal target of polyglutamine toxicity were expression profile analyses of mouse models of Huntington's disease and SCA1 showing that alterations to transcription are early events in neurodegeneration.

Elucidating the Normal Function of Disease Proteins Provides a Clue

The notion that transcription interference might be fundamental to polyglutamine toxicity is supported by the growing appreciation that many of the polyglutamine disease proteins normally function in regulation of transcription (Table 1). For example, the AR and TATA-binding protein are well-established transcription factors. Ataxin-7 was recently identified as a component of a multimeric ►histone acetylation complex SPT3-TAF-GCN5 acetylase (►STAGA), the homolog of the complex found to be impaired in a yeast model of HD (see below). Both ataxin-3 and atrophin-1 (mutated in SCA3 and DRPLA, respectively) have been implicated in regulating the function of ►histone deacetylases. Huntingtin augments transcription of brain-specific genes through interaction with the repressor element-1 transcription factor (►REST). If polyglutamine disease proteins are transcription regulatory factors, how might this relate to the toxicity of expanded polyglutamine? Recent evidence suggests that polyglutamine expansion results in partial loss of function for at least some proteins. For example, polyglutamine expansion in the androgen receptor results in a partial loss of androgen-responsive gene

expression. This is probably responsible for the feminization observed in KD and may also influence the range of neurons that are vulnerable to polyglutamine toxicity in this disease. Similarly, polyglutamine expansion is found to interfere with the ability of huntingtin to negatively regulate the neuronal repressor REST in model systems. This results in reduced expression of brain-specific genes such as brain-derived neurotrophic factor (►BDNF) (3). Reduced levels of this neurotrophic factor are reportedly found in HD brain and could conceivably contribute to the neurodegeneration seen in HD. This hypothesis is supported by the observation that conditional knockout of either BDNF or huntingtin in the mouse leads to progressive neurodegeneration, although not with overlapping patterns.

Can Gain of Function Lead to Loss of Function?

It is clear, however, that loss of disease protein function alone does not account for the degeneration observed in the polyglutamine diseases. A preponderance of evidence indicates that polyglutamine expansion endows the disease proteins with some toxic property. One simple proposal to explain this toxicity is sequestration and functional depletion of some limiting factor that is critical to neuronal function and survival. Thus, there have been extensive efforts to identify the cellular components that interact with deposited aggregates of polyglutamine-expanded disease proteins. Two classes of proteins stand out as most frequently and consistently found to interact with polyglutamine aggregates, 1) components of the UPS, and 2) an extensive list of transcription regulatory factors. The association of UPS components with polyglutamine aggregates (including ubiquitin, chaperones and subunits of the proteasome) has been interpreted as a cellular response to accumulating misfolded protein and an effort by the cell to eliminate the aggregates. The association with transcription factors, on the other hand, was unexpected. In some cases, the sequestered proteins represent normal binding partners of the disease protein. For example, the transcription factor CRX, which regulates retinal-specific gene expression, is sequestered and depleted by aggregates of polyglutamine-expanded ataxin-7. In a transgenic model of SCA7, loss of CRX activity is found and believed to contribute to the cone-rod dystrophy that occurs in this disease (4).

Among the first transcription-related factors found to interact with polyglutamine-expanded disease proteins was CREB-binding protein (►CBP). This transcription co-activator is sequestered within polyglutamine inclusions in numerous cell culture and animal models of different polyglutamine diseases and also found to colocalize with the intranuclear polyglutamine

inclusions observed in samples from patients with Huntington's disease, Kennedy's disease and DRPLA (5). CBP is a transcription co-activator that augments transcription through regulation of chromatin structure in the vicinity of target genes. CBP mediates transcriptional activation by a wide array of transcription factors including CREB, NF- κ B, AP-1 and p53, among others. The mechanism of CBP activity involves post-translational modification of ►histones by an intrinsic ►histone acetyltransferase (HAT) activity. The observation that CBP is sequestered by multiple disease proteins may relate to an affinity between the acetyltransferase domain of CBP and long polyglutamine stretches. A role for CBP depletion in polyglutamine disease is supported by cell culture studies demonstrating that polyglutamine toxicity is associated with reduced levels of histone acetylation as well as loss of CBP-dependent activation of transcription. Moreover, up-regulation of CBP was found to reduce polyglutamine cytotoxicity and prevent neurodegeneration in a *Drosophila melanogaster* model of polyglutamine disease.

Polyglutamine Disease and Aberrant Acetylation

A primary level of chromatin organization is the wrapping of DNA around cores of histone proteins to form nucleosomes. Post-translational modification of histones has emerged as an important epigenetic mechanism regulating gene expression leading to the recognition of a "histone code". Of the known histone modifications, acetylation is the longest recognized and perhaps best understood. Hyper-acetylation of histones is associated with transcriptionally active regions of chromatin, while hypo-acetylated histones are typically associated with transcriptionally silent chromatin domains. Homeostasis of histone acetylation is maintained by opposing enzyme activities; histone acetyltransferases (HATs), such as CBP, that attach acetyl groups to lysine residues in the tails of histones and histone deacetylases (HDACs) that remove these same acetyl groups. Acetylation of lysine residues in the amino-terminal tail of histones reduces their charge attraction for DNA, thereby reducing the degree of chromatin compaction and allowing greater accessibility for transcription factors.

The earliest evidence implicating aberrant histone acetylation as a mechanism of polyglutamine toxicity was provided by a study carried out by Hughes and colleagues prior even to recognition that many of the polyglutamine disease proteins are involved in regulating transcription (6). These investigators demonstrated that expression of expanded polyglutamine in the nucleus of *Saccharomyces cerevisiae* disrupted transcription in a pattern very similar to that seen in yeast carrying mutations in the Spt/Ada/Gcn5

acetyltransferase (►**SAGA**) complex that maintains transcriptionally active chromosomal regions by promoting histone acetylation. The authors proposed that expanded polyglutamine in the nucleus resulted in a deficiency in histone acetylation, leading to transcriptional dysregulation. As described above, ataxin-7 is a component of the homologous mammalian histone acetylase complex, STAGA.

The toxicity of expanded polyglutamine in cell culture is ameliorated pharmacologically by ►**HDAC inhibitors**, which restore levels of histone acetylation. Furthermore, polyglutamine-mediated neurodegeneration in *Drosophila* is prevented both by pharmacological treatment with HDAC inhibitors and by up-regulation of the expression of the histone acetyltransferase CBP. The most encouraging news comes from drug trials using transgenic mouse models of polyglutamine disease where pharmacological augmentation of histone acetylation with HDAC inhibitors was found to ameliorate neurodegeneration, reduce motor deficits and extend lifespan (7, 8).

Clinical Relevance

In the decade since the genetic basis of Huntington's and related diseases was determined, tremendous advances have been made in understanding the molecular basis of neurodegeneration. While the details remain far from clear, a promising target for therapeutic intervention has emerged. Independently and in parallel over the past decade, a novel class of drugs has been developed that can augment levels of histone acetylation. These drugs inhibit histone deacetylases and thus promote increased histone acetylation. Phase I and II clinical trials show that the histone deacetylase inhibitors have good safety and tolerability profiles in humans. The efficacy of these drugs in model systems from cell culture to invertebrates to transgenic mice gives reason to be optimistic that the era of targeted therapeutics for the polyglutamine diseases may be at hand. Indeed, a clinical trial of the HDAC inhibitors in Huntington's disease is currently planned in the US.

►**Reverse Transcriptase**

Polymerase Chain Reaction

►**PCR**

Polymorphism/Polymorphic

Definition

Polymorphism/polymorphic refers to the state where a gene exists in more than one version (allele), and where the rare allele can be found in more than 1% of the population. (A frequency less than 1% is called a rare variant). A polymorphism does not usually directly cause altered phenotypes, even when present in homozygous form.

Polytene Chromosomes

Definition

Polytene chromosomes that emanate in certain cells in Diptera are long thick chromosomes with alternating dense bands and diffuse interbands. They are produced by over-replication of large parts of the genome within one S phase.

- ▶ DNA Amplification

Population Stratification

Definition

Population stratification (also called population admixture) refers to differences in allele frequencies between cases, and controls due to systematic differences in ancestry rather than association of genes with disease. When there are different ethnic subgroups in an association study group this can result in false

positive or false negative associations. For example, a false positive result could occur if one ethnic group had a higher prevalence of COPD (based on unmeasured environmental factors) and a different frequency distribution of candidate SNP alleles. If the study population contains a mixture of ethnic groups, these alleles would appear to be associated with the disease although they may have no functional effects. It has been proposed that false positive associations due to stratification can be controlled by genotyping a few dozen unlinked genetic markers.

j.van_den_hoff@fz-rossendorf.de

Definition

► [PET](#) (short for “► [Positron Emission Tomography](#)”) is a tomographic imaging technique that provides the ability to investigate cellular and molecular processes quantitatively *in vivo*, thus allowing truly functional imaging. Today, PET is firmly established in preclinical and clinical research as well as for clinical applications. The PET technique assesses the three-dimensional distribution of special radioactive substances (radio ► [tracers](#)) *in vivo*. These PET tracers are molecules containing short-lived ► [positron](#) emitting isotopes (► [labels](#)). Frequently utilized labels are ^{11}C , ^{13}N and ^{18}F , with half-lives of 20 m, 10 m, 110 m, respectively. These positron-emitting isotopes can substitute for the corresponding stable isotopes (e.g. ^{12}C , ^{14}N) in relevant biomolecules, leading to a wide class of PET tracers whose *in vivo* behavior is unaltered in comparison to their naturally occurring counterparts.

The label can also replace other elements in the molecular structure – for example the widely used ^{18}F can replace hydrogen in many organic compounds. This approach leads to PET tracers whose chemical properties deviate from systemic substances. In this

way it is possible to create tracers with desirable special properties such as enhanced trapping in the target regions. A notable example of this approach is [^{18}F]-2-fluoro-2-deoxy-D-glucose (^{18}F -FDG), which is currently the most widely used PET tracer for clinical oncological investigations.

Unlike X-ray computed tomography (CT) and magnetic resonance imaging (MRI) the primary signal detected with PET (namely the time dependent regional concentration of the radioactive tracers used) is always a ‘functional’ signal from the living organism, which is closely related to different phenomena (depending on the tracer used) such as blood flow, transport across diffusion barriers (e.g. glucose transport into the cell), substrate metabolism, protein synthesis, enzyme activity, receptor affinity and so forth.

At the same time, the “imaging agent”, i.e. the radioactive tracer, is applied in true tracer amounts (usually at the picomolar level), which guarantees that no effects of the tracer on the system under investigation are present.

Consequently, it is possible to obtain specific information concerning selected molecular processes with the PET imaging technique (‘molecular imaging’).

Description

Introductory Remarks

From its beginning as a novel experimental technique some 20 years ago, PET has evolved into an important tool in clinical practice as well as in basic research. The growing interest in the PET technique has been accompanied by major improvements in hardware and infrastructure – e.g. in tomograph performance (spatial resolution, sensitivity), isotope production, radiochemistry laboratories and computer hardware – as well as by advances in tracer development and quantitative evaluation of the resulting data. Recently, the field has seen the emergence of special brain tomographs (2.5 mm resolution) and dedicated ultra-high resolution animal scanners (1–2 mm resolution). Moreover, combined PET/CT systems have become available which integrate functional and anatomical imaging in one instrument.

In the field of drug development and evaluation PET is generally positioned in pre-phase I clinical trials. Due to the very high sensitivity of radio tracer based measurement techniques, PET investigations can be applied with a dose which is much smaller than the common starting dose for phase I trials (typically by a factor of about 1,000).

With pharmacokinetic measurements the distribution, metabolism and clearance of a potential drug can be determined. Pharmacodynamic measurements can determine the pharmacological effect of a new drug. Hence PET can play an important role in proof-of-concept

studies. Moreover, classical phase I studies (aiming at finding the maximum tolerated dose) are inappropriate for e.g. gene therapy, cell transplantation or anti-angiogenic drugs if they target only focal pathophysiology or exhibit only minimal normal tissue toxicity.

With the availability of ultra-high resolution animal tomographs, the potential of PET to rationalize and economize the earliest phases of drug development has increased considerably.

Mode of Operation

In PET investigations, the radioactive tracer is typically injected intravenously, but other application schemes (intra-arterial, inhalation) are possible – and might be necessary – depending on the properties of the tracer and/or the question addressed by the investigation.

The measurement of the regional tracer distribution in the PET method rests on the detection of the decay of individual atomic nuclei of the radioactive label used. Upon the decay of the radioactive label a positron is emitted from the atomic nucleus that is rapidly stopped in the surrounding tissue (mean ranges in water, 1.1 mm, 1.5 mm and 0.6 mm for ^{11}C , ^{13}N and ^{18}F , respectively). The positron then annihilates with an electron, accompanied by collinear emission of 2 photons, i.e. electromagnetic radiation, in opposing directions (annihilation radiation).

These high energy (511 keV) photons are detected by scintillation detectors arranged in a ring coaxial to the patient's body axis. The coincident detection of two photons (within a time window of a few nanoseconds) defines for each detected pair of photons a so-called line of response along which the primary decay of the radioactive label has occurred. Accepting only these coincident events yields the necessary collimation (i.e. directional information) that is required for subsequent tomographic image reconstruction of the tracer distribution.

To derive quantitative images, corrections for effects such as scattering and attenuation of the annihilation radiation in the traversed tissue have to be included in the data processing.

Inclusion of these corrections ensures that the resulting images directly yield the regional concentration of the applied tracer substance in absolute terms (usually units of Bq/ml, i.e. amount of radioactivity per unit volume, are used).

Data Evaluation Methods

A PET investigation basically yields the three-dimensional spatial distribution of a radiopharmaceutical as a function of time.

The most elementary approach to evaluation of this distribution is visual inspection. In many cases, changes in the regional distribution of the radiopharmaceutical as compared to the normal distribution

can be detected visually and can as such be useful for diagnosis, therapy evaluation or for the assessment of the effect of a drug. However, this approach represents a qualitative assessment of image contrast only, which is a serious drawback. For example, changes in image contrast may be due to a changed uptake in target tissue, reference tissue or both. Furthermore, global alterations of the uptake cannot be analyzed visually. Therefore, visual analysis is often accompanied by simple quantification methods such as regional tracer concentration calculations and relative uptake determination. In practice, these methods are adequate for many investigations, in particular for clinical diagnosis. However, there are also circumstances where the above methods are not adequate or not even applicable because the (time varying) tissue concentration of a radiopharmaceutical is determined by the subtle interplay between (time varying) plasma concentrations on the one hand and a number of parameters used to describe the kinetics of the tracer on the other. Consequently, the relation between the measured distribution and the parameters may be strongly non-linear and sometimes a one-to-one relation between single parameters and the distribution may not even exist. In these cases it is essential to employ more advanced data analysis methods (1).

Today, essentially all approaches to quantitative evaluation of PET investigations are utilizing (directly or implicitly) the concepts of [compartment modeling](#). The central postulate of compartment modeling is the assumption that the process/system under investigation can be decomposed into a (hopefully small) number of functional units, called compartments, which are interpreted as structureless pools containing the tracer in distinct states. This implies especially that, by definition, no concentration gradients are present within the compartments. It is important to realize that a compartment does not need to have an anatomical correlate. Rather, it might describe the tracer in a certain identifiable chemical modification. Taking into account the tracer principle, one usually ends up with pure first order kinetics, which corresponds to a mathematical description by first order differential equations. In the majority of cases, this description is adequate. However, in the special case of carrier-added experiments it may no longer hold.

The transport can be the physical transport from one physical space to another, e.g. from plasma to intracellular fluid or a biochemical transformation within a single physical space, e.g. the phosphorylation of FDG to FDG-6-PO₄ in the cell. Although each of these steps may be composed of many intermediate processes, only the rate-limiting step is of importance. For example, a tracer may be transported first from plasma to extracellular fluid, then into the intracellular fluid and finally into the nucleus or the mitochondria.

Nevertheless this can be modeled as a single step process provided that these subsystems approach steady state sufficiently rapid.

Summary

The PET method offers a set of advantageous properties, which are, in this combination, not provided by other means:

- Very high sensitivity with respect to applied amount of tracer substance, which is typically in the nanomolar or picomolar range. In comparison to MRI the sensitivity is higher by more than a factor of 10^6 .
- Simultaneous imaging of the whole field of view (for clinically used systems, typically 60 cm (transaxial) \times 15 cm (axial)) with nearly isotropic resolution in all three dimensions. The spatial resolution of the method is about 4–5 mm in all three dimensions in currently used clinical tomographs (1–2 mm with state of the art small animal systems).
- Dynamic, i.e. time dependent, imaging of the complete imaged volume with a time resolution down to a few seconds in favorable cases.
- Truly quantitative measurement of tracer accumulation in terms of regional concentration with good spatial resolution.
- Ability to quantify the observed phenomena (e.g. blood flow, metabolic turnover) in absolute terms.

Clinical Applications

Today PET is firmly established as a valuable diagnostic tool in oncology, neurology, and cardiology (2, 3, 4). The impact on other disciplines is less pronounced. PET investigations yield important information complementary to the more anatomically oriented tomographic techniques of X-ray computed tomography (CT) and magnetic resonance imaging (MRI).

In terms of application frequency, ^{18}F -FDG is today by far the most important PET tracer in clinical applications.

Oncology

The major clinical impact of PET in the field of oncology is due to the highly successful utilization of ^{18}F -FDG for assessment of tumor viability. The basis of the success of this approach is the fact that the majority of tumor entities exhibit a massively elevated energy metabolism accompanied by a corresponding increase in glucose consumption. FDG-PET directly assesses this parameter.

Successful applications can be noted especially in lung cancer, colorectal carcinoma, lymphoma, melanoma, head and neck cancer and certain brain tumors.

The near future will probably see further increased contributions of PET to problems of tumor therapy, e.g. biologically targeted radiation therapy for individually optimized treatment plans.

Neurology

Historically, neurological (and cardiological) applications of the PET method were the first that became relevant for clinical applications.

In neurology, the major clinical impact of PET is in dementia diagnosis (especially Alzheimer's disease), the search for epileptic foci, brain tumors (see above) and Parkinson's disease.

Cardiology

Here, the relevant clinical applications are quantitative assessment of myocardial viability and perfusion prior to therapeutic decisions.

Therapeutic Consequences

The utilization of PET has proven (or highly probable) benefits for a wide variety of indications (2, 3, 4). The nature and extent of these benefits are dependent on the stage of the disease already reached when the PET investigation is performed. In short the possible benefits might be summarized as follows:

- avoidance of unnecessary therapies. Examples are assessment of myocardial vitality with PET, which can help to decide the question whether to perform revascularisation, and avoidance of surgery for primary bronchial carcinoma in the presence of distant metastases detected with PET.
- early assessment of chemotherapy effectiveness.
- early assessment of surgery and radiation therapy effectiveness in tumor diseases. PET provides a means to decide whether a transition to systemic therapy (e.g. chemotherapy) is necessary.
- cancer of unknown primary. PET is frequently able to detect hitherto unknown primary tumors thus opening the way to local therapy approaches.

Post-Translational Modification

Definition

Post-translational modification is the chemical modification of a protein into the biologically active form following release from the ribosome. This includes removal and/or derivatization of specific amino acid residues, proteolytic cleavage, loss of signal sequences, and formation of disulfide cross-links. Other common post-translational modifications are phosphorylation, glycosylation, acetylation, hydroxylation, myristoylation, isoprenylation, and many other reactions, such as spontaneous oxidation or deamidation. All amino acid side chains, except those of alanine, glycine, isoleucine, leucine, and valine, can be modified. Posttranslational modifications may be causative for differences in the contents of a protein crystal or crystallization drop as compared to the original protein, especially over time.

PP2A

►Protein Phosphatase-2A

PPAR

►Peroxisome Proliferator-Activated Receptor

PPAR

Definition

PPAR protein is a member of the ►nuclear hormone receptor family. PPARs are ligand-activated transcription factors that increase transcription of target genes, by binding to a specific nucleotide sequence in the gene's promoter. Three different PPAR isotypes can be distinguished in vertebrates: PPAR α (NR1C1), PPAR β/δ , (NR1C2) and PPAR γ (NR1C3). Each of them is encoded in a separate gene and binds fatty acids and eicosanoids. It has been established that PPAR nuclear factors are key regulators of metabolism and energy homeostasis. They also play an important role in various signaling pathways (immunity, inflammation, apoptosis and cell differentiation). Evidence indicates that PPARs can also affect the pathogenesis and development of tumors.

PPAR α γ -Consensus Elements

Definition

PPAR α γ -consensus elements are transcription factor binding elements for the peroxisome proliferator-activated receptors (►PPAR) α and γ , respectively.

►Tangier Disease

PR

►Progesterone Receptor

PR (Protease)

Definition

PR (protease) refers to the retrovirus enzyme (product of the *pro* gene) that is responsible for cleaving the Gag, Pro, and Pol precursors to their final form, and altering the virion from an immature to a mature, infectious, state.

Prader-Willi and Angelman Syndromes

BERNHARD HORSTHEMKE

Institute for Human Genetics, University Clinic Essen, Essen, Germany

b.horsthemke@uni-essen.de

Definition

The Prader-Willi syndrome (PWS) and the Angelman syndrome (AS) are two distinct neurogenetic disorders that are caused by the loss of function of genes located within the chromosomal region 15q11-q13 (1). The two syndromes serve as a paradigm for diseases involving imprinted genes. ►Imprinting refers to an ►epigenetic process in which the male and the female germlines confer a specific mark onto certain chromosomal regions so that only the paternal or the maternal copy of a gene is active in somatic cells (2). The nature of the parental marks is unknown, but methylation of cytosine residues within the promoter region of genes as well as ►histone modifications play a major role in this process. Whereas PWS is caused by the loss of function of one or more paternally expressed genes, AS is caused by the loss of function of a maternally expressed gene.

Characteristics

PWS is characterized by neonatal ►muscular hypotonia, ►hypogonadism, ►hyperphagia and ►obesity, short stature, small hands and feet, ►sleep apnea, behavioural problems and mild to moderate mental retardation. As shown in Table 1, it is caused by the loss of genetic material from the paternal chromosome 15 [deletion, del(15)(q11q13)pat], the maternal origin of both chromosomes 15 [maternal ►uniparental disomy, upd(15)mat] or the presence of a maternal imprint on both chromosomes [imprinting defect]. All three

lesions lead to the lack of expression of imprinted genes that are active on the paternal chromosome only. At present, several such genes are known: *MKRN3*, *MAGEL2*, *NDN*, *SNURF-SNRPN* and more than seventy C/D box snoRNA genes (Fig. 1). The latter genes are located within introns of the *SNURF-SNRPN* transcription unit and encode small nucleolar RNAs (3). Unlike other snoRNAs, these snoRNAs lack any telltale complementarity to ribosomal RNA and may be involved in the modification of mRNAs. There is tentative evidence that the snoRNA genes and *NDN* play a role in PWS (see below).

AS is characterized by ►microcephalus, ►ataxia, absence of speech, abnormal ►EEG pattern, severe mental retardation and frequent laughing. Similar to PWS, the major lesions in AS are a deletion, uniparental disomy and an imprinting defect, but these lesions affect the maternal chromosome. Therefore it was concluded that AS involves a maternally expressed gene. Based on the finding of point mutations in patients with AS who do not have one of the above-mentioned lesions, *UBE3A* has been identified as the gene affected in AS (4, 5). Interestingly, *UBE3A* is imprinted only in the brain.

Cellular and Molecular Regulation
Chromosomal Mechanisms Leading to PWS and AS

Deletions in PWS and AS comprise approximately 4 million base pairs and include most of the imprinted

domain plus several non-imprinted genes (Fig. 1). They do not differ in size between PWS and AS, but only in the parental origin. Most often, the deletions arise as a consequence of non-homologous crossovers between duplicated DNA sequences that flank this region. In a few patients, the deletion is the result of an unbalanced translocation. Because the PWS genes are silent on the maternal chromosome, a paternally derived deletion leads to a complete loss of function of these genes. Likewise, a maternally derived deletion leads to a complete loss of function of *UBE3A* in brain cells, because in this tissue *UBE3A* is silent on the paternal chromosome

Uniparental disomy arises in most cases from the mitotic correction of a meiotic error (6). During ►meiosis, the diploid set of chromosomes ($n = 46$) is reduced to a haploid set ($n = 23$). ►Non-disjunction of the homologous chromosomes 15 or the two sister chromatids during female meiosis results in an oocyte with two chromosomes 15 or no chromosome 15. In these cases, fertilization by a sperm with one chromosome 15 will lead to a zygote that is trisomic or monosomic for chromosome 15. These conditions are not compatible with normal development, but can be “rescued” by loss of one chromosome 15 from a trisomic cell or duplication of the paternal chromosome 15 in a monosomic cell. In two thirds of cases, one of the two maternal chromosomes will be lost from the trisomic cell. This will result in a normal set of

Prader-Willi and Angelman Syndromes. Table 1 Estimated frequency of genetic lesions and recurrence risk in PWS and AS

	del(15)(q11q13)	upd(15)	imprinting defect	gene mutation	other lesions
PWS	70% (pat)	28% (mat)	1%	unknown	0.1%
AS	70% (mat)	1% (pat)	4%	5%	20%
recurrence risk	<1%	<1%	0–50%	0–50%	unknown

The *SNURF-SNRPN* transcript is indicated by a blue line and serves as a host for the snoRNAs. For clarity, not all snoRNA genes are shown. (not drawn to scale).

chromosomes. If, however, the paternal chromosome is lost, the cell is left with two maternal chromosomes 15 [upd(15)mat]. Duplication of the paternal chromosome 15 in a monosomic cell will lead to upd(15)pat. Most often, a trisomic cell line is found only in the placenta (confined placental **▶mosaicism**), because only very few **▶blastomeres** contribute to the embryo. As the genes involved in PWS are silent on the maternal chromosome, upd(15)mat is associated with a complete loss of function of these genes. Likewise, upd(15)pat is associated with a complete loss of function of the *UBE3A* gene in brain.

Imprinting Control and Imprinting Defects in 15q11-q13

Imprinting in 15q11-13 is controlled by an imprinting centre (IC), which is located in the middle of the imprinted gene cluster and overlaps the *SNRPN* gene (7). It appears to consist of two elements. One IC element is required for the maintenance of the paternal imprint during early embryogenesis. A deletion of this element can be transmitted silently through the female germline, but leads to an incorrect, maternal imprint on the paternal chromosome when inherited from a male. A child with this chromosome will develop PWS, because the maternal imprint silences the PWS genes. The second element is required for maternal imprinting in the female germline. A deletion of this element can be transmitted silently through the male germline, but leads to an incorrect, paternal imprint on the maternal chromosome after transmission through the female germline. A child inheriting this chromosome will develop AS, because the paternal imprint silences the *UBE3A* gene. Imprinting defects can also occur without any DNA mutation. In fact, such epimutations are much more frequent than IC deletions. There is tentative evidence suggesting that assisted reproduction may increase the risk of imprinting defects.

Genes and Pathways Affected in PWS and AS

UBE3A encodes a ubiquitin-protein ligase that transfers ubiquitin to substrate proteins. Ubiquitin is a highly conserved 76 amino acid peptide that targets proteins for degradation. Although there is some evidence of a role for ubiquitin-mediated proteolysis during central nervous development, the pathogenesis of AS remains unclear.

In contrast to AS, the gene defect underlying PWS is less clear. As there is no patient with a point mutation in one of the paternally expressed genes, it is generally assumed that PWS results from the loss of function of two or more of these genes. Knock-out experiments in the mouse suggest that a deficiency for *NDN*, which is thought to play a role in cell cycle arrest in terminally differentiated neurons, may contribute to the respiratory abnormalities in individuals with Prader-Willi

syndrome through a suppression of the central respiratory drive (8).

In addition to *NDN*, one or more snoRNA genes may play a role in the pathogenesis in PWS. This hypothesis is based on the analysis of rare patients with a balanced translocation as well as the study of mouse models. Although the HBII-52 snoRNAs have an 18-nt phylogenetically conserved complementarity to a critical segment of serotonin 2C receptor mRNA and this receptor is known to play a role in the regulation of food intake, it is unclear whether this mRNA is the snoRNA target.

Clinical Relevance

The clinical diagnosis can easily be checked by probing differentially methylated sites for the presence of a methylated and an unmethylated allele, but further molecular studies are required to distinguish between the different lesions, or to search for *UBE3A* mutations in AS. In particular, the methylation test is an important diagnostic tool to identify patients with PWS among newborns with severe muscular hypotonia and among children with obesity and mental retardation.

PWS and AS are a paradigm for diseases involving imprinted genes. Other diseases in this category are the **▶Beckwith-Wiedemann syndrome**, **▶Silver-Russell syndrome** and transient diabetes mellitus. Each of these diseases is rare, but it is being suspected that epigenetic defects may also contribute to more frequent genetic disorders including complex diseases.

Prader-Willi Syndrome

Definition

PWS is a congenital disorder (1:15000 newborns) that is caused by functional loss of imprinted genes on the maternal chromosome 15q11-q13 by different mechanisms (70% deletion of paternal 15q11-q13, 28% maternal uniparental disomy, and <2% imprinting center mutation on paternal allele). Signs include extreme hypotonia of the newborn, hypothalamic dysfunction, excessive eating from around age two years, uncontrolled weight gain and extreme obesity, hypogenitalism, cardiomyopathy and often death at 30–40 years. Mental retardation is variable and mild. The outcome can be improved by strict diet and growth hormone therapy.

Predictive Testing and Genetic Counseling

ANNEMARIE SCHWAN, JÖRG T. EPPLEN

Human Genetics, Ruhr-University Bochum, Bochum, Germany

joerg.t.epplen@rub.de

Synonyms

Presymptomatic testing

Definition

Predictive diagnostics concerns the investigation of healthy persons for genetic changes that predispose to diseases later in life. There are different forms of predictive testing. Testing is used in

1. screening of newborns,
2. PND / PGD (► [prenatal diagnostics](#)/► [preimplantation genetic diagnostics](#)),
3. ► [multifactorial diseases](#),
4. hereditary cancer and
5. late-onset monogenic disorders.

Thus, diagnostics of hereditary diseases is not limited to genetic investigations *sensu stricto*, but sometimes it is also based on the results of different clinical examinations [e.g. diagnosis of ► [familial adenomatous polyposis](#) (FAP) after colonoscopy]. Nevertheless, genetic diagnostics is more comprehensive, allows virtually certain diagnostic statements for monogenic disorders and in addition differential diagnoses and subclassification of some disease entities.

Growing knowledge with respect to the pathophysiology and genetics of different disorders has led to new investigative possibilities, i.e. comparatively simple DNA tests. Besides diagnostics by applying genetic

Prechondrogenic

Definition

Prechondrogenic is a generic term describing the precursor status of a cell, which has the potential to become a chondroblast/chondrocyte.

► [Bone and Cartilage](#)

Precipitant

Definition

Different methods can be used to lower protein solubility and reach a supersaturated state. Most commonly, salts and solvents and polymers that compete with protein for water are used as precipitants.

Precursor Cell

Definition

Precursor cell is an umbrella term encompassing both ► [stem cells](#) and progenitor cells. It is normally used

tests for the diseased, the possibility has arisen of testing healthy persons for their risk of developing symptoms in later life. Genetic tests are offered to persons at risk for a genetic disease, who wish to determine whether or not they have inherited a mutated gene. Predictive genetic tests and the information about the respective results are invariably linked to (preceding) genetic counseling in an appropriate setting performed by specially educated experts.

From the perspective of the client, a principal differentiation can be made according to the following aspects in the field of predictive testing:

1. Are there therapeutic options or even effective treatment available after demonstration of a mutation in the genetic test? Do preventive therapeutic options (e.g. operations, nutritional changes) arise on account of a mutation in the predictive test?
2. Are any predictions possible concerning the clinical consequences?

Characteristics

Predictive diagnostics relate to the possibility of recognizing the predisposition to a disease before any clinical symptoms have occurred. In addition, the likelihood of the appearance of the disease can potentially be specified (with statistical precision). These diagnostics can potentially be performed even prenatally—and then have special difficulties, which must be considered and responded to during counseling. As indicated above, predictive diagnostics should take place exclusively after genetic counseling, except for the special cases of newborn screening.

After personal contact has been made initially and all general aspects are clarified, the patient should be informed about results of tests in a later session of counseling. The first counseling session preceding the initiation of predictive testing aims to discuss the counselee's self-determination and, therefore, it may influence and/or strengthen the autonomous decision for or against a genetic test. In order to allow completely self-determined action by the client, it is necessary to be able to judge the outcome of a gene test as well as the possibilities and risks and especially the individual consequences. Genetic counseling provides the basis for autonomous decisions by supplying pertinent information in an understandable form to the counselee (and his family). Thus, human genetic counseling comprises initially the pathophysiological basics of the disease and the individual genetic risk of the person. Furthermore, the diagnostic possibilities are explained and the importance of the test result is weighed. All in all, emphasis is put on the individual life situation and help is offered for consequent action (1). There are different forms of predictive testing that

should encompass different leads or strategies of counseling.

Clinical Relevance Newborn Screening

Newborn screening for inherited metabolic diseases is in a wider sense also predictive testing of persons within the scope of screening an entire population. Newborn screening aims at the earliest possible recognition of disorders so that intervention with effective treatment can prevent the most serious consequences of the disorder. The investigation is not primarily of a molecular genetic nature. Nevertheless, a pathological result leads to the diagnosis of a (clinically yet unapparent) genetic disease. Evidently, the consent to the investigation cannot be given by the person to be examined, but by his or her parents. There is a generally approved consensus that these investigations are only carried out if the disease in question—whenever untreated—causes severe health defects. At the same time the disease must be recognizable *via* a biochemical test before its outbreak and should be preventable by therapeutic measures. A pertinent example is ►**phenylketonuria**. A test result demonstrating the metabolic defect has effects on the parents and/or additional members of the family and their subsequent child planning. Therefore, additional counseling is needed concerning the specifics of the disease as well as further implications. At present, newborn screening programs have been implemented in nearly 30 countries for different diseases.

Prenatal Diagnostics (PND) and Preimplantation Genetic Diagnostics (PGD)

Obviously, predictive genetic diagnostics can already be carried out 'for the unborn child'. The intensity of genetic counseling before PND is dependent among other things on the progress of the pregnancy, the disease in question, the kind of investigation and/or the results to be expected or possible and finally the specific problems of the counselees and prospective parents. The contents and the progress of the counseling concerning a monogenic disease of a fetus with a high recurrence risk differs from chromosome diagnostics on account of the advanced age of the mother. These differences arise due to the variable impact of the results, the likelihood for a positive result and the preexisting general experience with the disease. Besides invasive PND, PGD is available in certain countries for a limited spectrum of genetic disorders. For all these predictive tests the approval is not given by the person to be examined herself or himself (embryo, fetus), but essentially by the mother or the parents instead. In contrast to newborn screening, no cures are at hand for the diseases in question, at least in the foreseeable future.

Predictive Diagnostics with Regard to Multifactorial Diseases

Multifactorial diseases are considered to be due to complex pathogeneses influenced by several to many genes and additionally by unknown environmental factors. Predisposing factors are known for several ►common diseases (either disease-favoring or protecting genetic variations). Therefore, nowadays the investigation of predisposing alleles within the scope of multifactorial diseases could already be offered for several diseases (e.g. morbus Crohn etc.). The magnitude of the relevance and the difficult interpretation of predisposing alleles in the context of further factors requires definitive statements about the limitations and most often rather 'soft' statements of predictive testing in cases of a multifactorial disease. These relations are generally quite complicated and need suitable mediation and interpretation of the results. In the future more knowledge about the predisposing factors will become available, particularly concerning diseases with a high frequency in the population (e.g. hypercholesterinemia, high blood pressure, coronary heart disease, but also morbus Alzheimer and parkinsonism). General doubts have been raised as to what extent this knowledge is helpful for an individual. Given basic scientific advances and the development of the population structure especially in western countries in the near future, the demand for such diagnostics may increase substantially.

Predictive Diagnostics for Cancer

A Mendelian disposition is presumed for ~5–15% of all human cancer diseases. Some of the responsible genes are already defined (e.g. *BRCAI*, *-II* for breast cancer; *MLH1*, *MSH2*, *-6* for colon cancer). During counseling it is initially clarified whether pedigree information and clinical findings are compatible with hereditary cancer in the family or if sporadic disease or a multifactorial disposition to cancer is more likely to be present in this family. Two specific features are notable during genetic counseling of persons at risk for cancer, which are involved in the test and the consequences. Relatives of cancer patients can be counseled while diseased relatives (index patients) must be involved obligatorily in testing. The necessity of the genetic investigation of sick relatives, so that for persons at risk a genetic testing can be offered, implies further family conflicts. On the other hand preventive examinations are possible against specific types of malignancies. Frequent and intensified clinical screening procedures (mammography, colonoscopy etc.) are recommended for persons with high risk. If a genetic change is known as the cause of the familial cancer disease, after predictive testing, classification into non-risk and (depending on the type of cancer) high-risk persons is possible and usually certain. High-risk

patients should undergo intensified cancer screening; non-risk patients only need the usual precautionary investigations. Carriers of predisposing mutations to cancer have, depending on the cancer type, different risks for disease manifestation. The cancer risk is dependent on the type of malignancy and the specific mutation. Female carriers of a *BRCA II* mutation have for example a cumulative risk of ovarian cancer of 27% by the age of 70 years. The cumulative risk for FAP is estimated to be around 93% before the age of 50 years. Definitive knowledge about patients bearing a hereditary risk factor or not conveys many potential problems for the tested person and also for the members of the family (2). Because of these aspects, several family members may need detailed counseling during which the medical facts and the specific psychic load factors are identified, discussed and taken care of appropriately.

Predictive Diagnostics of Late Onset Diseases

Predictive genetic diagnostics of hereditary late onset diseases, as for example ►chorea Huntington (HD), Huntington disease, lead to special problems (3). Today's knowledge about the cause of this genetic disease exceeds the present-day potential for therapy by far. In this and related fields, the gap in knowledge will certainly enlarge during the next few years. This discrepancy is an important factor that must be considered in predictive tests. Nevertheless, human genetic investigations also increase knowledge of the genetic background and they are essential for future causal therapy. The expertise from the genetic counseling of persons at risk for HD can be transferred to other late onset diseases.

Until 1993, 10 years after the genomic region bearing the HD mutation had been described, only indirect diagnostics were feasible. At least one affected family member was required, as well as as many as possible other direct relatives. Hence the phase of the transmission could be followed for the portion of chromosome 4 supposedly carrying the then unknown mutation. Since then direct tests can be performed with a reliability of >99% for the individual without the cooperation of any other family member. Nevertheless, knowledge about genetic testing of a person at risk is still at times not pertinent exclusively to the single person, but it permits (risk or carrier) statements about other members of the family. Before predictive diagnostics are performed, intense genetic counseling is mandatory, including different aspects. The complexity of the subject and the psychic load of the persons at risk usually require several counseling appointments. Together with the patient, the available theoretical knowledge is summed up for this devastating disease. The individually preexisting knowledge is based on the contact with the family member in question (*cave* e.g. genetic

heterogeneity etc.). During counseling, knowledge already available in the family is deepened and complemented by the counselor. In addition, the counselor refers to the disease symptoms, onset and course, possible treatments, the biological bases, inheritance and individual disease risk. Furthermore, genetic testing will be explained in detail with respect to the meaning of the results, i.e. their potential impact for the counselee and the family. The interpretation of negative and positive results has to be discussed beforehand. It must be differentiated clearly, whether a normal test result means a safe exclusion of later disease or not. The importance of genetic testing within the scope of personal and professional development and also in the family context is discussed in detail with the patient. The counseling should also be expanded to topics aside from the medical and psychological, such as social security and professional consequences.

A main focus of the counseling is the discussion of the psychic load that arises from definitive knowledge about the personal risk. Persons with high risk who are informed recently about their own disease risk often express the wish to receive a definitive result immediately. Many persons tend to ignore and/or deny the potentially arising load. Counseling serves, therefore, also for internalizing the conflict potentials that can arise from genetic testing. The conflicts can be of a personal, individual kind or they can encompass lifelong companions, siblings, children and parents. The result of a genetic test can also lead to social conflicts. The argument usually mentioned against a test is the concern about receiving a test result with demonstration of a mutation in the absence of therapy reversing or influencing progression of the disease. The most widespread argument for a test is the removal of unspecified uncertainty and help with decisions in respect to family planning.

After an initial counseling session or—whenever necessary several additional meetings—ample time to reflect and for conversations with members of the family is necessary for the persons at risk. The minimum time to reflect is normally one month. Expert psychological care is provided, too. After this time to reflect, the patient can get in touch with the counselor on his own initiative in order to furnish a blood sample. After at least another month, the test results may be disclosed to the clients, and they are supported thereafter. Either additional counseling sessions or at least telephone contact will be maintained for as long as required by the counselee.

Support measures after disclosure of the test results differ markedly, depending upon the needs of the individual counseled person. The psychological processes of coping with the DNA test result takes at least several (weeks to) months according to the experience of the many counselees who have passed through the

entire protocol. Exclusion of carrier-status does not always lead to immediate relief from suffering. Some non-carriers do not experience the expected relief about their test results at all. They may suffer from feelings like ‘survivor’s guilt’ and find it difficult to cope with the effects of the test results on the family system. Irrational debt feelings, e.g. regarding siblings carrying the disease-gene, are sometimes not simply dealt with by non-carriers. Another problem can develop if a person at risk was sure of being a carrier and had arranged their past life on this basis. Then the exclusion of a carrier-status can take their entire life planning into question and lead to temporary disorientation, before the new situation can be accepted and lived through in a fulfilled manner. With proof of a carrier status, partly displaced or shifted fears become an indelible certainty. These possible difficulties should be discussed with the persons at risk. Ideally genetic counseling should contribute to the fact that the tested person does not repent of having had the test—independently of the outcome of the test.

Preimplantation Genetic Diagnosis

Definition

Preimplantation genetic diagnosis describes the procedure following *in vitro* fertilization. One or two cells are removed from the developing embryo at 8 cell stage after fertilization and tested for the presence of a known mutation (single cell diagnostic). Embryos without the mutation are implanted into the uterine cavity to initiate a normal pregnancy. However, the molecular heterogeneity of many monogenic diseases requires a diagnostic strategy capable of detecting a range of mutations and compound genotypes. At present the procedure is not legal in all countries.

Preinitiation Complex

Definition

Preinitiation complex is the complex of transcription factors and RNA polymerase that forms at a gene promoter DNA prior to the initiation of transcription.

- ▶ RNA Polymerase I
- ▶ Transcription Factors and Regulation of Gene Expression

Preintegration Complex

Definition

Preintegration complex (PIC) refers to a poorly understood structure, derived from the viral capsid that contains the viral DNA, integrase and probably other proteins. It is defined by its ability to directly correct integration of the viral DNA into added target DNA.

- ▶ Retroviruses

Premature Termination Codon

Definition

Premature termination codon (PTC) designates a termination (stop) codon that is located upstream of the normal termination codon.

