Several types of junctions mediate cell-cell interactions and contribute to the barrier function characteristic of epithelia (Fig. 2) (1). All simple epithelial cells have an adhesive belt called the zonula adherens that encircles the cell just below the apical surface and forms the ▶adherens junction (AJ). In vertebrates, tight junctions (TJ) or zonula occludens (ZO) form apical to the AJ and mark the morphological and functional boundary between the apical and basolateral membrane domains. Adherens junctions and desmosomes, which lie below the AJ, are thought to provide mechanical strength to the cells. ▶Gap junctions are formed by ▶connexins, which form hemichannels that link the cytoplasm of adjacent cells and allow for intercellular communication. In *Drosophila*, epithelial cells have septate junctions basal to the AJ, which form membrane contacts that extend over a large area of the lateral plasma membrane. Although TJs are absent in *Drosophila*, the sub-apical region, which is apical to the AJ, has protein complexes that colocalize with vertebrate TJs

Epithelial Cells. Figure 1 (a). A simple tubular epithelium showing the apical and basolateral surfaces demarcated by tight junctions (TJs) which create a physical barrier to the movement of macromolecules. Asymmetric protein distribution in the apical and basolateral surfaces enables intracellular vectorial solute transport. While transcellular transport is vectorial, energy-dependent and relies on cell-specific transporters and channels, paracellular transport occurs by passive diffusion down a concentration gradient and does not exhibit directionality. The relative contribution of each route to total transepithelial flux depends on the physical characteristics of the solute because TJs exhibit charge and size selectivity. (b) The organization of an epithelial cell depicting the main structural features that contribute to the polarized phenotype. See Section II for details.

Epithelial Cells. Figure 2 Junctional complexes in epithelial cells. The vertebrate epithelial cell contains the tight junctions (TJ) and the subjacent adherens junction (AJ) that form the apical junctional complex (blue box). Although *Drosophila* epithelial cells do not have TJs, many proteins in the sub-apical region (SAR) colocalize with TJs. The septate junction is present basal to the AJ in *Drosophila*. The epithelial cells of *C. elegans* have a single junction, the *C. elegans* apical junction (CeAJ). See Table 1 for the molecular composition of these junctions.

(see below). In the nematode *Caenorhabditis elegans*, the *C. elegans* apical junction (CeAJ) resembles the AJ of *Drosophila* and vertebrates (Fig. 2). In vertebrates, TJs form a selective permeability barrier that restricts the paracellular movement of molecules and water (gate function). Tight junction proteins include the transmembrane occludin and claudins and peripheral scaffolding proteins like ZO-1 (Table 1). As seen in electron micrographs, these proteins appear as parallel strands that form an anastomosing network

around the apical pole between adjacent cells and form the physical basis for the diffusion barrier. A qualitative estimate of a junction’s gate function is provided by the average number of strands along the apical-basal axis; a precise quantitative estimate of this gate function is provided by the [trans-epithelial electrical resistance](#) (TER). In addition to the gate function, TJs also form an intramembranous fence that prevents the intermixing of apical and basolateral plasma membrane proteins and lipids, which helps to maintain cell surface polarity

Cell Adhesion

Epithelial cells interact with one another *via* ►cadherin-mediated cell-cell adhesion and with the ►extracellular matrix (ECM) *via* ►integrin-mediated cell-matrix adhesion on the basal side of the cells. Accumulation of an endogenously secreted ECM generates an initial level of cellular asymmetry and orients the apicobasal axis of polarity that is necessary for vectorial transport of solutes and ions. Contacts between cells or between a cell and the ECM trigger the compartmentalization of proteins into contacting (basolateral) and free (apical) surface domains (2).

All adhesion complexes share a common architecture, a set of transmembrane proteins that interact with extracellular components (ECM or neighboring cells) on the outside and are anchored to other proteins or the cytoskeleton on the inside. Extracellular domains of the epithelial cell-specific E-cadherin mediate Ca^{2+} -dependent homophilic interactions between cells, mainly at the AJs. Cadherins also have two cytoplasmic domains, one of which binds β -catenin and the other p120 catenin, a regulator of cadherin clustering. β -catenin anchors cadherin to the actin cytoskeleton *via* α -catenin. Another actin-binding protein, vinculin, also helps in anchoring cadherins to the actin cytoskeleton and organizes cadherin into circumferential AJs. Cell-cell adhesion mediated by E-cadherin plays an important role in specifying membrane asymmetry and is required to restrict the localization of apical and basolateral proteins to their respective domains.

Interactions between epithelial cells and the ECM are mediated by the integrin superfamily of adhesion receptors. These receptors, which consist of an α subunit non-covalently linked to a β subunit, bind all major constituents of the ECM including collagens, laminins and fibronectin. Integrins serve as transmembrane linkers, mediating interactions between the ECM and the ►actin cytoskeleton with the help of proteins such as α -actinin, talin, tensin and filamin. These linkages lead to a clustering of integrins and the formation of focal adhesions. Integrin binding to the ECM activates intracellular signaling pathways, which inform the cell about the character of the underlying matrix, and influences intracellular gene expression. Integrin-mediated signaling pathways mainly involve focal adhesion kinase (FAK) and integrin-linked kinase (ILK). Activation of FAK triggers intracellular signaling cascades such as the extracellular signal-regulated kinase (ERK) pathway, which regulates cell

proliferation and survival. Activation of ILK activates transcription factors LEF/TCF and AP-1.