- ▶ Repetitive DNA
- ▶ RNA Stability

Premenstrual Manifestation

Definition

Premenstrual manifestation is a special type of manifestation of acute intermittent porphyria in women with cyclic attacks (of abdominal and nerve pain) prior to their menses.

- ▶ Acute Intermittent Porphyria

pre-miRNA

Definition

Pre-miRNA is an intermediate precursor of microRNA, typically 60~70 nt in length, which is generated during animal miRNA biogenesis.

- ▶ MicroRNA

pre-mRNA

Definition

Pre-mRNA is the primary RNA transcript from genomic DNA before it is processed and altered into mature forms of mRNA by pre-mRNA splicing.

- ▶ Alternative Splicing
- ▶ Morpholino Oligonucleotides, Functional Genomics by Gene 'Knock-down'

Premutation

Definition

Premutation refers to the fragile-X mental retardation 1 (FMR1) gene of fragile X mental retardation syndrome. Carriers of premutation alleles (who have a trinucleotide repeat blood containing between 59 and 200 CCGs) of the FMR1 gene are often regarded as being clinically uninvolved, and do not typically have symptoms.

- ▶ Fragile X Syndrome

Prenatal Diagnostics

Definition

Prenatal diagnostics comprise all diagnostic procedures that are undertaken during pregnancy in order to investigate the health (and disease) of the growing fetus. Either non-invasive (ultrasound) or invasive strategies (e.g. chorionic villous biopsy or amniocentesis) may be pursued, depending on the needs of the pregnant woman.

Synonyms

Transmissible spongiform encephalopathies (► [TSE](#))

Definition

► [Prion](#) diseases are rapidly progressing, invariably fatal, neurodegenerative diseases associated with dementia and neurological deficits such as ataxia, visual disturbances and myoclonus. Histologically, nerve cell loss, spongiform change and various forms of prion protein deposits are found in the brain. They are a heterogeneous group of diseases that can be acquired, hereditary or idiopathic (sporadic). All prion diseases are experimentally transmissible with a relatively long incubation time and a comparatively short clinical duration. Prion diseases in humans include Creutzfeldt-Jakob disease, kuru and familial prion diseases (Table 1); prion diseases in animals are ► [scrapie](#) in sheep, ► [BSE](#) in cattle, chronic wasting disease in deer and others (Table 2).

Characteristics

Human prion diseases were shown to be transmissible after intracerebral inoculation of brain tissue from kuru and ► [CJD](#) patients into chimpanzees in the 1960s. The nature of the infectious agent of prion diseases has been the subject of numerous studies for many years. The assumption, which seemed natural in the early 1970s, that the agent must be a slow virus or a virino was challenged by the failure to detect viral nucleic acids and by the resistance of the agent to radiation, nucleases and other reagents that damage nucleic acids. In contrast, infectivity was closely associated with a protein, ► [PrP^{Sc}](#), and if any nucleic acid is to be associated with the infectious agent it cannot contain more than 50 nucleotides. The term “prion” was

proposed by Stanley Prusiner to distinguish the infectious pathogen from viruses and viroids. Albeit not formally proven, the prion hypothesis is supported by many lines of evidence.

Prions were originally defined as small, proteinaceous infectious particles that resist inactivation by procedures that modify nucleic acids, and they have been redefined as a proteinaceous particle that lacks nucleic acid (2). The change in conformation of a normal protein encoded by the host genome, the cellular isoform of the prion protein (PrP^{C}), into an altered isoform, the scrapie isoform of the prion protein (PrP^{Sc}), is the core of this hypothesis. The term PrP^{Sc} is used for the isoform of the prion protein that is closely associated with infectivity and that is part and parcel of the prion. Whether PrP^{Sc} is the only necessary constituent of prions is at present unknown. According to the prion hypothesis, the infectious agent, the prion, would require PrP^{C} molecules for its propagation, and organisms devoid of PrP^{C} should not be susceptible to

prion diseases. Indeed, this has been shown experimentally by the resistance of PrP gene knockout mice ($\text{Prnp}^{-/-}$ mice) to scrapie.

Cellular and Molecular Regulation

Human PrP^{C} is a glycoprotein of 253 amino acids before cellular processing. There is an 85–90% homology to prion proteins of other mammalian species. PrP^{Sc} is a membrane protein expressed mainly in neurons, but also in astrocytes and a number of other cells. It has an N-terminal signal sequence of 22 amino acids, which is cleaved off the translation product. Twenty-three terminal amino acids are removed when glycosylphosphatidylinositol (GPI) is attached to serine residue 230. Mature PrP^{C} is attached to the cell surface by this GPI anchor and undergoes endocytosis and recycling. It seems, however, that PrP may exist in alternative membrane topologies (ctmPrP and ntmPrP), whose implications for the function of PrP^{C} and its role in pathogenesis are just beginning to be elucidated. There are two N-glycosylation sites that are glycosylated differently in different human CJD variants. The N-terminal moiety of the protein contains an octapeptide repeat, (PHGGGWGQ) $\times 4$, which has been suggested to function in copper binding.

Whereas PrP^{C} is found on the surface of many cell types in all mammals and birds studied so far, PrP^{Sc} is generated from PrP^{C} in a posttranslational process and is closely associated with infectivity. In terms of the prion hypothesis, it is part and parcel of the infectious agent, the prion. NMR structural studies have shown that the C-terminal half of PrP^{C} contains a two-stranded antiparallel β -sheet (S1 and S2) and three α -helices, whereas the N-terminal moiety is thought to have no definite structure in aqueous solution. PrP^{C} and PrP^{Sc} seem to differ mainly in their folded structures. PrP^{Sc} purified from hamster brain consisted of 42% α -helical and only 3% β -sheet structure, whereas PrP^{Sc} purified from scrapie-infected hamster brain is composed of 30% α -helix and 43% β -sheet. PrP^{Sc} shows increased protease resistance, is insoluble in aqueous solution and tends to form fibrils that show birefringence after binding of Congo red.

The human PrP gene (*PRNP*) has a simple genomic structure and consists of two exons and a single intron 13 kb in length. The entire protein-coding region is located in exon 2. In families with inherited prion diseases, a large number of different point mutations and insertion mutations have been described in the open reading frame of *PRNP*. The insertional mutations are situated in the N-terminal half of the protein in an octapeptide repeat region, whereas the point mutations cluster in the central and C-terminal regions of the protein.

The common polymorphism at amino acid position 129 of the prion protein, where humans carry a methionine

(M) or valine (V), clearly influences susceptibility to the sporadic and iatrogenic types of prion diseases (Fig. 1) and, furthermore, determines in part the phenotype of the sporadic as well as of some inherited prion diseases. Studies have revealed a marked overrepresentation of homozygotes (mainly for methionine) at this position in cases of sporadic CJD compared to the normal population. CJD homozygotes at codon 129 also show a higher susceptibility to iatrogenic CJD and a shorter incubation time as well. There is also a strong correlation of codon 129 genotype and clinicopathological phenotype.

The Conversion Process of PrP^C to PrP^{Sc}

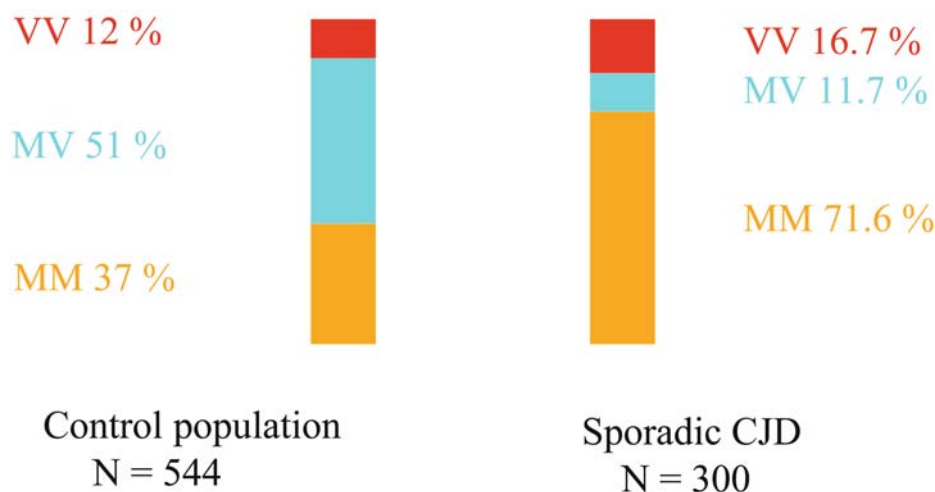

Conversion of PrP^C to PrP^{Sc} seems to be a late posttranslational process, which in scrapie-infected cells occurs after PrP^C has reached its normal location on the cell surface or even later during ►endocytosis. Why this is such a rare event and how PrP^{Sc} triggers the conversion of PrP^C are not understood. In the nucleation model, PrP^C and PrP^{Sc} are in equilibrium. PrP^{Sc} is stable only when it adds onto a seed or PrP^{Sc} aggregate, a process that has been compared to crystal formation. The spontaneous formation of an initial PrP^{Sc} aggregate (seed) would be a very rare event. Once the seed has been formed, the ensuing addition of PrP monomers could follow at a fast rate. In contrast, the refolding model holds that PrP^C is unfolded and that the conversion process consists of a refolding of the molecule under the influence of a PrP^{Sc} molecule. In this process, a high activation energy barrier must be overcome and chaperones and an energy source may be required. The two hypotheses, which have also been named the Lansbury and the Prusiner mechanisms, are by no means mutually exclusive.

Clinical Relevance

Prion Diseases in Animals

Scrapie, a disease that naturally occurs in sheep and goats, has been known for more than 200 years and was the first prion disease to be shown to be infectious in 1936 by two French scientists, Cuillé and Chelle. Affected sheep clinically show abnormal behavior, such as excessive scraping as well as trembling and ataxia and other motor disturbances. There are no known hereditary prion diseases in animals; however, allelic variations in the ovine PrP^C sequence exert a strong influence on susceptibility to natural and experimental scrapie. Although the disease has been known for centuries and its infectious nature was recognized more than 60 years ago, the exact mode of natural transmission is not known. Maternal transmission seems to be an established fact, but there are also reports of transmission by keeping sheep on pastures that were previously occupied by scrapie-infected flocks. Scrapie is experimentally transmissible to many mammalian species. Epidemiological studies show that scrapie is not apparently transmissible to humans by the oral route.

BSE is a disease of cattle that was first described in Great Britain in 1986. It is estimated that since then almost 1 million animals have been infected. The mean incubation time is about 5 years; therefore, most animals did not manifest disease because they were slaughtered at age 2 or 3 years. Nonetheless, more than 160,000 affected animals were diagnosed and killed over the years. It is now clear that BSE was spread by feeding cattle with contaminated meat and bone meal (MBM) prepared from the offal of sheep, cattle and pigs. However, the origin of BSE is still obscure. It is now thought that changes in the hydrocarbon extraction

Prion Diseases. Figure 1 Distribution of the genotypes at codon 129 of the human prion protein gene (*PRNP*) in sporadic CJD and the normal population (controls).

method, including temperature changes, that were made in the rendering of offal in the late 1970s allowed the infectious agent to survive the manufacturing process and pass from sheep to cattle. Because by strain typing and PrP^{Sc} banding pattern in Western blots all scrapie strains tested so far are different from BSE, an alternative hypothesis, i.e., transmission of pre-existing natural BSE at low incidence as a consequence of the preceding changes in the rendering process, cannot be dismissed. BSE is experimentally transmissible to many species and seems to have passed the species barrier to humans.

In addition, a number of other prion diseases exist, some of which are of unknown origin such as chronic wasting disease in mule deer and elk, and others are transmitted by contaminated offal from sheep or cattle such as transmissible mink encephalopathy, feline spongiform encephalopathy and exotic ungulate encephalopathy.

Prion Diseases in Humans

CJD and Gerstmann-Straussler-Scheinker syndrome (GSS) were first described as neurodegenerative diseases in the 1920s, whereas kuru was first reported in 1957. The exceptional nature of GSS as a hereditary disease that is experimentally transmissible to laboratory animals was discovered in 1981. In 1989, the first mutation of the prion protein gene was identified in a GSS family. Neuropathology has played a lead role in defining the various entities that are now known as human prion diseases and is still of particular importance in routine diagnosis. The classical neuropathological changes consist of (1) spongiform degeneration (Fig. 2), (2) PrP^{Sc} deposition, (3) neuronal loss, and (4) astrocytic gliosis. PrP^{Sc} deposition is found as diffuse delicate accumulations in the gray matter in areas of high synaptic density and in a distribution similar to that of synaptophysin. This type of PrP^{Sc} deposition has therefore been called synaptic. Other forms are described as pericellular, perivacuolar, in kuru plaques that are visible in routine H&E stains and plaque-like, i.e. in small plaques that are only visible after immunohistochemical staining of PrP^{Sc}.

Kuru

Kuru was first described as a deadly neurodegenerative disease affecting the Fore people in the eastern highland of New Guinea. This disease was mainly characterized by ataxia and predominantly affected women and children. William Headlow, a veterinary pathologist, noted the neuropathological similarities of scrapie and kuru and suggested that infection experiments be performed in apes. Gajdusek and Gibbs were successful in transmitting the disease to chimpanzees in 1966. Later, ritualistic cannibalism of deceased clan members was identified as the mode of transmission in

Prion Diseases. Figure 2 Spongiform change (small vacuoles in the neuropil) in the molecular layer of the cerebellum in a Creutzfeldt-Jakob disease case. H&E stain.

the Fore population. After cannibalistic practices ceased, the disease disappeared. Kuru incubation times of more than three decades were reported.

Sporadic (Idiopathic) Creutzfeldt-Jakob Disease

Sporadic CJD (sCJD) most often affects patients in their 60s. It usually presents with dementia and various neurological signs such as myoclonus, ataxia, pyramidal and extrapyramidal signs, EEG changes (periodic sharp wave complexes) and the 14-3-3 protein in the CSF. It runs a relentless course, leading to death usually within 6 months. A definite diagnosis can only be made by neuropathological or biochemical examination of the brain.

Parchi and co-workers described two different molecular types of PrP^{Sc} associated with distinct clinical and pathological phenotypes in sCJD (1) (Fig. 3). The two types of PrP^{Sc} are distinguished by their different physicochemical properties, particularly their appearance on Western transfers after digestion with proteinase K. The full spectrum of sCJD variants was defined in a large series of 300 CJD patients and was compared with molecular and pathological phenotypes. Six distinct types of sCJD were described by molecular analysis. Almost 90% of sCJD patients were homozygous at codon 129, the vast majority being MM homozygotes, whereas only half of the normal population in Europe and the United States is homozygous. PrP^{Sc} types 1 and 2 were found to be associated with all *PRNP* genotypes. However, there was a strong association between PrP^{Sc} type 1 and MM homozygosity as well as between PrP^{Sc} type 2 and VV or MV patients.

Sporadic CJD is often thought to arise spontaneously. This would be compatible with the encountered worldwide incidence of 1 case per million per year and would be an attractive model in terms of the prion

Prion Diseases. Figure 3 Western blot analysis of human prion proteins. Shown are the primary structure of PrP^C and the protease-resistant core of PrP^{Sc} as well as their appearance on Western blots. The insert on the left side shows an original Western blot with the three PrP^{Sc} bands after pK digestion of two sporadic CJD cases (PrP^{Sc} type 1 with the unglycosylated PrP^{Sc} at 21 kD, PrP^{Sc} type 2 with the unglycosylated PrP^{Sc} at 19 kD) and an vCJD case in which the three PrP bands correspond in size to PrP^{Sc} type 2 but show a different glycosylation pattern.

hypothesis. However, the sporadic origin is by no means proven.

Hereditary Prion Diseases

About 10–15% of all prion disease cases are hereditary. A large number of different point mutations and insertion mutations of the prion protein gene have been identified in familial prion diseases. Insertion mutations represent additional repeats of the N-terminal Cu²⁺-binding octapeptide. Depending on their clinical and neuropathological characteristics, familial prion diseases are designated as familial CJD, Gersmann-Sträussler-Scheinker syndrome (GSS), or fatal familial insomnia (FFI).

Familial CJD often is indistinguishable from sporadic CJD and is most often associated with the E200K mutation and less often with D178N-129V, V180I, R208H, V210I, M232R and insertion mutations. GSS is thought to be distinguishable from CJD by the predominance of ataxia, whereas dementia and myoclonus are more prominent in CJD. Neuropathologically, GSS is quite distinct and is characterized by large, multicentric PrP-containing amyloid plaques; spongiform change is variable. It is found most often in families with the P102L mutation and less often with P105L, A117V, F198S, D202N, Q212P, Q217R and insertion mutations. Fatal familial insomnia (FFI) often presents with insomnia and dysautonomia and later shows signs of ataxia, dysarthria, myoclonus and pyramidal tract dysfunction. Neuropathologically, FFI is characterized by neuronal loss and astrocytic gliosis preferentially affecting the ventral anterior and medial

dorsal nuclei of the thalamus and the inferior olive. FFI is caused by a D178N mutation of *PRNP* associated with a methionine codon at position 129 of the same allele.

Iatrogenic CJD

The first possible person-to-person transmission of CJD was reported in a recipient of a corneal transplant from a donor with CJD in 1974. Other modes of accidental iatrogenic transmission were reported in the following years, including the use contaminated EEG depth electrodes, neurosurgical instruments, cadaveric pituitary-derived gonadotropin and human growth hormone (hGH) and dura mater grafts. Transmission by contaminated hGH has raised major concern because of the large number of possibly affected persons. Worldwide more than 120 hGH-associated cases have been reported to date, whereas 8000 persons received hGH between 1963 and 1985 in the United States alone. The affected patients commonly present with gait abnormalities and ataxia, whereas dementia is a late manifestation and is mild. The incubation time in these cases has been estimated to be 12 years or longer.

New Variant CJD and the Transmission of BSE to Humans

A new variant of CJD was described in 10 patients in the United Kingdom in 1996 (3). These patients had a mean age of 29 years and presented with psychiatric disturbances, whereas signs more typical of CJD developed later in the course of disease. Neuropathology at autopsy was exceptional, showing extensive depositions of PrP^{Sc} in various areas of the brain in a fashion that had only been described in hereditary disease before 1996. In addition, there were florid plaques (Fig. 4) with a central PrP accumulation and

Prion Diseases. Figure 4 A typical florid plaque consisting of delicate strands and surrounded by confluent vacuoles in a case of nvCJD. H&E stain (by courtesy of Dr. James Ironside, Edinburgh, Scotland).

surrounding vacuoles that had not been seen in human prion disease before. From 1996 to date, 137 cases (October 2003) of this variant were identified in the United Kingdom, 6 were found in France and 1 in Italy. Information on the clinical appearance has been compiled, and a definition for suspect ►vCJD cases is now available. All vCJD patients to date have been methionine homozygotes at codon 129 of the prion protein gene; the youngest patient was 15 years old and the oldest was 73 years old at death. It is not possible at present to define the clinical and pathological features to be expected in codon 129 valine homozygotes or in heterozygotes that are likely to be observed in the future. vCJD has shown significantly new features in the pattern of extracerebral deposition of PrP^{Sc} in the tonsils, lymph nodes, spleen and appendix. This has raised concern that blood cells may also harbour the infectious agent and that the disease might be spread by blood transfusions. Although this suspicion is unsubstantiated to date, measures have been taken to prevent the spread by blood transfusion in various countries.

It is hypothesized that vCJD cases have been caused by the consumption of food or other products containing large amounts of the BSE agent (BSE prions). This hypothesis is strengthened by epidemiological and experimental findings. The appearance of vCJD 10 years after BSE in the country with the highest incidence of BSE is highly consistent with this hypothesis. The banding pattern of PrP^{Sc} in vCJD has been shown to be different and resembles the pattern in BSE. Although BSE and vCJD show significant differences pathologically, upon transmission to genetically homogeneous animals (inbred mice) they elicit practically identical patterns, whereas in these strain typing experiments all tested scrapie strains and sporadic CJD cases were different. These findings have been confirmed in transgenic animals expressing bovine PrP.

If we assume that vCJD is caused by transmission of the BSE agent to humans, the available epidemiological data are insufficient to predict the number of cases that must be expected to occur in the future.

Processed Pseudogene

Definition

Processed pseudogene (Retropseudogene) refers to DNA sequences that are very similar to known genes.

Processed pseudogenes lack introns, contain a poly-A tail, and are framed by short direct repeats, suggesting that an mRNA was copied into DNA that was then integrated into the genome. The vast majority of processed pseudogenes are non-functional.

Promoter

Definition

Eukaryotic gene transcription is driven by specific promoter sequences. The promoter is the regulatory site on DNA to which the enzyme RNA polymerase can bind, initiate the transcription of DNA into RNA, and control cell-type specific expression of the gene. A typical eukaryotic promoter contains the site of transcription initiation (Inr), an A+T rich sequence motif ("TATA box") located some 25 bp upstream of Inr, and one or more binding sites for DNA binding transcription factors, located at -50 to -100 bp from the site of initiation. Another type is the G+C-rich so-called CpG island that usually does not contain a TATA box and contains factor binding sites both upstream and downstream of the (multiple, scattered) start sites of transcription.

Promoter Clearance

Definition

Promoter clearance designates a regulatory step, which ensures that the RNA polymerase, along with a complement of general transcription factors, have

traversed 50 to 60 nucleotides after initiation before it is fully engaged in elongation.

- ▶ Core Promoters

Proneural Transcription Factors

Definition

Proneural Transcription Factors refer to genes that specify clusters of potential neuroblasts in the *Drosophila* ectoderm and were originally called "proneural genes". These genes encode transcription factors of the ▶ [basic-helix-loop-helix](#) (bHLH) family. In vertebrates, the term proneural refers to the function of bHLH factors in inducing neurogenesis.

- ▶ Neural Development

Pronuclear (Micro)Injection

Definition

Pronuclear injection is the injection of recombinant DNA (or other substance) into the pronucleus of fertilized zygotes (at embryonic development day 1 in the mouse). It is a standard procedure to generate transgenic mice. Microinjected DNA integrates randomly into the genome of the host animal. Integration sites and numbers of integrated copies of the transgene are normally unpredictable. Thus, every resulting founder animal may have a unique phenotype and needs to be tested separately for transgene expression.

Definition

Proteases, also termed peptidases, are defined as ►enzymes that break down proteins by catalyzing the ►hydrolysis of ►peptide bonds. Peptidases consist of two groups of enzymes: 1) endopeptidases that cleave peptide bonds within the protein and 2) exopeptidases that remove amino acids (►Amino Acids: Physico-chemical Properties) sequentially from either the N or C-terminus. Endopeptidases are also termed proteinases and are divided into five mechanistic classes (1), which are characterized below.

Proteolysis is ubiquitous in all cells and elementary in numerous biological processes such as cell growth and death, blood clotting, matrix remodeling and immune defense. In addition, proteases are involved in the pathogenicity of several diseases including cancer, arthritis, HIV, and Alzheimer's and as such these enzymes are important targets for drug design. Proteolytic activity can be divided into two different categories: 1) limited proteolysis, in which a protease cleaves a limited number of peptide bonds of a target protein usually leading to the activation or maturation of the formerly inactive protein and 2) unlimited proteolysis, in which a protease degrades a protein into its amino acid constituents. Regulation of protease activity is important in maintaining homeostasis and is accomplished by inhibitors, compartmentalization of the enzyme and activation cascades.

Characteristics

Proteases are classified by: 1) their site of action and 2) the nature of their active site residues and reaction mechanisms. A complete list of proteases can be found in the MEROPS database (2) and in a review by Puente and coworkers (3). Here we will focus in general on the five major classes of endopeptidases: serine, cysteine, aspartic, metallo and threonine proteases.

Serine Proteases

Serine proteases are among the earliest studied enzymes and are involved in a number of physiological processes including digestion, blood clotting and proteolytic activation cascades (1). Traditionally, serine proteases have been divided into two distinct families: 1) the chymotrypsin family, which includes mammalian enzymes such as chymotrypsin, trypsin and elastase, and 2) the subtilisin family, which includes the bacterial enzyme subtilisin. Recently three additional families have been identified: 1) the wheat serine carboxypeptidase II family, 2) the human cytomegalovirus serine proteinase family and 3) the proteolytic component of ClpP of the ATP-dependent protease family. Although the general 3D structures of the five families are different, they do contain the same active site geometry, which includes an active serine residue,

and their catalytic process proceeds *via* the same mechanism.

Cysteine Proteases

Cysteine proteases are categorized into two superfamilies: 1) the papain family of cysteine proteases and 2) the family of enzymes related to interleukin 1 β converting enzyme (ICE) (4). Although both the papain and the ICE superfamilies contain a cysteine residue in their active sites, these two superfamilies share no sequence homology. The papain superfamily consists of plant proteases such as papain, which is the archetype and the most studied member of this family, bromelain, mammalian lysosomal cathepsins and the cytosolic calpains. The involvement of cysteine proteases in biological processes is observed in apoptosis by caspases and ICE, in tumorigenesis by cathepsin B and in membrane signaling by calpains.

Aspartic Proteases

There are two families of aspartic proteases: 1) the pepsin family that includes digestive enzymes such as pepsin and chymosin, lysosomal cathepsin D and the processing enzyme renin and 2) viral aspartic proteases including the HIV protease (1). The crystal structure of aspartic proteases shows that these enzymes are bilobed molecules with the active site, which contains two aspartic acid residues, located between two homologous lobes. Aspartic proteases are involved in a number of biological processes. Pepsin hydrolyses acid-denatured proteins in the stomach, renin has a hypertensive action *via* the renin-angiotensin system, HIV protease is essential for viral maturation and cathepsin D is involved in tumorigenesis.

Metalloproteinases

Metalloproteinases are classified into four families: 1) matrix metalloproteinases (MMP) (5); 2) disintegrin and metalloproteinases (ADAM); 3) angiotensin-converting enzymes (ACE) and 4) neprilysins (NEP) (1). Although each family of enzymes differs widely in their sequences and structure most contain a catalytically active zinc atom. In some cases, cobalt or nickel replaces the zinc atom without loss of activity. MMPs are the best-studied metalloproteinases. Most MMPs have a common domain structure that includes pro, metalloprotease and hemopexin-like domains. These enzymes are involved in embryonic development, tissue remodeling, arthritis, cancer and cardiovascular disease. ADAMs contain a common domain structure that includes pro, metalloprotease, disintegrin-like, cysteine-rich, transmembrane and cytoplasmic domains. These enzymes function in fertilization and development, membrane protein shedding and signal transduction. ACEs are cell surface proteins and are

important regulators of blood pressure homeostasis, immunity, reproduction and neuropeptides. NEPs are cell surface enzymes that are involved in degradation of brain enkephalins and amyloid β peptides

Threonine Proteases

The most studied member of the threonine proteases is the 26S proteasome, often termed “the proteasome” (6). The ▶proteasome is a multiprotein complex consisting of a 20S core particle that is associated with one or two 19S regulatory particles. The 20S core particle is composed of four stacked rings: two outer α subunits rings and two inner β subunits rings. The β subunits are responsible for the enzymatic activity that is associated with N-terminal threonine residues. In general, proteins degraded by the proteasome are tagged ATP-dependently by the ubiquitin-conjugation system. Although the proteasome was originally thought to be a recycler of misfolded or damaged proteins, recent evidence indicates that the proteasome is also involved in the cell-cycle, cell survival, signal transduction and antigen processing.

Molecular Interactions

The molecular interaction between a protease and a substrate is described using a well-established nomenclature. The amino acid residues of the polypeptide substrate are considered to bind to the subsites of the enzyme's active site. Hence, the peptide substrate amino acid residues are termed “P” and the protease subsites are termed “S”. The scissile bond in the peptide substrate is the bond that is cleaved by the protease. The amino acid residues of the N-terminal side of the scissile bond are numbered P3, P2, P1 and those residues on the C-terminal side are numbered P1', P2', P3', etc. Thus, the P1 and P1' residues are those adjacent to the scissile bond. The subunits on the protease that interact with the substrate are numbered complementary to the substrate binding residues (i.e. S3, S2, S1, S1', S2', S3'). As mentioned above, the residues in the active site and the catalytic mechanisms differ among the families of proteases.

Serine Proteases

Serine proteases contain the three amino acid residues histidine, aspartic acid and serine in their active sites. These form a catalytic triad and are essential in the catalytic process. ▶Catalysis by serine proteases follows two steps: 1) formation of the acyl enzyme intermediate between the substrate and the essential serine residue of the protease, which results in the cleavage of the scissile bond and 2) ▶deacylation in which the acyl-enzyme intermediate is hydrolyzed by a water molecule to release the peptide. In the first step the ▶hydroxyl group of serine residue is the attacking

▶nucleophile, whereas the water molecule acts as the attacking nucleophile in the second step, and the histidine residue acts as a general base in both steps.

Cysteine Proteases

Cysteine proteases contain essential cysteine and histidine residues in their active sites that play roles similar to serine and histidine, respectively, in serine proteases. Catalysis by cysteine proteases is similar to that of serine proteases following a two-step process: 1) formation of an acyl enzyme intermediate between the substrate and the essential cysteine residue, which results in the cleavage of the scissile bond and 2) deacylation resulting in the release of the peptide. The ▶thiolate ion of the cysteine residue acts as the attacking nucleophile in both steps and is stabilized through the formation of an ion pair with the neighboring ▶imidazolium group of the histidine residue.

Aspartic Proteases

Aspartic proteases are bilobed molecules that contain one aspartic acid residue in each of their lobes. These aspartic residues are in close proximity in the active molecule and contribute to the catalytic diad of the enzyme. Catalysis by aspartic proteases differs from that of serine and cysteine proteases in that activated water molecules in the protease's active site directly attack the substrate's scissile bond. The nucleophilic attack is achieved by two simultaneous proton transfers: 1) from a water molecule to the diad of the carboxyl groups and 2) from the diad to the carbonyl oxygen of the substrate thus resulting in the cleavage of the substrate.

Metalloproteinases

Metalloproteinases contain one zinc atom in their active site that is bound to two histidines and one glutamic acid. Like aspartic proteases, metalloproteinases use an activated water molecule as the attacking nucleophile. The zinc-bound water molecule attacks the carbonyl group of the scissile bond leading to the formation of a non-covalent tetrahedral intermediate. The transfer of the glutamic acid proton to the departing amine group breaks down this intermediate, resulting in the cleavage of the substrate.

Threonine Proteases

The proteasome is the least understood of the proteases with respect to its molecular interactions. It is a threonine protease with three different active sites corresponding to: 1) trypsin-like, 2) chymotrypsin-like and 3) peptidylglutamyl ▶peptide hydrolase or caspase-like activities. These active sites are located on subunits β 1, β 2 and β 5, respectively, of the 20S core

particle. Each subunit contains an N-terminal threonine that functions as the attacking nucleophile. It is speculated that lysine and glutamate/aspartate residues in the active sites may play roles similar to histidine and aspartate in serine proteases. Proteins that are degraded by the proteasome must first be tagged with ubiquitin, which is recognized by the 19S regulatory particles. Multi-ubiquitination of target proteins is carried out by a cascade of enzymes, e.g., E1, E2 and E3.

Regulatory Mechanisms

Proteases are involved in a number of biological processes and as such need to be stringently regulated. Posttranslational mechanisms of protease regulation include compartmentalization, high substrate specificity, activation cascades and inhibitors.

Spatial control and compartmentalization of proteases can limit protease activity to a subcellular localization. For example, cathepsins are predominately restricted to **lysosomes**, which have an acidic environment that is favorable for activity and stability of the enzymes. Similarly, the association of proteases with the plasma membrane as in the case of membrane-type MMPs limits the activity of these proteases to substrates that are in contact with the cell surface. Compartmentalization can also occur within the protease itself. For example, the proteasome is designed as a narrow cylinder with its active sites on the inside of the cylinder, with entrance to the interior monitored by the regulatory particles that cap the ends of the cylinder. Substrate specificity is critical to the functional activity of the enzyme. The residue in the P1 position of the substrate usually determines the binding and cleavage of the substrate to the protease. Residues in P3, P2, P1', P2', etc. sites are also important in influencing substrate binding and protease specificity. For example, chymotrypsin, trypsin and elastase essentially share identical catalytic triads yet their specificity for substrates differs. Specific proteolytic activity is demonstrated by caspases, which are cysteine proteases that cleave substrates at their aspartic acid residues. Another example of specificity is collagenases (MMP-1, MMP-8, MMP-13 and MMP-14), the only MMPs that can efficiently degrade interstitial collagens I, II and III at specific sites in their triple-helical domains.

Activation cascades are important processes that regulate various proteolytic events. Activation may involve the conversion of an inactive proenzyme to its active form by the cleavage of the proregion. This process can be accomplished by autocatalysis or may require the activity of other proteases. For example, procathepsin B can be activated by cathepsin D or can autoactivate itself. Activation cascades involve the activation of one protease leading to the successive activation of other proteases. An example is seen on the surface of cancer cells where active cathepsin B will

convert pro-urokinase plasminogen activator to active urokinase plasminogen activator that in turn converts plasminogen to active plasmin. Plasmin can activate proMMPs to active MMPs, which degrade extracellular matrix proteins during tumor invasion.

Protease inhibitors are probably the most effective regulators of proteolytic enzymes (7). They can bind tightly to proteases and produce inactive complexes. Inhibitors can be found both inside and outside cells and can function both irreversibly and reversibly depending on the specific enzyme-inhibitor complex. The specificity of inhibitors is determined by the catalytic mechanism and the structural conformation in and around the active site of the protease. Commonly, the most effective protease inhibitors are those that mimic specific substrates. Like proteases, endogenous inhibitors are often grouped into families and/or classes. For example, serpins, cystatins and tissue inhibitors of metalloproteinases are common inhibitor families against serine, cysteine and matrix metalloproteases, respectively. The role of protease inhibitors is important since changes in inhibitor concentrations alone can alter proteolytic activity within the cell.

Synthetic inhibitors are usually small peptide molecules that are often used as experimental tools in deciphering the roles of one or more proteases within a system. There are both broad spectrum inhibitors such as E64, which irreversibly inhibits most papain-like cysteine proteases, and selective inhibitors such as CA074, which inhibits cathepsin B. Selection of an inhibitor for a protease is challenging, considering that proteolytic pathways often involve the degradation of common protein substrates. For example, the calpain inhibitor, calpain inhibitor I, can also inhibit proteasomal activity. A listing of endogenous and synthetic protease inhibitors can be found in the MEROPS (2) databases.

In conclusion, it is evident that the role of proteases is integral to the growth and survival of living systems. Aberrant regulation of proteases and their inhibitors has been shown to result in the onset of various diseases and pathological conditions. The development of more selective inhibitors will facilitate our understanding of the biological and/or pathological functions of these proteases.

Proteasome

Definition

The proteasome, also known as prosome or macropain, is a large cytoplasmic protein complex composed of multiple proteins, which are responsible for degrading proteins that have been marked for destruction by ubiquitination or by some other means. The proteasome is characterized by its ability to cleave peptides with arg, phe, tyr, leu and glu adjacent to the leaving group at neutral or slightly basic pH. It has an ATP-dependent proteolytic activity, and may also catalyze basal processing of intracellular antigens. The proteasome is composed of the cylindric 20S core particle (20S proteasome) and a 19S cap particle, which docks onto both ends of the 20S proteasome to yield the 26S proteasome. The 26S proteasome is thought to be the biologically active unit in the cell. Proteasomes are found in the cytoplasm and in the nucleus.

Protein and Membrane Transport in Eukaryotic Cells

MICHAEL KRAUSS, VOLKER HAUCKE

Institute for Chemistry-Biochemistry, Free University, Berlin, Germany

vhaucke@chemie.fu-berlin.de

Definition

Eukaryotic cells contain distinct compartments that are characterized by specific protein and membrane compositions. To establish compartment identity and to allow for communication between the different organelles, transport processes take place that ensure the delivery of proteins to their proper destination. Two principal mechanisms of transport need to be distinguished. The first one is used to translocate nascent polypeptides into or across the membrane of a compartment through a proteinaceous channel. This holds true for proteins initially destined for the ► [endoplasmic reticulum](#) (ER), mitochondria, chloroplasts, ► [peroxisomes](#) or the ► [nucleus](#). In this essay we will focus exclusively on the second type of sorting process, which transports proteins and lipids in vesicles or tubules along the secretory and the endocytic pathways (Fig. 1). The transport along both routes is predominantly mediated by membrane-bounded vesicles or tubules, which bud from donor compartments and subsequently fuse with a specific acceptor compartment. In the secretory pathway, proteins are initially transported from the ER to the *cis*-Golgi. They are passed through the Golgi stacks by cisternal progression until they finally end up in the *trans*-Golgi network (TGN). From the TGN, transport can proceed into two different directions. The first branch leads to the plasma membrane where transport vesicles can fuse by constitutive or regulated exocytosis. The second branch delivers proteins to the late endosomes and lysosomes. The endocytic pathway serves to internalize nutrients, pathogens, growth factors and recycling receptors from the plasma membrane. These cargo

Protein and Membrane Transport in Eukaryotic Cells. Figure 1 Transport routes along the secretory and the endocytic pathway in eukaryotic cells. During the secretory pathway newly synthesized proteins are initially transported from the ER to the *cis*-Golgi. After passage through the Golgi stacks they reach the *trans*-Golgi network, from where they can be delivered to the plasma membrane or the endosomal/lysosomal system. The endocytic pathway serves to internalize cargo proteins from the plasma membrane. These are initially transported to endosomes. From here some are recycled back to the cell surface, whereas others are forwarded to late endosomes and lysosomes for degradation. The best characterized transport vesicles are those that bud with help of COPI, COPII or clathrin coats (taken with kind permission from T. Kirchhausen (2000), *Nat Rev Mol Cell Biol* 1:197–198).

molecules are initially delivered to endosomes; from here some return to the plasma membrane, whereas others are transported to lysosomes for degradation.

Characteristics

To preserve the identity of individual compartments during the dynamic exchange of proteins and lipids, the generation of vesicles at different donor membranes and the fusion of vesicles with the appropriate target membranes must be highly selective. Accordingly, membrane transport within the secretory and endocytic pathways employs specific sets of transport vesicles. Despite the inherent complexity, the majority of transport events make use of similar overall principles. Vesicle formation is generally initiated by the binding of individual coat proteins to the surface of the parent membrane. Coat proteins serve two main functions. First, they recognize **▶sorting signals** within the cytosolic domains of cargo proteins and thereby ensure incorporation of specific cargo proteins into the nascent vesicle. Second, due to their propensity to assemble

into higher ordered multimeric complexes on the donor membrane, coat proteins have the ability to deform the underlying lipid bilayer. Components of the coat may drive membrane curvature until a coated bud is formed which eventually pinches off. After fission the released vesicle is rapidly uncoated and targeted to its appropriate acceptor membrane. Following an initial docking step, vesicle-bound v-**▶SNARE proteins** tie up in a complex with their cognate t-SNARE proteins in the target membrane. Formation of a SNARE complex is essential to bring vesicle and target membranes into close apposition, thus allowing fusion of the two lipid bilayers. Finally, the SNARE complex is disassembled and – together with other components of the transport machinery – recycled back to the initial donor compartment.

Molecular Interactions Vesicle Formation

At least three different types of transport vesicles have been described (1). These can be distinguished on the basis of the different types of coat complexes which assemble onto the respective donor membranes and have been termed COPII, **▶COPI** and **▶clathrin** coats (Fig. 1). Although coat formation appears to follow similar principles, significant mechanistic details between the different types of coats have emerged. COPII-coated vesicles bud from specialized regions of the ER devoid of ribosomes, termed ER exit sites and transfer newly synthesized proteins to the *cis*-Golgi (1, 2). Coat formation at the ER is initiated when a guanine nucleotide exchange factor (GEF), Sec12p, recruits and activates Sar1p, a member of the **▶Ras superfamily of small GTP binding proteins**. Membrane translocation of Sar1p induces recruitment of a complex of Sec23p and Sec24p proteins and stimulates the association of Sec23p with SNARE proteins needed for later fusion events. The ternary complex consisting of Sar1p and Sec23/24 in turn associates with a complex of Sec13p and Sec31p proteins to form the complete COPII coat structure. Indeed, Sar1p, Sec23/24 and Sec13/31 together comprise the minimal machinery necessary for vesicle budding. A large protein bound to the cytosolic side of the ER, Sec16p, interacts with both Sec23/24 and Sec13/31 complexes; it appears to serve as an anchor defining ER exit sites and seems to coordinate coat formation. Membrane proteins containing sorting signals are incorporated into the coat by direct binding to the Sec23/Sec24 complex. These sorting signals are diverse and can contain hydrophobic, di-acidic or di-basic motifs. Soluble cargo proteins may associate with members of the p23/p24 family of transmembrane proteins, which form a complex with Sec23p. After fission of the vesicle the release of all coat constituents is triggered by hydrolysis of GTP bound to Sar1p.

ARF1 (ADP ribosylation factor 1), another small GTPase similar to Sar1p plays a central role in initiating budding processes at Golgi membranes. ARF1 is myristoylated at its amino terminus; specific exchange factors catalyze loading of ARF1 with GTP and thereby induce a conformational change that triggers exposure of the myristoyl anchor and subsequent membrane insertion. Membrane-bound ARF1 recruits distinct coats to different regions of the Golgi. One of them is COPI or coatomer, a complex of seven proteins, that functions in retrograde transport from the *cis*-Golgi to the ER and between Golgi cisternae. COPI recognizes proteins that expose a basic sorting signal (KKXX or KKKXX, where X is any amino acid) in their carboxy terminal domain. COPI coated vesicles also incorporate KDEL receptors which retrieve escaped luminal proteins to the ER. These soluble proteins are tagged with a retrieval signal at their carboxy terminus (KDEL). After fission, hydrolysis of bound GTP triggers release of ARF1 and the residual coat components from the vesicle.

In addition to its role in recruiting COPI to the *cis*-Golgi, ARF1 triggers coating with clathrin at the *trans*-Golgi network (TGN). Membrane binding of clathrin is mediated by AP1 ►adaptor protein complexes and ►GGA proteins (3). AP1 adaptors are heterotetramers formed by two large, one medium and one small subunit that shuttle cargo between the TGN and the endosomal system. A large number of membrane proteins bear sorting signals (tyrosine-based YXX Θ or dileucine motifs, with Θ being an amino acid with a bulky hydrophobic residue) in their cytosolic tails, which are recognized by AP1, including the ►mannose 6-phosphate receptor (MPR), which itself associates with soluble enzymes destined for lysosomes. The large subunits of AP1 adaptor complexes associate with clathrin and accessory proteins. Clathrin triskelia polymerize into polygonal lattices forming a shell around the adaptor-coated bud. GGA proteins seem to have partially overlapping or complementary functions with AP1 as they share common binding partners including clathrin and some accessory proteins. In addition, GGAs have been implicated in the transport of cargo proteins (including the MPR but also other transmembrane proteins) from the TGN to endosomes. The precise interplay of these two clathrin adaptors remains to be elucidated. Distinct regions of the TGN serve as binding sites for non-clathrin associated AP4 adaptors which may fulfill important sorting functions in polarized cells.

Clathrin-coated vesicles also originate at the plasma membrane and transport cell-surface proteins to endosomes (4). In this case clathrin recruitment is mediated predominantly by AP2 adaptor complexes that have a heterotetrameric organization analogous to AP1 and associate with overlapping sets of sorting signals.

Besides AP2 additional clathrin binding proteins have been identified that recognize a more limited set of cargo proteins, like ARH and Dab2 which interact selectively with the cytoplasmic tail of the LDL receptor, β -arrestin which binds to G-protein coupled receptors or epsin which contains a ubiquitin interacting motif and thus might help to internalize mono-ubiquitinated cell surface receptors. Each of these proteins can bind to clathrin, but also displays affinity for AP2. Thus, these proteins might function independently of AP2 or cooperate with AP2 during assembly of the clathrin coat. The AP2/clathrin coat may contain additional adaptor proteins such as AP180/CALM, which appears to regulate the size of the coated vesicle. A number of accessory proteins have been identified which serve to assist vesicle formation and, together with clathrin and its adaptors, form a dynamic network of complex protein-protein and protein-lipid interactions. One of these factors is dynamin, a large GTPase mediating fission of clathrin/AP2 coated-vesicles. Dynamin assembles into oligomeric rings around the neck of a coated vesicle. GTP hydrolysis induces a conformational change within dynamin thereby driving scission of the vesicle. Other accessory proteins, namely the ►molecular chaperones Hsc70 and auxilin, mediate uncoating of AP2/clathrin coated vesicles.

Alternative processes by which membrane and proteins are internalized from the plasma membrane are macropinocytosis and ►phagocytosis (4). Both are actin-dependent processes that serve to internalize large volumes of extracellular fluids or particulate material, respectively. Neither of the two processes recognizes specific cargo. Accordingly, macropinocytosis and phagocytosis are not mediated by coats.

Coat recruitment to endosomes is less well understood. Different adaptors have been localized to endosomes. One of them is AP3, which might be recruited to the membrane in response to the activation of an ARF protein. Whether AP3 co-assembles with clathrin in a coat is still a matter of debate. Another coat protein recruiting clathrin onto endosomal membranes is Hrs, which recognizes mono-ubiquitinated membrane proteins and segregates them into the lysosomal pathway.

Membrane Fusion

After fission the free vesicle is rapidly uncoated and targeted to the appropriate acceptor membrane. In most cases this process is assisted by a member of the Rab family of small GTPases. More than 60 different Rabs are encoded by the mammalian genome; they localize to specific intracellular compartments and might thus contribute to organelle-specific sorting events (5). Rab proteins cycle between a cytosolic GDP-bound inactive state and a GTP-bound activated state, in which they associate with membranes by insertion of a geranylgeranyl anchor. Upon GTP loading, Rab proteins interact

with a set of specific effector molecules residing in the acceptor membrane thereby docking the vesicle to the target bilayer. Rab effectors often form larger complexes by associating with proteins that might help to temporally and spatially coordinate discrete transport events. A prominent example of such an effector complex in yeast is the ►**exocyst**, which is assembled stepwise onto Rab-associated membranes and promotes docking of secretory vesicles at the plasma membrane. It is important to note that a single Rab (i.e. Rab5 in endosomes) can function in multiple stages of vesicular traffic including budding, docking and fusion. In addition, some Rabs have been shown to interact with actin- and myosin-based motor proteins, implicating Rabs in the transport of vesicles from their site of formation to the site of fusion.

The actual fusion of the vesicle requires the tight association of so-called SNARE proteins (6). They form a large family of mostly transmembrane proteins, which reside in the donor as well as in the acceptor membrane. Their functional amino terminal domains contain a conserved α -helical stretch, the SNARE motif, which is exposed into the cytosol. After Rab-assisted docking of a vesicle to the membrane one helix of the monomeric v-SNARE and three helices of the oligomeric t-SNAREs assemble into a coiled-coil structure forming a tight four helix bundle, the *trans*-SNARE complex. As only distinct combinations of v- and t-SNAREs can engage into a stable complex, the specificity of this reaction has been proposed to control the site of vesicle fusion, although the formation of non-physiological SNARE-complexes has been observed *in vitro*. The zippering of SNAREs moves vesicle and target membranes into close apposition and may provide the free energy necessary for subsequent membrane fusion. Members of a small family of soluble proteins, Sec1p/Munc18-like (SM) proteins associate with Rab effectors and/or SNARE proteins and appear to couple Rab-mediated membrane docking with SNARE complex formation. Since the SNARE complex is extremely stable, its disassembly depends on the activity of the soluble ATPase NSF. NSF in concert with NSF-attachment proteins (SNAPs) promotes disassembly of post-fusion *cis*-SNARE complexes.

One of the best-studied fusion events is the exocytosis of ►**synaptic vesicles** (SVs) at the neuronal plasma membrane. Rab3 has been shown to regulate targeting and docking of SVs to the active zone. In addition, deletion studies have demonstrated that Rab3 functions at a post-docking step during fusion. The SNARE complex that tethers SVs to the plasma membrane is made by the v-SNARE synaptobrevin and two t-SNAREs, syntaxin 1 and SNAP-25, with SNAP-25 contributing two α -helices to the complex. Several additional proteins, like synaptotagmin I, complexins,

►**Munc18**, ►**Munc13** and RIM, bind to these individual SNAREs or the assembled SNARE complex and are thought to regulate docking, priming or fusion of SVs.

Regulatory Mechanisms

As outlined above members of the ARF and the Rab families of small GTPases are important regulators of protein and membrane transport. Accordingly, to ensure the selectivity of distinct transport events the activity cycles of both types of GTPases need to be tightly controlled by guanine nucleotide exchange factors (GEFs) and GTPase-activating proteins (GAPs) (1). In this respect the activity of Sar1p is regulated by the exchange factor Sec12p mentioned above which restricts COPII coat formation to the ER and by the coat constituent Sec23p which simultaneously serves as a GAP, inactivating Sar1 upon completion of the coat. Similarly, in agreement with a role of ARF1 in COPI and clathrin recruitment to the Golgi, a number of ARF1-specific GEFs have been identified that reside at the Golgi membranes (Fig. 2). Together with COPI an ARF1-specific GAP becomes incorporated into the coat which associates with ligand-bound KDEL receptors. This mechanism links ARF1 activity with cargo recognition. GAP activity appears to be modulated by membrane curvature; this ensures that ARF1 hydrolyzes GTP after fission of the coated vesicle. The activation of Rab proteins appears to be more complex (6). In the inactive state Rabs reside in the cytosol bound to a GDP-dissociation inhibitor (GDI). The activity of a GDI displacement factor (GDF) facilitates dissociation of GDI and membrane recruitment of Rab. The localization of Rabs to the appropriate membrane is ensured by the activity of specific GEFs. Once activated, Rabs engage in effector complexes that covalently link the Rab-associated membrane with the cognate acceptor membrane. After fusion, GAPs catalyze GTP hydrolysis on the Rab and Rab-GDP is recycled into the cytosol by associating with a Rab-GDI.

Another important regulatory mechanism is contributed by membrane lipids, in particular ►**phosphoinositides**. Different species of phosphoinositides have been identified that seem to be enriched in distinct cellular membranes. Phosphatidylinositol 4,5-bisphosphate (PI4,5P₂) and phosphatidylinositol 4-phosphate (PI4P) are generated at the plasma membrane and at the TGN, respectively. Phosphatidylinositol 3-phosphate (PI3P) and 3,5-bisphosphate (PI3,5P₂) are abundant in endosomes. Several proteins involved in budding or fusion processes contain domains that selectively interact with distinct phosphoinositides and thereby contribute to the correct localization of these proteins. Accordingly, regulators of homotypic docking and fusion of endosomes and the endosomal mono-ubiquitin binding

Protein and Membrane Transport in Eukaryotic Cells.

Figure 2 Schematic overview of distinct steps that lead to coated vesicle formation. Coat formation is initiated when a specific guanine exchange factor (GEF) triggers activation of a small GTPase and promotes its translocation to the donor membrane. Together with membrane factors which act as primers (P) (these can be specific proteins or certain phospholipids) the membrane-bound GTPase subsequently recruits individual coat components to form a priming complex. Components of the coat also associate with cargo proteins (C), which expose appropriate signal sequences in their cytoplasmic tails. Coat oligomerization leads to a deformation of the underlying lipid bilayer. Cargo molecules are concentrated in the emerging coated bud. GTPase-activating proteins (GAPs) become incorporated into the coat. They are activated before or after fission of the coated vesicle and trigger release of the GTPase into the cytoplasm (adapted from S. Springer et al. (1999), *Cell* 97:145–148).

adaptor Hrs specifically associate with PI3P, whereas AP1 and AP2 adaptors display binding specificity for PI4P and PI4,5P₂. Interestingly, the kinases involved in the generation of the latter lipid species have turned out to be ARF effectors, suggesting a feed-forward loop driving coat formation. As recruitment of AP2 to the plasma membrane does not seem to be directly supported by a specific GTPase, PI4,5P₂ might provide a trigger to initiate coat formation (4). Indeed, many accessory proteins involved in clathrin-mediated endocytosis from the plasma membrane display binding specificity for PI4,5P₂, including AP180/CALM, epsin and dynamin. Correspondingly, the inositol phosphatase synaptojanin 1 which hydrolyses PI4,5P₂ was found to affect the stability of AP2/clathrin coats. By a yet unidentified mechanism PI4,5P₂ also enhances Ca²⁺-triggered exocytosis

of SVs at the neuronal plasma membrane. One potential effector protein is **▶synaptotagmin I** which combines both Ca²⁺- and PI4,5P₂-binding properties.

Definition

Before the three-dimensional structure of a protein molecule can be determined by X-ray crystallographic methods, the protein molecules have to be assembled into a regular and periodic three-dimensional lattice – a crystal. This process is called protein crystallization. The principles of protein crystallization as well as many experimental and technical approaches to it will be discussed in the following description.

Description

Introduction

The three-dimensional structure of a biological macromolecule constitutes not only the basis for investigating

its function but can also serve as a template to determine how and where small molecule ligands bind to it. Such an approach has proven to be extremely useful for the identification and characterization of putative lead compounds that affect the function of a macromolecular target and which, at some point, may lead to the development of new drugs. Of the two techniques, which can provide three-dimensional structural information, nuclear magnetic resonance (NMR) and X-ray crystallography, the latter contributes about 85% of all structures deposited in the ► [Protein Data Bank](#). Furthermore, X-ray crystallography is basically without limitations as long as the macromolecular targets to be investigated are properly folded. Although many steps in NMR and X-ray crystallography have been greatly improved during recent years, there are still common and specific bottlenecks. Common to both methods, and other structural and imaging techniques as well, is the need to purify mg amounts of pure samples. Specific to X-ray crystallography is the need to grow crystals diffracting to sufficient resolution (typically 3 Å or better). Presently available crystallization methods and associated technologies are outlined in this review.

Principles

The process of crystallization of any substance can be defined as a change of its state of aggregation. For proteins, in almost all cases such a process is defined by the change from an aqueous protein solution to the solid, crystalline state. In order to trigger this transition, the crystalline phase needs to be thermodynamically more stable than the protein in solution. To reach such conditions one may change the environmental parameters either to lower the thermodynamic stability of the solution phase or to increase that of the crystalline phase. In practical terms, these two effects are normally not distinguished.

The process of crystallization may be divided into two principle processes, the formation of crystal nuclei (nucleation) and the growth of these nuclei to crystals (crystal growth). A simple and schematic phase diagram of an aqueous protein/precipitant system is shown in Fig. 1. In the solution zone at low protein concentration c_{Protein} and low precipitant concentration $c_{\text{Precipitant}}$, the solution is thermodynamically the most stable phase. If the protein concentration, the precipitant concentration or both are increased, the solubility line is crossed and the meta-stable zone is reached. In this zone, the solution becomes supersaturated and hence is not the most thermodynamically stable phase anymore. Unless crystal nuclei are present, e.g. from a seeding experiment, no crystals will grow because new nuclei cannot form. Increasing the protein and/or the precipitant concentration further, the third zone, referred to as the labile zone, is reached. Both

Protein Crystallization for X-Ray. Figure 1 Schematic phase diagram of an aqueous protein/precipitant mixture. The precipitant can be any chemical compound that is able to reduce the thermodynamic stability of the protein solution phase.

crystal nucleation and crystal growth take place in this zone. At even higher protein and/or precipitant concentrations, the precipitation zone is reached. In this zone, the protein precipitates too rapidly to allow the formation and growth of crystal nuclei.

The aim of a crystallization experiment is the formation of only a few crystals, which then grow large enough (>0.1 mm in their smallest dimension) for subsequent analysis by X-ray crystallography. In order to achieve this, the experiment should start at some point A in the stable solution zone, then slowly move across the meta-stable zone (point B) into the labile zone (point C) in the phase diagram. The whole process needs to be on an appropriate time scale to allow for sufficient time for the formation of crystal nuclei. Once nucleation has occurred, a course that leads the system back into the meta-stable zone (point D) is desirable. Such a process would ensure the formation of only a few nuclei and subsequent crystal growth without competition from the formation of more nuclei.

Techniques

In order to move from the solution zone into the labile zone (Fig. 1) two methodologically distinct methods can be applied, the batch method and the diffusion-based method. In the batch method, the protein and the precipitant solution are mixed and placed in a sealed container so that no further transport process takes place. Super-saturation needs to be achieved (point C in

Fig. 1) at the outset of the experiment. The formation of the first nuclei and their subsequent growth into crystals will subsequently lower the protein concentration, leading to a path in the phase diagram towards point D. In the diffusion-based methods, the crystallization experiment starts in the stable solution zone (point A in Fig. 1). Depending on the experimental design, there may be some differences in the path of crystallization. Nowadays, the hanging-drop set-up (Fig. 2) is the most popular and widespread approach. In this technique, the hanging drop contains the protein and some precipitant in a defined volume ratio while the reservoir solution only contains the precipitant. The solutions are separated by a vapor phase and the whole system is sequestered by sealing it with silicon oil or grease. The system is initially not in thermodynamic equilibrium because of the differences between the precipitant concentration in the reservoir and that in the drop. Eventually equilibrium is achieved by the diffusion of water and other volatile components (if present) from the drop to the reservoir. Hence, both the protein and the precipitant concentration of the drop will increase, moving the protein solution from the solution zone (point A), into the meta-stable (point B) and then to the labile zone (point C).

Other diffusion-based techniques are the sitting-drop technique, which also makes use of diffusion across the vapor phase, dialysis, which utilizes diffusion across a membrane, diffusion across an oil barrier, diffusion

Protein Crystallization for X-Ray. Figure 2 The hanging-drop vapor diffusion experimental set-up. Such an experiment can be carried out using commercially available cell culture plates with 24 or 96 depressions.

across a phase boundary when the protein solution and the precipitant solution are placed next to each other without mixing them or diffusion through gels.

Screening

There are many physicochemical parameters affecting the solubility of a protein. Just to name a few, there are the ionic strength of the solution, the nature of the precipitant, the pH, the temperature, the presence or absence of certain chemicals such as detergents etc. Since it is impossible to predict which combination of parameters will yield a phase diagram and a path through the phase diagram that leads to crystal formation and since the total number of combinations of parameters exceeds by far what is realistically doable, the whole parameter space cannot be sampled completely. This required the development of a number of efficient screening protocols.

Usually, crystallization experiments are performed immediately after the biological macromolecule has been purified. The experiment begins with a solution of the purified biological macromolecule at fairly high concentration (1.5–200 mg/ml) in order to be close to the solubility limit. It is also essential that the purity level is as high as possible (>95%). This includes both the chemical purity (are other molecules still present in the mixture?) and the conformational purity (does the molecule to be crystallized occur in different conformational states?).

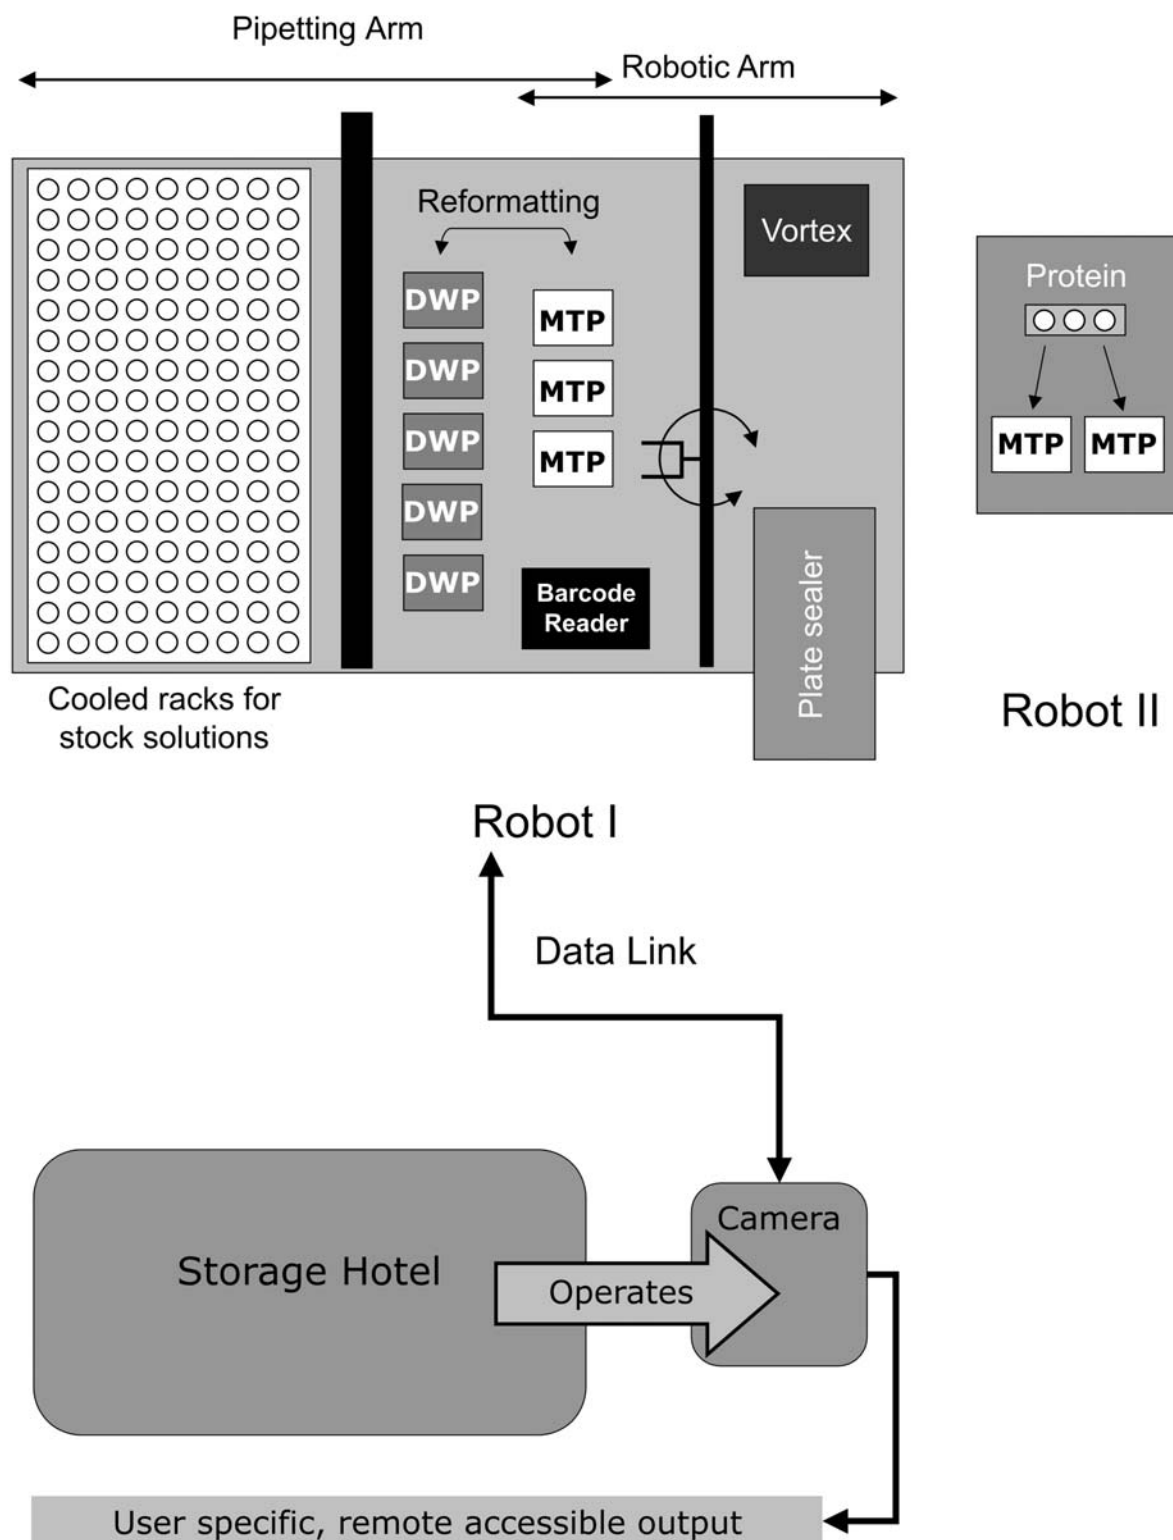

The most common sampling protocols include the grid screening approach of McPherson (3), the footprint screening approach of Stura (1) and the random sampling approach (4). A very popular approach is also the sparse matrix protocol of Jancarik and Kim (2), mainly because the first commercially available screens were designed after it. The incomplete factorial approach pioneered by Carter (1) has also been used occasionally. Over the past ten years or so, many researchers have designed their own screens based on the original ideas of Jancarik and Kim (2), mixed with their own expertise. Many of these screens are now commercially available from different companies (Hampton Research, Emerald Biostructures, Molecular Dimensions, Jena Bioscience and possibly others as well). Most of them comprise about 100–300 single experiments. Considering that for each experiment about 5–100 μg of the biological macromolecule (depending on the concentration needed to achieve super-saturation) is needed, the initial amount of pure protein to be prepared is in the mg range.

The content of the various screens has also been the subject of many discussions. From a purely statistical point of view, no assumptions about the crystallization conditions should be made in the absence of any prior knowledge. However, this is not realized in most commercially available screens, which are formed from empirical or even anecdotal data of previous successes in some cases. The assumption is that they will be more likely to produce crystals from samples that have not been crystallized yet. However, it can be shown that this is not correct (5). The best chance for success in cases where no prior knowledge exists is the uniform distribution of crystallization conditions in the N -dimensional crystallization hyperspace. Here, N represents the number of variable crystallization parameters, which is essentially unlimited. Such a distribution is achieved through the purely random design of experiments and is realized in the computer program CRYSTOOL (5).

A large number of crystallization conditions for biological macromolecules can be found in the Biological Macromolecule Crystallization Database.

The Future of Protein Crystallization

In the past decade, the sequencing of entire genomes from many organisms has led to a dramatic revolution in biology. Although this wealth of information that has emerged from the availability of a huge number of sequences certainly contributes enormously to the understanding of life on a molecular level, it has been realized that it is in no way sufficient to explain the functioning and inner workings of the cell. In order to proceed in this direction, the three-dimensional structures of all molecules in the cell (proteins, RNA, DNA and polysaccharides) have to be known (► [structural](#)

Protein Crystallization for X-Ray. Figure 3 Layout of a typical HT-crystallization platform. Robot I performs the liquid handling up to the preparation of reservoir filled MTPs (see text). Additional functionalities include the sealing of DWPs and MTPs after their completion, the vortexing of the sealed DWPs after cocktail preparation and the registration of barcodes. All DWPs and MTPs are barcoded for record keeping and relevant information is stored in a relational database, which is administered by the software running Robot I. A data link with the camera software allows the display of the reservoir and protein information alongside the crystal images and crystallization specific data, like temperature, date of setup or experiment type.

genomics). However, despite numerous improvements in X-ray crystallographic methodology, it is still a slow technique when compared to other techniques such as gene sequencing. The main reason for this is the necessity of obtaining relatively large amounts of very pure sample and of growing crystals of it. New and faster procedures have to be developed in order to overcome this problem. Here, some of the recent developments to improve and accelerate the process of crystallization of biological macromolecules are outlined and discussed.

Since neither the ability to crystallize nor specific crystallization conditions for biological macromolecules can be predicted, a large number of different molecular constructs have to be scrutinized with respect to a large number of different crystallization solutions in order to identify appropriate crystallization conditions. An aggravating restriction to this approach is the fact, that there is usually only a limited amount of very pure and structurally homogenous biological sample available. The obvious response to the latter is to decrease the volumes of sample solution in crystallization experiments. This led to the miniaturization of the hardware necessary to set up a large number of experiments and to the developments of robotics which could perform these experiments with high precision and reliability. The term nano-crystallization has been coined to refer to the crystallization drops smaller than 1 μ l. The current limit seems to be at drop volumes of about 50 nl.

Setting up a very large number of crystallization experiments (300–1500 per construct and per temperature) is a very repetitive task and as such predestined for automation. As a consequence, the processes of crystallization, crystal visualization and handling rely heavily on automated methods. Such methods have been developed both in academic institutions and in commercial enterprises. Currently, there are a few academic facilities available, to which external users can submit samples for high-throughput (HT) crystallization free of charge, provided they allow the experimental results to be stored anonymously for subsequent statistical analysis. An increase in sites offering such crystallization services (for hire or free of charge) for the general user community is to be expected in the near future. Combined with automated structure solution suites, this offers the possibility of quick and relatively inexpensive structure determination to non-expert users.

All HT crystallization platforms consist of a combination of liquid handling devices, storage and retrieval and visualization systems. Within the last 2–3 years there has been a huge increase in suppliers providing these modules. The precise selection of equipment and the extent of its inter-connection depend largely

on the goals and throughput demands of the individual laboratories. A schematic outline of a HT-crystallization platform is shown in Fig. 3. The various components perform different tasks. Robot I begins with stock solutions and prepares the crystallization cocktails in volumes of 1–2 ml in deep-well plates (DWPs). In a second step, smaller volumes (about 100 μ l) are taken from the DWP and pipetted into micro-titerplates (MTPs), which are the ones finally used for the crystallization experiment. These MTPs are then handed over to Robot II, which pipettes a small volume (about 100 nl) from the reservoir into the crystallization depression. Afterwards, the same volume of protein solution is pipetted into the crystallization depression, also by Robot II. Now, the MTP is sealed and placed into the storage hotel. The storage hotel retrieves the MTPs on a user-defined schedule and delivers them to the visualization system, which is a computer controlled camera mounted on an xy-table. The visualization system combines the information from Robots I and II with respect to the reservoir composition and the information on the protein with the imaging information and writes everything into a remotely accessible (e.g. web based) database.

With the advent of such high degrees of automation of crystallization experiments, new bottlenecks appeared. Probably the most serious, is the accumulation of an unprecedented number of experiments, which have to be evaluated. This has traditionally been done by experienced crystallographers. Naturally, these experimenters also decided *in situ* which experimental results to consider in the absence of crystal producing experiments and which parameters to vary in future experiments, based on all experiments examined. In the future, this task has to be done by software programs. The urgency for the development of such software is recognized and under way in commercial and academic settings.

Definition

A ►protein database is a collection of data that has been constructed from physical, chemical and biological information on sequence, ►domain structure, function, three-dimensional structure and protein-protein interactions. Collectively, protein databases may form a protein sequence database. It is therefore important to use appropriate protein databases which can 1) analyze and store data pertaining to protein science and 2) facilitate usage of analytical software available to the scientific community. Protein databases can generally be divided into two types. The first type is a universal database, which covers the proteins present in all known biological species. The second type is a specialized database, as described here, which

deals with the proteins belonging to a specific group or family of proteins of certain species (1). Each protein database can be further classified into more specialized categories according to the type of information sought.

Characteristics

Recently, massive numbers of data sets have been accumulated due to the rapid development of various high throughput analytical techniques and tools. This increases data redundancy and brings even more difficulties in data analyses. To standardize data formats and minimize redundancy, there have been worldwide efforts, as follows:

- 1) Protein data format standardization through the Human Proteome Organization (HUPO) Proteomics Standards Initiatives (PSI). Due to the tremendous increases in uncontrolled vocabulary and differing formats (4), HUPO launched PSI in 2001 to standardize informatics tools and to promote integration between databases, using ontology-based, controlled vocabulary and ►XML format. The PSI (►<http://psidev.sourceforge.net>) aims to define community standards for data representation in proteomics to facilitate data comparison, exchange and verification. PSI currently focuses on two limited, feasible domains of proteomics data standardization, mass spectrometry and protein-protein interactions. In addition, there is a clear need for a modular, integrative standard for functional ►genomics data. Intensifying these efforts in this domain is the major challenge for the immediate future.
- 2) Provision of a highly curated protein index, IPI (International Protein Index). Use of different identification systems may lead to increasing redundancy between protein databases. To minimize this redundancy, the ►EBI research team has been working to establish a new protein index that allows minimal overlaps between species (human, rat and mouse).
- 3) Construction of controlled vocabulary. The Gene Ontology Consortium (GOC) has produced a controlled vocabulary that can be applied to all organisms even as knowledge of gene and protein roles in cells is accumulating and changing. The GOC provides three structured networks of defined terms to describe gene product attributes. The GOC has a hierarchical structure that employs three principles, molecular function, biological process and cellular components. Use of ►gene ontology not only makes the role of proteins clearer but also minimizes protein redundancy.
- 4) Use of human readable and machine readable file format. XML represents an object-oriented file format and contains hierarchical structure, making

it suitable for expression of biological data and easy parsing of each program. This is a primary reason why many protein databases use XML file format.

Categories of a Protein Database

Because protein datasets are being created from various experimental groups, it would be desirable to provide appropriate databases to meet their needs. Currently there are several types of protein database available to the public. Although commercial protein databases are not described here, it is presumed that many private protein databases are operating *via* paid subscriptions. Protein databases can be further classified into more specialized categories according to the type of information sought.

- Protein sequence database
- Protein structure database
- Protein-protein interaction database
- Protein pattern and profile database
- 2D PAGE database
- Metabolic and pathway database
- Signaling pathway

Protein Sequence Database

A protein sequence is composed of 20 different amino acids; this sequence is termed the **primary structure** of a protein. The primary amino acid sequence is not only related to the three dimensional structure and function of a protein but also to the protein identity. This type of protein database, which collects amino acid sequences of proteins and related information, is termed a protein sequence database. Protein sequences can be determined experimentally or translated from nucleotide sequences found in nucleotide libraries.

Examples

- **Entrez Proteins** (Protein Database in Entrez at **NCBI**) has been compiled from a variety of sources, including Swiss-Prot, PIR, **Protein Research Foundation PRF**, PDB and **translations** from annotated coding regions in **GenBank** and **RefSeq**. This database can retrieve protein sequence records by accession number, author name, organism, gene/protein name and a variety of other text terms. For retrieval of large data sets, **Batch Entrez** is available. Entrez Proteins also includes **BLink** (BLAST Link), a feature that displays **BLAST** search results for every protein sequence in the Entrez Proteins data domain. For access, follow the BLink link displayed beside any hit in the results of an Entrez Proteins search.
- Swiss-Prot is a highly informative cross-referenced, protein-sequence library available through the Internet. This protein sequence database provides a high level of **annotations** (such as a description of the

function of a protein, its domain structure, **post-translational modifications** and variants) and a high level of cross-linked integration with about 60 external databases. This site is jointly managed by the **Swiss Institute of Bioinformatics** (SIB) and EBI (European Bioinformatics Institute). As of 7 Feb 2006, Swiss-Prot contains 207,132 sequence entries.

- TrEMBL is a computer-annotated supplement of Swiss-Prot that contains all the translations of **EMBL** (European Molecular Biology Laboratory) nucleotide sequence entries not yet integrated in Swiss-Prot. 2,605,584 TrEMBL sequence entries are available as of 7 Feb 2006.
- PIR provides the protein sequence database (PSD) of functionally annotated protein sequences, which grew out of the Atlas of Protein Sequence and Structure (1965–1978). PIR has been incorporated into an integrated knowledge based system of value-added databases and analytical tools. Since 2002, PIR-PSD has been integrated into UniProt knowledgebase.
- There are many specialized protein sequence databases. Although the total size of such databases is small, they are well classified according to specific subjects and therefore may be very practical for biologists in specialized fields. In many cases, this type of database provides not only protein sequence data on the specific organism or family, but also related information such as annotation data, pathway data and structural information.

Protein Structure Databases

Protein structure determines function, given that the specificity of active sites and binding sites depends on the precise three-dimensional conformation. **Nuclear magnetic resonance** (NMR) and **X-ray crystallography** are the most important techniques in determining protein conformation. Protein structure databases contain information related to protein three-dimensional structure and **secondary structure** obtained from analyses by X-ray crystallography and NMR.

Examples

- PDB, a typical, worldwide repository for processing and distribution of 3-D structure data on large molecules of proteins, nucleic acids and other biological macromolecules, is operated by the Research Collaboratory for Structural Bioinformatics (RCSB). Using the Protein Structure Explorer interface, the molecular structure, PDB files and file headers can be viewed as HTML and downloaded. A significant number of proteins are present in PDB for a variety of reasons, either because they have been crystallized under different conditions or by different groups or because they were subjected to

site-directed mutagenesis and different entries have been deposited for each of the variants. Common molecular structure visualization program tools such as ►RasMol (►<http://www.openrasmol.org/>) and ►Swiss-Pdb Viewer (►<http://kr.expasy.org/spdbv/>) are used to see 3-D protein structures. As of June 2005, 31,217 structures have been deposited in PDB, 85% are from X-ray crystallographic studies and 15% are from NMR studies.

- CATH refers to a database in which proteins are classified at the level of class, architecture, topology and homologous superfamily. This database provides a good lexicon of protein structure descriptions with a new classification hierarchy. Structures within each H-level are further clustered on sequence identity.
- The DALI domain dictionary is based on the automatic classification of protein domains by sequencing identity. This is constructed by clustering protein neighbors within an abstract file space.
- DSSP (Dictionary of Secondary Structure in Proteins) is a database containing derived information on secondary structure and solvent accessibility for protein 3-D structures stored in PDB.
- PSSH (protein sequence-to-structure homologies) are derived from HSSP2, an improved version of the ►HSSP (homology-derived secondary structure of proteins) database. Whereas each HSSP entry lists all protein sequences related to a given 3D structure, PSSH is the inverse, with each entry listing all structures related to a given sequence.
- SCOP (structural classification of proteins) is a simple resource database in which known proteins are grouped by their secondary structure properties (e.g. coiled coil, all-alpha, all-beta and mixed alpha-beta structures).
- Swiss-3D image is a database of high-quality annotated images of biological macromolecules with known 3-D structure. The goal of this image collection is to provide non-expert users with essential structural information about any particular protein.

Protein-Protein Interaction Databases

A protein-protein interaction database is constructed on the basis of protein-protein interaction information obtained from yeast two-hybrid, co-purification, affinity column chromatography, *in vitro* binding and IP/coIP methods.

Examples:

- BIND (biomolecular interaction network database) is a complex database, which contains interaction, molecular complex and pathway records. This database will span the complexity of interaction

gathered through experimental studies of biomolecular interactions.

- DIP (database of interacting proteins) catalogs experimentally determined interactions between proteins. It combines information from a variety of sources to create a single, consistent set of protein-protein interactions. The data stored within the DIP database were compiled manually by expert curators and also automatically using computational approaches that utilize knowledge about protein-protein interaction networks extracted from the most reliable core subset of DIP data.
- MINT (molecular interactions database) is a database designed to store functional interactions between biological molecules (proteins, RNA, DNA). Beyond cataloguing the formation of binary complexes, MINT was conceived to store another type of functional interaction, namely enzymatic modifications of one of the partner molecules. At present, MINT focuses on experimentally verified protein-protein interactions. Both direct and indirect relationships are considered.

Protein Pattern and Profile Databases

►Motifs can be detected in protein, DNA and RNA sequences, but the most common use of motif-based analysis is the detection of sequence motifs corresponding to structural or functional features in proteins. The use of protein sequence patterns or profiles to determine the function of proteins is an essential tool of sequence analysis (1, 5).

Examples:

- InterPro, an integrated documentation resource of ►protein families, domains and functional sites, was created in 1999 for amalgamation of the major protein signature databases into one comprehensive resource. ►PROSITE, ►Pfam, ►PRINTS, ►ProDom, ►SMART and ►TIGRFAMs have been manually integrated and curated and are available in InterPro for text- and sequence-based searching. The latest release of InterPro (10.0 version) contains 11,972 entries describing 8,597 families, 3,079 domains, 228 repeats and 20 post-translational modifications (3).

2-D PAGE Databases

As ►proteome research progresses rapidly, databases containing 2-D gel profiling and annotation may have a significant impact on protein mapping of any biological sample. 2-D PAGE databases consist of gel image data obtained by scanning the 2-DE and textual information on gel spots with regard to molecular mass (M.W.), isoelectric point (pI), status information on the identified spot and cross-reference links.

Examples:

- SWISS-2D PAGE database is a federated 2-D gel database containing data on proteins identified on various 2-D PAGE and SDS-PAGE reference maps and provides a link to other related databases through active, online hypertext. With Swiss-Prot one may locate proteins on 2-D PAGE maps or display any region of a 2-D PAGE map where one might expect to find a protein.
- YPRC-PDS (Yonsei Proteome Research Center – Proteome Database System). With this ►[laboratory information management system](#), one can store, retrieve and analyze various data, including two-dimensional electrophoresis (2-DE) images and associated spot information obtained during studies of hepatocellular carcinoma (HCC) (2).

Metabolic Pathway Databases

Metabolic databases provide descriptive information on enzymes, biochemical reactions and metabolic pathways.

Examples:

- ENZYME is not a metabolic database in the strictest sense, as it is a repository of information relative to ►[enzyme](#) nomenclature. It is primarily based on the recommendations of the Nomenclature Committee of the International Union of Biochemistry and Molecular Biology (IUBMB) (NC-IUBMB 1992). ENZYME is used as the nomenclature source for enzyme names and reactions by most metabolic databases as well as by other biomolecular databases.
- The BioCyc collection of databases provides electronic reference sources on the pathways and genomes of different organisms. Currently, detailed organism-specific databases are available for 14 species. In addition, the MetaCyc metabolic pathway database contains literature-derived metabolic pathway data for 160 species.
- KEGG (Kyoto Encyclopedia of Genes and Genomes) is an ambitious effort to computerize the current knowledge of molecular and cellular biology in terms of the information pathways that consist of interacting molecules or genes. KEGG consists of four types of data, pathway maps, molecule tables, gene tables and genome maps. It builds a functional map representing metabolic and regulatory pathways.
- WIT (what is there) is a metabolic pathway reconstruction resource, that is the curators of WIT are attempting to reconstruct complete metabolic pathway models for organisms whose genomes have been completely sequenced.
- PathDB. Although it contains almost the same information as KEGG, PathDB enables users to find

any set of interrelated reactions. It also contains a pathway visualization interface that enables inspection of any selected pathway.

Signaling Pathway Databases

This signaling pathway database is to stimulate complementary research in individual laboratories and to facilitate access to necessary information on biological signaling pathways. This database can be classified into the following areas, depending on the format, for it contains both graph and tree-type data structures.

Examples:

- TRANSPATH is an information system on gene-regulatory pathways and an extension module to the TRANSFAC database system. Because this database provides tree, graph and hand drawn images, one can perform pathway queries using graph traversal algorithms.
- CSNDB (cell signaling network database) provides a tool for searching the pathway related to molecules through pathway finder, from pathways in human cells. This database displays starting- and end-points of each pathway and data representing collection of reactions, including nodes.
- SPAD (signaling pathway database) displays as an image the signaling pathway being used most frequently for a growth factor, cytokine, hormone or stress. Images can also be shown in hyperlink.

Clinical Relevance

A bioinformatician usually predicts the function of human proteins using the ►[homology](#), similarity, motif search and structure similarity of annotated proteins of other species. This may be useful for designing experiments to determine protein functions. Both EBI and SIB provide highly curated information on human proteins through HIS (Human Proteomics Initiative). This has also been applied to screen diagnostic marker proteins using a search program that is protein sequence-based mass spectrometry.

Definition

Proteins are long polymers of amino acids, and are essential for all biochemical processes within the cell. Most proteins can perform their various functions only when folded, i.e. if they have adopted a specific, stable structure. Many secretory proteins use disulfide(s) that is/are covalent bond(s) between the side chains of two cysteine residues in order to ensure extra stability. It is achieved by imposing distance and angle constraints between the C^β and S^γ atoms of the joined cysteine residues, thus destabilizing the unfolded state by

reducing its entropy. Disulfide bonds may also stabilize the folded state enthalpically through favorable local interactions, e.g., by contributing to the packing of a local cluster of hydrophobic residues.

►[Protein disulfide](#) bonds are formed in the endoplasmic reticulum of the cell both co- and post-translationally. This composite process by which a reduced, unfolded protein recovers both its native disulfide bonds (disulfide-bond regeneration) and its native structure (conformational folding) is called oxidative folding. This process is facilitated *in vivo* by folding-catalysts such as protein disulfide isomerase (PDI)(1). Nevertheless, our basic understanding of the oxidative folding process comes from *in vitro* studies of multiple disulfide-containing single-domain proteins (2, 3, 4, 5). Protein disulfide bonds are also used as a tool to study a variety of conformational properties of proteins (6).

Characteristics

Disulfide-Bond Reactions

Oxidation, reduction and reshuffling are based on a single chemical reaction, thiol/disulfide exchange, in which a thiolate anion approaches a disulfide bond closely enough to react (Fig. 1).

Factors Affecting the Course of Disulfide-bond Regeneration

The course of oxidative folding is affected by three general structural factors that have been identified from *in vitro* oxidative folding studies and model systems, namely the proximity, reactivity and accessibility of the disulfide bonds and thiol groups. The proximity of two reactive groups (defined as their effective intramolecular concentration) is determined by the propensity of the backbone to bring the two groups into juxtaposition; in unfolded species, this proximity is largely determined by the loop entropy, although enthalpic interactions may contribute significantly as well. The reactivity of the two groups depends on the fact that most disulfide reactions occur through thiol/disulfide exchange and that only the thiolate (not the thiol) form is reactive; hence, changes in pH and in the local electrostatic environment may affect the rate of disulfide-bond reactions. However, in structured intermediates, the most critical factor seems to be the accessibility of the thiol groups and disulfide bonds. Thiol/disulfide exchange reactions can occur only when a thiol and a disulfide bond come into contact; hence, burial of the disulfide bond or the thiol by the protein structure prevents their contact and blocks the reaction.

The Stages of Oxidative Folding

Accordingly, the formation of stable tertiary structure that protects the native disulfide bonds is a key event in the oxidative folding of proteins, because it stabilizes

Protein Disulfide Bonds. Figure 1 Chemistry of disulfide bond reactions. (a) In thiol/disulfide exchange, a thiolate anion R_1S^- displaces one sulfur of a disulfide bond R_2SSR_3 . Protein disulfide bonds are formed and reduced by two such thiol/disulfide exchange reactions with a redox reagent, the first of which involves the formation of a *mixed disulfide bond* between the protein and the redox reagent. For completeness, the reactions

such bonds by making them inaccessible to the redox reagent and to protein thiols (in structured intermediates). Indeed, the rate of intramolecular **▶disulfide reshuffling** is sufficiently high to ensure that no native disulfide bond would survive much longer than a few minutes in an unstructured disulfide intermediate with a free thiol group, unless it was buried in protective tertiary structure. Thus, the rate-determining step in oxidative folding is often the formation of a disulfide-containing intermediate with stable tertiary structure. Accordingly, the oxidative folding process may be divided into pre- and post-folding stages. The prefolding stage is characterized by rapid interconversions of unstructured **▶disulfide species** by disulfide reshuffling, at rates determined largely by loop entropy and the conformational biases of the polypeptide chain (given a pH around the physiological values). By contrast, the postfolding stage is characterized by folded, native-like disulfide species, in which the reaction rates may deviate strongly from the corresponding rates in unstructured disulfide species.

Prefolding Stage

The prefolding stage of oxidative folding of multiple-disulfide-containing proteins consists of disulfide reactions among unstructured disulfide species. The reduced protein is successively oxidized to populate ensembles of species with each ensemble having the same number of disulfide bonds, which establishes a pre-equilibrium (steady-state-like condition) among the ensembles (i.e., the rates of formation and consumption of a particular ensemble are the same). The disulfide species within each unstructured ensemble likewise reach a quasi-equilibrium distribution, because the disulfide reshuffling within the ensembles is generally more rapid than the redox reactions between the ensembles [the fully oxidized ensemble (scrambled species) is an exception because it has no free thiols to facilitate disulfide reshuffling]. Hence, the distribution of disulfide species within each ensemble is relatively insensitive to the redox conditions and the relative concentrations of the other unstructured ensembles. These pre-equilibrium and quasi-equilibrium conditions may be observed qualitatively in the HPLC elution profiles of the unstructured ensembles, each of which is relatively unchanged throughout the regeneration.

are illustrated with (b) cyclic (DTT^{red}/DTT^{ox}) and (c) linear (GSSG/GSH) redox reagents. (d) Thiol/disulfide exchange reactions can also occur intramolecularly; e.g., a protein thiolate group may attack a disulfide bond of the same protein, leading to *disulfide reshuffling*.

Folding-Coupled Regeneration Steps

When a disulfide species acquires a critical number of native disulfide bonds that are enough to stabilize the protein sufficiently under the given conditions, it folds conformationally. There are alternative interpretations for the mechanism of these folding-coupled regeneration steps that are the subject of current research (7). Through these folding-coupled regeneration steps, all the unstructured species constituting the pre-equilibrium distribution of ensembles convert to a structured one, and/or to the native protein.

Postfolding Stage

The postfolding stage consists of disulfide reactions that take place in structured species. Such intermediates can significantly alter the subsequent regeneration by burying reactive groups in stable tertiary structure, thereby inhibiting their rearrangement by thiol/disulfide exchange. Two kinds of structured intermediates are distinguished, disulfide-secure, and disulfide-insecure. Productive intermediates tend to be disulfide-secure, meaning that their structural fluctuations preferentially expose their thiol groups, while keeping their disulfide bonds buried. By contrast, dead-end species tend to be disulfide-insecure, in that their structural fluctuations expose their disulfide bonds in concert with their thiol groups. Under typical oxidative folding conditions, ►**disulfide-secure species** preferentially oxidize to the native protein, whereas ►**disulfide-insecure species** preferentially reshuffle to the unstructured ensemble. Obviously, the ratio between reshuffling and oxidation depends on the redox conditions as well; at very low concentrations of an oxidizing agent, even disulfide-secure species will preferentially reshuffle, albeit at slow rates. However, the distinction between disulfide-secure/disulfide-insecure is a conformational one that is independent of the redox conditions, depending only on the relative free energies for structural fluctuations that expose the thiol groups and disulfide bonds. Stable conformational structure in productive disulfide-secure species seems to be the critical factor accelerating the regeneration of the native protein. This regeneration becomes drastically slower if it is carried out under conditions that destabilize the tertiary structure of these intermediates. The rapid regeneration can be restored if other agents (e.g., phosphate) are added to restabilize the conformational structure.

Generic Pathways of Oxidative Folding of Single Domain Protein

Four generic pathways of oxidative folding can be discerned from oxidative folding studies, depending on whether any disulfide intermediates are structured, whether the structured disulfide species are metastable (i.e., bury both their disulfide bonds and thiol groups,

thereby inhibiting them from subsequent reactions) and whether the ►**metastable disulfide species** are disulfide-secure or -insecure (Fig. 2).

Protein Disulfides as a Tool to Study Conformational Properties of a Protein

Since disulfide-bond reactions are inhibited by the burial of reactive groups (such as protein disulfide

Protein Disulfide Bonds. Figure 2 Four generic types of oxidative folding pathways for a typical disulfide-containing protein. For simplicity, we assume that only des species are capable of folding to a native-like structure (indicated by the N subscript). The U and Iu subscripts indicate that the corresponding species are unfolded or locally unfolded, respectively (although such species may have some conformational order, as observed in ribonuclease A). In pathway I, the native protein N regenerates directly from an unfolded precursor des_U (a des_U pathway). Pathway II involves the formation of a folded disulfide-secure intermediate, des_N that is not metastable; des_N is oxidized directly to the native state (a des_N pathway). Pathway III likewise involves a folded intermediate des_N that oxidizes preferentially to the native protein but is metastable (a metastable des_N pathway). To become oxidized to the native protein, this metastable intermediate must undergo a local unfolding step (des_{IU}). Finally, pathway IV involves a folded, metastable disulfide-insecure species des_N that preferentially reshuffles rather than being oxidized to the native protein (a metastable dead-end pathway). The rate-determining steps of pathways I and II are associated with the formation of the structured species, while that of the metastable dead-end pathway IV is associated with conformational unfolding of the metastable species. In this respect, pathway III is intermediate between pathways II and IV; the rate-determining step may be either the formation or the (local) unfolding of the structured intermediate, depending on the conditions and the δG of local unfolding required to oxidize the metastable species.

bonds, ►mixed disulfide bonds, and protein thiol groups) in stable tertiary structure, disulfide-bond reactions can monitor the accessibility of the reactive groups and indirectly assay the stability of the protective tertiary structure, similar to H/D exchange and proteolysis experiments. The rate of disulfide-bond formation also depends on the proximity of the two cysteine residues, defined here as the probability of their sulfur atoms coming within the distance required for thiol/disulfide exchange. This rough assay of inter-residue distances can be used to characterize secondary, tertiary, and quaternary structure in proteins and complements other distance-measuring methods such as fluorescence resonance energy transfer (►FRET) and the nuclear Overhauser effect (NOE) of NMR spectroscopy. As mentioned previously, disulfide-bond reactions are also sensitive to the reactivities of the thiolate and disulfide groups, which depend on the pH of the solvent and the pK_a values of the thiol groups involved and, more generally, on the electrostatic environment of the reactive groups.

Disulfide Methodologies

The instantaneous and quantitative blocking of the thiols are critical technical issues in all protein disulfide studies. Improper blocking has been the origin of many contradictory results in the field. There are basically three blocking methods in use, namely alkylation of thiols, “freezing” of the reaction by dropping the pH, and reversible blocking techniques that utilize reagents such as 2-aminoethylmethanethiosulfonate (AEMTS). While alkylation of the thiols is an irreversible blocking technique, it is not generally sufficiently rapid to compete with the fast intramolecular disulfide reshuffling. Thus, it is successfully applied to block disulfide-secure intermediates, where this reshuffling does not take place on the time scale of blocking and to block unstructured ensembles where the blocking does not disturb the equilibrium distribution of the rapidly interconverting species. Quenching of the reaction by lowering the pH or by addition of a reversible blocking reagent such as AEMTS (in excess of all free thiols) can occur sufficiently rapidly to freeze all disulfide reactions; however, extra precautions must be taken to avoid subsequent rearrangements during further processing of the sample.

Protein Domains

JÖRG SCHULTZ

Department of Bioinformatics, Biocenter, Würzburg University, Würzburg, Germany
joerg.schultz@biozentrum.uni-wuerzburg.de

Definition

When the first structures of proteins were solved by ►X-ray crystallography, it became clear, that especially larger proteins could consist of different structural subunits, which were named domains. Surprisingly, some of these domains were found in otherwise unrelated proteins. This observation gained importance with the rise of automated sequencing and the parallel invention of algorithms for the detection of remote homologues. These developments facilitated the detection of domains in a plethora of different proteins, indicating that the shuffling of domains was an important mechanism in the evolution of proteins. Therefore, domains cannot only be seen as structural units, but also as units of evolution. With a size of 30–400 amino acids, most domains can fold independently around a relatively hydrophobic core, further underlining their role as independent building blocks. Although structure determination is an important part of the understanding of a domain family, nowadays domains can be discovered in proteins using sequence only. With the rise of large sequencing projects, this turned out to be a powerful tool to fight one of their major problems, namely the step from sequence to function. Biochemical analysis showed that domains of the same family detected in different proteins perform similar functions. As therefore domains also represent units of function, detecting a domain in a protein sequence can give the first clues about its function. In summary, domains are evolutionarily conserved units of structure and function.

Description

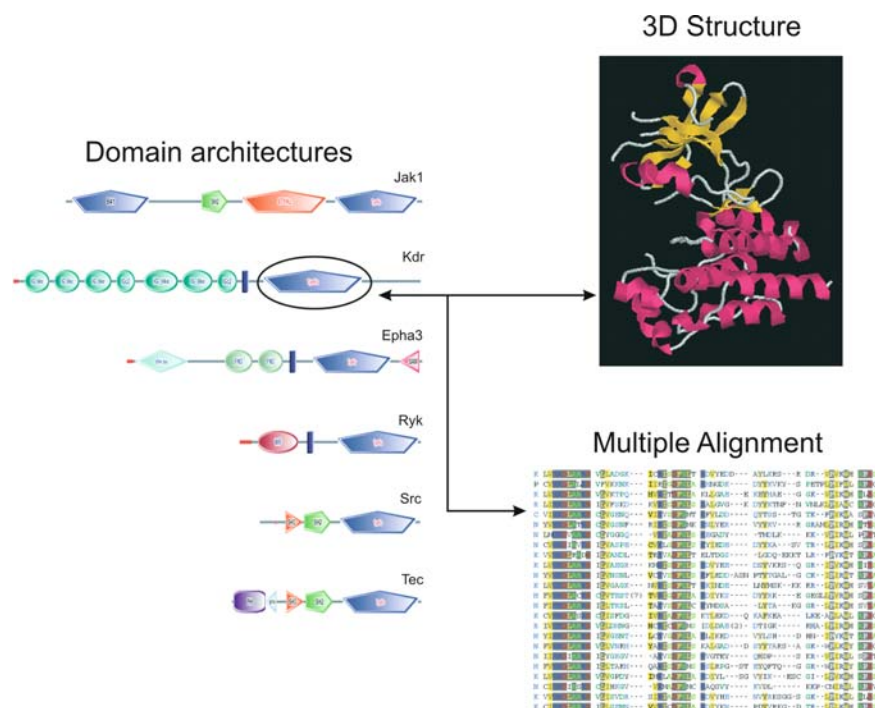

One of the basic questions in sequence analysis is how one could predict functional features of a protein using sequence data only. To address this problem, one makes use of evolution. If two sequences are sufficiently

similar, one can assume that they have originated from a common ancestor, they are homologs. In this case, sequence similarity implies a similar structure and, thereby, a similar function. If the function of one of the homologous proteins is known, one can transfer this knowledge to the other proteins, predicting their function. Obviously, the detail of prediction is highly correlated with the degree of sequence similarity and care has to be taken that one does not end up with overpredictions. A crucial difficulty in this process arises from multi-domain proteins, as here the homology is restrained to defined parts of the proteins. This is illustrated by the proteins depicted in Fig. 1, for example Src and EphA3. Both contain a tyrosine kinase domain (TyrKc), thus the functional aspect of phosphorylating other proteins is conserved between them. But, other regions of the proteins do not show any similarity. In this example, EphA3 is a receptor protein kinase with a transmembrane region and extracellular domains, whereas Src is cytoplasmic. Transferring functions like the binding of ephrins from EphA3 to the Src kinase would obviously be wrong. This example should illustrate, that a careful analysis of the domain content of a protein is a crucial step in the prediction of

its function and should precede any more general homology searches.

Whereas in the example above domains can be used to understand the detailed molecular function of a protein, they can, on the large scale, provide a first functional classification of proteins. Within the analysis of the human genome, different domain families were grouped into broader functional classes and proteins containing these domains were assigned into these classes. It turned out that humans, compared to *Drosophila melanogaster* and *Caenorhabditis elegans*, have more proteins involved in cytoskeleton, defence and immunity, and transcription and translation. These expansions can be related to vertebrate physiology (1).

As outlined above, domains are not only units of function but also of evolution. Their continuous re-use in different proteins leads to the question of their evolutionary origin. Using sensitive methods for the detection of even very divergent members of a domain family (see below) this question was addressed by searching in different bacterial, archaeal and eukaryotic genomes. It was found, that there is a fundamental difference between catalytic and non-catalytic

Protein Domains. Figure 1 Different representations of domains – The domain architecture view shows the whole protein and all domains found within. It illustrates the re-use of the tyrosine kinase domain (TyrKc) within a different context. The multiple sequence alignment of the TyrKc family (only a section is shown here) highlights sites that are conserved throughout all members of the family. It also shows sites that are in corresponding positions within the three dimensional structure. The structure shown here is of the kinase domain of the human endothelial growth factor receptor 2.

domains. Whereas the former seem to have been already present in the last common ancestor, the non-catalytic domains have mainly been evolved in the eukaryotes. The analysis also revealed that a substantial number of domains has been horizontally transferred from eukaryotes into bacteria, further underlining the re-usability of domains as fundamental building blocks in protein evolution (2).

Identification of New Domains

The importance of domains for the evolution, structure and function of a protein raises the question as to how they can be detected within a protein sequence in the first place. In the following, the general procedure will be outlined; detailed descriptions, hinting at many pitfalls, can be found in different reviews (3, 4).

Within the process of predicting the function of a protein, one usually starts with a ►homology search against all currently known protein sequences. The most commonly used tool here is the ►BLAST program suite (►<http://www.ncbi.nlm.nih.gov/BLAST>). In addition to finding ►orthologs of the protein in other species and additional ►paralogs, one might find a partial homology to other proteins. As proteins sharing one domain are homologous only in the region of the domain, the homology found might be the first sign of the existence of an independent domain in the query protein. To further validate this assumption, it is useful to restrain the search to the region detected in the partial homology. After these searches have uncovered the first members of the domain family, more sophisticated methods should be used to uncover additional divergent members of the family. Here, one usually follows two directions. First, one can use a newly detected homologue as the starting point for a further search. This reciprocal search on the one hand strengthens the homology, if the original sequence is found. On the other hand, one will find additional sequences not detected in the first search, caused by an asymmetry in the BLAST algorithm. Obviously, these can be the starting points for an additional round of searches further gathering remote homologues. The second direction uses information gained by combining multiple members of a domain family. The most straightforward approach here is to perform ►PSI-BLAST searches. These automatically build a multiple sequence alignment of all homologues found. In the next search, this alignment rather than a single sequence is used to identify new members, which then are iteratively added to the search alignment. The same principle is used in hidden-Markov-model (►HMM) searches. HMMs are a statistical representation of an alignment, including preferences of amino acids at specific sites and gaps/insertions, which can be used to search against sequence databases (a frequently used implementation is HMMer, which can be found at

►<http://hmmer.wustl.edu>). Retrieved novel sequences have to be added to the alignment, which will then be used as a starting point for a next iteration of HMM searches. Although this procedure will be laborious, the high sensitivity of HMM searches will result in the detection of more members of the new domain family. In general, combinations of the methods mentioned will lead to the best description of the domain family. A cornerstone in this process is the generation of a reliable ►multiple sequence alignment as it allows the highlighting of features common to the whole domain even when sequence identity is low. It is not only the basis for further homology searches; careful interpretation of the alignment will give the first hints about the structure and possible functional residues of the domain. It has to be noted that although the quality of alignment programs is still improving, manual optimisation of the alignment will be needed to gain maximal information.

Having extracted as many members of a domain family as possible, the next step is the elucidation of the function of the domain. Here, one has to rely on previously published experimental characterisations of proteins containing this domain. These might report mutations of sites within the domain or even deletion experiments. Experimental results obtained with single proteins might hint at the function of the domain family.

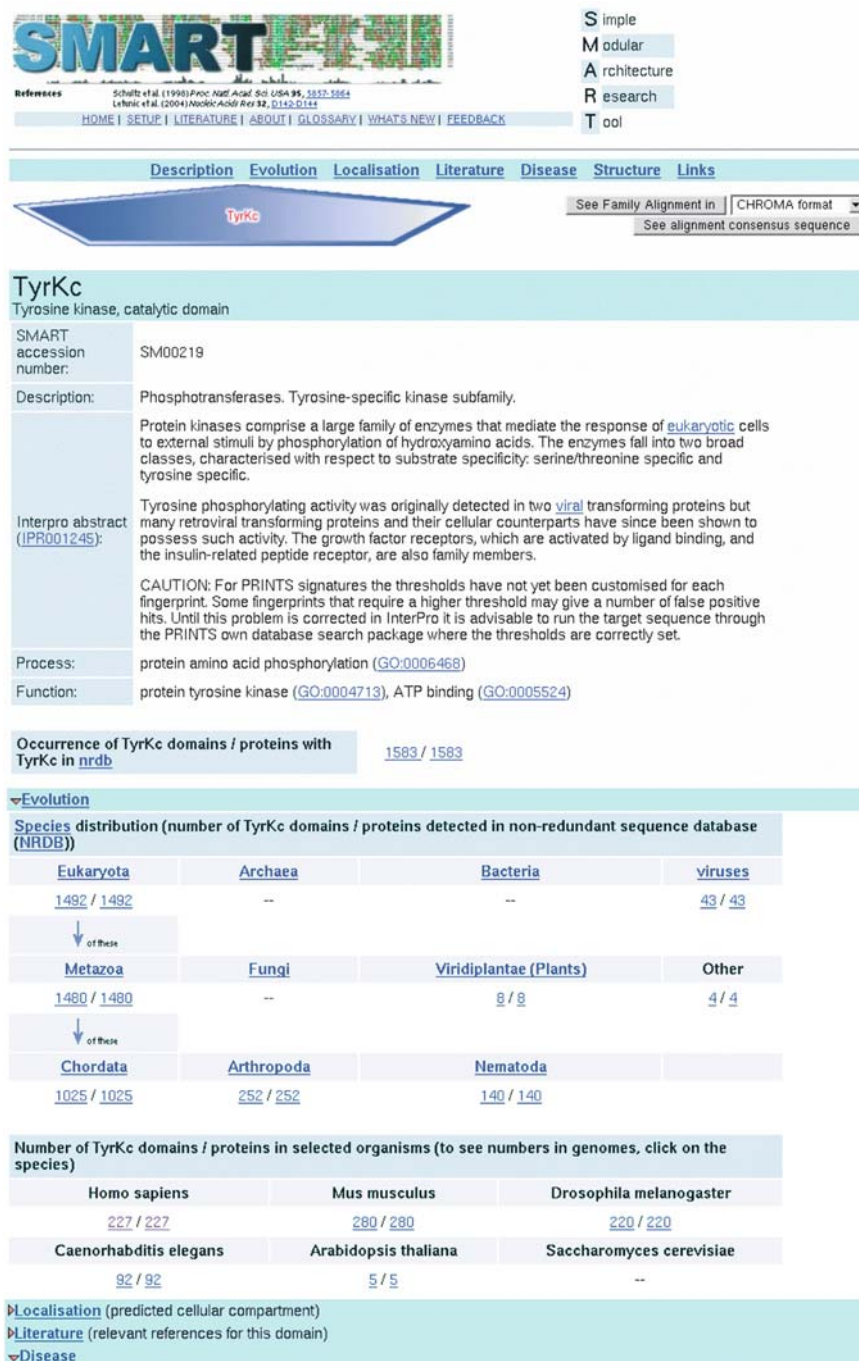

Domain Databases

As outlined above, the detailed description of a domain family is laborious and contains many pitfalls. Fortunately, there exist databases of domain families and Web servers, which allow the automatic identification of domains in given sequences. With the common goal of domain identification, different resources are based on different approaches. The cores of many of them are multiple sequence alignments of representative members of the domain family. As their quality is crucial for the sensitivity and selectivity of domain identification, most databases rely on manually curated alignments. Based on them, Pfam (►www.sanger.ac.uk/Software/Pfam), SMART (►databasesmart.embl-heidelberg.de) and ►TIGRFAM (►www.tigr.org/TIGRFAMs) use HMMs for the actual detection of domains. These databases provide for each of the domain families a manually adjusted threshold for the distinction between members and false positives. Other databases like Blocks (blocks.fhcrc.org) use shorter, ungapped alignments. A different approach, used by CDD (►www.ncbi.nlm.nih.gov/Structure/cdd/cdd.shtml), is the automatic, intrinsic generation of these alignments by storing profiles generated by PSI-Blast searches. Possibly the most straightforward, but also less accurate method is the identification by domain specific patterns as used by Prosite (►www.expasy.org/prosite). In addition to these original domain databases, there exist

metadatabases, which combine the results of searches within different domain databases, for example InterPro (www.ebi.ac.uk/interpro). In general it is advisable to search in several of these databases, as the type of detected domains and the sensitivity may differ.

A great advantage of all these databases is that they offer additional information about each domain. In the

following, the SMART domain database will be briefly discussed as an example of the domain annotations provided by these databases (Fig. 2). In the case of the SMART database, manual annotation is combined with automatically generated information. Within the manual annotation a short description of the function of the domain family is given and references to publications

TyrKc
Tyrosine kinase, catalytic domain

SMART accession number: SM00219

Description: Phosphotransferases, Tyrosine-specific kinase subfamily.

Interpro abstract (IPR001245): Protein kinases comprise a large family of enzymes that mediate the response of *eukaryotic* cells to external stimuli by phosphorylation of hydroxyamino acids. The enzymes fall into two broad classes, characterised with respect to substrate specificity: serine/threonine specific and tyrosine specific.

CAUTION: For PRINTS signatures the thresholds have not yet been customised for each fingerprint. Some fingerprints that require a higher threshold may give a number of false positive hits. Until this problem is corrected in InterPro it is advisable to run the target sequence through the PRINTS own database search package where the thresholds are correctly set.

Process: protein amino acid phosphorylation (GO:0006468)

Function: protein tyrosine kinase (GO:0004713), ATP binding (GO:0005524)

Occurrence of TyrKc domains / proteins with TyrKc in nrdb 1583 / 1583

Protein Domains. Figure 2 Annotation of the tyrosine kinase domain as given by the SMART domain database.

concerning its detection, structure and function are provided. The automatically generated information includes not only a summary of all proteins containing this domain, but also their phylogenetic breakdown. This allows a fast overview of the evolution of the domain but also of the spread within defined taxonomic subgroups. Furthermore links to all structurally characterised members are provided. A more recent addition includes outlinks to the [►OMIM](#) (online Mendelian inheritance in man) database, which characterises genes involved in diseases. Starting with a domain of interest, all genes linked to diseases with missense mutations in this domain can be retrieved.

In summary, current domain databases not only allow the fast and easy identification of domains within a sequence, they also offer a wide variety of additional information about the domains found. When analysing a new protein sequence, it is therefore advisable to search against these databases before performing more traditional homology searches by e.g. BLAST.

From Domain to Function

As noted above, one of the major reasons for analysing the domain architecture of a protein is to gain insight into its function. Indeed, after the identification of the first domains, it was assumed that all members of a domain family perform more or less identical functions. With ongoing sequencing and improvement of similarity search algorithms, more divergent members of a family were unravelled. Experimental characterisation revealed that the ‘one domain – one function’ hypothesis had to be rejected. An impressive example might be the PTB (phosphotyrosine binding) domain. The first characterised, name-giving members of this

domain family bound other proteins on phosphorylated tyrosines. Further experiments revealed that other members of the domain family could bind proteins on unphosphorylated tyrosines or even in a tyrosine independent manner. Only recently, PTB domains were found that do not bind proteins at all but phospholipids. A similar scenario can be established for many other domains. Therefore, to go the step from domain to function, further characterisation is needed. One current approach uses phylogeny to identify subgroups with similar functions within one domain family. Another identifies key functional sites and tries to classify members of a domain family based on the amino acid at this site.

Complementary to the detection that one domain family can perform multiple functions is the observation that different domain families have similar functions. In addition to the aforementioned PTB domain, the SH2 domain and subfamilies of the tyrosine phosphatases can work as phosphotyrosine adaptor domains. Similarly, FHA, BRCT, WW and WD40 can bind to phosphorylated serines and threonines. The combination of these modules in different proteins allows the building up of a complex and changing interaction network, crucial for regulation of cellular processes (5).

Protein Expression Profiling

Definition

Protein expression profiling designates a global analysis of protein expression status in a given cell or tissue (on, off, strong, weak, etc). Usually it is performed with 2-dimensional gel electrophoresis or mass spectrometry.

► [Proteomics in Human-Pathogen Interactions](#)

Protein Family

Definition

Protein family indicates a group of proteins, sharing regions with conserved amino acid sequences and tertiary structure, called domains, and performing similar functions. These proteins are encoded by sets of duplicated genes, called gene families.

Protein Fold

Definition

Protein fold classifies and simplifies the three-dimensional (tertiary) structure of a protein. For large proteins, which are often assembled from a number of globular domains, it is often easier to characterize their tertiary structure by classifying the domain folds of these independent units.

Definition

Proteins are only functional when their amino acids are arranged in a defined three-dimensional structure. Protein folding is the process that leads from a non-native arrangement of the amino acids of a polypeptide chain, to the distinct spatial structure characteristic for the native protein. Thus, folding of newly synthesized polypeptides converts the linear, genetically stored information into a 3D-structure, which is subsequently subject to evolutionary selection. Protein folding is therefore the final part of gene expression after transcription, RNA-processing and translation. Protein folding processes are often, but not always, linked to translation occurring either cotranslationally, domain-wise or immediately posttranslationally. Proteins destined for posttranslational translocation across a biological membrane, for example for import into mitochondria, plastids, the ER or other organelles, unfold upon transition through the membrane, and refold in the interior of their target compartment. In the case of chloroplasts, proteins targeted for the lumen of the thylacoids fold and unfold repetitively until they have reached their final destination.

Protein folding processes comprise, in a wider sense, any formation and rearrangement of secondary structure elements and/or protein domains. The refolding of stress denatured proteins and large conformational changes in proteins due to ligand binding, protein-protein interactions or posttranslational modifications can, therefore, also be considered protein-folding processes (1).

Characteristics

Energy Landscapes and Folding Funnels

The entire information necessary to reach the native conformation is encoded in the amino acid sequence of a polypeptide, as originally demonstrated by Anfinsen, who was able to refold a denatured protein *in vitro* to

the native, active state. Thus, the two central questions of protein folding are: how the primary sequence of a polypeptide encodes the final spatial arrangement, and in which way the native structure is reached.

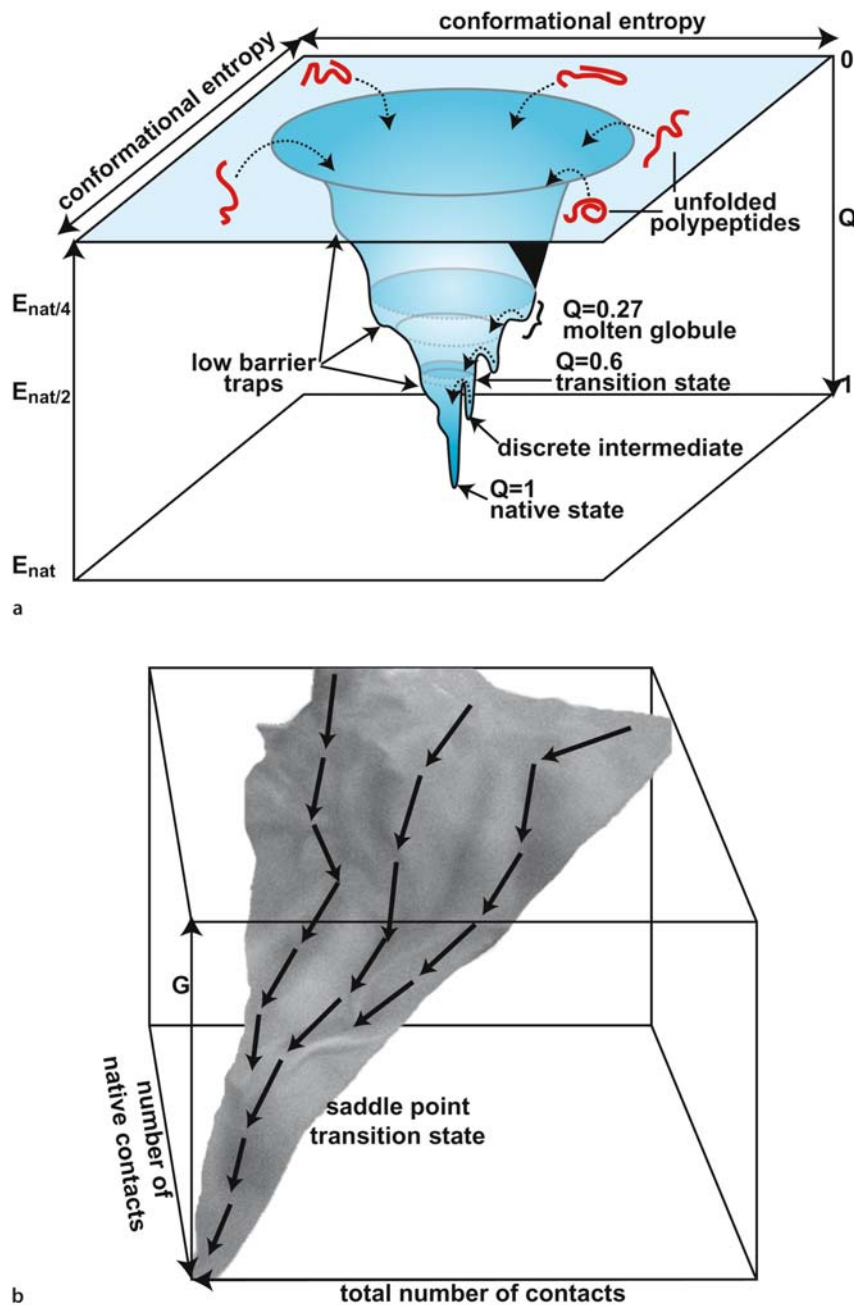

There is still very rudimentary understanding about the first question, which goes little beyond the propensity of residues to favor certain types of secondary structure. The prediction of the protein fold, based solely on the amino acid sequence, is therefore not possible so far. Much more progress has been made concerning the way the final structure is reached. Native states of isolated protein molecules almost always correspond to the most thermodynamically stable structures. Consequently, polypeptides fold by following a folding path that leads down a slope of free energy to the native state. However, since the ensemble of unfolded molecules of a protein comprises of a vast variety of conformations, there is no mandatory succession of partly folded states on the way to the native state. This is best illustrated in the form of a folding funnel, which is a concept for understanding the mechanism of self-organization of proteins (Fig. 1). The width of the funnel signifies the conformational entropy; the depth indicates the decrease of enthalpy during protein folding. At the top of the funnel, the protein exists in a large number of random states that have relatively high enthalpy and high entropy. The drive for maximization of entropy keeps the protein as random as possible at the top of the funnel, while the tendency for minimization of enthalpy tries to drag the protein down the funnel. The decrease in enthalpy is caused by an increase in the fraction of native-like contacts Q , defined as the number of native-like contacts in a given folding state divided by the total number of pair wise contacts in the native state. The polypeptide chains proceed folding by a random search of many conformations that are accessible and preferably downhill of the folding funnel. The wall of the folding funnel is not smooth because some of the non-native-like contacts may have a significant stabilization enthalpy that needs to be overcome in order to continue folding. The change in free energy can be calculated from the change in enthalpy and entropy during the folding reaction, which is usually plotted in a 3D-diagram versus the total number of contacts and the number of native-like contacts, resulting in an energy surface or energy 'landscape' (2, 3). If the shape of the energy landscape is favorable, the number of accessible conformations that needs to be sampled is greatly restricted and the protein is able to fold rapidly. This energy landscape that guides protein folding is encoded in the amino acid sequence, sculpted by the environment, and consequently subject to natural selection. In evolution, proteins were not only optimized for functionality but also folding efficacy and protein

stability, and natural proteins are a compromise between these, sometimes conflicting demands.

Stages of Protein Folding

Three major models were proposed to explain the early events in protein folding. The simple framework model suggests that the secondary structure elements form first, based on the intrinsic properties of the amino acids in the sequence of the polypeptide chain. The secondary structure elements subsequently collide to form tertiary contacts. The alternative nucleation-condensation model suggests that a short region of the polypeptide chain forms a transient secondary structure that acts as a template for the condensation of additional structural elements from adjacent segments of the polypeptide chain. The third alternative, the hydrophobic collapse model, assumes that the hydrophobic residues conglomerate nonspecifically to minimize solvent exposure. The hydrophobic collapse is followed by rearrangements to the final native structure. The actual mechanism of protein folding most likely involves some or all of these processes, and there is evidence for each mechanism from folding studies of different proteins.

These early processes lead to a compaction of the polypeptide chain, whereby the loss of conformational entropy is partly counter balanced by the increase in entropy of the water that is released from the surface of hydrophobic side chains when they pack together into a hydrophobic core. The first compact state formed is called the molten globule, which stands for an ensemble of conformations that still lacks a large number of native contacts and secondary structure elements. In this highly dynamic state, inherent fluctuations in the conformation of the partly folded polypeptide chain enable even residues that are highly separated in the amino acid sequence to come into contact with each other. As, on average, native-like contacts are more stable than non-native interactions, they will be more persistent and the polypeptide proceeds towards the native state. The bottleneck of folding, the transition state, is the formation of the native topology stabilized by contacts of key residues. Mutational replacement of these residues greatly slows down protein folding, demonstrating the importance of these residues for the folding process (4). The ensemble of transition states continues folding towards the native state. Under native conditions, folding of small single domain proteins usually appears to be a highly cooperative process. However, in some proteins intermediates may form that slowly convert into the native state. Multidomain proteins fold largely independently in each domain, with the docking of the domains as a relatively late process.

Protein Folding. Figure 1 Folding funnel and energy landscape. (a) A schematic representation of a protein folding funnel depicting the changes in enthalpy and conformational entropy during protein folding. Unfolded polypeptides (red) have a high degree in conformational freedom and a high enthalpy and are therefore found in the entropy plane at the top of the folding funnel. During folding the polypeptide chains form contacts, whereby native-like contacts are more stable and persistent. As the fraction of native-like contacts (Q) increases the protein loses enthalpy and entropy as a result of the concomitant compaction. By jumping small energy barriers the polypeptide passes through the molten globule and the transition states to the native state at the bottom of the folding funnel. (b) A schematic representation of an energy landscape which depicts the change of Gibbs free energy ΔG as a function of total number of contacts and number of native-like contacts. Unfolded polypeptides start at the top and follow a different path (black arrows) down the energy slope towards the native state.

Peptide Bond cis/trans Isomers

The peptide bond has a considerable double bond character, imposing an energy barrier for rotation of around 60 kJ mol^{-1} for Xaa-Xaa bonds (Xaa, any amino acid except proline), and ca. 80 kJ mol^{-1} for Xaa-Pro bonds. Peptide bonds are thus planar, and the flanking $\text{C}\alpha$ atoms can be either in the trans or the cis conformation. Due to steric hindrance, the cis conformation is disfavored by 14 to 17 kJ mol^{-1} for Xaa-Xaa bonds, and by only 2 kJ mol^{-1} for Xaa-Pro bonds. As a consequence, the cis conformation only occurs in the unfolded state in a negligible fraction of the Xaa-Xaa bonds, but in 10 to 30% of all Xaa-Pro bonds, if enough time for equilibration of the conformational states is allowed. Therefore, [▶peptidyl-prolyl-cis/trans-isomerization](#) is in many cases rate-limiting for folding, and a cause for the occurrence of intermediates that slowly convert into the native state.

About 5 to 7% of all Xaa-Pro bonds in native proteins are in the cis conformation, and of 1435 non-redundant protein structures in the Brookhaven Protein Database, 43% contain at least one cis proline. For these proteins, the trans to cis isomerization of the Xaa-Pro bonds is necessary before folding can be completed. The cis conformation of Xaa-Xaa peptide bonds also occurs in native proteins, though only 43 cis peptide bonds were found in 571 proteins. In these cases, a trans to cis isomerization of these non-proline peptide bonds may retard protein folding, and be the cause for the formation of a folding intermediate.

Cis peptide bonds decelerate folding reactions, but they nevertheless do occur frequently in folded proteins, as mentioned above, mainly before proline and occasionally before other amino acid residues. Cis prolines are very well suited to introduce tight turns into loop structures. More importantly, however, prolyl isomerization increases the energetic barriers of folding, and thus not only folding but also unfolding is decelerated, thereby stabilizing the native state of a protein. Non-prolyl cis peptide bonds are strongly destabilizing, because they introduce strain into the peptide backbone. They are found preferentially near the active sites of enzymes, where strained conformations might be important for catalytic activity.

Molecular Interactions

Protein Folding in a Crowded Environment

Folding processes inside the cell are much more complex than the refolding of denatured model proteins *in vitro*. Proteins are synthesized *in vivo* at the ribosomes in a vectorial manner from the N to the C terminus. In contrast to *in vitro* experiments, which are performed with diluted proteins ($0.1 \text{ g}\cdot\text{l}^{-1}$) and complete polypeptide chains, nascent polypeptides emerging from the ribosome do not contain the complete information necessary for folding. In addition,

the cytosolic concentration of macromolecules including ribosomes, nucleic acids and proteins, is enormously high ($340 \text{ g}\cdot\text{l}^{-1}$). In this crowded macromolecular environment, exposed hydrophobic amino acids of nascent polypeptides and folding intermediates may interact inappropriately leading to misfolding and aggregation. While, as a consequence of this problem, cytosolic proteins should fold as fast as possible, the folding of proteins destined for another compartment should be delayed in order to allow rapid unfolding for translocation through the membrane. Due to Brownian motion and thermal vibrations, even native proteins are always in danger of spontaneously unfolding and thereby losing their active structure. This feature of proteins is probably the evolutionary price for conformational flexibility, which is essential for protein function. For most proteins there are only small energy barriers between the native and the misfolded state. A number of proteins are specifically thermo labile, and their folding status is even more susceptible to changes in the cellular environment. Stress conditions, like a sudden increase in temperature, can therefore lead to unfolding, aggregation, or degradation of many proteins (3).

To optimize cellular protein folding, protective systems have developed in the course of evolution. These systems consist of families of highly conserved proteins, the so-called [▶molecular chaperones](#) (5). Chaperones are found in high concentrations in all cells, from bacteria to humans. They guide a large variety of folding processes throughout the life cycle of proteins, from synthesis to degradation. For example, they assist the *de novo* folding of proteins or form repair machines for misfolded or even aggregated proteins, and are therefore especially important for the survival of cells during stress situations. Since heat shock can induce the synthesis of many chaperones, those are also called [▶heat shock proteins](#) (Hsps). The name of each of the chaperone families is derived from the molecular weight of the corresponding main representative (for example, Hsp70: a protein with a molecular weight of 70 kDa). Table 1 summarizes the structure and function of the most important chaperone families and lists some of their prokaryotic and eukaryotic members, as well as their cochaperones (regulatory and cooperating proteins). In addition to these more general chaperones, there are also very specific chaperones that are specialized for very few or even a single substrate (e.g. FimC in *E. coli* is specialized for the folding of the pili subunits FimA, FimF, FimG and FimH; Hsp47 in the ER is specialized for collagen).

The minimum definition for a chaperone is the ability to prevent the aggregation of its substrate proteins. This function is called the “holder” function and is generally energy independent. Chaperones that are able to refold

denatured proteins to the native state are called “folder” chaperones. The folder function is generally dependent on ATP hydrolysis and the regulation by cochaperones. Protein folding in the cell is not only assisted by chaperones, but also by so-called folding catalysts like peptidyl-prolyl-cis/trans-isomerases (PPIase), which catalyze the cis/trans isomerization of Xaa-Pro bonds, and by protein disulfide isomerases (PDI), which reduce disulfide bonds and reoxidize free cysteines, thereby assisting the formation of correct disulfide bonds.

Families of Chaperones

sHsp

The family of small heat shock proteins consists of ATP-independent chaperones that are characterized by their homology to the α -crystalline domain. This signature domain is extended at the N and C terminus by unrelated domains of variable length to give a molecular weight of 10 to over 40 kDa. sHsps form oligomeric spheres of 8 to 24 subunits, which at least in some cases dissociate into dimers upon temperature increase. By binding to unfolded proteins, these sHsp dimers coaggregate with their substrates. Such coaggregates of sHsps and misfolded proteins are more efficiently dissolved by the action of Hsp70 chaperones in cooperation with Hsp100 chaperones, than pure aggregates of misfolded proteins alone. At least one member of the sHsp family, Hsp27, is involved in the regulation of programmed cell death.

Hsp60

The family of Hsp60 proteins, also called chaperonins, consists of two distantly related subfamilies of ATP-dependent oligomeric chaperones. The Group I chaperonins, which exist in bacteria (GroEL), mitochondria and chloroplasts (Cpn60), form a barrel out of two stacked rings with seven identical subunits of 57 kDa each. GroEL/Cpn60 cooperates with the cochaperones GroES/Cpn10 (ca. 10 kDa), which also forms a seven-member ring and acts as a lid on the GroEL barrel. Unfolded proteins and folding intermediates bind to the central cavity of one of the two rings, and ATP and GroES binding to the substrate-containing ring leads to an enclosure of the substrate, which then may fold isolated from aggregation promoting influences in the cytosol. ATP- and GroES-induced conformational changes in the substrate-enclosing ring are proposed to promote conformational changes in the substrate, including global unfolding and global compaction, which further promote the folding to the native state. GroEL has a large variety of substrates (10–15% of *E. coli* proteins), most of them below 60 kDa, the size-limit for enclosure in the GroEL cavity. Substrates that are too big for an enclosure in GroEL under the GroES dome are folded in trans, meaning that GroES binds to the empty and

not the substrate-containing ring triggering folding, and substrate releases through the cooperativity of the two rings.

The Group II chaperonins, which exist in the eukaryotic cytosol (CCT/TRiC) and in archaeans (thermosome), also form a barrel out of two stacked rings, but with eight different subunits this time. These subunits have a built-in lid, and therefore do not cooperate with a lid-forming cochaperone. CCT is believed to work in a GroEL analogous way. The main substrates for CCT in the eukaryotic cytosol are actin and tubulin, but a number of other substrates have also been identified.

Hsp70

The 70 kDa heat shock proteins are central components of the cellular chaperone network, and are involved in a large variety of protein folding processes (6). These processes include *de novo* folding of newly synthesized polypeptides; refolding of spontaneously unfolded or stress misfolded proteins; disaggregation of protein aggregates; translocation of polypeptides across biological membranes, where Hsp70s often act on both sides of the membrane; assembly and disassembly of oligomeric protein complexes, e.g. clathrin uncoating or assembly and disassembly of virus capsids; control of activity and stability of many regulatory proteins including transcription factors and protein kinases; and regulation of the heat shock response. The highly conserved Hsp70 proteins are found in almost all organisms and are essential for all eukaryotic organisms, where they reside in all major cellular compartments. In *E. coli*, three distinct Hsp70s are found called DnaK (major form), HscA (specialized for iron-sulfur-cluster proteins) and HscC (unknown function). In yeast and higher eukaryotes, 10 to 15 Hsp70s plus 3 to 4 Hsp70-related proteins with higher molecular weight (Hsp110 and Hsp170s) exist. In the cytosol there are at least one Hsp70 (called Hsc70, heat shock cognate), which is constitutively at high levels, and one Hsp70, which is stress induced. Pathogenic processes like cancer often lead to a continuously high level of the stress inducible Hsp70 form. In the human cytoplasm, three Hsp110 are found called Hsp105, Apg-1 and Apg-2. The Hsp70 in the endoplasmic reticulum is called Bip (Immunoglobulin **B**inding protein) and the Hsp170 is named Orp150 (**O**smotic shock regulated protein). The mitochondrial Hsp70, mortalin, is also found in the cytoplasm, often as a sign of ongoing pathological processes.

All functions of Hsp70 proteins are based on an ATP driven cycle of transient binding and release of a short peptide stretch within the substrate polypeptide. This cycle is regulated by cochaperones of the family of J-domain proteins (Hsp40s) and nucleotide exchange factors. The family of J-domain proteins, which has

Protein Folding. Figure 2 Protein folding in the cell. A newly synthesized protein starts folding either cotranslationally while still attached to the ribosome or posttranslationally. Folding proceeds generally through intermediary states towards the native state. Due to the exposure of hydrophobic side chains in the crowded environment of the cell intermediates may interact with each other and aggregate. Proteins, which have completed folding, may also unfold again and subsequently aggregate due to natural or mutation-induced instability, physiological or non-physiological modifications, or environmental stress. Chaperones of the Hsp60, Hsp70 and Hsp90 families assist de novo folding and refolding of denatured proteins. In bacteria, yeast and plants Hsp70 chaperones cooperate with Hsp100 chaperones in disaggregation of protein aggregates and subsequent refolding to the native state. Hsp70 also interacts with the ubiquitin ligase Chip, which leads to ubiquitination of misfolded proteins and ensuing unfolding and degradation by the proteasome.

increased tremendously in the course of evolution (*E. coli*, 6; yeast, 20; humans, 44), couples substrate binding by their Hsp70 partner protein with ATP hydrolysis, therefore acting as a targeting factor. Four families of nucleotide exchange factors for Hsp70s have been discovered so far: the prokaryotic GrpE (Mge1 in mitochondria), the family of Bag proteins in the cytosol of higher eukaryotes, the family of HspBP1 proteins in the cytosol and ER (Bap), and the Hsp170 protein Lhs1 in the yeast ER, which acts as nucleotide exchange factor for the ER-resident Hsp70 Kar2. Other known interacting cochaperones of Hsp70 proteins are the Hsp70-Hsp90-organizing protein Hop, the ubiquitin ligase Chip, and the Hsp70-interacting protein Hip.

Hsp90

The 90 kDa heat shock proteins are highly abundant and essential ATP-dependent chaperones in all eukaryotes (7). Mammalian cells contain four full-length Hsp90 proteins, the constitutive Hsc90 β , the heat inducible Hsp90 α , both in the cytosol, the ER-localized Grp94 (gp96), and the mitochondrial Hsp75 (Trap1). All four proteins consist of an N-terminal ATPase

domain, a middle domain implicated in substrate binding, and a C-terminal dimerization domain. In addition, an Hsp90 relative, Hsp90N, without N-terminal ATPase domain has been found. The interaction of the cytosolic Hsp90s with substrate proteins is regulated by a plethora of cochaperones and cooperating chaperones. These are either involved in substrate loading onto Hsp90, like the Hsp70 chaperone and the Hsp70-Hsp90 organizing protein Hop, or in the regulation of Hsp90's ATPase cycle and substrate release, like Aha1, p23, and the immunophilins, FKBP51, FKBP52 and cyclophilin-40. The interaction of Hsp90 with protein kinases often involves the protein p50^{cdc37}. In addition, the protein phosphatase PP5 and the ubiquitin ligase Chip interact with Hsp90. Hsp90 forms the core component of a dynamic multimeric chaperone complex, which in cooperation with Hsp70 interacts with more than 120 natively folded proteins, many of which are involved in signal transduction processes, regulation of cell homeostasis, cell cycle, differentiation and apoptosis. These substrate proteins, which include numerous transcription factors and kinases, are converted by the chaperone

complex into conformational states that permit rapid activation through signaling events, including post-translational modifications (phosphorylation) and interactions with specific ligands such as hormones. Many of the protein kinases and transcription factors, which are substrates of the Hsp70-Hsp90 chaperone machinery, are implicated in physiological and pathophysiological processes like tumorigenesis, neurodegenerative diseases, inflammation, autoimmunity, viral and bacterial infections, ischemia/hypoxia, and ageing. Hsp90 and Hsp70 are, therefore, prime targets for pharmacological intervention.

Hsp100

The Hsp100 chaperones (Clp proteins in prokaryotes) belong to the superfamily of AAA+ proteins, which also includes the 'ATPase associated with a variety of cellular activities' (AAA) proteins. Characteristic of this superfamily is a considerable sequence homology in their 'AAA' domains, which are important for ATP hydrolysis and oligomerization. Generally, AAA+ proteins form ring-shaped homohexamers, which drive the assembly and disassembly of macromolecular complexes by ATP-dependent remodelling of their substrates. ClpB in *E. coli*, Hsp104 in yeast and Hsp101 in plants cooperate with Hsp70 proteins to dissolve protein aggregates and reactivate the misfolded proteins. Other members of the Hsp100 family associate with peptidases and unfold proteins for degradation. Hsp100 proteins of the ClpB/Hsp104 subgroup are essential for the development of thermotolerance and survival at extremely high temperatures. Homologues of Hsp104/ClpB have not so far been found in the cytosol of metazoans.

Regulatory Mechanisms

Regulation of Protein Conformation

For many proteins, evolution has not selected for the most stable conformation because conformational flexibility is essential for protein function. Some proteins, especially those that act as molecular switches in signal transduction pathways, and also potentially dangerous proteins like the caspase activated DNase (CAD), are particularly unstable, either unfolding spontaneously or existing in more than one native conformation. These proteins are generally already bound by Hsp70 chaperones during translation at the ribosomes, and are subsequently handed over to the Hsp90 chaperone complex or a specific inhibitory binding protein (ICAD in the case of CAD). In both cases, the substrate protein is kept in an inactive state but is poised for activation. This regulation of protein conformation is best investigated for the steroid hormone receptors. The current hypothesis assumes that Hsp70 induces conformational changes in the hormone receptor, thereby opening up the ligand-binding site

and subsequently transferring the receptor onto the Hsp90 chaperone complex, which holds it in an open state ready for hormone binding. With a certain half-life (ca. 5 min) this complex is thought to decay, whereupon the substrate is rebound by Hsp70 and the activation cycle restarts. Hormone binding stabilizes the receptor in the active conformation, leading to the dissociation from the chaperone complex, followed by dimerization, entry into the nucleus and transcriptional activation of the target genes. In the absence of the chaperones, the hormone binding activity of the receptor is very low, underlining the importance of the induced conformational changes.

Global Regulation of Protein Folding

The cellular protein folding system is a robust self-sustaining system, where the need for folding assistants is regulated by the total amount of unfolded and misfolded proteins. In a process generally known as heat shock or stress response, an elevated level in unfolded proteins leads to an increase in transcription of heat shock genes, and a subsequent rise in the total amounts of chaperones and proteases to assist refolding or degradation of hopeless cases. Key players in this regulation are Hsp70 and Hsp90 proteins, which in the eukaryotic cytosol bind to the heat shock transcription factor ►**HSF**, and keep it in a monomeric form probably by regulating its conformation. This interaction is thought to be a dynamic binding and release cycle, and an increase of unfolded proteins competes with HSF for binding to Hsp70 leading to an increase in free and active HSF, which in turn transcriptionally induces an increase of the Hsp70 and Hsp90 levels, until enough free Hsp70 and Hsp90 is available to sequester HSF again. In the mammalian ER, the Hsp70 protein Bip binds to the ER stress sensors IRE1, PERK, and ARF6. Like in the cytoplasm, unfolded polypeptides compete with the stress sensors for binding to Bip, and the free stress sensors activate the so-called unfolded protein response (UPR), leading to an inhibition of general translation into the ER and an increase in transcription and translation of ER resident chaperones.

Protein Interaction Analysis, Variations of the Yeast Two-Hybrid System

IGOR STAGLJAR

Institute of Veterinary Biochemistry and Molecular Biology, University of Zurich, Zurich, Switzerland
stagljar@vetbio.unizh.ch

Definition

Besides protein identification and quantification of differences in protein profiles of cells, tissues and

organs, the characterization of physical protein-protein interactions (so-called “interactive proteomics”) is being recognized as a key objective of proteomics research. One of the best tools available to analyze protein-protein interactions is the yeast two-hybrid system (YTH). The YTH system has spun-off several modified versions that provide additional utility to academic and pharmaceutical research, such as the repressed transactivator (RTA) system and the split ubiquitin membrane yeast two-hybrid method (MbYTH).

Characteristics

Protein-protein interactions play a fundamental role in the regulation and execution of almost all cellular processes. One of the most widely used techniques to detect protein-protein interactions is the YTH. It takes advantage of the finding that many eukaryotic [▶transcription factors](#) can be divided into two functionally distinct domains that mediate DNA binding and transcriptional activation. In the classical yeast two-hybrid approach, a [▶bait](#) is constructed by fusing a protein X to the DNA-binding domain (DBD) derived from a transcription factor and a [▶prey](#) is constructed by fusing a protein Y to the activation domain (AD) of a transcription factor. The bait and prey fusions are co-expressed in yeast, where the interaction of X and Y leads to the reconstitution of a functional transcription factor. Reconstitution of the transcription factor is measured by assaying the activity of [▶reporter genes](#). Commonly, auxotrophic markers that can be selected for are used in combination with the *lacZ* gene encoding bacterial β -galactosidase. *HIS3* and *LEU2* allow selection of interactions by monitoring growth on selective plates lacking histidine or leucine respectively, whereas *lacZ* can be easily measured using a colorimetric assay. The ability to screen large cDNA libraries quickly for proteins that interact with a given protein of interest is the major advantage of the YTH system over other, biochemical methods utilized for the identification of protein-protein interactions (1). A major limitation of the YTH method is that interaction between bait and prey occurs in the nucleus. Consequently, transmembrane proteins cannot be efficiently studied by the YTH method because they tend to form aggregates when expressed in the nucleus in their full-length form. In addition, interactions between many membrane proteins are dependent on post-translational modifications, such as glycosylation and disulfide bond formation, that take place within the endoplasmic reticulum but not in the nucleus. Lastly, [▶transcriptional activators](#) cannot be used as ‘bait’ proteins in the YTH assay as they can constitutively activate the reporter genes even in the absence of protein interactions.

The Repressed Transactivator (RTA) System

In the past few years, two alternative YTH-based technologies have been developed to address the above-mentioned technical difficulties associated with the conventional YTH method. These include the repressed transactivator (RTA) system (2), and the split ubiquitin membrane yeast two-hybrid method (MbYTH) (3). RTA technology (Fig. 1) was developed to address limitations of the standard YTH method, which precludes use of transcription activators as baits for identification of interacting proteins. In the RTA system, the activator 'bait' is fused to the GAL4 DNA-binding domain and the 'prey' is fused to the repressor domain of the yeast TUP1 protein. Interaction of the activating bait fusion with the prey-TUP1 fusion represses expression of the reporter gene, which is generally detected using counter selection (2, 4). Hirst et al. validated their RTA system by demonstrating its ability to detect interactions between the mammalian basic helix-loop-helix proteins MyoD and E12 and between the c-Myc oncoprotein and the Bin1 tumor suppressor. They also used the RTA assay to screen for novel proteins interacting with the activation domain of the VP16 transcriptional activator (2). In addition, the RTA approach has recently been used to identify a novel interacting partner of the human androgen receptor (AR) called DDC (L-dopa decarboxylase) (4). Thus, the RTA system should prove useful for identifying co-activators and regulators of transcription from any model organism. A drawback of this

technology is that, like any other genetic system, it identifies a large number of false positives and it detects binary interactions.

The Split-Ubiquitin Membrane Yeast Two-Hybrid System

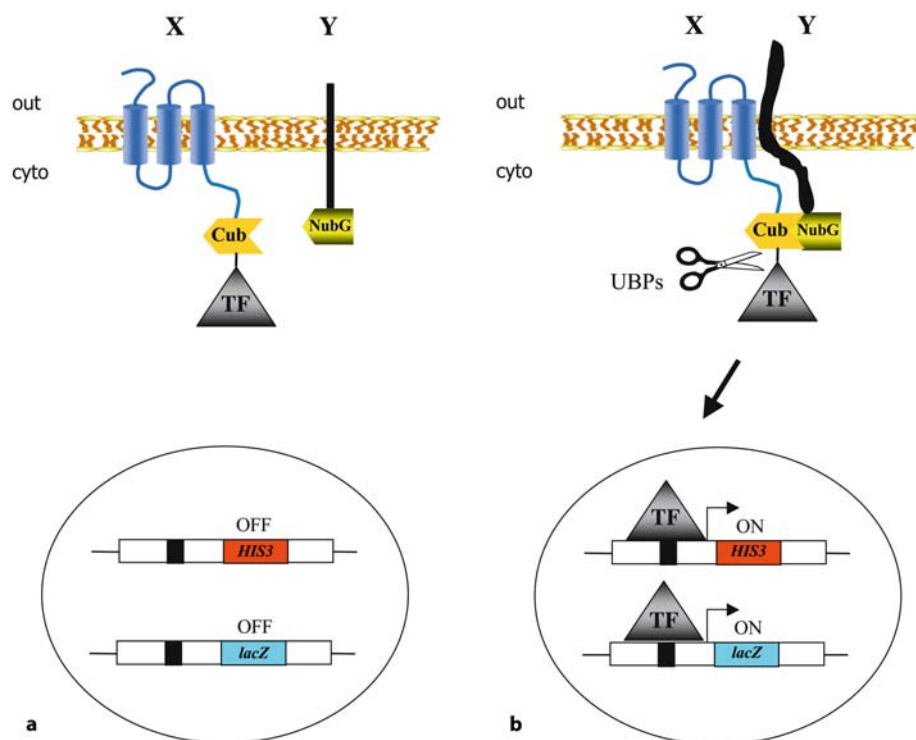

An alternative YTH approach that is applicable to studying membrane proteins is the split-ubiquitin membrane yeast two-hybrid system (MbYTH) (3, 5). MbYTH uses the split-ubiquitin approach in which the reconstitution of two ubiquitin halves is mediated by a specific protein-protein interaction. Like the YTH, where a transcription factor is reassembled upon interaction of two test proteins, the split-ubiquitin system consists of two fragments of ubiquitin that are brought together by interacting proteins. ► **Ubiquitin** (Ub) is a small, highly conserved protein that is attached to lysine residues of proteins in order to tag the proteins for proteasomal degradation. Ubiquitin-tagged proteins are recognized by ubiquitin-specific proteases (UBPs) that cleave after the C-terminal (Gly 76) residue of Ub and the first residue of the target protein, allowing release of the protein for degradation by the 26S proteasome. Johnsson and Varshavsky (6) found that native ubiquitin could be split into an N-terminal (Nub) and a C-terminal (Cub) half. The two halves retain a basic affinity for each other and spontaneously reassemble to form quasi-native ubiquitin. If a reporter protein is fused to the C-terminus of Cub, it will be cleaved off by UBPs upon assembly of the Nub and Cub moieties. A point mutation in the N-terminal

Protein Interaction Analysis, Variations of the Yeast Two-Hybrid System. Figure 1 Repressed transactivator (RTA) method, a two-hybrid system for transactivator bait proteins. Like the conventional yeast two-hybrid system, a bait protein of interest (X) is fused to a GAL4 DNA binding domain (DBD). However, the prey protein (Y) is created by fusion of the cDNA library with a TUP1 repressor protein. (a) If there is no interaction between the bait X and the TUP1-prey Y fusion protein, the bait activator allows constitutive expression of the *URA3* reporter gene. This permits the growth of yeast cells in the absence of uracil, but causes sensitivity to 5-FOA, which is converted into a toxic product through the enzyme encoded by the *URA3* gene. (b) In a situation where there is an interaction between X and Y, TUP1 will cause repression of the *URA3* expression, which can be detected by growth of yeast in the presence of 5-FOA. Therefore, viability of the reporter strain (or colony growth) on 5-FOA media represents a positive interaction between the bait and prey protein.

domain of ubiquitin (NubG) abolishes the affinity of the two halves for each other, such that NubG and Cub fail to refold into split-ubiquitin when coexpressed in yeast. However, if the two ubiquitin halves are fused to the interacting proteins X and Y, this interaction brings the NubG and Cub moieties close enough together to reconstitute quasi-native Ub, resulting in the release of the reporter protein by the UBPs. In the MbYTH assay (Fig. 2), an artificial transcription factor (TF) consisting of the bacterial LexA protein and the *Herpes simplex* VP16 transactivator protein is fused to the Cub moiety. An integral membrane protein (X) is expressed as a fusion to the Cub-LexA-VP16 reporter cassette, with this cassette attached to either the N- or C-terminus of the transmembrane protein, depending on the orientation in the membrane of this protein. The second protein under investigation (Y), either another

transmembrane protein or a cytoplasmic protein, is expressed as a fusion to NubG. If interaction between the X and Y proteins occurs, a split-ubiquitin molecule can be reconstituted, leading to the proteolytic release of the transcription factor to activate a reporter gene (2, 5, 7). Thus, the reassociation event initiated by the protein interaction is converted into a transcriptional output that can be easily detected. This assay has been used to investigate the influence of mutations on the assembly of fragments of presenilin (►PSEN1/PSEN2) (a protein implicated in ►Alzheimer's disease), to characterize the interaction between the yeast α 1,2-mannosidase Mns1p and Rer1p in the endoplasmic reticulum and to study intra- and inter-molecular interactions between plant sucrose transporters (7). Moreover, Thaminy et al. (5) have recently successfully adapted the MbYTH system for prey library screening and have identified three novel

Protein Interaction Analysis, Variations of the Yeast Two-Hybrid System. Figure 2 The split-ubiquitin membrane yeast two-hybrid system (MbYTH), a yeast-based genetic assay for characterization of membrane protein interactions. Here, the membrane bait protein of interest X is fused to the C-terminal domain of ubiquitin (Cub) followed by the artificial transcription factor TF, and the potential interacting prey protein Y is fused to the mutated N-terminal domain of ubiquitin (NubG). Note that prey Y can also be a cytosolic protein. (a) If both proteins (X; Y) do not interact, TF is not cleaved from Cub and remains associated with the membrane. In this case, reporter genes *HIS3* and *lacZ* remain silent, which renders cells unable to grow on medium lacking the amino acid histidine and colorless when exposed to X-gal. (b) If both membrane proteins X and Y interact, the re-associated NubG and Cub are recognized and cleaved by the ubiquitin-specific proteases (UBPs) (scissors), liberating the TF, which is transported into the nucleus. This in turn activates the *lacZ* and *HIS3* reporter genes resulting in β -galactosidase activity and histidine synthesis, respectively.

interacting partners of the mammalian ErbB3, a receptor tyrosine kinase involved in the regulating of proliferation and differentiation in many tissue types. Thus, MbYTH allows rapid and sensitive characterization of proteins associated with a particular full-length transmembrane protein of interest and is generally applicable to most transmembrane proteins of any organelle. Like the RTA technology, the major disadvantage of MbYTH is that it identifies a large number of false positives, presumably through interactions between proteins that do not normally occur *in vivo*. In addition, this technology cannot be applied to study membrane protein complexes, as it detects mostly binary interactions.

Clinical Relevance

Transcriptional activators play key roles in establishing the development and activation stages of cells by mediating responses to inter- and intra-cellular signals. Accordingly, transcriptional activators represent approximately 20% of the protein coding genes of the human genome. Similarly, proteins associated with membranes total approximately one third of all proteins in a typical eukaryotic cell and execute a variety of essential cellular tasks that include cell signaling, transport of membrane-impermeable molecules and cell adhesion. Thus, characterization of novel interacting partners of transcriptional activators and membrane-associated proteins is an important parameter in understanding their function and will have a great impact on biological research and pharmaceutical target discovery. In particular, its application in linking disease pathways and tractable targets, elucidating the function of targets and refining strategies to modulate protein function will accelerate pharmaceutical R&D. The studies on protein interactions will thus provide predictors of toxicity and may be used to develop biomarkers as fingerprints for particular disorders or cellular responses.

Definition

Protein interaction analysis is one of the main fields of functional proteomics, covering an array of traditional protein chemical and newly developing techniques that center primarily either on identifying components or determining mechanisms of protein-protein interactions in both short-lived and long-lived protein complexes. The stability of a complex is determined, in part, by the surface contact area or protein interface formed between interacting proteins. Surface contact areas are generally unique for interacting pairs of proteins, with some proteins containing several protein-binding domains that permit multiple contacts in large protein complexes. ►**Chemical cross-linking**, an extension of protein chemical modification, is an established technique used to join two or more of the proteins in a complex covalently using multi-functional chemical compounds, termed ►**cross-linking reagents**. These reagents generally contain two or more functional groups that target reactive amino acid side chains on adjacent peptides located within or in close proximity to the protein interface of a protein complex. The architecture and chemical potential of the protein interface are important determinants in complex formation and have a direct impact on the type of cross-linking reagent that can be used successfully to probe the interaction.

Characteristics

Chemical cross-linking provides essentially a snapshot of binding events or other physiological processes that

require the interaction of two or more proteins. Cross-linking reagents generally sample only a few of the possible interactions that can occur throughout surface contact regions between two interacting proteins; such regions may vary in area from approximately 500–5000 Å². Although cross-linking provides information for only a fraction of the potential contacts that are possible between proteins in a complex, it can be used to determine the spatial organization of proteins in a complex, to measure the distance between interacting surface residues and to detect either small structural rearrangements or global conformational changes in proteins. Resurgence in the use of chemical cross-linking has occurred with the advent of recent advances in mass spectrometric techniques and the development of large protein data bases; the combined power of these methodologies significantly increases the potential for determining protein-protein interactions with increasingly smaller amounts of starting material.

Proteins as Chemical Reactants

Numerous physiological processes are mediated through protein-protein interactions, including enzyme catalysis, ►[muscle contraction](#), receptor-ligand binding, antibody-antigen immunocomplex formation and many others. Both structural and chemical factors (hydrogen bonding, hydrophobic and electrostatic forces) that facilitate protein-protein interactions also influence chemical cross-linking of protein complexes (1). The chemical nature of the protein is another important determinant in bioconjugation reactions. Proteins, which are also considered to be reactants in cross-linking reactions, are linear polymers containing different combinations of amino acids, each with side chains of differing chemistries varying in charge, shape, size and polarity. Cross-linking generally occurs between appropriate ►[nucleophilic](#) amino acid side chains (Table 1) at distinct sites on the protein where both limited steric constraints and the chemical environment complement the size and chemistry of the cross-linking reagent. Intramolecular cross-linking occurs only when proximal residues on one protein target are covalently linked. Chemical coupling of amino acid side chains on adjacent proteins in a complex, termed intermolecular cross-linking, can occur either at sites forming the interface or at sites in close proximity to the contact surface. In some protein complexes, over 30% of the surface area of a monomer can be subsumed by the protein interface. This comprises numerous contact sites with varying hydrophobic and/or hydrophilic potentials, partially influencing the type of cross-linking reagent that can access the sites. Protein interfaces also contain water-filled cavities, which can accommodate hydrophilic (polar) cross-linkers of appropriate size. Many enzymes have substrate-binding sites or hydrophobic patches that can

bind hydrophobic reagents. Phosphorylase kinase, a regulatory enzyme complex containing sixteen subunits, has several high affinity binding sites for the hydrophobic cross-linker, phenylenedimaleimide (Table 1), that are in close proximity to the protein interfaces between its regulatory α and β and catalytic γ subunits (2).

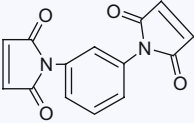

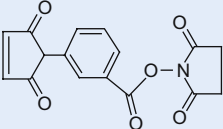

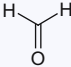

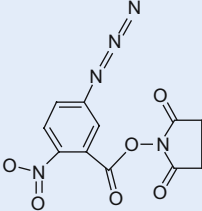

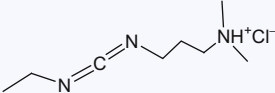

Environment of Chemical Cross-Linking

Although the chemical environment of a protein has a direct impact on its interactions with potential partners, the complexity of its environment determines the level of information that can be gained in a cross-linking experiment (3). Cross-linking either *in vitro* or *in vivo* forms the basis for the two most basic approaches to cross-linking.

In the *in vivo* approach, proteins of interest are cross-linked directly within cells or tissues. ►[Hydrophobic cross-linkers](#), such as formaldehyde (Table 1), which are able to penetrate cell membranes, are generally required for this approach. The primary advantage of cross-linking *in vivo* is that it has the potential to couple proteins in their native environment and is less likely to generate non-specific conjugates for a given group of interacting proteins, particularly if reagents with short cross-linking spans are used. The major disadvantage of this technique however, is that it is very difficult to control conditions of cross-linking within the cell or target any specific protein or protein complex. Once the cross-linker is introduced into the cell, it is free to interact with numerous potential targets, which complicates interpretation of the data.

Cross-linking *in vitro* permits greater control over the conditions of cross-linking for a given protein; in addition, the number of potential interacting partners can be adjusted, as well as the concentration of reactants, pH, ionic strength, temperature, time of cross-linking and the type of cross-linkers used. Thus both non-polar and water-soluble cross-linkers can be used to probe hydrophobic and hydrophilic sites respectively on target proteins. As opposed to the *in vivo* method, the level of purity for many proteins of interest can be manipulated, effectively reducing the number of potential conjugates that can be formed, so that ►[cross-linking patterns](#) can be more easily interpreted. The primary disadvantage of the *in vitro* technique is that proteins are modified under non-physiological conditions. Detergents and other reagents used to disrupt cells can have a deleterious affect on protein function, altering both intrinsic intermolecular interactions and extrinsic near-neighbor interactions (3). Moreover, many proteins are compartmentalized in cells, potentially limiting their accessibility to other cellular proteins, which are targeted by non-specific cross-linking only under non-physiological conditions.

Protein Interaction Analysis: Chemical Cross-Linking. Table 1 Cross-linkers

Structure and Name	Type	Characteristic Solubility	Reactive Groups	Selectivity
 1. N,N'-m-Phenylenebismaleimide	Homo-bifunctional	Hydrophobic	Maleimide	Sulfhydryl
 2. m-Maleimidobenzoyl-N-hydroxysuccinimide ester	Hetero-bifunctional	Hydrophobic	Maleimide/ N-hydroxysuccinimide ester	Sulfhydryl/ amine
 3. Formaldehyde	Mono-functional	Hydrophilic	Carbonyl	Broad/ amine
 4. N-5-Azido-2-nitrobenzoyloxy-succinimide	Hetero-bifunctional: Photo-reactive	Hydrophobic	N-hydroxysuccinimide ester/azide	Amine
 5. 1-Ethyl-3-[3-dimethylaminopropyl] carbodiimide hydrochloride	Zero-length	Hydrophilic	Carbodiimide	Carboxyl/amine

Cross-Linking Reagents

Two comprehensive treatises by Wong and Hermanson cover both the mechanisms and actions of most of the cross-linking reagents that are commercially available (4, 5). Several basic types of cross-linkers will be covered herein. Cross-linking reagents can be separated into two basic classes on the basis of their solubility in either organic solvents and/or water and are termed hydrophobic or **hydrophilic cross-linkers**, respectively. Hydrophobic cross-linkers are often introduced into aqueous environments with carrier solvents such as acetonitrile or acetone. The most commonly used cross-linkers are bifunctional reagents (Table 1); these compounds contain two reactive groups, separated by a spacer group. The reactive groups react with two neighboring amino acid side chains, covalently joining them at a distance defined primarily by the length of the spacer group. Both the geometry of cross-linking and

the solubility of the reagent are determined, in part, by the spacer group. **Cleavable cross-linkers** possess modified spacer groups that can be readily cleaved by oxidizing reagents, reducing reagents or bases. Homo-bifunctional and heterobifunctional cross-linkers are bifunctional reagents that have identical and different reactive groups, respectively. Photoactivatable cross-linkers are heterobifunctional reagents that combine both chemically active and photoreactive groups, permitting an extra layer of control in the cross-linking process. For example, the protein of interest can first be labeled with the chemically reactive group, purified to remove excess cross-linker and then cross-linked to a subsequently added target by exposing the complex to activating wavelengths of light.

Zero-length cross-linkers primarily activate the carboxyl-containing side chains of aspartate and glutamate, forming reactive intermediates that are

targeted by proximal ϵ -amine side chains of lysine. Ultimately, the two amino acids are coupled directly through an amide bond, without any residual, intervening atoms from the cross-linking reagent. The use of formaldehyde, a reagent traditionally used for fixing tissues, approximates zero-length cross-linking by forming a methylene bridge ($-\text{CH}_2-$) between two proximal lysine (or other nucleophilic) side chains, covalently joining reactants at distances between 2 to 3 Å. Other amino acid side chains are also cross-linked by this reagent, including those of tyrosine, histidine and arginine.

Detection of Cross-Linked Proteins

Cross-linking is not a stand-alone technique. In order to detect the formation of a conjugate and determine the identity of its integral components, cross-linking must be coupled with methods that enable visualization, purification and detection of cross-linked proteins. Rapid screening of cross-linked proteins is commonly carried out using polyacrylamide gel electrophoresis (▶PAGE), which is a technique used to separate proteins on the basis of their size. ▶Two-dimensional polyacrylamide gel electrophoresis techniques, which are capable of resolving proteins based on their charge and size, are employed for analysis of conjugates formed in more complex mixtures of proteins. The proteins are visualized by staining in polyacrylamide gels. There are many traditional forms of chromatography that can be used to purify cross-linked proteins from complex mixtures of proteins, including ▶size exclusion chromatography, ▶affinity chromatography, ▶hydrophobic interaction chromatography and ▶high performance liquid chromatography (HPLC). These methods often require large quantities (nanomolar amounts) of starting material to provide enough of the purified conjugate of interest for further analysis. A more popular method for analyzing conjugates combines 2D-PAGE and mass spectrometric techniques. Cross-linked proteins are first resolved and visualized by 2D-PAGE. Appropriate samples are then excised from the gel and digested directly in the gel matrix with proteases or chemical reagents that cleave proteins after specific amino acids, generating mixtures of peptides that are characteristic of the interacting proteins. The peptide digests are then analyzed by mass spectrometric techniques on the basis of their charge to mass ratios. The masses measured for peptides in the digest are then compared against those masses predicted for families of peptides that result from the cleavage of potential protein candidates with a specific cleavage reagent. Integral proteins that are cross-linked in the isolated complex are identified from best matches generated by an appropriate predictive program; sites of cross-linking on specific peptide stretches between interacting partners are determined by similar methods.

There are many Web sites (ExPASy, SWISS-PROT, NCBI and other data bases) that contain search engines and predictive programs for these forms of analyses. Analysis of fmole quantities of peptides is now possible with modern mass spectrometric techniques, significantly enhancing the potential for detecting protein-protein interactions by cross-linking.

Clinical Relevance

Protein-protein interactions underlie many critical cellular processes that are important in both the normal functioning of cells and disease states, including ▶prion diseases and ▶Alzheimer's diseases. Chemical cross-linking has proven invaluable in determining the identity, spatial organization and sites of interaction between the protein components of numerous enzyme and structural protein complexes, further defining their role in physiological processes. Additionally, chemical cross-linking is used by industries in both the areas of therapeutics and diagnostics to couple proteins with different functions. For example, enzymes catalyzing specific reactions can be tethered to proteins that bind specific targets, facilitating either their detection or destruction.

Bacteriophage display; bacteriophage surface display; phage surface display

Definition

Phage display is a technology that allows the identification of interaction partners *in vitro*. The interaction can be of any type, protein-protein, DNA- or RNA-protein or compound-protein interaction. The key feature of phage display is allowing a (poly-) peptide molecule of any type to be presented on the surface of a **bacteriophage** by fusion to one of the virion's capsid proteins. The gene corresponding to the fusion molecule is incorporated into the phage genome inside the capsid and hence results in the physical linkage between the genotype and the phenotype. By cloning different cDNA-fragments into the phage genome, large libraries of up to 10^{10} different molecules can be generated and presented on the capsid surfaces. By applying these libraries to a selection process based on affinity purification, individual binders for individual target molecules can be enriched, while non-binders are discarded. Simply sequencing the cloned DNA fragment integrated into the phage genome reveals the identity and amino acid sequence of the binder.

Characteristics

The most prominent surface display technology is based on the filamentous bacteriophage M13, but other – alternative – phage display systems, such as the phages λ , T7 or T4 are also available (Fig. 1). All bacteriophages used have in common that they infect only Gram-negative *Enterobacteriaceae* and are used in conjunction with different laboratory *Escherichia coli* strains.

The viral coat of M13 contains only five different proteins, one major and four minor proteins in ~2700 and 5 copies, respectively. By now, fusions to all five coat proteins have been exploited for phage display, resulting in mono- or multi-valent displays of combinatorial libraries (1).

The most common application is amino-terminal fusion to the coat proteins pVIII or pIII. Fusion to pVIII is primarily suitable for peptides of ~8 amino acids only, since larger inserts hamper the phage capsid assembly process. In contrast, pIII tolerates larger polypeptide inserts of up to 300 amino acids but only if phage infectivity is not disturbed. To overcome size limitations and to present proteins as large as 86 kD, **phagemid** vectors are in use, which need **helper**

Protein Interaction Analysis: Phage Display.

Figure 1 Bacteriophages used for surface display. M13 phages are most commonly used, but the number of applications for alternative systems is steadily growing. Green squares represent the foreign polypeptide displayed as a fusion protein to one of the coat proteins on the surface of the phage.

phage superinfection. The helper phage contributes all the wild type proteins necessary for phage assembly and infectivity and therefore the desired recombinant peptide/protein is presented on the phage surface as a mixture with wild type proteins (1).

In an affinity driven *in vitro* selection process called **biopanning** (Fig. 2), phage display allows the screening of these large recombinant libraries for specific binders against virtually any type of target molecule, such as proteins, peptides, nucleic acids or chemical compounds. The selection is usually carried out on immobilized target molecules attached to a solid support material, e.g. plastic surfaces of immunotubes or microtitre plates or by directed, tag-dependent attachment of the selection targets to magnetic beads. After incubation of the library with the target, unbound phage particles are washed away and specifically bound virus particles are used for infecting *E. coli*. The propagated phage population is applied to the next round of biopanning. After several rounds, single clones of binders are isolated and tested individually for specific interaction.

Thus, phage display enables the rapid isolation of desired molecules from hugely diverse libraries. However, the system has some obvious limitations. Not all eukaryotic proteins can be expressed in *E. coli* and not all proteins can be presented on the phage surface due to biological limitations, e.g. failure to traverse the membrane. Also, there are no post-translational modifications, which may play a role in naturally occurring protein-protein interactions, carried out on these proteins.

Protein Interaction Analysis: Phage Display.

Figure 2 General scheme of phage display technology. (a) Generation of a phage display library by mRNA extraction, cDNA cloning into a phagemid vector and phage propagation. (b) Biopanning: affinity-driven enrichment of target-specific binders during several rounds of selection. (c) Generation of arrayed target-specific libraries suitable for high throughput screening by picking individual clones into microtitre plates. (d) Evaluation of selected binders by biochemical means such as ELISA, dot-blot, surface plasmon resonance (SPR) or by DNA hybridization on DNA microarrays.

There are three types of phage display libraries commonly used. The libraries consist either of recombinant **antibody fragments** originating from different species including human, random peptide

sequences or tissue or organism specific cDNA expression products.

In conclusion, phage display allows for the identification of artificial ligands and of natural binding partners specific for any given target molecule (2).

Clinical Relevance

With currently more than 1800 references in PubMed, phage display is a successful technique applied to various fields of protein engineering and detection of protein-protein interactions. Here, a short overview is given of the clinically most relevant fields of application, namely antibody engineering, allergen and autoantigen discovery and finding marker molecules in cancer.

Phage Display Derived Antibodies as Global Monitoring Tools, Diagnostics and Therapeutics

Antibodies or fragments thereof are the most commonly used biological reagents for the specific detection of proteins and hence they are the most prominent and promising candidates for a fast application in proteome-wide analyses. Especially after the completion of sequencing efforts such as the human genome project, the focus is steadily shifting to post-genomic research – the analysis of the gene expression products. For successful investigation on the whole proteome level, many individual proteins have to be characterized – in parallel – in respect of function, localization, post-translational state or just simply amount. Antibody arrays are believed to fulfill all the necessary requirements for a single multiparameter experiment best and therefore, large numbers of antibodies are needed. To overcome limitations of traditional immunization and hybridoma approaches (e.g. time, cost, quantity and reproducibility), biomolecular diversity selection methods, such as phage display are advantageous. Phage display is fast and very cost-effective and monoclonal antibody fragments are simply obtained. Furthermore, the process of phage display selection has been automated and utilizing this system, specific monoclonal antibodies can be generated against virtually all types of target molecules, peptides (i.e. epitopes), proteins, small signaling molecules or chemical compounds (3). By now several studies on antibody arrays with phage display derived antibodies have been reported and it has been shown that phage display derived antibody fragments can be used for protein expression profiling.

Generally, three types of antibody libraries can be distinguished, immunized, naïve and synthetic (4). The main difference between these libraries is the origin of diversity. Immunized libraries are generated from antibody genes amplified from an immunized individual (e.g. cancer patients, patients after infection etc.), naïve libraries are generated from germline antibody

genes of several individuals (i.e. without immunization), while in synthetic libraries the variability is introduced by DNA mutagenesis. The mutagenesis can be site-directed by degenerate primers/oligonucleotides or unspecific. Until the recent introduction of transgenic mice with fully human Ig repertoires, phage display was the only way of obtaining human monoclonal antibodies. An advantage of phage display derived antibodies is the possibility of generating fully human antibodies against human proteins, which can be used for *in vivo* diagnostic or therapeutic purposes and which have no or reduced immunogenicity and show no human anti-mouse antibody effect (HAMA). To date, the majority of commercially available therapeutic antibodies are still ►chimeric or ►humanized. However, the first fully human phage display-derived antibody (HUMIRA®) for the treatment of ►rheumatoid arthritis is on the market and a number of others, still in clinical trials, are to follow.

Display of Complex cDNA Expression Product Libraries from Tissues and Whole Organisms

In recent years, the numbers of applications utilizing cDNA expression product libraries displayed on phage surfaces are steadily increasing. The general concept became available in the mid-nineties with the development of vectors allowing the cloning of cDNA libraries as C-terminal fusions to M13 phage coat proteins. Carboxy terminal fusion is desirable since cDNA inserts obtained after poly(A)-priming and reverse transcription always contain translation stop codons and prevent the synthesis of hybrid coat proteins in N-terminal fusion vectors. In M13 however, the most commonly used phage coat protein for display (pIII) presents its N-terminus to the solvent and the integrity of its C-terminus is believed to be obligatory for efficient phage assembly. The vector pJuFo overcomes this problem by utilizing the strong natural interaction of leucine zippers to indirectly display cDNA expression products on the phage surface. For this purpose, the leucine zipper domain of c-jun is cloned at the 5' terminus of the phage coat protein pIII and the leucine zipper domain of c-fos is cloned as an N-terminal fusion to the cDNA expression product to be displayed. Both domains are expressed from the same phagemid vector and during phage assembly the jun-decorated pIII heterodimerizes with a fos-decorated cDNA product in the periplasm of the host, establishing the physical link between geno- and pheno-type (1). Meanwhile, cDNA libraries were also displayed as C-terminal fusions with pVI on M13, gpD in phage λ and gp10B in phage T7, but these types of cDNA display vectors have been less frequently used. A comprehensive list of cDNA libraries displayed on phage can be found in reference 2.

The main clinically relevant applications of cDNA phage display libraries have been the identification of natural binders to antibodies derived from patients suffering from ►allergy, ►autoimmune diseases or ►cancer.

Phage Display in Allergy: Identification of Allergens

Allergies are one of the most common health threats in industrialized countries. According to the World Health Organization, as much as 20% of the Western population suffers from type-I allergic symptoms such as allergic rhinitis, conjunctivitis or asthma characterized by an immunoglobulin E (IgE) response against normally innocuous antigens (allergens). Despite the gradually increasing knowledge about the mechanisms underlying allergic reactions, only a little is known about the repertoire of allergenic proteins provoking these responses. Typically, allergenic sources such as moulds, foods and mites contain complex mixtures of IgE-binding molecules which all need to be determined to allow the production of standardized allergen panels for successful diagnosis and allergy typing or subtyping, as well as application for desensitizing.

By cloning cDNA libraries of allergenic sources into phage display vectors and sequential enrichment on IgE purified from patient serum, many allergens have been identified (5), for example, allergens from birch, peanut, house dust mite, celery, wheat and different moulds.

A very prominent example of a highly complex allergenic source is the mould *Aspergillus fumigatus*. Due to the complex nature of both the cDNA expression library and the patient's IgE, the identification of large numbers of allergens demands that large numbers of individual clones be tested. This could only be achieved by combining phage display with genomic DNA array technology. Hence, DNA arrays were generated by picking and spotting ~13,400 individual clones of an enriched *A. fumigatus* phage displayed cDNA expression library. Sequential DNA hybridization of the arrays with already known allergens of the mould and randomly chosen clones from the array resulted in an additional 67 novel allergens being identified, adding up to a total of 81 IgE-binding proteins in *Aspergillus fumigatus*. Knowledge of large numbers of allergenic molecules is clinically relevant, since the occurrence of sensitization against different allergens can vary greatly between different individuals and because allergens with lower frequency (minor allergens) have been found to be cross-reactive structures in many allergenic sources (e.g. profilin in birch and in peanut). Many of the allergens have been recombinantly expressed and evaluated for their diagnostic performance. Recombinant allergens were found to show superior specificity in comparison with allergen extracts and hence, allow for elucidating patient- and disease-specific sensitization patterns.

Further information and references to allergens can be obtained from the database of allergens (► www.allergens.org) maintained by the Allergen Nomenclature Sub-Committee of the International Union of Immunological Societies.

Phage Display in Autoimmunity: Identification of Autoantigens

Autoimmune disorders affect 3% of the population in Western countries and are characterized by an impaired immune system leading to self-reactive autoantibodies and finally, as a consequence, to tissue destruction. In spite of the clinical importance of these diseases, little is known about their aetiopathogenesis. In recent years, considerable progress has been made in understanding immune function with regard to response specificity (e.g. major histocompatibility complex and T-cell activation). However, the underlying dysregulation leading to autoimmunity is still largely unknown. As studies with identical twins have shown, next to genetic factors environmental factors are of great importance for disease manifestation and onset (6). These factors are presumably also infectious events, which – non-specifically or stochastically – lead to the inflammatory cascade. For example, systemic autoimmune rheumatic diseases are characterized by the intense activation of the humoral immune system. Here, autoantibodies and immune complexes dominate the pathogenic and clinical picture. Autoimmune disease entities are characterized by the initial activation of the (auto) immune system leading to the inflammatory cascade (initiation phase), the chronification and perpetuation of the inflammatory processes at certain sites (transformation phase) and finally the destruction of the target tissues resulting in irreversible organ damage (effector phase).

Recently, the focus has been on establishing disease-specific autoreactivity patterns, since the diagnosis of the more than 80 autoimmune disorders is primarily based on clinical symptoms. To support the diagnosis however, specific and sensitive serological tests are essential and their availability can lead to an early diagnosis of the disease. Early diagnosis and treatment is important in order to reduce disease specific tissue destruction, for example of the joint in rheumatoid arthritis and the gut lining in celiac disease. Unfortunately, for most disorders, no conclusive serological markers are available, since in many diseases the currently identified autoantigens are mostly abundant, highly conserved and/or modified and able to form big complexes often associated with RNA and situated in apoptotic blebs.

In the pursuit of novel autoantigens, the application of cDNA expression product libraries displayed on phage

is becoming more and more popular, since phage display retains a high degree of variability. This is an important feature, as pathogenetically relevant autoantigens may differ markedly from patient to patient and the number of cells expressing them may be low. Hence using phage display, autoantigens can be found which would have been missed using different methods such as cell separation techniques, even when cells were pooled.

For example, a melanocyte cDNA library displayed on phage was used to identify new autoantigens in vitiligo, a common pigmentation disorder of the skin. Furthermore, phage display was used in thyroid-specific autoimmune disorders, such as Graves' disease and Hashimoto's thyroiditis, for autoantigen discovery as well as for the investigation of antigens in autoimmune diabetes, Sjögren's syndrome, multiple sclerosis, systemic lupus erythematosus and rheumatoid arthritis. However, except for rheumatoid arthritis, none of the autoimmune disorders have yet been investigated with the combined phage display and DNA array technology described for *Aspergillus fumigatus* allergy above. By applying this technology to other autoimmune disorders, various new autoantigens will be discovered. In future, the application of these methods might allow early diagnosis of numerous autoimmune diseases.

Phage Display in Cancer: Identification of Marker Molecules and Potential Therapeutic Targets

In cancer research, phage display has just started to be used for the elucidation and identification of marker and therapeutic target molecules. In the first instance, phage display peptide libraries were applied to *in vivo* screening in mice and man for the identification of peptide sequences that specifically attach to tumor vasculature, so-called homing peptides. These peptides can potentially be used for the specific delivery of anti-cancer drugs to tumor tissues (7). Another aspect in cancer research is the use of cDNA expression product phage display libraries for the discovery of marker molecules. For example, a phage-displayed cDNA library from an invasive ductal breast carcinoma tumor was used to investigate the humoral response of breast cancer patients, identifying a number of immunogenic antigens.

Different cancer tissues or cell lines derived cDNA expression product phage display libraries, e.g. breast carcinoma, prostate cancer and colorectal cancer cell line are available. Also available are libraries from tissues frequently associated with cancer, such as brain, leukocytes, kidney and lung. The screening of these libraries will undoubtedly identify a panel of marker molecules applicable in the serological diagnosis of different cancers in the future.

Protein Interactions

Definition

Protein interactions describe the formation of non-covalent reversible complexes between proteins, usually mediated by specific macromolecular recognition sites. In a wider sense, it also comprises the mutual influence of protein molecules on their dynamics, due to either attractive or repulsive forces, which may be mediated by a variety of sources, including the solvent, electrostatic, van der Waals or hydrophobic interactions, or steric repulsive forces.

Protein Ligand Interactions Studied by X-Ray

MILTON T. STUBBS II

Institute for Biotechnology, Martin Luther University Halle-Wittenberg, Halle (Saale), Germany
stubbs@biochemtech.uni-halle.de

Definition

Knowledge of the binding mode of a ligand for its target protein – hydrogen bonding patterns, hydrophobic, electrostatic and van der Waals' interactions – can greatly facilitate the drug discovery process. X-ray crystallography is at present the only technique that can deliver information in atomic detail for both target protein and ligand simultaneously. Increasingly, crystallographic experiments involving state of the art technologies accompany the progress of potential drug candidates. Such experiments are helping us to understand the driving forces behind protein-ligand complex formation, which in turn will aid computational approaches to drug design.

Description

Rationale

The ultimate goal of any pharmaceutical research is the launching of a new drug. Currently, research efforts in the pharmaceutical industry are restricted to around 500 drug targets, most of which are proteins. The sequencing of the human genome has revealed a total of some 35,000 genes encoding for proteins. Clearly, genomics will have a massive impact on determining new drug targets and developing novel therapies.

The route from target identification to drug is long and arduous, however – it may take up to two decades to get a new compound on to the market. Even if a large number of compounds are available from natural and synthetic sources (such as compounds synthesised for other drug design efforts), it is not an easy task to find out which ones might be useful for a particular indication. This requires time consuming and expensive screening of the compound libraries. The screening process can be divided into three basic stages: primary screening of the whole or part of the library, resulting in a 'hit', modification of the hit to yield compounds of suitable pharmacological and physico-chemical properties (a 'lead') and finally refinement of the lead in biological assays to provide a drug candidate for entry into clinical trials.

While high throughput screening and combinatorial chemistry are ideally suited to generating initial hits, translation of these into leads and drugs is fraught with

difficulties. Knowledge of the detailed binding mode of hit compound to target protein can greatly enhance this process. The three dimensional structure of a protein–ligand complex allows rationalisation of the existing experimental data and facilitates further evaluation and modification of the compounds in question. The full potential of structure-based techniques is obtained when integrated into an iterative process, the drug design cycle (Fig. 1). Structural information can be achieved *via* computational methods (1), through NMR (2) or by means of X-ray crystallography (3) (Fig. 2). This last method is the subject of this chapter.

Characteristics of Protein Crystals

Protein crystals are highly ordered molecular arrays, formed by equilibration of supersaturated solutions under special conditions of pH, temperature and salt and/or solvent concentration. In the case of protein–ligand interactions, crystallisation conditions for the target molecule are usually already known. Nevertheless, each protein has its own peculiar crystallisation conditions, which can change significantly through, for example, a change in purification protocol, protein source (e.g. it is extremely rare for homologous proteins from different species to crystallise under the same conditions) or complex partner. This should always be borne in mind when attempting to repeat a published crystallisation procedure; even when the chosen protein construct is identical, it is always advisable to vary the conditions systematically to

maximise the chance of obtaining diffraction quality crystals.

Contrary to an often-held misconception, protein crystals are highly solvated (Fig. 3); up to 80% solvent content has been reported. Thus, it is possible to diffuse substrates, ligands and inhibitors into protein crystals, so that in favourable circumstances one can follow catalytic reactions and determine ligand-binding modes at atomic [resolution](#) accurately.

Protein–Ligand Interactions in Crystals: Co-Crystallisation vs. Soaking Experiments

Before a high resolution X-ray experiment can be carried out, it is necessary to introduce the chosen ligand into a crystal of the target protein. The most obvious way to do this is to co-crystallise the ligand with the protein. The ligand is incubated at a typical concentration of 1–10 mM together with the target protein prior to crystallisation. As noted above, such a small change in the protein preparation may lead to changes in crystallisation behaviour; it is therefore advisable to carry out a small scale screening (e.g. variation of the pH by ± 0.5 units, adjustment of precipitant concentrations). Ligands to be analysed often exhibit poor solubility, particularly under the often high salt conditions prevailing in the crystallisation experiment; this can be alleviated through addition of small concentrations of DMSO.

Co-crystallisation can consume large quantities of target protein. Far more convenient (and cost effective)

Protein Ligand Interactions Studied by X-Ray. Figure 1 The structure-based drug design cycle. Starting with a 'hit' or a 'lead' from biological screening, the structure of the compound is determined in the presence of the target protein. This allows analysis of the interactions made between the ligand and protein, and suggests strategies for modifying the test compound. More complete biological testing of these new generation compounds (including e.g. animal models) results in new leads whose binding mode can often differ from that of the parent compound. It is therefore necessary to go through this cycle in an iterative manner until a novel drug candidate is achieved.

Protein Ligand Interactions Studied by X-Ray. Figure 2 (a) Starting with sufficient quantities of protein, (b) crystals may be obtained given the correct biochemical conditions. (c) The crystals are measured using an X-ray camera to produce (d) a diffraction pattern. Evaluation and phasing of the diffraction pattern yields (e) an electron density whose interpretation results in (f) the three-dimensional structure of the complex under investigation.

is the establishment of a crystal soaking system. Prerequisite for such an approach is a crystal form in which the binding site of interest is free both chemically (absence of covalently bound or high affinity ligand) and crystallographically (i.e. the binding site faces towards the bulk solvent, Fig. 3). A suitable crystal is introduced into a harvesting solution containing the chosen inhibitor, which is then free to diffuse through the crystal. The harvesting solution is a modified form of the crystallisation buffer, usually containing a higher concentration of precipitant to compensate for the missing protein and serves to stabilise the crystal. As in the co-crystallisation experiments, it is possible to increase the solubility of the ligand through addition of DMSO. A practical alternative is the chemical cross-linking of the crystals using e.g. glutaraldehyde (5), allowing buffer exchange to more favourable conditions.

From Crystal to Electron Density Map

The collection and processing of X-ray data (structure factors) from protein-ligand complex crystals follow

standard crystallographic procedures. As changes in the diffraction pattern produced by the inclusion of the ligand are very small, the resulting **electron density** is very sensitive to the quality of the data. It is therefore necessary to collect a very complete data set with good merging statistics. Experience shows that it is useful to use a **resolution** cut-off where the diffraction pattern is still strong ($I/\sigma(I) > 3$ in the outermost resolution shell).

Having collected the data, the **phase problem** must be solved; this is covered elsewhere in this volume. In most cases, the structure of the target is known prior to the study of protein ligand interactions, so that the complex can be solved using difference Fourier techniques. It is then sufficient to submit the known model to a rigid body refinement prior to calculating a new electron density. Occasionally, however, it is necessary to resort to molecular replacement methods, for example when co-crystallisation results in a new crystal form. This involves positioning the known model in the new crystal cell to maximise the fit between the calculated and observed structure factors.

Protein Ligand Interactions Studied by X-Ray. Figure 3 Protein crystals are ordered molecular arrays; one protein molecule (trypsin, in yellow) is depicted here together with some of its nearest neighbours (4). As can be readily seen, large solvent channels are present through the crystal; the solvent content of protein crystals ranges typically between 30% and 80%. It is therefore possible to diffuse small molecule ligands such as substrates or inhibitors into the crystal. If the ligand-binding site faces these solvent channels (also known as ‘bulk solvent’), then soaking the crystal in an inhibitor solution will allow the inhibitor molecules to reach the active sites (shown in orange), facilitating rapid structure determinations of a large number of compounds.

The quality of the resulting electron density map is not only dependent on the quality of the experimental data, it is also very sensitive to the molecular model used. Every atom of the model contributes throughout the diffraction pattern and misplaced atoms therefore have an effect on the whole of the electron density. It is therefore extremely important to model the electron density correctly throughout the structure – not simply in the neighbourhood of the ligand. To this end, it is good practice to remove all non-covalently bound molecules (for the most part solvent molecules) from the model prior to map calculation. Unless the density for the ligand is absolutely clear (Fig. 4), it pays to check the density of the whole protein model and all solvent molecules, rebuilding where necessary. The final model should be refined in the usual way, monitoring the crystallographic R-factor $\Sigma|F_{\text{obs}} - F_{\text{calc}}| / \Sigma|F_{\text{obs}}|$ and model geometry.

Problems Associated with X-Ray Protein-Ligand Complexes

Unfortunately, there are no objective criteria for determining whether the ligand density has been

correctly modelled – the R-factor is rather insensitive to inclusion of the few atoms of the inhibitor. The interpretation of the ligand electron density is therefore highly subjective; a series of representative examples are given below.

One oft quoted criterion for the quality of a structure is that of resolution. While ambiguous electron density becomes harder to interpret at lower resolution (see Figs. 4, 5 for examples), this does not mean that low resolution studies are of no value. If the data are well phased (i.e. the model fits the density well) and the ligand has a well defined binding mode, then a 3 Å structure can be as ‘correct’ as one at high resolution. The greatest problem to be dealt with when studying protein-ligand interactions using X-ray crystallography is breaks in the electron density (Figs. 4, 5). Unlike interpreting electron density for the protein, where the covalent connections between individual atoms allow an ‘educated guess’ in regions of ambiguity, the only guides available to map the ligand are the shape of the electron density, chemical knowledge of the ligand and inspection of the protein environment. Ambiguities may arise from a variety of causes. If a region of the

Protein Ligand Interactions Studied by X-Ray. Figure 4 (a) Problems in interpreting protein-ligand interactions occur when the electron density is incomplete. In this case, the form of the density within the binding pocket clearly shows the presence of the piperidinyl/pyridinyl group in the specificity pocket of trypsin. The absence of density outside the binding pocket is a result of a lack of preferred contacts for the chloronaphthyl group. Despite the limited resolution of 3 Å, the quality of the density allows ready interpretation (note the definition of the sulphate ion) as the model (and thereby the phases) are well characterised. (b) X-ray data for the same inhibitor in a different crystal form reveals electron density for the complete ligand at a resolution of 2.1 Å. In contrast to 4(a), the chloronaphthyl group enters the specificity pocket, while the piperidinyl/pyridinyl moieties occupy a secondary binding site specific for the structurally related coagulation proteinase factor Xa. The alternative binding modes are less a result of different crystal packing effects than of alternative crystallisation conditions; crystals corresponding to 4(a) grow at a pH of 7, whilst 4(b) crystals grow at pH8 (6). The binding mode (b) could be confirmed in rat trypsin variants designed to mimic the binding pocket of factor Xa (7). This as well as Figs. 5, 6 are in stereo; focusing the left eye on the left image and the right eye on the right one will result in being able to observe the structure in three dimensions.

ligand makes no preferred contacts with ordered atoms, then the electron density becomes weak and cannot be interpreted (Fig. 4a). Alternatively, there may be incomplete binding of the compound, resulting in an overlap of densities from the ligand and from partially bound solvent molecules. An extension of this problem

is the presence of several species that bind, as in racemic or enantiomeric mixtures (Fig. 5).

Having built an atomic model, the resulting structure must be checked for validity. It is becoming apparent that the concept of 'the' structure is a gross oversimplification. However, the presence of electron

Protein Ligand Interactions Studied by X-Ray. Figure 5 (a) Electron density of the bis-benzamidino inhibitor in co-crystals with a trypsin variant at 1.8 Å resolution reveals clearly the (Z,Z)-configuration of the ligand, apparently favoured in this crystal form. (b) Soaking of the same inhibitor into a different crystal form indicates the presence of both (Z,Z) (white) and (E,Z) (green) configurations at a resolution of 2.0 Å (5). As witnessed here, the presence of several ligands and/or multiple binding modes can result in ambiguities in the electron density that are often difficult to interpret; in most cases only the dominant binding species can be identified correctly. This can be a particular problem with ligands of low occupancy with partially bound solvent molecules.

density proves that the observed structure must exist under certain circumstances. One striking example is provided by the pH dependent ligand-binding mode detected in trypsin crystals (Fig. 4) (6). Thus the conditions of the crystallographic experiment should be taken into account in interpreting the results. Furthermore, the crystal environment itself can affect the observed interaction (Fig. 6), with neighbouring molecules influencing the conformation and interactions taken up by the ligand. In such cases, it appears reasonable to assume that the binding of the compound is weak; nevertheless, multiple binding modes have been observed for strong inhibitors (unpublished

results). Such multiple crystal forms are proving highly useful as a tool for studying protein ligand interactions.

Therapeutic Consequences and Clinical Relevance

The unravelling of the human genome, as well as those of important human pathogens, promises identification of novel drug targets for the treatment of disease. However, mere knowledge of a candidate gene sequence is insufficient for the production of new therapeutic agents. Detailed information on structural aspects of protein-ligand interactions will have important repercussions for the translation of the one dimensional

Protein Ligand Interactions Studied by X-Ray. Figure 6 The binding of this inhibitor is strongly influenced by packing effects. In crystal form (a) (that also depicted in Fig. 3), the basic benzamidine function of the ligand binds to the active site in its 'target' molecule (green), whilst the terminal tosyl group nestles against the neighbouring symmetry related molecule (blue). In crystal form (b), the tosyl group is sandwiched between its 'target' and a symmetry molecule. This suggests that the tosyl group contributes little to binding, at least under the conditions prevailing in the crystal (8).

genome data into novel pharmaceuticals. While considerable progress has been made using crystallography as a tool – for example, the use of protein crystallography for screening compound mixtures (9) – our understanding of the biophysical foundations underlying these non-covalent interactions is still rather rudimentary. For example, it is still not possible to predict the affinity of a ligand accurately from the structure alone (10), particularly in cases where target flexibility is an issue (8). Nevertheless, considerable advances are to be anticipated in the near future, forming a solid basis for computational methods in drug design.

Protein array, antibody array, protein chip, antibody chip

Definition

Protein microarrays contain a defined set of proteins immobilized at high density in a geometric pattern on a solid surface, typically a glass ►microscope slide. Each single sample on this solid surface can be addressed in a similar way to the organization of samples in a multiwell plate.

Ideally the complete ►proteome of an organism, either as the proteins themselves or as highly specific capture molecules (Table 1) directed against all proteins of the proteome, is represented in a protein microarray. Both types open the possibility of monitoring time-resolved dynamic events in a cell, tissue or organism and are expected to impact biological and biomedical knowledge. Protein microarrays are envisaged as overcoming the well-known technical demands of ►standard proteome research technologies by allowing detailed studies with less material, higher throughput, better reproducibility and in less time.

According to the classification introduced by Kodadek, protein microarray applications can be divided into two principal types (1). Microarrays containing antibodies to assess the concentration of proteins are called protein detection arrays and typically antibodies are immobilized as capture agents. This type of protein microarray corresponds to the technology employed for ►RNA expression profiling. Nevertheless, as RNA expression-profiling data do not necessarily correspond to the actual protein concentration in a cell and RNA levels do not deliver information on functional aspects, protein detection microarrays are a necessary and valuable adjunct, allowing determination of the actual protein concentration in a cell. The functional properties of a large collection of immobilized recombinant proteins are usually investigated by the second category of protein microarray, the protein-function

Protein Microarrays as a Tool for Protein Profiling and Functional Proteomics. Table 1 Comparison of different capture agents for protein microarrays¹

Capture Agent	Affinity	Specificity	Production time	Amount starting material	Automation	Immobilization
Monoclonal antibody	medium-high	high	very long	high	no	difficult
Polyclonal antibody	high	medium-high	long	high	no	difficult

Antibody-like scaffold	medium	high	short	low	yes	easy
Aptamer	medium-high	medium-high	short	low	yes	easy
Imprinted polymer	low-medium	medium	short	high	potentially	n.a.

array. Both principal types of protein microarrays present unique ways to screen biochemical properties at the proteome level.

Characteristics

Fabrication of Protein Microarrays

The fabrication of protein microarrays relies on methods and instruments originally developed for production of [▶DNA arrays](#). In order to generate an addressable pattern on the microarray surface a high-precision instrument, a microarray spotter, which delivers a tiny droplet of the dissolved protein (sub-nl volume) is employed as a printing device. This results in the formation of microscopic spots approximately 200–250 μm in diameter. The distance between spots varies between 300–500 μm . In principal, proteins can be arrayed at high spatial density (1000 spots/ cm^2) and a standard microscope slide (25 mm \times 75 mm) can accommodate thousands of samples in parallel as shown in Fig. 1. The droplet can be delivered to the surface by direct contact between the tip and the solid support. In surface contact printing, the pins are dipped into the sample solution, resulting into sample uptake into [▶split pins](#) or transfer of a small volume to the tip of a solid pin. The volume delivered to the microarray surface by direct contact depends on parameters such as pin type, sample fluidity and slide surface. Drop delivery in a non-contact fashion using piezo-element based arrayers is accomplished in a more gentle way with higher precision. Up to now the use of

piezo-element based arrayers has been restricted by the comparatively low throughput.

Proteins can be immobilized on the solid surface by covalent attachment or by absorption. Covalent attachment requires the activation of the surface of a glass microscope slide with a functionalized [▶silane reagent](#). Alternatively a thin pad can be attached to the glass slide, trapping proteins into a 3-dimensional structure. Frequently, applied materials are ultra-thin polyacrylamide gel pads or nitrocellulose layers, but carbohydrate-based matrices have also been employed to generate a 3-dimensional coating. A 3-dimensional coating or a pad is assumed to accommodate the tertiary structure of proteins better than will a regular glass surface. However, in order to maintain the native character of immobilized proteins, the effect of the solid surface on the stabilization of the proteins has to be examined for each experimental set-up. Table 2 gives an overview on the different surface coatings provided by commercial suppliers.

Methods for Detection

Proteins captured on the protein microarray need to be visualized for detection. Methods such as [▶chemiluminescence](#), [▶fluorescence](#) and [▶radioactivity](#) facilitate the quantification of proteins and were successfully adapted to the microarray surface. Each method has advantages in terms of [▶sensitivity](#) and signal-to-noise ratio. Nevertheless, instruments employed for detection of microarray spots have to offer a resolution matching the small spot size.

Fluorescence-based detection is currently the most popular type of detection in microarray experiments because standard microarray readers rely on fluorescence detection to generate the experimental read-out. Therefore a huge collection of reagents is commercially available, which includes pre-labeled secondary antibodies and labeling reagents. Chemiluminescence, widely applied in ►Western blotting, although highly sensitive has drawbacks in terms of ►dynamic range and compatibility with multiplexing. However, certain types of enzymatic activity, e.g. ►kinase activities are best assessed by the incorporation of radioactive label into substrate proteins and subsequent exposure to a ►phospho-imaging plate. In addition, signal amplification based on enzymatic methods is used in protein microarray detection; for example the signal intensity has been magnified by adapting the rolling circle detection method (►RCA) to the microarray format (2) and by the application of the ►TSA method.

Applications

Protein-Detection Microarrays

A reliable method for estimating protein concentration over several orders of magnitude still presents a challenge. A specific protein has to be detected among 10,000s of other different proteins. This challenge is multiplied by the fact that the copy number of proteins varies between a few copies per cell and 100,000s copies per cell. In addition, proteins, unlike DNA, are not very stable. Many proteins quickly denature upon lysis and undergo degradation. Furthermore, proteins are ►posttranslationally modified, e.g. by ►phosphorylation, and distinguishing between different modified protein species has to be accomplished as well.

Antibodies have been widely used for the detection of proteins. The antibody-based detection of analytes was first described in 1929 and this technique was greatly advanced by the development of enzyme-linked immunosorbent assays (ELISA) in which an antibody is immobilized to a solid support to capture the

Protein Microarrays as a Tool for Protein Profiling and Functional Proteomics. Figure 2 ELISA principle.

corresponding antigen from a complex mixture of proteins. Standard ELISA techniques rely on two antigen-specific antibodies. The first antibody is immobilized onto the carrier surface while the second antibody is employed to detect the captured analyte. The immuno complex is commonly quantified using a secondary antibody that results in a readable and quantifiable signal. This mode of detection *via* a sandwich antibody complex (Fig. 2) is called indirect detection. In the late 1980s Roger Ekins opened the way to miniaturization of immune assays by the introduction of the “microspots” concept (3). According to Ekins, extremely sensitive multianalyte detection can be achieved by immobilizing antibodies in extremely small spots to a solid support. The critical point is, that in contrast to standard ELISA technology, analyte consumption can be neglected and accurate measurements are possible even at low protein concentrations. The degree of ►antibody cross reactivity and the signal-to-noise ratio are crucial for accurate protein quantification. By combining the ideas of multiplexing and increased sensitivity, the development of antibody microarrays for quantification purposes became the subject of

Protein Microarrays as a Tool for Protein Profiling and Functional Proteomics. Figure 3 (a) Antigen capture assay performed by labeling of sample proteins with a fluorescent dye. (b) Sandwich immunoassay employing two independent antigen-specific antibodies.

intense research. Protein-detection microarrays can be thought of as multiplexed ELISAs, requiring a set of highly specific antibodies. Two different strategies were developed for the detection of captured proteins on the protein microarray.

Antigen Capture Assay

The antigen capture approach requires introduction of a detectable label into all proteins of the sample. In general, a suitable marker is introduced into all proteins by covalent attachment to functional groups of specific amino acid side chains. Chemically activated fluorescent dyes are frequently used as directly readable marker. In this case, the signal-intensity is proportional to the amount of sample bound to the capture agent. Since the direct detection does not involve a signal amplification step, it is therefore of limited sensitivity (1 ng/ml). Alternatively, a small molecule ▶**hapten**, which can subsequently be recognized with a corresponding antibody, can be used. This hapten-based approach opens access to further signal amplification. The antigen capture assay is typically employed for direct comparison of two different samples and therefore requires the introduction of two different markers (indicated by a black star and white star in Fig. 3a) that can subsequently be distinguished. The read-out is ratiometric and for this reason only relative information on protein concentration is gained. The need to label the protein may present a problem: Some proteins are labeled preferentially on their antigenic epitopes and may thus escape detection. In this case the sandwich immunoassay presents an alternative.

Sandwich Immunoassay

The sandwich approach does not require the protein to be labeled and significantly lower detection levels can be achieved. In addition to the capture antibody, a second antigen-specific antibody (detection antibody) directed against a different epitope of the protein is used (Fig. 3b). The fact that independent and highly specific antibodies are required as affinity agents for each protein has slowed down the broad application of this type of assay. In sandwich immuno assays the sample preparation is less demanding and not prone to batch-to-batch variation. This approach will probably dominate microarray based immunoassay techniques. All antibody-based strategies are complicated by the fact that antibody specificity is less restricted than expected and in general foreign epitopes on different proteins will be recognized. Especially in a multiplexed assay format, this can be problematic with regard to signal specificity. Because the recognition of contaminating proteins by two independent antibodies is less likely, the application of two independent antibodies guarantees a higher degree of signal specificity. Microarray-based sandwich immunoassays have been most successfully employed for the quantitative detection of cytokines in body fluids.

Protein-Function Microarrays

The protein microarray technology provides a platform to study *in vitro* protein function on a ▶**genome**-wide or a system-wide basis. Immobilized proteins can be assayed in parallel under many different conditions and with many different samples. Functional protein arrays

are envisaged to be a promising tool for drug discovery. Thus, due to the inherent potential of process automation, protein microarrays present an ideal tool for the study of biological systems.

Whole proteome microarrays are difficult to achieve for higher organisms and have only been realized for the yeast proteome. The greatest obstacle so far has been to produce a high number of pure ►recombinant proteins in parallel. This step initially requires the ►cloning of ►cDNAs into appropriate ►expression vectors. In addition to a simple cloning strategy, protein function arrays covering the full genome require access to normalized ►cDNA libraries.

Protein-Protein Interactions

In functional genomics, protein microarrays are employed to screen a defined collection of proteins for interactions with a certain protein employed as a probe. This technique provides a controlled *in vitro* basis to study protein function on a system-wide or genome-wide basis. In the latter case, the protein microarray contains an ordered library of recombinant proteins representing the complete proteome of an organism. However, studying a limited set in a low-throughput fashion has proven to be successful for the characterization of unknown proteins.

The advantage of this approach is that conditions such as pH, ionic strength, temperature and state of posttranslational modification can be controlled in the microarray experiment. On a genome-wide basis, this approach has been realized for yeast. Pioneering work has been carried out by analyzing the entire proteome of the budding yeast *S. cerevisiae* for kinase substrates of all yeast kinases (4). Microscope slides were spotted with 5,000 different proteins cloned from yeast and expressed with an epitope tag for detection. The microarray was incubated with fluorescently labeled calmodulin to probe for calmodulin binding proteins. Based on the sequence analysis of all calmodulin-binding proteins, a novel binding site for calmodulin was identified that was not detected by a yeast-two-hybrid screen. The outcome puts this microarray-based approach next to established technologies employed to probe for protein-protein interactions. The analogous protein microarray representing the human proteome has not been produced. The complex ►exon-intron structure of the human genome makes the task of converting this information into functional recombinant proteins more challenging. In addition, the human genome is 6–7-fold larger than the yeast genome. However, 30,000 genes of the human genome are represented on large filter sets and bacterial protein expression can be induced on these filters (5).

Protein-Small Molecule Interactions

A proteome array can be screened with drugs to identify proteins that interact with the investigated

compound. This was first achieved with the yeast protein microarray and demonstrated the usefulness of protein microarrays in probing for interactions between proteins and small molecules. Interaction of a specific binding protein with several small molecules with dissociation constants in the micro-molar to nano-molar range was demonstrated. The same array was also employed to probe for lipid binding proteins. In a different experiment, binding of radioactive GTP to microarray-immobilized GTP-binding proteins was performed. A dose response analysis for one of the proteins on the array revealed that results were close to published data (6).

Immune Profiling and Antibody-Specificity Profiling

Protein microarrays spotted with well-known autoantigens can be used to screen serum for the presence of autoantibodies. For certain types of ►autoimmune disease, with well-known autoantigens, the use of microarray technology can increase throughput and reduce sample size. Novel autoantigens can be identified by employing proteome-wide protein microarrays. Recent reports have identified tumor specific autoantibodies in cancer patients. This may lead the way to the identification of new molecular markers useful for the early detection of certain tumors.

Clinical Relevance

Protein microarray technology has an impact on clinical diagnostics. The analysis of cytokines has been multiplexed and commercial kits are available for parallel detection of cytokines. Compared to standard ELISA technology, the sample consumption during analysis is insignificant and detection therefore volume-independent.

In addition, protein microarrays will soon influence the diagnostics of autoantibodies, screening for autoantigens, identification of tumor-specific antibodies and the characterization of antibody specificities in general.

Protein Misfolding Disorders

► Defective Protein Folding Disorders

Protein Phosphatase-2A

Definition

Protein phosphatase-2A (PP2A) is a heterotrimeric serine-threonine phosphatase that is involved in Wnt signaling and many other signaling pathways. It catalyses the cleavage of phosphate groups, e.g. the conversion of fructose-1, 6-biphosphate in fructose 6-phosphate at release of inorganic phosphate.

Definition

Protein prenylation is a post-translational modification involving the attachment of a 15 or 20 carbon

►isoprenoid group to a protein. In each case the ►prenyl group is attached to a specific cysteine amino acid residue near the C-terminus of the protein *via* a ►thioether linkage. The ►farnesyl (C15) group consists of three repeating isoprene subunits, while the ►geranylgeranyl group (C20) consists of four of such subunits. Two chemical representations of a farnesyl group attached to the C-terminal cysteine of a protein are shown below in Fig. 1. Protein prenylation is a three-step process that involves attachment of the isoprenoid followed by proteolysis and ►methyl esterification of the C-terminal prenylated cysteine. In most cases, this modification is essential for the proper function of the targeted protein. Protein prenylation occurs only in eucaryotes and is of particular interest because it is found in proteins involved in signal transduction pathways that regulate critical cellular functions including cell growth and proliferation. The enzyme ►Ras is farnesylated and is an example of such a protein. Since specific mutations in *ras* genes result in oncogenic variants that lead to uncontrolled cell proliferation, molecules that interfere with the prenylation and subsequent processing of Ras can stop the growth of cells that contain transforming *ras* mutants. Such compounds may have utility as anticancer drugs and there are currently a number of candidates in clinical trials for this purpose.

Characteristics

Protein prenylation was first discovered in 1979 by Kamiya in studies of fungal mating factors; these are short polypeptides involved in signaling between different cells. Although originally considered to be a biochemical oddity, it is now clear that protein prenylation is widespread in eucaryotes and is of critical importance for a variety of proteins involved in oncogenesis, secretion, nuclear structure and signal transduction (1). A large number of prenylated proteins

Protein Prenylation. Figure 1 Examples of structural representations prenyl groups. Right: conventional line-angle representation of a farnesylated protein. Protein Prenylation. Figure 2 Pathway for the process of protein prenylation exemplified with farnesylation.

have been identified and the number is increasing rapidly. Farnesylated proteins include Ras proteins, lamins, transducin, mating factors, rhodopsin kinase and cGMP phosphodiesterase- α . Geranylgeranylated proteins include numerous members of the Ras superfamily of small **G-proteins** and many others; this latter modification is the more common of the two. There are also examples of proteins that can be modified with more than one type of prenyl group. It has been estimated by growth of mammalian cells on ^3H -mevalonic acid, the precursor for all isoprenoids, that as many as 5% of all proteins are isoprenylated. This prevalence, coupled with the central role that many of these modified proteins play in cellular signaling, underscores the significance of this post-translational modification.

Enzymology of Prenylation Process

Prenylation is the first reaction in a three-step maturation process that involves initial attachment of the prenyl group to a specific cysteine residue present near the C-terminus of a protein *via* the formation of a thioether bond. This reaction is catalyzed by a class of enzymes called protein prenyl transferases that use either farnesyl diphosphate or geranylgeranyl diphosphate as the source of the prenyl group. There is at least one protein farnesyl transferase and two different protein geranylgeranyl transferases located in the cytosol of all eucaryotic cells. Following this event, the resulting prenylated proteins manifest increased hydrophobicity that targets them to the cell membrane, where the residues C-terminal to the prenylated cysteine are removed by an endoprotease to yield a polypeptide possessing a prenylcysteine at its C-terminus. The final step in the prenylation process involves the methylation of the **anionic C-terminal**

carboxylate to generate a neutral methyl ester. That reaction is catalyzed by a methyltransferase that utilizes S-adenosyl methionine (SAM) as the methyl group donor. The resulting mature prenylated proteins have a high affinity for the cell membrane due to the presence of the nonpolar prenylcysteine methyl ester positioned at their C-terminus; a summary of the overall prenylation process is shown in Fig. 2. In contrast to other lipid modifications of proteins such as palmitoylation, prenylation is not reversible. Instead, it appears that prenylated proteins are degraded by proteases down to prenylated cysteines, which are then oxidatively deprenylated to free cysteine and the corresponding prenyl aldehydes.

Protein Prenyl Transferases

Of the enzymes that participate in the process of protein prenylation, the protein prenyl transferases are the best understood. Protein farnesyl transferase (PFTase) and protein geranylgeranyl transferase (PGGTase) types I and II have been cloned from a number of species ranging from yeast to mammals. In an effort to understand how certain proteins are targeted for prenylation, considerable effort has been devoted towards determining the primary sequence elements that dictate prenylation. Several classes of signals for prenylation have been described. The most general motif is the **CAAX box** which represents the carboxy-terminal four residues of the prenylated protein. Proteins terminating in CAAX may be either farnesylated or geranylgeranylated depending on the identity of the terminal X residue. In addition to the simple CAAX motif, other classes of geranylgeranylation signals exist that are considerably more complex in their behavior. PFTase and PGGTase I that recognize the CAAX motif are composed of two subunits, α and

β . These heterodimeric proteins share a common α subunit but differ in their β subunits. The type II (prenylates a non-CAAX sequence) PGGTase has been shown to be a heterotrimer composed of a similar $\alpha\beta$ core together with a third type of subunit termed an escort protein. These enzymes are zinc containing metalloenzymes that use coordination of the substrate-derived thiol from cysteine with Zn(II) to form a more [▶nucleophilic](#) Zn(II)-thiolate complex. Steady state kinetic analyses of the mammalian and yeast prenyl transferases clearly indicate that these enzymes catalyze prenyl group transfer *via* sequential pathways in which the isoprenoid binds first followed by protein substrate binding. [▶Peptides](#) as short as four residues that contain a CAAX box can substitute for the peptide substrate; this has greatly facilitated studies with these enzymes. A number of x-ray crystal structures of PFTase alone and in complexes with isoprenoids and peptide substrates have been solved. These structures have proved to be particularly useful for understanding the substrate specificity of this enzyme. A representation of the overall PFTase structure and a close up view of the active site are shown in Fig. 3 (2).

Medicinal Chemistry of Protein Prenylation

A major motivation for research on protein prenylation came from the observation that Ras proteins are farnesylated and that inhibition of Ras prenylation reverses the cancer promoting effects of oncogenic ras mutants. That discovery suggested that the development of PFTase inhibitors ([▶FTIs](#)) might lead to the creation of a new class of highly specific anticancer drugs distinct from the more common but less specific DNA damaging agents (3). In response to this, chemists have synthesized a diverse array of molecules that

inhibit PFTase (4, 5). These compounds can be broken down into several classes including [▶peptidomimetics](#) that incorporate features of the CAAX box substrate described above, isoprenoid mimics that include elements of the farnesyl group and bisubstrate inhibitors that combine features of both. Natural products that inhibit PFTase activity have also been isolated. Representative structures for each of these classes are given in Fig. 4. To date, the peptidomimetic class has shown the greatest promise and has been investigated the most. Interestingly, the molecules in this class have been developed using a variety of approaches. Some have been developed from CAAX box peptides while others have been created by grafting key structural features from CAAX box peptides onto rigid molecular scaffolds. High throughput screening of large libraries of existing drug collections has also yielded useful leads. Using similar approaches, inhibitors of PGGTase have also been developed. In most cases the above inhibitors were initially evaluated using *in vitro* enzyme assays, although many have been examined in cell based systems and a few have progressed to animal testing and human clinical trials. A limited amount of work has also been done on designing inhibitors that target the enzymes involved in the proteolysis and methylation of prenylated proteins, although the utility of such compounds for medical purposes is currently unclear.

Function of Protein Prenylation

There are currently two distinct roles for protein prenylation in biological systems. One of these is to increase the hydrophobicity of proteins and cause them to associate with the cell membrane by insertion of the isoprenoid into the lipid bilayer. Such targeting allows

Protein Prenylation. Figure 3 Some structural features of proteins involved in the process and function of prenylation. Left: structure of PFTase showing the alpha subunit (blue), beta subunit (white), FPP (red), clinical candidate drug L-739,750 and Zn(II) (yellow). Center: close up view of the active site of PFTase showing the bound drug (same color scheme as Left). Right: complex between RhoGDI (white) and CDC42 (red) showing the C-terminal geranylgeranyl group (green) from CDC42 occupying an extensive binding pocket present in RhoGDI.

Protein Prenylation. Figure 4 Representative examples of different types of farnesyl transferase inhibitors (FTIs).

them to interact with other proteins involved in signal transduction pathways. For Ras proteins, this appears to be the function of prenylation. Under normal conditions farnesylated Ras associates with the membrane; however, in cells treated with PFTase inhibitors, the (unfarnesylated) Ras localizes to the cytosol and is thus incapable of interacting with its requisite signaling partner proteins. A second role for prenylation is based on the idea that there are specific prenyl group receptors or binding sites on other proteins. It has been shown that prenylation is required for protein-protein interactions in a number of cases. One of the clearest examples of this type of interaction occurs in the complex between Rho-GDI and CDC42 whose structure has been solved by x-ray crystallography. CDC42 is a geranylgeranylated protein involved in the regulation of cytoskeletal assembly while Rho-GDI is a modulator of CDC42 activity (6). The structure of the complex of these two proteins (Fig. 3, right) clearly shows the geranylgeranyl group from CDC42 enveloped within a lipid-binding cavity present in Rho-GDI. Thus, at least in some cases, it appears that prenyl groups play an important role in stabilizing protein-protein interactions, although how commonly this occurs is presently not clear.

Clinical Relevance

Prenylation and Tumor Biology

As noted above, the initial motivation for the development of FTIs stemmed from the observation that inhibition of farnesylation of Ras oncoproteins stops the growth of certain tumor cells. Since Ras proteins participate in a number of signaling pathways, it is not surprising that cancer cells expressing oncogenic Ras exhibit a broad range of phenotypic and biochemical effects when treated with FTIs; while it is clear that treatment of FTIs prevents the farnesylation of Ras, the mechanism by which this event causes growth arrest or cell death is unclear. FTIs have been implicated as inhibitors of angiogenesis and the cell-cycle but the precise molecular mechanisms underlying those events

remain controversial. A significant complication in studies of FTI action is that these compounds also act on tumor cell lines lacking Ras mutations. While some of these cell lines are characterized by oncogenic mutations in proteins that act upstream from Ras and can signal through normal Ras, others cause transformation *via* Ras independent pathways. Given that there are more than 20 farnesylated proteins in a mammalian cell, this raises the question of whether FTIs act, at least in part, by inhibiting the prenylation of other key proteins; efforts to identify such proteins are in progress.

Clinical Trials of FTIs for Cancer Treatment

Currently, a number of FTIs are being examined in human clinical trials (7, 8). The structures of four of such drug candidates are shown in Fig. 5. These compounds have been used to treat a broad range of advanced human cancers in Phase 2 and Phase 3 trials. Unfortunately, the results of these experiments have not been promising. While the drugs have been generally well tolerated with little discernable toxicity, no significant positive results have been observed when these drugs have been administered alone. However, the fact that FTIs act by a mechanism (inhibition of protein prenylation) that is distinct from other types of chemotherapeutic drugs suggests that these new molecules could have significant application in combination therapy approaches. Accordingly, a large number of trials involving FTIs administered in combination with drugs such as 5-fluorouracil, gemcitabine, cisplatin, paclitaxel and several others have been performed. FTIs have also been used in concert with radiation therapy. The results of these combination treatments have been more positive, including several cases of partial or complete remission or disease stabilization.

Future Directions for Prenylation Research

Given that clinical trials are still in their early stages and that much needs to be learned about the timing and administration of FTIs in combination modalities, it is

Protein Research Foundation. Figure 5 Structures of FTIs in human clinical trials.

too soon to know whether FTIs will be useful agents for cancer therapy. However, it is noteworthy that the discovery and subsequent biochemical studies of protein prenylation have led to new ideas about how cancer and other human diseases might be treated. The ubiquitous occurrence of protein prenylation in fungi, protozoans, mammals and viruses coupled with the complex biochemistry of prenylation that involves a number of enzymes and prenyl group receptor proteins suggests that there are a plethora of possible targets for drug development. Research on the chemistry and biology of protein prenylation is an exciting area and will remain so for many years.

volkhard.helms@bioinformatik.uni-saarland.de

Definition

The expression *ab initio* protein structure prediction is used for theoretical or computational approaches that aim at predicting the three-dimensional structure of a folded protein from its amino acid sequence alone. Although significant progress has been made in this area over the past fifteen years, this task is still considered a grand challenge project. *Ab initio* structure prediction actually involves two difficult parts: (a) sampling the large accessible conformational space of a polypeptide chain to identify putative low energy conformations, and then (b) picking the most favourable structure among those in terms of its **free energy**.

Due to the availability of more and more experimentally determined protein structures deposited in the protein data base (**www.rcsb.org**), alternative knowledge based methods such as **homology modelling** or threading are nowadays considered more reliable than *ab initio* methods, as soon as sequence similarity to proteins with known structure can be exploited. Also, these methods provide results much faster than *ab initio* methods.

Nonetheless, *ab initio* structure prediction has its own value because (i) certain protein folds may forever escape experimental structure determination, (ii) because it is now being estimated that up to twenty percent of all proteins may be fully or partially unstructured and (iii) because some of the *ab initio* methods also allow the investigation of the folding pathways of proteins.

Description

According to Anfinsen all of the information necessary for a protein to fold to the native state resides in the protein's amino acid sequence. In the absence of large kinetic barriers in the free energy landscape, this suggests that the native conformations of most proteins are the lowest free energy conformations for their sequences.

According to the “new view of protein folding” (1) that became popular during the late 1990's folding does not proceed as a naïve random search of the polypeptide chain on a “golf-course” model of the energy surface.

Instead, the free energy surfaces are in general funnel-shaped with the native, folded state at the bottom. The **protein folding** process can thus be thought of as a diffusional motion on such surfaces. The important implication for structure prediction is that this characteristic property allows one to concentrate the sampling efforts on favourable regions of the conformational space.

Successful structure prediction requires a free energy function sufficiently close to the true potential for the native state to be at one of the lowest free energy minima, as well as a method for searching conformational space for low energy minima. *Ab initio* structure prediction is challenging because current potential functions have limited accuracy and the conformational space to be searched is vast. Therefore, many methods use reduced representations, simplified potentials and coarse search strategies in recognition of this resolution limit.

Brute-Force Sampling Without Bias: Molecular Dynamics

Molecular dynamics simulations solve Newton's equation of motion to follow the atomic motions in a molecular system. They are the method of choice to describe the equilibrium dynamics of folded proteins. When combined with an efficient continuum description of the surrounding solvent, they are now able to generate microsecond long simulations within a few days of computing time. This is sufficient to study the folding of isolated secondary structure elements, of small peptides and of fast folding single domain proteins.

Alternatively, the group of Vijay Pande (Stanford) has attracted nearly one hundred thousand volunteers who downloaded their simulation software and computed short folding trajectories on their home PCs (2). This model of dividing a grand task into many small tasks is perfectly adapted to the paradigm of distributed computing. Assembling the individual results into a big picture then allows characterisation of the folding landscape of fast-folding proteins up to 60 residues in length. These calculations belong to the world's largest computational efforts to date.

Another promising approach to increase the folding efficiency is based on multicanonical multi-replica simulations where many simulations of the same system are run in parallel at different temperatures. At regular intervals, the systems may exchange particle velocities, thus enhancing the likelihood of the systems overcoming energy barriers.

Smart Sampling: Use Information About Preferred Conformations

As mentioned above, it is usually not necessary to exhaustively search the huge conformational space of a

polypeptide chain. “Rosetta” (3) is one of the most successful modern methods for structure prediction. It uses a precomputed set of preferred conformations of nine residue long sequence stretches extracted from the ►protein database. An optimisation algorithm then randomly assigns these conformations to short segments of the target sequence and scores their suitability by an energy function. The main advantage of methods like this one over simpler Monte Carlo schemes is that relatively large structural changes can be accomplished by a few optimisation trials and again only favourable regions of the conformational space need to be explored.

Smart Sampling: Concentrate on Important Degrees of Freedom

Another way of reducing the computational complexity is to restrict the conformational search to the torsional degrees of freedom. In doing so, it becomes advantageous to use techniques such as internal coordinate Monte-Carlo (4) that provide the advantage of a seven-fold reduction of degrees of freedom over conventional optimisation in Cartesian coordinates. Successful applications include optimisation of protein loops or of terminal segments of proteins that remained unresolved in experimental structure determinations.

Structure Prediction of Membrane Proteins

Membrane proteins make up about 30% of the human genes and are drug targets for about half of the known drugs. Despite their great significance, only about thirty structures of membrane proteins have been determined so far, compared to 25,000 structures of soluble proteins. The reasons for this are of a technical nature; membrane proteins don’t like to crystallize in three dimensions etc. Therefore, applying molecular modelling to generating structural models of membranes is a highly rewarding area.

In the hydrophobic bilayer environment, the backbone atoms of the polypeptide chain have no other alternative for satisfying their hydrogen bonding capacities than folding into alpha-helices (or beta-sheets for proteins in the outer membranes of bacteria). Therefore, structure prediction of the transmembrane parts can be considered as a task of simply assembling a set of seven or more alpha helices in more or less straight conformations.

Recent crystal structures, e.g. of the CIC channel, revealed that this simple picture is not generally true, but it may still apply to a number of classes of membrane proteins like ►G-protein coupled receptors.

Structural Refinement of Coarse Models

After generating an atomic model, ►molecular mechanics methods (energy minimisation and ►molecular

dynamics simulation) can be used to energetically relax strained regions of the modelled structure. This is often done in a hierarchical manner, e.g. first relaxing the side chains while keeping the modelled backbone fixed and then relaxing everything. Care should be taken about using a suitable environment (aqueous solvent or membrane environment).

Clinical Applications

Can, in this (post-)genomic era, *ab initio* protein structure predictions play a practical role in the drug discovery process? Yes. Although it is not always possible to deduce a protein’s function from its three-dimensional structure, low to moderate resolution structures may be suitable for predicting the biochemical/enzymatic function of a protein by matching to a known active site template extracted from some other previously solved structure. Using such template matching, one can suggest in many cases what the protein does or suggest a small number of experiments to establish its function.

Also, if one has a known inhibitor, one can use these predicted low-resolution structures to predict where it binds (5). Even if it turns out that one cannot predict the best lead molecule – if one could guarantee that such a lead is in the top 100 or 1,000 compounds, this could accelerate the drug discovery process and reduce its cost.

The clear direction for the future is to elucidate the role that proteins play in cellular pathways in order to pick and choose those that are likely to be “druggable.” Preliminary indications are that structure prediction can assist in the automated assignment of proteins to known pathways – a first step in this process.

Protein Tags

KAY TERPE

Proteins and Nucleic Acids, IBA GmbH, Göttingen, Germany
terpe@iba-go.com

Definition

A polypeptide or protein fused to a protein of interest allowing a single step purification of the protein of interest on a specific matrix is termed a protein or ►**affinity tag**. Protein tags are mainly used in the field of protein purification, detection and localization and are therefore an important tool for protein binding studies and for protein complex analysis. Most vectors and ►**expression systems** designed to produce the tagged fusion protein enable recombinant protein production in prokaryotic or eukaryotic cell systems for cost efficient ►**large scale protein production**.

Characteristics

Affinity or protein tags share the following features: (a) one-step adsorption purification, (b) a minimal effect on tertiary structure and biological activity of the protein of interest, (c) easy and specific removal to retrieve the native protein, (d) simple and accurate assay of the recombinant protein during purification and (e) applicability to a number of different proteins. The most frequently used systems are: Arg-Tag, calmodulin-binding peptide, cellulose-binding domain, DsbA, c-myc-tag, glutathione S-transferase, FLAG-tag, HAT-tag, His-tag, maltose-binding protein, NusA, S-tag, SBP-tag, Strep-tag and thioredoxin (1). Other not so frequently used tags are Protein A, Protein G, Z domain, Avi-tag, PinPoint-tag, Bio-tag, T7-peptide, V5-peptide, hemagglutinin A and Glu-Glu. In general, small size protein tags have not so much influence on the ►**fusion protein** as larger tags. Small size protein tags consist of a maximum of 12 amino acids, medium size tags of a maximum of 60 amino acids and large tags of more than 60 amino acids.

Small Size Tags

Polypeptide tags with a maximum of 12 amino acids can be defined as small size tags.

The Arg-tag was first described in 1984 and usually consists of five or six arginines. Arginine is the most basic amino acid (1). Arg 5-tagged proteins can be purified on the cation exchange resin SP-Sephadex, to which most of the contaminating proteins do not bind. After binding, the tagged proteins are eluted with a linear NaCl gradient at alkaline pH. Polyarginine might affect the tertiary structure of proteins whose C-terminal region is hydrophobic. The C-terminal series of arginine residues can be removed by carboxypeptidase B treatment. This enzymatic process has been successfully used in several instances, but has often been limited by poor cleavage yields or by unwanted cleavage occurring within the desired protein sequence. The Arg-tag can be used to immobilize functional proteins on flat surfaces; this is important for studying interactions with ligands. While the Arg-tag is not used very often, in combination with a second tag it can be an interesting tool for protein purification.

The His-tag was first described in 1987 (1, 3) and usually consists of from five up to ten histidines. Histidine is the amino acid that exhibits the strongest interaction with immobilized metal ion matrices, as electron donor groups of the histidine imidazole ring readily form coordination bonds with the immobilized transition metal. ►**Immobilized metal-affinity chromatography (IMAC)** (1, 2) is based on the interaction between a transition metal ion (Co^{2+} , Ni^{2+} , Cu^{2+} , Zn^{2+}) immobilized on a ►**matrix** and specific amino acid side chains. Hochuli has developed a nitrilotriacetic acid (NTA) adsorbent for metal-chelate affinity chromatography. Other materials like iminodiacetic acid (IDA), carboxymethylaspartate (CMA) and a specific silica matrix (SiMAC) are also applicable. Peptides containing sequences of consecutive histidine residues are efficiently retained on IMAC. Following washing of the matrix material, peptides containing polyhistidine sequences can be easily eluted by either adjusting the pH of the column buffer or by adding free imidazole (Table 1). The His-tag is also a useful tool for purifying recombinant proteins under denaturing conditions with urea or guanidinium HCl.

The Strep-tag was first described in 1993 and consists of eight amino acids (for the sequence, see Table 2). The core of the Strep-tag is a histidine-proline-glutamine sequence. The tag binds to the biotin-binding pocket of streptavidin. A streptavidin mutant with a specific mutation at positions 44, 45 and 47 has a higher affinity for the Strep-tag than the native form. The streptavidin variant is called Strep-Tactin. In physiological buffer conditions, Strep-tagged proteins are bound to the biotin-binding pocket and can be eluted gently with biotin derivatives (1, 4). Elution is also possible by transiently reducing the pH. Elution with 2.5 mM desthiobiotin is recommended. The matrix can be regenerated with 4-hydroxy azobenzene-2-carboxylic

Protein Tags. Table 1 Matrices and elution conditions of affinity tags

Affinity Tag	Matrix	Elution condition
Arg-Tag	Cation-exchange resin	NaCl linear gradient from 0 to 400 mM at alkaline pH > 8.0
His-Tag	Ni ²⁺ -NTA, Co ²⁺ -CMA (Talon)	Imidazole 20 to 250 mM or low pH
FLAG-Tag	Anti-FLAG monoclonal antibody	pH 3.0 or 2-5 mM EDTA
Strep-Tag II	Strep-Tactin (modified Streptavidin)	2.5 mM desthiobiotin
c-myc-Tag	Monoclonal antibody	Low pH
S-Tag	S-fragment of RNaseA	3 M guanidine thiocyanate, 0.2 M citrate pH 2, 3 M magnesium chloride
HAT-Tag (natural histidine affinity Tag)	Co ²⁺ -CMA (Talon)	150 mM imidazole or low pH
Calmodulin-binding peptide	Calmodulin	EGTA or EGTA with 1 M NaCl
Cellulose-binding domain	Cellulose	Family I: Guanidine HCl or urea > 4 M
SBP-Tag	Streptavidin	Family II/III: Ethylene glycol 2 mM biotin
Chitin-binding domain	Chitin	Fused with Intein: 30-50 mM dithiothreitol, β -mercaptoethanol or cysteine
Glutathione S-transferase	Glutathione	5-10 mM reduced glutathione
Maltose-binding protein	Cross-linked amylose	10 mM maltose

acid, which is yellow in solution and red when bound on the matrix. The binding conditions are very specific and buffer conditions are variable. Purifications under anaerobic conditions, with chelating agents, with low or high salt concentration, with non-ionic, ionic and zwitter-ionic detergents are possible. The Strep-tag is a useful tool for [▶protein-protein interaction](#), purifying membrane proteins and [▶protein chips](#).

The FLAG-tag was first described in 1988 and consists of a short, hydrophilic 8-amino-acid peptide (for the sequence, see Table 2). The FLAG peptide binds to the antibody M1. Whether binding is calcium-dependent or -independent remains controversial. Additional targets are the monoclonal antibodies M2 and M5, each with different recognition and binding characteristics. The system is non-denaturing and thus allows active fusion proteins to be purified. The complex can be dissociated by chelating agents such as EDTA or by transiently reducing the pH (Table 1). The FLAG-tag can be removed by treatment with enterokinase, which is specific for the five C-terminal amino acids of the peptide sequence. A disadvantage of the system is that the monoclonal antibody purification matrix is not as stable as others, e.g. Ni-NTA or Strep-Tactin.

The murine anti-c-myc antibody 9E10 was developed in 1985 (5) and is used as an immunochemical reagent in cell biology and in protein engineering. The antibody epitope of eleven amino acids (for the sequence, see Table 2) can be expressed in a different protein context and still confer recognition by the 9E10 immunoglobulin. The c-myc-tag has been successfully used in Western blot technology, immunoprecipitation and flow cytometry. It is therefore useful for monitoring expression of recombinant proteins. The successful co-immunopurification of interacting proteins expressed in *Agrobacterium*-transformed *Arabidopsis* cells was also reported. C-myc-tagged proteins can be affinity-purified by coupling Mab 9E10 to divinyl sulphone-activated agarose. The washing conditions are physiological followed by elution at low pH, which could exert a negative effect on protein activity. It is a widely used detection system but is rarely applied for purification.

Medium Size Tags

In general, polypeptide and protein domain tags with a minimum of 13 and a maximum of 60 amino acids can be defined as medium size tags.

Protein Tags. Table 2 Sequence and size of affinity tags

Tag	Residues	Sequence	Size (kDa)
Polyarg-Tag	5-6 (most 5)	RRRRR	0.80
Polyhis-Tag	2-10 (most 6)	HHHHHH	0.84
FLAG-Tag	8	DYKDDDDK	1.01
Strep-Tag II	8	WSHPQFEK	1.06
c-myc-Tag	11	EQKLISEEDL	1.20
S-Tag	15	KETAAAKFERQHMS	1.75
HAT-Tag	19	KDHLIHNVHKEFHAAHNK	2.31
3xFLAG-Tag	22	DYKDHDGDYKDHDIDYKDDDDK	2.73
Calmodulin-binding peptide	26	KRRWKKNFIAVSAANRFKKISSSGAL	2.96
Cellulose-binding domains	27-189	Domains	3.00-20.00
SBP-Tag	38	MDEKTTGWRGGHVVEGLAGELEQLRARLEHHPQGQREP	4.03
Chitin-binding domain	51	TNPGVSAWQVNTAYTAGQLVTYNGKTYKCLQPHTSLAGWEPSNVPALWQLQ	5.59
Glutathione S-transferase	211	Protein	26.00
Maltose-binding protein	396	Protein	40.00

The S-tag was first described in 1990 and consists of 15 amino acids (for the sequence, see Table 2). The sequence of the fusion-peptide allows detection by a rapid, sensitive homogeneous assay or by colorimetric detection in Western blots (1). The system is based on the strong interaction between the 15-amino-acid S-tag (Table 2) and the 103-amino-acid S-protein, both of which are derived from RNaseA. The S-protein/S-tag complex has a k_d of $\sim 0.1 \mu\text{M}$ which depends on pH, temperature and ionic strength. The tag is composed of four cationic, three anionic, three uncharged polar and five non-polar residues. This composition makes the S-tag soluble. The S-tag rapid assay is based on the reconstitution of ribonucleolytic activity. Tagged proteins can be bound on S-protein matrices. The elution conditions are very harsh, e.g. buffer with pH 2 (Table 1); however, cleaving the tag with protease is recommended to get functional proteins.

The HAT-tag was first described in 1999 and consists of 19 amino acids. It is a natural poly-histidine affinity tag (see His-tag) and has been developed to purify fusion

proteins under mild conditions. Purification with Co^{2+} -CMA resulted in higher elution product purity. Adsorption of weakly bound unspecific proteins was eliminated by using 5 mM imidazole in the equilibration and loading buffers and 150 mM imidazole was used to elute the HAT-tagged proteins. Elution of tagged proteins was also possible by decreasing the pH to 5.0. Urea turned out to have a much stronger negative effect on the binding of HAT-tagged proteins than guanidinium HCl.

The 3xFLAG system has been developed to improve the detection of the FLAG-tag, which was first described in 1988. This three-tandem FLAG epitope consists of 22-amino-acids (for the sequence, see Table 2) and can detect up to 10 fmol of expressed fusion protein. The 3x FLAG-tag binds in the same manner as the FLAG peptide to the antibody M1. The system is non-denaturing and thus allows active fusion proteins to be purified. The complex can be dissociated by chelating agents such as EDTA or by transiently reducing the pH (Table 1). The 3x FLAG-tag can be

removed by treatment with enterokinase, which is specific for the five C-terminal amino acids of the peptide sequence.

The calmodulin-binding peptide was first described in 1992. The peptide has 26 residues (for the sequence, see Table 2) derived from the C-terminus of skeletal muscle myosin light-chain kinase, which binds calmodulin with nanomolar affinity in the presence of 0.2 mM CaCl_2 . The tight binding allows more stringent washing conditions, ensuring that few contaminating proteins will be co-purified with the fusion protein. A second elution step with EGTA and 1 M NaCl is useful if the protein does not elute completely in the first step. Reducing agents and detergents in amounts up to 0.1% are compatible with the system.

The SBP-tag was first described in 2001. It is a new streptavidin-binding peptide and has a length of 38 amino acids (for the sequence, see Table 2). The dissociation constant of the tag from streptavidin is 2.5 nM. SBP-tagged proteins can be purified with immobilized streptavidin. The elution conditions are very mild, using 2 mM biotin. Proteins with C-terminal SBP-tagged proteins were expressed in bacteria and successfully purified. Little is known regarding further applications, but the tag seems to be an interesting tool for immobilizing proteins on streptavidin-coated chips. The chitin-binding domain from *Bacillus circulans* was first described in 1996 and consists of 51 amino acids. The affinity tag is commonly available in combination with self-splicing inteins. The [▶intein](#) from the *Saccharomyces cerevisiae* VMA1 gene, which consists of 454 amino acids, is often used. Other, shorter inteins have also been employed (6). Self-cleavage of the thioester bond can be induced by thiol reagents, such as 1,4-dithiothreitol or β -mercaptoethanol (Table 2). The C- or N-terminal amino acid residue of the target protein has an effect on *in vivo* and *in vitro* cleavage (6). A high salt concentration or the use of non-ionic detergents can be employed to reduce non-specific binding, thus increasing purity. The uncleaved fusion precursor and the intein tag remain bound to the chitin resin during target protein elution and can be stripped from the resin by 1% SDS or 6 M guanidine HCl.

More than 13 different families of proteins with cellulose-binding domains (CBDs) were classified and described between 1997 and 2002. CBDs can vary in size from 4 to 20 kD and occur at different positions within polypeptides, N-terminal, C-terminal and internal. Some CBDs bind irreversibly to cellulose and can be used for immobilization of active enzymes; others bind reversibly and are more useful for separation and purification. CBDs of family I bind reversibly to crystalline cellulose and are useful tags for affinity chromatography. Hydrogen bond formation and van der Waals interaction are the main driving forces for binding.

The advantages of cellulose are that it is inert, has low non-specific affinity, is available in many different forms and has been approved for many pharmaceutical and human uses. CBDs bind to cellulose over a moderately wide pH range, from 3.5 to 9.5. The affinity of the tag is so strong that an immobilized fusion protein can only be released with buffers containing urea or guanidine hydrochloride. These denaturing elution conditions make refolding of the fused target protein necessary. Fused proteins with CBDs of families II and III can be eluted gently from cellulose with ethylene glycol. This low-polarity solvent presumably disrupts the hydrophobic interaction at the binding site. Ethylene glycol can be removed easily by dialysis.

Large Size Tags

In general, protein domain and protein tags with a minimum of 61 amino acids can be defined as large size tags.

The glutathione S-transferase tag ([▶GST](#)) was first described in 1988 (7). A 26-kD GST of *Schistosoma japonicum* was cloned in an *E. coli* expression vector. Fusion proteins could be purified from crude lysate by affinity chromatography on immobilized glutathione. Bound fusion proteins can be eluted with 10 mM reduced glutathione under non-denaturing conditions. In the majority of cases, fusion proteins are soluble in aqueous solutions and form dimers. The GST-tag can be easily detected using an enzyme assay or an immunoassay. The tag can help to protect against intracellular protease cleavage and stabilize the recombinant protein. In some cases, GST fusion proteins are totally or partly soluble. It remains unclear which factors are responsible for insolubility, but in several instances insolubility of GST fusion proteins was associated with the presence of hydrophobic regions. Other insoluble fusion proteins either contain many charged residues or are larger than 100 kD. In some cases insoluble fusion proteins can be purified by [▶affinity chromatography](#) if they are solubilized in 1% Triton X-100, 1% Tween, 10 mM dithiothreitol, 0.03% SDS or 1.5% sarcosyl buffer. Sarcosyl inhibits co-aggregation of proteins with bacterial outer membrane components. Purification of other insoluble proteins must be done by conventional methods. A [▶site-specific protease](#) such as thrombin or factor X_a is recommended for cleaving the GST-tag from fusion proteins. The PreScission protease contains the human rhinovirus 3C protease including the GST-tag; the GST carrier and the protease can be removed after proteolysis by affinity chromatography on glutathione-agarose. GST fusion proteins have become a basic tool for the molecular biologist. They are also commonly used in studies on protein-DNA interactions, protein-protein interactions and as antigens for immunology or vaccination studies.

The 40-kD maltose-binding protein (MBP) was first described in 1988 and is encoded by the *malE* gene of *E. coli* K12. Fused proteins can be purified by one-step affinity chromatography on cross-linked amylose. Bound fusion proteins can be eluted with 10 mM maltose in physiological buffer. Binding affinity is in the micro-molar range. Some fusion proteins do not bind efficiently in the presence of 0.2% Triton X-100 or 0.25% Tween 20, while other fusion proteins are unaffected. Buffer conditions can range from pH 7.0 to pH 8.5 with up to 1 M salt. Denaturing agents cannot be used. A spacer sequence coding for ten asparagine residues between the MBP and the protein of interest increases the chances that a particular fusion protein will bind tightly to the amylose resin. The MBP-tag can be easily detected using an immunoassay. It is necessary to cleave the tag with a site-specific protease. N-terminal location can reduce the efficiency of translation. The MBP system is widely used in combination with a small affinity tag.

One disadvantage when heterologous proteins are produced in *E. coli* is that proteins frequently aggregate as insoluble folding intermediates, known as **inclusion bodies**. In order to recover an active protein, these must be solubilized with denaturing agents such as 8 M urea or 6 M guanidine hydrochloride. One possibility for avoiding inclusion bodies is to use large affinity tags such as GST or MBP. Hydrophilic tags, such as transcription termination anti-termination factor (NusA), *E. coli* thioredoxin (TrxA) or protein disulfide isomerase I (DsbA) can increase solubility. A disadvantage is, however, that proteins with these tags cannot be purified with a specific affinity matrix. The fusion construct must be used in combination with a small affinity tag for purification. The NusA protein increases the solubility of fusion proteins. Usually, *E. coli* NusA protein promotes hairpin folding and termination. Some insoluble proteins expressed in *E. coli* remained soluble when tagged N-terminally with NusA. NusA has often been used in combination with the His-tag. Thioredoxin can be fused to the amino or carboxyl terminus of the protein of interest, but typically the *trxA* sequence is placed at the 5' end. DsbA increases the solubility of the target protein in the cytoplasm and periplasm of *E. coli*. A site-specific protease is recommended for the cleavage of fusion proteins with NusA, TrxA or DsbA; the cleavage site can be used as a linker peptide.

Other Tag Systems

There are other tag systems in use, which are not described in detail here. Staphylococcal protein A gene fusion vectors were developed to purify recombinant proteins by IgG affinity chromatography. This protein is well suited for affinity purification due to its specific binding to the Fc part of immunoglobulins of many

species including human. Analogously to protein A, protein G from *Streptococcus* strain G148 and the Z-domain can be used in the same manner because they bind the Fc portion of IgG. Biotinylation of proteins using small peptide tags is commonly used for detection, immobilization and purification. Different tags, such as the Avitag, PinPoint X a protein purification system and Bio-tag have been described. The bacteriophage T7 and V5 epitopes are interesting tags for sensitive detection. Other epitope tags for detection are ECS (enterokinase cleavage site), HA (hemagglutinin A), and Glu-Glu.

Clinical Relevance

Protein tags are an important tool for protein purification. Disease relevant proteins can be isolated and used as drug targets. Some tags allow the rapid purification of specific complexes and are a useful tool for proteome exploration. Many tags with high affinity to their binding partner are also useful tools for immobilizing peptides or proteins on surfaces. Furthermore, the importance of affinity tag technology for use in peptide/protein chip design, high-throughput purification, peptide/protein libraries, large-scale production systems and drug delivery strategies will increase.

Protein Transduction Domains

Definition

Protein transduction domains are small protein regions that cross biological membranes through a still poorly

understood mechanism. Various compounds and macromolecules including proteins can penetrate living cells when linked covalently to PTDs. The most commonly used PTDs are the third alpha helix of the *antennapedia* transcription factor, a peptide derived from the basic domain of HIV Tat, a peptide derived from the HSV VP22 transcription factor and poly-arginine peptides.

► **Peptide Aptamers**

Protein/DNA Interaction

PATRICE MORAND, CHRISTOPH W. MÜLLER
EMBL, Grenoble Outstation and University Hospital,
Grenoble, France
mueller@embl-grenoble.fr

Definition

Protein/DNA interactions allow DNA-binding proteins to recognize different DNA sites within the genome in order to fulfill central roles during DNA transcription, replication, packaging and repair. Atomic interactions between DNA-binding proteins and the DNA backbone and bases involve direct and water-mediated ► **hydrogen bonds** as well as ionic, van der Waals and ► **hydrophobic interactions** (1). Sequence specific DNA-binding proteins achieve specificity through a combination of contacts with DNA bases in the major or ► **minor grooves** of the DNA and with the DNA backbone (Fig. 1).

Characteristics

Double-stranded DNA is the central storage form of genetic information. The overall ► **conformation of double-stranded DNA** is rather uniform, although different DNA sequences influence the conformation and flexibility of DNA. To recognize specific DNA sequences, DNA-binding proteins mainly distinguish DNA bases in the major or minor groove of the DNA. To fulfill this function DNA-binding proteins have to be exactly positioned on the DNA through interactions with the DNA sugar-phosphate backbone. Protein residues contacting DNA bases and backbone jointly define a surface able to recognize specific DNA sequences. Biochemical and structural analyses have characterized a large number of DNA-binding proteins and their cognate DNA sequences. These analyses show a surprising variety in the architecture of DNA-binding proteins and in the way they interact with DNA (2, 3).

Interaction Characteristics

Amino Acid / DNA Base Interactions

Different DNA bases have different chemical properties resulting in a specific signature for a given DNA sequence. DNA-binding proteins preferably bind to those sequences that allow them to optimize the number of favorable interactions. Most amino acid-base interactions occur in the ► **major groove** of the DNA, where DNA bases adenine, guanine, cytosine and thymine are better distinguishable than in the minor groove. In addition, the major groove of B-form DNA is wider and therefore offers better access to DNA bases.

Hydrogen bonds between protein side chains and DNA bases account to a large extent for the sequence-specific recognition. About one third of these hydrogen bonds are single interactions between one residue and a DNA base; another third comprise bidentate interactions where at least two hydrogen bonds are formed between the protein residue and the DNA base or base pair. The remaining third comprise complex interactions where one residue contacts more than one base step (1).

► **Van der Waals interactions** also contribute to base specific recognition. For example, the exocyclic methyl group of thymine interacts with a number of hydrophobic side chains. Interactions of DNA bases with hydrophobic side chains like leucine, phenylalanine or proline are also particularly important for the binding of distorted DNA targets.

The increasing number of available protein/DNA complex structures allows the identification of certain preferences for interactions between protein side chains and DNA bases, like the bidentate interactions of arginine with guanine (Fig. 1) and of asparagine or glutamine with adenine bases. Despite such preferences, the overall conformation of the DNA-binding domain and its position on the DNA mainly determines the role of each residue in DNA recognition. No universal recognition code and no simple one-to-one relationship between amino acid residue and recognized DNA base has been established, and therefore the predictive power of such preferences remains limited.

Amino Acid / DNA Backbone Interactions

About two thirds of the total interactions between DNA-binding proteins and DNA comprise salt bridges, hydrogen bonds and hydrophobic interactions with the DNA sugar-phosphate backbone. Protein/DNA backbone contacts position DNA-binding domains onto the DNA to allow the formation of specific contacts with DNA bases. However, they also contribute to forming a complementary recognition surface able to recognize different DNA structures. Sequence-dependent variations in the DNA structure and flexibility can be “sensed” through protein/DNA backbone contacts. This mechanism allows the recognition of specific

Protein/DNA Interaction. Figure 1 Details of protein-DNA interactions. Sequence-specific recognition of a guanosine/cytosine base pair in the major groove through direct (1) and water-mediated (2) hydrogen bonds with an arginine residue. The arginine residue also contacts the DNA sugar-phosphate backbone (3). Hydrophobic interactions are observed between a phenylalanine residue, the guanine base and the backbone ribose (4). Note also additional water molecules interacting with the Gua:Cyt base pair.

DNA bases without directly contacting them and is often referred to as **indirect readout**. Protein/DNA backbone contacts are also particularly important for non-sequence specific DNA-binding proteins like the abundant **histone** proteins that form the protein core of the **nucleosome**.

Water-mediated Contacts

Water-mediated hydrogen bonds form a large part of all protein/DNA interactions. They are almost as abundant as direct hydrogen bonds and provide further complexity in protein/DNA interfaces. Most water molecules only appear to serve as “glue”, filling spaces between protein and DNA moieties. However, in some

cases precisely positioned water molecules partake directly in DNA sequence specific recognition.

Multimerization upon DNA-Binding

Many DNA-binding domains bind their target sites cooperatively as homo- or heterodimers. Homo- and heterodimerization allow sequence-specific DNA-binding proteins to increase their site specificity but also to extend the spectrum of potential binding sites by combining with various interacting partners. This principle is even taken one step further when different DNA-binding proteins bind cooperatively to DNA to form multimeric complexes.

Classes of DNA-Binding Proteins

X-ray crystallography and ▶NMR spectroscopy have elucidated a large number of different structures of protein/DNA complexes with a surprising variety in the observed intermolecular interactions (Fig. 2). DNA-binding proteins often contain distinct DNA-binding ▶domains specialized in DNA-binding (2, 3). Many of these domains are rather small and consist of less than 100 amino acid residues with easily recognizable sequence signatures. More rarely, DNA-binding

requires large regions spanning several hundred amino acids. Different classification schemes have been proposed, which often use protein secondary-structure elements contacting the DNA as a criterion for classification.

DNA Recognition by α -Helices

Prominent examples of DNA-binding domains using α -helices inserted into the major groove for sequence specific recognition are proteins of the ▶helix-turn-helix

Protein/DNA Interaction. Figure 2 Examples of different protein/DNA complexes. (a) Engrailed homeo domain in complex with DNA. The helix-turn-helix motif is formed by the second and third helix. (b) Zn-finger protein Zif268 with three Zn-fingers arranged in tandem contacting the DNA. Zn-ions are depicted as spheres. (c) Basic-region-leucine zipper (bZip) DNA-binding domain of transcription factor GCN4. (d) NFκB P52 homodimer bound to DNA. DNA-binding is mediated by 5 loops per monomer.

transcription factor family as well as various Zn-coordinating or ▶leucine zipper containing DNA-binding domains (2, 3).

Helix-turn-helix DNA-binding domains are generally characterized by a stretch of 20 amino acid residues forming two α -helices connected by a short turn. The second of the two helices inserts into the major groove and contacts DNA bases and the backbone. N-terminal and/or C-terminal extensions are generally required to stabilize the helix-turn-helix motif and provide variability in site recognition. The helix-turn-helix motif forms the core of a large number of different prokaryotic and eukaryotic DNA-binding domains. Prominent examples are the bacterial repressors, eukaryotic homeodomain transcription factors that play crucial roles in development and winged helix-turn-helix proteins like the cell-cycle transcription factor E2F or the Ets domain transcription factors.

▶Zn-finger proteins of the Cys₂His₂ type form one group of Zn-coordinating DNA-binding domains where two anti-parallel β -strands are followed by an α -helix. Two cysteines and two histidines protrude from the two-stranded β -sheet and the α -helix to coordinate one Zn-ion. Each Zn-finger specifically recognizes three base pairs. DNA-binding domains generally contain several Zn-fingers arranged in tandem, which spiral around the DNA. Zn-fingers are a very abundant class of DNA-binding domains, with more than 300 representatives present in the human genome.

▶Basic-region-leucine zipper DNA-binding domains form dimers of uninterrupted α -helices that insert into the major groove. Prominent representatives are the yeast transcription factor GCN4, AP-1 (activator protein) and CREB (cAMP-response element-binding protein).

DNA Recognition by β -Sheets

DNA-binding proteins using β -sheets for sequence-specific recognition are less abundant. Examples include the bacterial repressors MetJ and Arc, where a two-stranded β -sheet runs through the major groove, the eukaryotic transcription factor GCM, which inserts a β -hairpin into the major groove and the general transcription factor TBP (TATA-box-binding protein), which binds in the minor groove and highly distorts the DNA.

DNA Recognition by Loops

▶Immunoglobulin-fold transcription factors share a common core related to immunoglobulin domains and use loops to contact DNA bases and backbone. Large regions of the protein and in some cases several domains are required for DNA-binding. So far, members of this family have only been observed in eukaryotes and include many medically important

transcription factors like P53, NF κ B, NFAT, STAT and T-box proteins.

Clinical Relevance

Normal development and physiology require the temporally and spatially coordinated expression of about 30,000 human genes. Regulation of gene expression is mainly provided by sequence-specific transcription factors that enhance or inhibit target gene expression by binding to specific promoter sequences. Up to 3000 human transcription factors are encoded in the human genome, and many diseases are entirely or partially caused by mutations affecting transcription factor activity.

In many cases, the mutations do not directly alter the transcription factor but rather change interacting partners upstream in the signaling cascade, like receptors, kinases or other effector molecules, leading to changes in the activation or repression of transcription factors. Nevertheless, a considerable number of disorders are directly caused by deletions, insertions and mutations of transcription factor genes. As a result the encoded proteins are either not properly expressed or deficient in DNA-binding, trans-activation or interaction with other partners.

For a number of human syndromes transcription factor ▶haploinsufficiency has been identified as the underlying cause (4 and references therein). Whereas one allele produces a functional transcription factor, the second allele is defective, consequently decreasing transcription factor levels to 50%. Haploinsufficiencies of T-box transcription factors TBX1, TBX5 and TBX3 have been identified as reasons for human DiGeorge, Holt-Oram and ulnar-mammary syndromes, respectively. Point mutations in TBX5, which directly affect residues contacting DNA in the major and minor groove, have been found in several Holt-Oram patients, providing a molecular explanation for this syndrome. In most human cancers a relatively small number of transcription factors, including c-JUN, STATs, NF κ B and AP-1, are over-activated and prevent apoptosis of cancer cells, whereas the activity of many tumor suppressors is down-regulated as is the case for P53. Most P53 residues that are frequently mutated in different cancers are near or at the protein/DNA interface. The two most frequently mutated residues in the DNA-binding domain of P53 are two arginine residues, of which one contacts the minor groove and the other forms a DNA backbone contact (5).

The pharmacological modulation of transcription factor activity represents an attractive therapeutic strategy. Mainly, two medical approaches have been explored to interfere with transcription factor activity. Currently, the most frequent strategies impact upon the signal transduction cascades that regulate transcription factor phosphorylation and dephosphorylation and/or nuclear

import. More specific strategies seek natural ligands or synthetic small molecules capable of binding to the transcription factor to modulate activation of the functional domains or inhibit their binding to DNA (6, 7). For example, tamoxifen or raloxifen used in breast cancer bind and induce a conformational change in the activation function domain 2 (AF2) of the estrogen receptor (a nuclear receptor belonging to the group of Zn-coordinating DNA-binding proteins), leading to a useful anti-estrogen effect. Some drugs may also inhibit the binding of transcriptional repressors to promoter elements and therefore allow the derepression of a gene of medical interest. Given the size and complexity of protein/DNA interfaces, the directed inhibition or stimulation of the interaction of DNA-binding proteins with their DNA target sites is difficult. Nevertheless, recent advances in drug discovery technologies may help to identify new molecules that act directly at the level of protein-DNA interaction.

Protein-Protein Analysis, Suppressor Hunting

RANDY STRICH

Fox Chase Cancer Center, Philadelphia, USA

r_strich@fccc.edu

Definition

The biochemical analysis of a protein often leads in two directions, namely what does this protein do and how is

this activity regulated. Identifying another factor that directly interacts with the protein of interest can provide significant insight into these two questions. The use of genetic approaches, in particular ►**second site suppression**, provides a powerful *in vivo* tool for identifying protein:protein interactions that can help define a particular pathway. Second site suppressors are defined as a ►**mutation** in a second gene that restores the wild type ►**phenotype** to an individual already harboring a mutation in the gene of interest. For a suppressor ►**allele** to encode a candidate interactive protein, it should have two characteristics. First, the suppressor allele should be dominant, not recessive in nature. Second, the suppressor should be ►**allele-specific** meaning that it is not able to suppress a deletion mutation in the gene of interest.

Characteristics

Classic Suppressor Analysis

A cartoon illustrating the second site suppressor analysis is shown in Fig. 1. Your favorite protein (YFP) is the protein of interest that has been defined in previous studies. For YFP to function properly, it requires the interaction of an unknown protein (X) (top line). A mutation in YFP that alters its conformation such that it no longer binds X (middle line) will no longer function thus producing a mutant phenotype. This phenotype makes the cell different under the particular experimental conditions employed, thus distinguishing it from the wild type. For example, this phenotype can result in cell death under certain growth conditions or be subtle such as a change in cell shape. A second round of mutagenesis generates a new mutation in X that restores its ability to interact with the mutant form of YFP thereby restoring wild type function (i.e. suppression, bottom of Fig. 1). This scenario makes two predictions for X if it is a direct binding partner of YFP. First, the mutated X should be able to suppress the YFP mutation even in the presence of the wild type X protein. This “dominant” activity over the wild type protein is the necessary gain of function required to recognize the mutant YFP protein. The second prediction is that the X-dependent suppression will only occur with the mutated YFP allele used in the suppressor hunt. For example, this suppression will not happen if the YFP gene has been deleted, as both proteins are necessary for normal function. Allele-specific suppression and genetic dominance are hallmarks of a directly interacting protein.

Dosage Suppressor Analysis

Like classical suppressor analysis described above, the rationale for dosage suppression is that a mutation in YFP reduces its ability to bind protein X causing a mutant phenotype (Fig. 2). The increased concentration

Protein-Protein Analysis, Suppressor Hunting. Figure 1 Classical suppressor analysis. The interaction between your favorite protein (YFP) and another factor (X) is required for wild type activity (top panel). The mutation in YFP (lightning bolt) disrupts this interaction causing a mutant phenotype (middle panel). A new mutation in X (second bolt) restores this interaction thereby reconstituting the pathway and generating a wild type phenotype (bottom panel).

of the X protein will compensate for this reduced binding affinity and therefore restore wild type activity. In this suppressor strategy, the increased “dosage” can be derived from increasing the copy number of X through use of a high-copy plasmid or placing X under the control of a strong promoter that causes X to be transcribed at a significantly higher frequency or both. Dosage suppression has three advantages over the classical suppressor analysis described in Fig. 1. First, elevated gene dosage is normally derived from a [▶library](#) of random genomic fragments or cDNAs inserted into a high-copy plasmid. Once a suppressor has been identified, the plasmid containing the activity can be rapidly isolated and the suppressor gene identified. Second, the source of the library can be derived from any organism thus allowing cross-species analysis. This option may be especially important if a heterologous system is being established (see below). Finally, a new mutagenesis cycle, which can introduce new and unwanted mutations, is avoided. The rules described for classical suppressor analysis (e.g. dominant activity and allele specificity) still hold for dosage suppression.

Selection or Screen, Phenotypic Choices

The use of suppressor analysis to identify interacting proteins must start with a phenotype that separates the individual harboring the mutant form of YFP from the rest of the population. Phenotypes can be sorted by two basic methods, selections or screens. A selectable phenotype usually relies on life and death to distinguish

Protein-Protein Analysis, Suppressor Hunting. Figure 2 Dosage suppression. As in panel A, wild type function requires the interaction between YFP and X (top panel). A mutation in YFP reduces the binding affinity to X resulting in a mutant phenotype. Increasing the effective concentration of X (lower panel) compensates for the reduced binding ability thus producing wild type activity.

between wild type and mutant individuals respectively. Many conditions can be used to provide the trigger that leads to lethality in the mutant strain. For example, growth at elevated temperatures is a commonly used condition that can render mutant proteins inactive even though they are functional at lower temperatures. In this example, a suppressor mutation would simply restore the ability of the individual containing a mutation in YFP to grow at high temperature. As only individuals that survive the elevated temperature are of interest, the use of a selection offers the power to examine a large number of individuals for suppressor activity. Conversely, a screen requires more effort as each individual must be examined for the restoration of the wild type phenotype. For example, the original mutation causes a fly eye to change color. A suppressor that reverts the eye back to the original color will only be found by examining each fly. Therefore, whenever possible, the use of a selective protocol is recommended both to save time and saturate the system.

All Mutations Are Not Created Equal

The selection of the target allele to initiate the suppressor hunt is critical for enhancing the chances of success. Two criteria must be satisfied for a target allele to be used in an interacting suppressor hunt. First, and foremost, the mutant protein must be present in the cell and be maintained at normal (or near normal) levels. Without the target protein present and in its normal cellular concentration and location, it is

unlikely that an interacting protein can be mutated in any fashion that will provide suppressor activity. Second, when at all possible, an allele in the target protein should be employed that harbors an inactivating ►[missense](#) mutation in an amino acid that is on the surface of the protein. If the goal is to identify interacting proteins, then mutations that cause large deletions of the coding region should be avoided.

Suppressor Analysis

The isolation of a second site suppressor requires several validation steps. The first step is to determine if the allele isolated is able to suppress a null mutation of YFP. If it can, then this allele is characterized as a bypass suppressor and is unlikely to interact directly with your protein of interest. These types of suppressor typically function downstream or independently of YFP activity and would be of interest if the entire pathway were under investigation. This characteristic of suppressor analysis has allowed investigators to cast a wide net for proteins that function within a particular pathway. For dosage suppressors, simply re-introduce the rescued plasmid into a strain harboring a null allele of the target gene. Suppressors that still function in the presence of a null allele again most probably represent bypass suppressors.

The second condition of allele specificity is the gold standard for directly interacting suppressors. Allele specificity suggests that the change in the suppressor protein is able to compensate specifically for the target mutation. This information is invaluable in delimiting interacting domains for both proteins as the mutant alleles can be sequenced to determine where the new mutations are located. For suppressor mutations, outcrossing to a different target allele is necessary. For dosage suppressors, the connection between allele specificity and direct interactors is less well documented. However, the dosage suppressor can be tested for allele specificity by simply re-introducing the suppressor-harboring plasmid into a mutant strain that harbors a different mutation in YFP.

Clinical Relevance

The genetic approach of second site suppression is most commonly conducted in model genetic organisms such as yeasts, fruit flies or nematodes. Similar approaches have proven difficult and/or too costly to recapitulate in mammalian cell culture systems or in whole animal studies. However, an alternative approach is to establish a genetic system in yeast based on a foreign target gene. The gene selected can have direct relevance to human disease or be a component of a basic biological process (e. g. cell-cycle control, signal transduction) that can have an indirect role in generating a disease state. This method takes advantage of the considerable homology observed between basic

biological processes in yeast and mammals. For example, the glucocorticoid receptor/transcription factor can activate reporter gene expression in yeast (1, 2). Moreover, G-coupled protein receptors have been modified to activate the mating pheromone mitogen activated protein (MAP) kinase cascade (3, 4). Establishing an assay with human YFP that provides a phenotypic readout in yeast will then allow suppressor analysis to be performed with a mutant YFP. An alternative approach is to find a homolog of the mammalian YFP in the model organism. This strategy relies on the conservation of pathways and activities of YFP in higher and lower eukaryotes. In either case, suppressor analysis may permit the isolation of interacting proteins with significance in human disease.

Protein-Ligand Interaction Studied by NMR

CHRISTIAN FREUND

Freie Universität Berlin and Institute for Molecular Pharmacology, Berlin, Germany
freund@fmp-berlin.de

Definition

The molecular interactions of a ►protein with a small organic molecule, a peptide or another protein can be followed by the acquisition of nuclear magnetic resonance spectra. Depending on the type of ►NMR experiments used, qualitative information about the amino acid residues important for binding can either be obtained for the protein or for the ►ligand or for both. In addition, a full NMR-based structure determination of the protein-ligand complex allows the interaction to be viewed at atomic resolution.

Description

►NMR spectroscopy represents a powerful method of examining the structural and dynamic properties of

molecules in aqueous solution. The interaction of a macromolecule of interest, for example a protein, with another molecule (referred to as the ligand) results in changes in NMR observable parameters. Typical NMR methods for the investigation of protein-ligand complexes make use of the difference in ►chemical shifts between free and bound protein (or ligand) resonances or they exploit the different biophysical properties (►relaxation, diffusion) of a small molecule ligand as compared to the target protein. In addition, ►NOE- and RDC- (residual dipolar coupling) based NMR methods allow the determination of high-resolution three-dimensional structures of protein-ligand complexes.

Ligand-Exchange Rates

Two limiting cases for the ►chemical exchange of protein and ligand binding can be observed by NMR spectroscopy. If the exchange rate is large compared to the chemical shift difference between the free and bound ligand/protein resonances, the observed signal from either the protein or the ligand will gradually shift upon addition of the interaction partner (►fast exchange limit). Alternatively, if the exchange rates are small compared to the chemical shift difference between free and bound ligand/protein resonances, the signal intensity of the free form will decrease, whereas the signals of the bound form will increase (►slow exchange limit). If the time scale of chemical exchange and the time scale defined by the chemical shift difference between the free and the bound forms are similar, the lines become very broad and coalescence is observed. Interactions defined by this intermediate exchange regime are difficult to analyse and it is advantageous to try to separate the time scales by temperature shifts, acquiring the spectra at different magnetic field strengths or by chemically modifying the ligand (thereby either enhancing or decreasing the kinetic on- or off-rates). Since the resonance frequency difference between the free and bound form of the binding partners can be small or large for individual nuclei, different exchange regimes might be observed for the different atoms of the protein or the ligand. In many cases the kinetic on-rate for a typical protein-ligand interaction is diffusion limited and the different off-rates of an intermolecular interaction determine whether fast or slow exchange is observed. Interactions described by dissociation constants larger than 10 μM often fall into the fast exchange limit of modern high field spectrometers, while smaller dissociation constants result in intermediate or slow exchange compared to the NMR defined time scale.

Biological systems provide many examples of interactions that belong to either of the two exchange regimes. For example, many interactions that are part of the signal transduction process in living cells are characterized by large off-rates that reflect the transient

nature of the respective molecular complexes. In contrast, molecular recognition of antigens by affinity-matured antibodies is exclusively characterized by relatively small off-rates and tight binding. Protein-ligand interactions that are characterized by the fast exchange limit have the advantage that the course of the chemical shift change can be followed when increasing amounts of the binding partner are added. Under the assumption that the change in chemical shift is proportional to the fraction of bound molecules, a binding constant can be derived in favourable cases. For example, if the change in protein resonances is followed after addition of increasing amounts of ligand and if the binding is characterised by a simple two-state mechanism ($A + B \leftrightarrow AB$) the fraction bound can be derived from the solution of a quadratic equation that includes the dissociation constant as a fit parameter. While the qualitative mapping of the binding site is easily possible for protein ligand complexes that comply with the fast exchange limit, an **▶NOE**-based elucidation of the three-dimensional structure is often difficult to achieve. The fast exchange of the ligand might hamper the build-up and detection of NOEs between the protein and the ligand that are crucial for the process of structure determination (1). However, chemically altered ligands, intramolecular tethering of the ligand to the protein or acquisition of NOESY spectra at different protein-ligand ratios and with different NOESY mixing times might offer ways to detect intermolecular NOEs under the fast-exchange condition. These NOEs have to be interpreted cautiously within the context of structure calculation algorithms, since the isolated spin-pair approximation less adequately describes the correlation between distance and signal intensity. In contrast, slowly exchanging ligands can often be analysed within a 1:1 complex and the structures of many protein-ligand and protein-protein complexes with tightly bound ligands have been solved.

Isotope Labelling

In many cases the resonances of the protein and the ligand will fall into overlapping spectral regions. To distinguish the resonances of the individual binding partners, isotopic labelling of either the protein or the ligand allows the acquisition of NMR spectra that select for or against the incorporated isotope.

In most labelling protocols either the protein of interest or the ligand will be labelled by isotopes that contain the favourable magnetic properties of spin-1/2 nuclei (aside from the naturally abundant protons). Incorporation of ^{13}C and ^{15}N is most frequently used and typically obtained by recombinant expression of the protein of interest in bacteria or eukaryotic cells that are grown on isotopically enriched media. Since the natural abundance of these isotopes is low (1.1% for ^{13}C and

0.36% for ^{15}N), it is possible to detect only the signals from the isotopically labelled component of the molecular complex. Alternatively, the protons of either of the two binding partners can be “silenced” by substitution with deuterons, and only the proton signals of the non-deuterated binding partner will be detected. For full deuteration, the adaptability of *E.coli* to grow on > 98% deuterated components is most often exploited in conventional labelling schemes. In the case of small molecule ligands, a synthetic incorporation of the desired isotope can often be achieved. Since many modern NMR pulse schemes rely on the selection of coherence pathways based on the direct coupling of two spin-1/2 nuclei, there are many different ways to selectively detect the resonances of the labelled component of a complex.

Chemical Shift Changes

The chemical shift is a very sensitive indicator of changes in the chemical environment of atomic nuclei. Chemical shift changes can therefore be seen in cases of temperature shifts, solvent exchange, chemical modifications, conformational changes or non-covalent interaction with other molecules. Protein-ligand interactions are defined by non-covalent interactions such as van der Waals interactions, hydrogen bonds and electrostatic forces. The change in chemical environment upon molecular encounter can be due to neighbouring effects of the closely bound protein/ligand or be caused by a conformational change that accompanies the binding event. For rigid proteins, the chemical shift change of the detected nuclei is therefore a direct qualitative measure of the distance from the ligand atoms (2).

Detection of Protein NMR Signals-SAR by NMR

For the detection of protein resonances in ligand binding experiments, one of the most widely used methods is the ^{15}N - ^1H correlation spectrum, where, under acidic to neutral pH conditions, all amide groups give rise to a resonance in the corresponding two-dimensional NMR spectrum. The abundant use of experiments that exploit this correlation is explained by the low price of ^{15}N -labelled $\text{NH}_4\text{Cl}/(\text{NH}_4)_2\text{SO}_4$ and the good dispersion of the ^{15}N -resonances. For folded polypeptides, the resonance of proteins and protein domains of up to 300 amino acids can often be resolved to the level of individual NH groups. In cases where the individual resonances have been assigned in the ^{15}N - ^1H spectrum, the amino acids that are involved in binding can be identified. This so-called structure activity relationship (SAR) by NMR has found wide application, especially in target based screening procedures (3). If the three-dimensional structure of the protein is known, the binding site can be qualitatively mapped onto the surface of the protein. The limitation of this

method is the restricted size of the protein that can be investigated. Since T_2 relaxation increases monotonously with molecular weight, resonance assignments get severely hindered for proteins with a molecular weight greater than 50–100 kD. Although spectroscopic techniques such as TROSY offer ways to select the slowly relaxing components of NMR signals, the effort and costs incurred in obtaining spectral assignments and determining structures of protein complexes greater than 50 kD are enormous. The size limitation does not apply to the detection of ligand resonances that are measured in the presence of substoichiometric amounts of a given protein.

Detection of Ligand Resonances

In order to selectively detect ligand resonances, isotopic labelling can be used to enable the selective NMR experiments to be used in a manner analogous to that described for proteins. Alternatively, if the molecular size difference of the protein and the ligand is large (>10), the biophysical properties associated with differently sized binding partners offer a way to distinguish the much sharper resonances of the ligand from the broad signals of the high-molecular weight component. NMR transverse relaxation (T_2 relaxation) is the major pathway for the rapid decay of magnetization and addition of increasing, sub-stoichiometric amounts of the protein will lead to line-broadening of ligand signals that are now affected by the much slower tumbling of the protein-ligand complex. The finding that protein-ligand interactions cause measurable NMR relaxation enhancement of the ligand even under conditions of large ligand excess is also the basis for the measurement of transferred-NOEs (4). The nuclear Overhauser enhancement (NOE) is dependent on the longitudinal cross-relaxation between nuclear spins that are close in space (2–6 Å). Small molecules display weakly positive or zero NOEs. In contrast, macromolecules are characterized by large negative NOEs. Within the molecular complex, NOEs between bound ligand protons build up and, under conditions of fast ligand exchange, are transferred to the free ligand molecules whose NMR resonance signals are monitored. Since NOE intensities as a first order approximation are proportional to the inverse sixth power of the distance between protons, the conformation of the bound ligand may be derived from transferred NOE measurements.

A widely used transferred NOE-based method for the screening of small molecules is the saturation transfer difference technique (STD-NMR) (6). Here, regions of the protein that do not show overlap of protein resonances with ligand signals are saturated and magnetisation is subsequently transferred to the whole protein by spin diffusion. Spin diffusion is mediated by NOEs between spatial neighbours and increases with

the size of a protein. Eventually, magnetisation will also spread to bound ligand molecules, which in turn is transferred into solution by chemical exchange. Therefore, ligands interacting with the protein show attenuated signals and a comparison of the saturation transfer experiment with a spectrum acquired without saturation of the protein results in a saturation transfer difference (STD) spectrum that selectively displays the resonances of the interacting ligand.

Another method for distinguishing free and bound ligand resonances is based on the diffusion time of molecules (5). Pulsed field gradients that are able to create a spatially encoded dephasing of magnetization have a differential effect on slow and fast diffusing molecules. The amount of magnetization that can be regained by a second gradient pulse (rephasing) will be different for the more slowly diffusing bound ligand molecules than for the free ligand.

Structures of Protein-Ligand Complexes

The NMR structure determination of protein-ligand complexes is based on the NOEs observed between the protein and the ligand (1). Once resonance assignments have been obtained for both molecules, distance restraints can be derived from NOESY-spectra. Isotope edited NOESY experiments that use isotopically labelled protein or ligand allow the identification of important intermolecular NOEs. For example, half-filtering methods select for or against the magnetization of certain nuclei based on spin-echo difference modules that distinguish between directly coupled and uncoupled magnetisation (7). Another approach uses the asymmetric deuteration of protein and ligand and the recording of a ^{15}N -NOESY-HSQC spectrum. NOEs observed between NH and aliphatic protons of a small ligand will be intermolecular. Novel methods exploit the selective $^{13}\text{C}/^1\text{H}$ -labelling of isoleucine, leucine and valine in a deuterated background (8). Complementary, protonated aromatic side chains might be introduced into the deuterated protein and both labelling schemes allow the identification of intermolecular NOEs between aliphatic methyl groups and/or aromatic side-chains. NOE signals are then converted into distance restraints that are used in structure calculation programs as for example CNS or CYANA. In addition to NOE derived distance restraints, dipolar couplings between spin-1/2-pairs can, in principle, be used to estimate distances between atom pairs. To measure non-zero internuclear dipolar couplings accurately, the molecules of interest must be either weakly aligned with the magnetic field in a dilute liquid-crystalline medium (9) or be investigated by solid-state NMR. Especially in cases where NOEs are scarce, the measurement of dipolar couplings can add significantly to the precision and quality of a three-dimensional structure determined by NMR spectroscopy.

Clinical Applications

Several of the techniques mentioned in the previous sections (SAR by NMR, STD-NMR) have been efficiently used in the screening of libraries of small molecules. The NMR based screening methods often provide complementary information to ►HTS-methods, since they are able to detect very weak intermolecular interactions. Structural information on ligands identified in a screen can often be obtained directly or in combination with a few additional NMR experiments. NMR can also be used to test for false positives obtained with an HTS-approach since NMR should always detect a direct molecular interaction in aqueous solution. For these reasons, protein-ligand interactions investigated by NMR have become an important tool for the development of drugs with biological and clinical potential.

Proteinogenic Amino Acids

Definition

Proteinogenic amino acids comprise of the twenty standard amino acids completed by some special amino acids like seleno cystein and others, which are coded in

the mRNA and incorporated in the peptide chain during protein synthesis at the ribosome.

►Amino Acids: Physicochemical Properties

►Classification of Active Centers

Protein-Protein Interactions

PETER UETZ, CAROLINA S. VOLLERT

Institute for Genetics, Forschungszentrum Karlsruhe, Karlsruhe, Germany
peter.uetz@itg.fzk.de

Definition

Specific interactions between two or more proteins, i.e. enzyme-inhibitor complex; antibody-antigen complex; receptor-ligand interactions; multiprotein complexes such as ribosomes or RNA polymerases (Fig. 1).

Characteristics

Protein-protein interactions affect all processes in a cell; proteins need to interact in order to shape the cell as well as organelles and molecular machines such as ribosomes and RNA polymerases. Multi-subunit channels or receptors in membranes are also held together by protein-protein interactions. Protein-protein interactions can be arbitrarily classified based on the proteins involved (structural or functional groups) or based on their physical properties (weak and transient, “non-obligate” vs. strong and permanent). Protein interactions are usually mediated by defined domains, hence interactions can also be classified based on the underlying domains. This domain specific interaction distinguishes such interactions from random collisions that happen by Brownian motion in aqueous solutions inside and outside cells. Note that many proteins are known to interact, although at present it remains unclear whether certain interactions have any physiological relevance. In a single-cell organism such as yeast each of the roughly 6000 proteins interacts with at least 3 other proteins, which adds up to a total of ~20,000 interactions or more. By extrapolation, there may be approximately ~100,000 interactions in the human body.

Most protein-protein interactions are detected as interacting pairs or as components of protein complexes. Simple eukaryotes such as yeast contain several hundred protein complexes, which may contain dozens or even hundreds of protein subunits each (e.g. ribosomes, spliceosomes). It has been proposed that all proteins in a given cell are connected in a complex

Protein-Protein Interactions. Figure 1 A large protein complex and its protein-protein interactions. (a) Ribbon representation of the RNA Polymerase II complex structure. (b) Schematic interaction diagram for the 10 subunits. The thickness of the connecting lines corresponds to the surface area buried in the corresponding subunit interface. Colors of subunits are identical in (a) and (b). From Cramer et al. (2001) Structural basis of transcription: RNA polymerase II at 2.8 Å resolution. *Science* 2001, 292:1863–1876.

network, in which distinct protein interactions are forming and dissociating constantly.

Structural Features of Protein-Interaction Sites

Hundreds of protein complexes have been analyzed by ▶X-ray crystallography and other methods. Data about the structures of proteins and complexes are available from the Protein Databank (PDB, ▶<http://www.rcsb.org/>). The following aspects about geometry and energetics of protein interactions have been drawn from comparative analyses of up to 100 protein pairs and complexes that have been crystallized.

The contact area between two proteins is usually larger than 1100 Å² with each of the interacting partners contributing at least 550 Å² of complementary surface. On average each partner loses about 800 Å² of solvent-accessible surface upon contact, contributed by some 20 amino acid residues of each partner, i.e. the average interface residue covers some 40 Å². On average, dimers contribute 12% of their accessible surface area

to the contact interface, trimers 17.4% and tetramers 20.9%. However, variations exist and total interface areas range from 6% in inorganic pyrophosphatase homodimers to 29% in tryptophan repressor homodimers. For data sets of 10 enzyme-inhibitor complexes and 6 antibody-antigen complexes, the mean interface area is about 780 Å².

Forces that mediate protein-protein interactions include electrostatic interactions, hydrogen bonds, the van der Waals attraction and hydrophobic effects. The average protein-protein interface is not less polar or more hydrophobic than the surface remaining in contact with the solvent. Water is usually excluded from the contact region. In contrast, non-obligate complexes tend to be more hydrophilic, as each component has to exist independently in the cell. It has been proposed that hydrophobic forces drive protein-protein interactions, whereas hydrogen bonds and salt bridges confer specificity. Van der Waals interactions occur between all neighboring atoms, but these interactions at the interface are no more energetically favorable than those made with the solvent. However, they are more numerous, as the tightly packed interfaces are denser than the solvent and hence they contribute to the binding energy of association. Hydrogen bonds between protein molecules are more favorable than those made with water. Interfaces in permanent associations tend to have fewer hydrogen bonds than interfaces in non-obligate associations. The number of hydrogen bonds is about 1/170 Å² buried surface. A standard size interface (~1600 Å²) buries about 900 Å² of the non-polar surface, 700 Å² of polar surface, and contains 10 (5) hydrogen bonds. In a set of reasonably stable dimers there are on average 0.9–1.4 hydrogen bonds per 100 Å² of contact area buried (interfaces usually covering >1000 Å²). The number of hydrogen bonds varies from 0 in some complexes (e.g. uteroglobin) to 46 in variant surface glycoprotein. Side-chain hydrogen bonds represent approximately 76–78% of the interactions.

Only 56% of homodimers were found to possess salt bridges (many having none, and at the most five).

Independent studies of the shape showed that 83–84% of interfaces are relatively flat. With few exceptions, the interfaces are approximately circular areas on the protein surface in both permanent and non-obligate complexes. Interfaces in permanent associations tend to be larger, less planar, more highly segmented (in terms of sequence) and closer packed than interfaces in non-obligate associations.

Complementarity can be measured in terms of “fitting surface shape”. Interfaces in homodimers, enzyme-inhibitor complexes and permanent heterocomplexes are the most complementary, while the antibody-antigen complexes and the non-obligate heterocomplexes are the least complementary.

Proteins consist of 3 kinds of secondary structures: α -helices, β -sheets and loops, which usually connect the first two types and lie on the surface of proteins. In one study (involving 28 homodimers), 53% of the interface residues were α -helical, 22% β -sheets and 12% $\alpha\beta$, with the rest being coils or unstructured loops. The amino acid composition of interfaces has been shown to be more hydrophobic than the exterior but less hydrophobic than the interior of a protein. In one study, 47% of interface residues were hydrophobic, 31% polar and 22% charged. Permanent complexes have interfaces that contain hydrophobic residues, while the interfaces in non-obligate complexes favor the more polar residues. Site-directed mutagenesis showed that in many cases a majority (i.e. >50%) of interface residues can be mutated to alanine with little effect on the K_d ; i.e. the functional epitope is a subset of the structural epitope.

Thermodynamics

Protein-protein interactions can be described as simple chemical reactions:

A = Protein A

B = Protein B

AB = protein complex, i.e. an interacting pair of proteins

Multiprotein complexes usually assemble subunits successively.

Qualitative Description of Stability

Protein interactions can be weak and extremely short-lived (“non-obligate”) or strong and permanent (“stable”). For example, an enzyme binds and phosphorylates a protein substrate and dissociates after less than a microsecond. Other protein complexes such as the triple-helix of collagen reside in bones and other tissues for weeks or even years without dissociation.

Quantitative Description of Protein-Protein Interactions

Quantitatively, the interaction of two proteins follows the mass action law:

$$\frac{[A][B]}{[AB]} = \frac{1}{K_a} = K_d = \frac{k_d}{k_a} \quad (2)$$

k_a = second-order rate constant for the bimolecular association reaction,

k_d = first-order rate constant for the uni-molecular dissociation reaction,

$K_d = k_d / k_a$ = equilibrium constant for dissociation.

K_d is related to the concentrations of A, B and AB at thermodynamic equilibrium. K_d has the dimension of a

concentration and is expressed in mole/liter (or “M”). The range of K_d values observed in biologically relevant processes that rely on protein-protein interactions is extremely wide and extends over at least 12 orders of magnitude from 10^{-4} to 10^{-16} M. K_d values in the micromolar range are considered to be weak, values in the nanomolar range or below to be strong interactions (e.g. trypsin – pancreatic trypsin inhibitor [PTI] has a dissociation constant of the order of 10^{-14} M). However, the biological strength may depend on other effects such as cooperativity. Several weak interactions between the subunits of a complex can result in a highly stable complex.

Energetics

With a K_d ranging from 10^{-4} to 10^{-14} M, the free ΔG_d of dissociation δG_d ranges from 6 to 19 kcal/mol, i.e. 19 kcal are required to separate 1 mol of trypsin-PTI. Actual K_d values can be retrieved from some of the databases (Table 1). A single pairwise interaction between amino acids may account for as much as 6 kcal/mol. Residue pairs that form salt bridges and charged hydrogen bonds yield the largest values. Pairs that make neutral hydrogen bonds or non-polar interactions are in the 0–3 kcal/mol range. This is much less energy than that of a hydrogen bond, which implies that an interaction between the two residues in a complex is only marginally stronger than an interaction with water, with which they interact as free proteins. In complexes of known 3D structure, the peptide group participates in at least half of the hydrogen bonds at protein-protein interfaces. It has been estimated from an empirical correlation that for non-polar surfaces (i.e. hydrophobic interactions), there is an energy gain of approximately $25\text{--}72 \text{ cal}/\text{\AA}^2$. Many strong dimeric interactions that have association constants greater than 10^{-16} M have to be denatured to separate the complex into monomers.

Methods for Studying Protein-Protein Interactions

Details on the methods for the analysis of protein-protein interactions can be found in other sections of this Encyclopedia. Important experimental techniques are listed in Table 2.

Regulation of Protein-Protein Interactions

Interactions between proteins are tightly regulated. The most important ways of regulation involve the following mechanisms.

Expression

Proteins can only interact when expressed in the same place. RNA and protein expression (i.e. transcription and translation) are therefore regulating such interactions in a time- and space-dependent manner. For example, various fibroblast growth factors (FGFs) are expressed in different tissues such as limbs, brain, kidney etc. while their cognate receptors are similarly expressed in particular tissues where their interaction activates signaling pathways that in turn lead to the expression of certain target genes. FGFs are also expressed in a time-dependent manner, e.g. FGF4 and 8 are only expressed in embryos while others are mostly expressed in adult tissues. The same is true for FGF receptors.

Modifications

Covalent modification of proteins can prevent or induce binding of others. Examples include proteins that contain the so-called SH2 domain that binds only

peptides which contain a phosphorylated tyrosine residue.

Subcellular Localization

Several transcription factors such as NF κ B are present in the cytoplasm or even in membranes (such as Notch). They can be activated by translocation to the nucleus where they interact with other transcription factors in order to activate gene transcription.

Stability

Proteins can only interact when they are present. Thus, regulated degradation of proteins prevents them from further interactions. Prominent examples are the cyclins, which are broken down at specific time points during the cell-cycle, so they can no longer interact with their partners, cyclin-dependent kinases (CDKs).

Ligands

Small molecules or other proteins can regulate protein interactions. For example, binding of guanosine triphosphate (GTP) to trimeric guanosine nucleotide binding proteins (G proteins) promotes their dissociation while binding of guanosine di-phosphate (GDP) favors their association.

Prediction of Protein-Protein Interactions

Proteins of Known Structure

Prediction of interaction sites in proteins of known structure usually focuses on the location of hydrophobic surface clusters on proteins. One such study

Protein-Protein Interactions. Table 2 Methods to study protein-protein interactions

Method	Notes
Purification of protein complexes and their separation by ►2-dimensional gel electrophoresis or ►liquid chromatography.	After separation the components of a protein complex can be identified by the staining of protein bands by various dyes such as Coomassie Blue. Furthermore, the protein bands can be analyzed by ►mass spectrometry which can also be used to sequence proteins.
In-vitro binding experiments	Involve purified proteins whose interaction is detected by retention of one partner by a second protein that has been immobilized on some sort of matrix (such as agarose or glass).
In vivo methods	E.g. ►two-hybrid systems, ►FRET
Equilibrium ultracentrifugation ►Microcalorimetry	Used to determine dissociation constants in the micromolar range. When K_d is in the nanomolar range, radioisotope labelling or ELISA techniques can be used.
Site directed mutagenesis	Used to identify the role of individual amino acids.
NMR X-ray crystallography	Physical methods to determine the 3D-structure of proteins and protein complexes

predicted the correct interaction site in 25 out of 29 cases. Other methods include ►[solvation potential](#), ►[residue interface propensity](#), ►[hydrophobicity](#), planarity, ►[protrusion](#) and ►[accessible surface area](#). Among a test set of 28 homodimers, the known interface site was found to be amongst the most planar, protruding and accessible patches and among the patches with highest interface propensity. Nevertheless, one of the algorithms (PATCH) that uses multiple parameters predicted the location of interface sites in known complexes only for 66% of the structures.

Protein Pairs from Genome Sequences

Several attempts have been made to predict protein-protein interactions from genome sequences. Two major methods employ ►[Rosetta stone proteins](#) and phylogenetic profiles.

Rosetta Stone Proteins

Some protein sequences are split into two independent proteins in some organisms, whereas they are maintained together in other organisms. From such sequences, it has been concluded that the two independent proteins form a complex, based on the association in the fusion protein. Such fusion proteins are called Rosetta stone proteins. Supposedly, they predict interactions among related proteins. For example, human succinyl CoA transferase is split in *E. coli* into acetate CoA transferases α and β subunits.

Phylogenetic Profiles

Some gene pairs (or groups) are maintained together in many different organisms during the course of evolution. It has been concluded that such “co-evolving” genes encode proteins that are associated either functionally or physically, i.e. by a protein-protein contact. While the latter is not always true, it has been found to be true in a number of cases, such as the yeast proteins Hog1 and Fus3 and their homologs in other eukaryotes.

Clinical Relevance

Biologically active proteins such as peptide hormones or antibodies act by interacting with other proteins such as receptors or antigens respectively. Knowing their interaction sites allows the modification of the activity of such proteins or the changing of their specificity. In addition, small molecules may be designed that block such interactions, e.g. molecules that inhibit the binding of virus coat proteins to their cellular receptors, thereby blocking infection. Proteins and their interactions are therefore potential drug targets.

Protein-protein interactions can also be disadvantageous. Insulin for example tends to form dimers and

hexamers which are less active than monomers. Genetically engineered insulin molecules do not dimerize and hence retain biological activity.

Proteomics and Complexity of Age-related Protein Modifications

Proteomics is the analysis of an entire protein set expressed by a biological system under given conditions. Classically proteome analysis is a two-step process, 2DGE separates proteins as spots that are quantified. Recent refinements of 2DGE include ▶ differential in-gel electrophoresis. Then, quantified spots of interest are identified by mass spectrometry (MS) methods. Peptide mapping determines the molecular weights of peptides obtained after proteolytic cleavage and peptide sequencing allows partial sequencing of isolated peptides.

Human ageing is characterized by a progressive loss of physiological functions, increased tissue damage and defects in various tissue renewal systems. A fundamental biogerontological question is how do cells slowly accumulate irreversible modifications in a normal physiological milieu or in response to abnormal stress, eventually reaching a critical threshold leading to irreversible degeneration, functional losses and eventually death?

Proteomics is excellently suited to analyze the complex age-related biochemical modifications of our multiple cell types and subcellular compartments. With ageing,

Definition

Proteomics is the large-scale systematic study of the proteins of an organism, a specific type of tissue or a cell, using biochemical, cell biological and genetic methods (2, 62). The word proteomics has traditionally been used to describe the separation of proteins prepared from tissues and cell lines by ►two-dimensional (2D) polyacrylamide gel electrophoresis (1). In this sense, the first proteomics studies were performed in the 1970s, when researchers started the systematic cataloguing of protein spots from 2D gels and the building of databases of all expressed proteins (39). However, although the separation of proteins on 2D gels could be performed reproducibly in many different laboratories, the identification of proteins was difficult because of a lack of analytical methods for protein characterisation. In the 1990s, this limitation was overcome by the development of highly sensitive ►mass spectrometry (MS), which has to be called the most significant breakthrough in proteomics research in the last 20 years (23). Thus, the combination of 2D gel electrophoresis for separation of complex protein mixtures with mass spectrometry techniques for protein identification marks the beginning of a new era of proteomics research. Since then, the area of inquiry covered by the term proteomics has widened considerably. Today, it includes the systematic analysis of ►protein-protein interactions using the two-hybrid system or protein arrays (46), as well as large-scale protein localisation studies by ►immunofluorescence (IF) microscopy or studies to determine protein structure by X-ray crystallography (43). However, strategies exclusively targeting genes or messenger RNA, such as large-scale mutagenesis screens (51) or systematic antisense experiments (18) are not usually considered to be part of proteomics.

Introduction

The human genome project has laid the foundation for proteomics by providing the sequence data essential

for systematic protein analysis. Now, our goal is to understand the complex biological processes in which proteins are involved, using high throughput biochemical and cell biological approaches. In this review, we will describe how proteomics in the future will contribute to our understanding of biology and medicine through the global analysis of gene products.

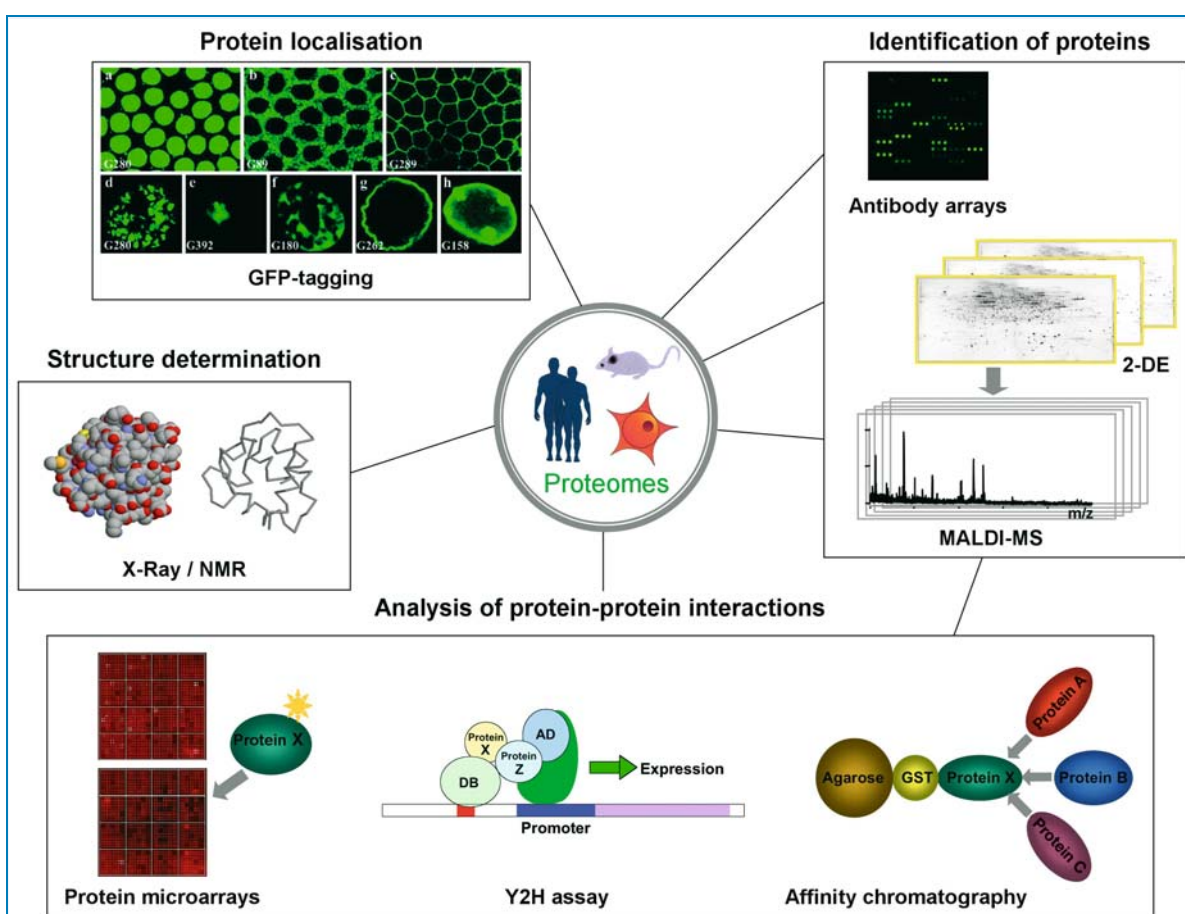

Why do we need proteomics research? During the past fifteen years, comprehensive DNA sequence information has been generated by the various genome projects. However, this information *per se* is not sufficient to understand the function of proteins in living organisms. A cell usually depends on a multitude of metabolic and regulatory pathways and there is no strict linear relationship between the genome and its protein complement, the “proteome”. Only a fraction of genes is activated in a specific cell type at a given time and protein synthesis and folding, rather than merely the genetic layout, determine the cell’s phenotype. Therefore, the systematic analysis of proteins and their interaction partners will significantly contribute to our understanding of cell function and the identification of novel drug targets for therapeutic intervention.

The analysis of ►open reading frames (ORFs) in genomic data sets for example, does not necessarily allow the prediction of functional proteins. This is particularly true for small genes and genes with low homology (9, 42). For reliable human gene prediction, it is therefore critical to verify the respective gene product by proteomics methods.

Modifications such as ►phosphorylation or ►methylation of proteins are also not apparent from the DNA sequence. Proteomics studies on tissue specific protein extracts are needed to identify active isoforms in protein complexes as well as post-translational modifications. As mRNA levels do not mostly correlate with protein expression levels (20), it is also necessary to quantify the amounts of proteins in cell extracts for the systematic analysis of gene regulatory networks. Moreover, the subcellular localisation of proteins as well as their interaction partners cannot be predicted from the DNA sequence. Co-localisation as well as protein-protein interaction studies are important to determine the molecular composition of cellular structures at the protein level. Together, these areas of proteomics research (summarised in Fig. 1) will increase our understanding of protein function and disease processes. They will allow the identification of new biomarkers for diagnosis as well as of new targets for therapy and accelerate drug development for complex diseases.

Identification of Proteins

A critical step in proteomics is the obtaining and handling of protein samples. Protein samples

Proteomics – from Proteins to Disease Mechanisms and the Development of Novel Therapeutic Strategies.

prepared from tissues or cell lines contain >10,000 different proteins, which can be partly separated by 1D and 2D gel electrophoresis (2-DE). Although the best 2D gels are capable of resolving up to 10,000 protein spots (25), only the most abundant proteins of crude protein extracts can be visualised by 2D gel electrophoresis because the amounts of several proteins lie below the detection limit of the protein stains used. Subcellular fractionation techniques or affinity based purification strategies are applied to overcome this difficulty and to reduce sample complexity prior to electrophoresis. After silver or Coomassie staining, spots/bands of interest are excised and proteins are identified by mass spectrometry, which has replaced the classical technique of Edman degradation, because it is much more sensitive and offers higher throughput.

There are two major approaches for mass spectrometric protein identification, the “peptide mass mapping” approach and the “peptide fragmentation” approach. In the peptide mass mapping approach, initially described by (23), the mass spectrum of the eluted peptide mixture is acquired by ▶**matrix-assisted laser desorption/ionisation** (MALDI) measurement. The method has been improved by the automation of the MALDI identification procedure, whereby hundreds of protein spots can be excised, enzymatically digested and automatically analysed (6). In the “peptide fragmentation” approach, individual peptides in a mixture are analysed to gain sequence information (12). The peptides are ionised by ▶**Electrospray Ionization Mass Spectrometry** (ESI) directly from the liquid phase. They are then sprayed into a “tandem mass spectrometer”, which has

the ability to resolve peptides in a mixture, isolate them by species and dissociate them into N- or C-terminal fragments. This tandem method (ESI-MS/MS) is technically more complex than MALDI fingerprinting, but has the advantage of yielding the sequences of peptides, rather than listing only peptide masses. The fragmentation data can be used to search protein sequence databases and also nucleotide databases such as ► **expressed sequence tag** (EST) resources, which increases the probability of identifying an uncharacterised protein.

The development of mass spectrometry techniques for the identification of proteins is a rapidly growing field. A mass spectrometer unit that combines a MALDI ion source with an efficient tandem mass spectrometer for fragmentation of peptides is now available (53). It combines the high throughput capacity of the peptide mapping method with the specificity of the peptide sequencing method and allows an automated one step analysis strategy. Ongoing efforts are directed at speeding up sample preparation and separation in highly integrated appliances.

A main future goal is to analyse complex protein mixtures by mass spectrometry without prior gel separation in a single automated experiment and thereby to overcome problems of the 2-DE based protein identification, such as missing the identification of hydrophobic and low abundance proteins. The introduction of a liquid chromatography based peptide separation strategy named “► **multidimensional protein identification technology**” (MudPIT) was an important step forward in this direction (33). The basis of this technique is the digestion of a complex mixture of proteins before they are separated by two independent liquid chromatographic separation systems. From the second column the peptides are eluted directly into an ion trap mass spectrometer, where they can be measured and identified in a fully automated fashion.

Quantification of Proteins and Differential Display Proteomics

2D Gel Electrophoresis Approach

In most proteomics laboratories, 2D gel electrophoresis is used to identify and quantify proteins that are up- or down-regulated in specific cells or tissues. Biological materials derived from two different conditions are separated by 2D gel electrophoresis and proteins are visualised by Coomassie or silver staining. Using image analysis, proteins that are only present in one condition are selected and identified by mass spectrometric analysis. Using this approach, several diagnostic markers as well as potential therapeutic targets were identified in the past (see

Clinical Proteomics section). A recent study compared the protein complements from different mouse strains by 2D gel electrophoresis and, surprisingly, over 1,000 genetically variant protein spots were identified (26), indicating that 2D gel proteomics can be used to study genetic variability in mice in high throughput. However, the 2D approach has the disadvantage that the reproducible preparation of protein samples is difficult and requires a lot of experimental experience. An important recently made improvement in the 2D gel approach is the use of difference gel electrophoresis (► **DIGE**), in which two pools of proteins are labelled with different fluorescent dyes and separated in the same 2D gel (58). The advantages of this system lie in the increased reproducibility of the protein separation because the samples to be compared are separated in the same 2D gel, which decreases the number of 2D gels to be run. A further advantage lies in the high sensitivity and the broad and linear dynamic ranges of the fluorescent dyes, which should help to quantify even low abundance proteins accurately.

Analytical Protein Microarrays

► **Protein microarrays** permit the analysis of hundreds or even thousands of addressable proteins in parallel, printed in a systematic order at high density on coated glass slides (69). To profile proteins or antibodies in crude protein samples of interest, analytical protein microarrays consisting of antibodies or protein antigens respectively, are increasingly used. In diagnostics, analytical microarrays are applied to discover new disease markers (see Clinical Proteomics).

To profile antibodies from biological samples by antigen arrays, the bound antibodies are often detected by fluorescently labelled secondary antibodies (49). Antibody arrays can be probed with protein extracts from two different cell states labelled with two different fluorescent dyes (55) or with unlabeled extracts followed by incubation with a fluorescently labelled antibody binding to a different epitope from that recognized by the capture antibody (sandwich) (37). To detect proteins present in low amounts, such as IgE or cytokines, by analytical microarrays, rolling circle amplification offers a very sensitive detection (52). Protein profiling experiments with antibody arrays depend very much on well-characterised antibodies and many technical problems have yet to be overcome for routine application (3). However, some promising results have already been obtained, such as the profiling of receptor kinases (37) or cytokines (52). We predict that antibody arrays for quantification of proteins in cell extracts will be a highly important and widely used proteomics tool in the future.

Protein Quantification by Mass Spectrometry

A combination of mass spectrometry and radioactive labelling can also be used to quantify proteins in cell extracts (38). Bacteria, for example, are grown in two different media, with the natural abundance of nitrogen isotopes or enriched in N^{15} . Protein preparations are then mixed, separated and analysed by mass spectrometry. Two versions of any peptide in the protein mixture can be detected by their number of nitrogen atoms leading to a pair of peaks from each peptide. The ratio of peak heights allows the accurate quantification of the corresponding proteins. As an alternative, the isotope-coded affinity tag (▶ICAT) method, where cysteine-containing peptides are labelled *in vitro* prior to mass spectrometry, was developed (19).

Protein Modifications

Post-translational modifications, such as phosphorylation, glycosylation and sulphation, while not apparent from genomic sequence or mRNA data, modulate the activity of many proteins and are enormously important for protein function.

The 2-DE protein separation technique often has sufficient resolution to separate the modification states of a protein directly. Some of these protein modifications can be recognized on the 2D gels, as “trains of spots”, namely groups of protein spots showing a regular spacing in their molecular mass or in their isoelectric point (pI) distributions. For example, phosphorylation changes the protein charge and is often indicated by a horizontal train of spots. Protein modifications can also be determined with the aid of mass spectrometry. The combination of function or structure based purification of modified “subproteomes”, such as phosphorylated proteins, with mass spectrometry is suitable. Stable isotope labelling strategies in combination with mass spectrometry have been applied to study the dynamics of protein modification (34).

Antibody arrays are other promising tools in this respect. Nielsen et al. (2003) used antibody microarrays to monitor the amounts and modification states of signal transduction proteins from crude cell lysates. They captured proteins of interest by specific antibodies. Phospho-specific antibodies were used to detect the phosphorylation state of the proteins.

To study protein phosphorylation *in vitro*, protein and peptide microarrays are increasingly used (11). Zhu et al. (2000) developed protein microarrays bearing microwells in which 17 different protein substrates were covalently immobilized. Nearly all of the protein kinases from *S. cerevisiae* were analyzed and many novel activities were found as well as 27 protein kinases with an unexpected tyrosine kinase activity.

To screen for potential protein substrates of barley CK2 α kinase, Kramer et al. (2004) generated protein microarrays including 800 different recombinant barley proteins and identified 21 substrates, including known as well as novel substrates of CK2 α .

Protein Localisation