►Cytoskeleton

As stated above, the actin cytoskeleton associates with both cadherin and integrin adhesion receptors. These interactions lead to localized cytoskeletal assemblies that strengthen cell-cell and cell-ECM contacts and serve as scaffolds for the recruitment of signaling molecules (see below). From the standpoint of polarity, these localized cytoskeletal assemblies result in the immobilization of different proteins at the basal and lateral domains, generating subcompartments within the basolateral membrane without a definite barrier in between them.

Distinct cytoskeletal elements function in the structural and functional organization of the apical and basolateral membrane domains in epithelial cells. The apical plasma membrane has numerous extensions, or microvilli ($\sim 1 \mu\text{m}$ long and $0.1 \mu\text{m}$ in diameter), that protrude into the extracellular milieu and create an increased surface area for secretion and absorption. At the core of each microvillus lies a bundle of parallel actin filaments cross-linked by the actin-bundling proteins villin and fimbrin. These actin filaments extend to the base of the cell and are embedded in a terminal web of fodrin and actin, which in turn is linked laterally to the zonula adherens by proteins such as α -actinin and vinculin. At the basolateral membrane, the principal cytoskeletal protein fodrin, actin and other associated proteins form a protein lattice on the cytoplasmic face of the membrane. Fodrin also binds ankyrin which binds with high-affinity to integral membrane proteins such as Na^+ , K^+ -ATPase and $\text{Cl}^-/\text{HCO}_3^-$ exchanger. This fodrin-based lattice may participate in the establishment of the basolateral membrane by directing the retention and accumulation of proteins that have an affinity for the fodrin lattice. Epithelial monolayers participate in organ morphogenesis through junctional complexes and the contractile cytoskeleton that is formed by actin filaments attached to AJs. Contraction of these filaments draws the apical surfaces of the connected cells together and causes an invagination of the epithelium at that point. Non-contractile cytoskeletal elements such as the intermediate filaments form an intracellular scaffold from one side of the cell to the other at desmosomes. This scaffold helps maintain the structural integrity of the epithelium against shear stress. Microtubules in epithelial cells are organized into a subapical web and longitudinal bundles to the base of the cells. These microtubules participate in the spatial organization of cytoplasmic organelles and serve as tracks in the vectorial transport of vesicles to and from the plasma membrane.

Polarized Membrane Traffic

Newly synthesized membrane proteins are synthesized in the endoplasmic reticulum and transported through the Golgi apparatus to the cell surface. Some plasma membrane proteins, particularly on the basolateral surface, are quickly internalized into endosomes and recycled back to the original cell surface (Fig. 3). Other proteins undergo transcytosis: after internalization into endosomes, the protein is not recycled back to its original surface, but is delivered to the opposite domain. The biosynthetic, recycling and transcytotic routes of plasma membrane proteins are controlled by

Epithelial Cells. Figure 3 Sorting pathways in epithelial cells. From the trans-Golgi network (TGN), proteins can be directly transported to either the apical (pink) or basolateral (orange) domains based on their sorting signals i.e., “selective delivery”. Alternatively, cargo can be first sent to the common recycling endosome (CRE, purple) from where the proteins are differentially sorted. At the basolateral plasma membrane, proteins are either “selectively retained” or re-endocytosed and transported to basolateral early endosomes (BEE, blue). These proteins can be recycled back to the basolateral surface, sent to lysosomes for degradation or transcytosed to the opposite plasma membrane. Transcytosing proteins and recycling apical membrane proteins are ferried from the CRE to the apical recycling endosome (ARE). Clathrin adaptor proteins such as AP1B and AP2 decode sorting signals and function in the polarized trafficking of proteins. For a detailed explanation of these pathways and other intermediate organelles that might be involved, please see Ref.5.

specific sorting mechanisms. These involve the recognition of specific “zip codes” (sorting signals) in the transported proteins by specialized “sorters” that mediate the incorporation of the protein into carrier vesicles (see below). All epithelial cells use biosynthetic sorting, recycling *via* ►endosomes and selective delivery/transcytosis to sort proteins, but the relative contribution of each pathway varies among different epithelia. For example, in hepatocytes, most proteins are delivered to the basolateral membrane, after which a subset is selectively retained there, while others undergo transcytosis to the apical membrane. Some proteins may be additionally stabilized at specific membrane domains by interactions with scaffolding proteins, which often contain specialized interacting domains such as ►PDZ domains.

Basolateral proteins are sorted into post-Golgi transport vesicles based on specific motifs in their cytoplasmic domains that are thought to interact with adaptor coat proteins (Fig. 3). In contrast, apical sorting signals are less well understood and seem to be present in either the luminal domain or the membrane anchor. ►Glycosylphosphatidylinositol (GPI) anchors, N- or O-glycosylation or clustering of proteins into ►lipid rafts have been reported to confer apical targeting on some proteins, although exceptions exist in all cases. Transport vesicles are delivered from the trans-Golgi network (TGN) to the relevant plasma membrane with high fidelity. Microtubule motors, the actin cytoskeleton and specification of vesicle docking and fusion with the correct membrane all contribute to the accuracy of polarized protein sorting. The molecular nature of the sorting signals and vesicle targeting and fusion machinery are discussed below.

Polarized membrane traffic also underlies the role of epithelia as active barriers. Epithelial cells modify their environment by secretion, ion and nutrient transport and transcytosis of macromolecules across the cell. Secretion can occur at either the apical or basolateral surface and can be constitutive (production of ECM components) or regulated. Ion transport, which is essential for maintaining cell volume and osmotic balance, occurs with the help of transporters and channels. Transcytosis of macromolecules such as immunoglobulins from one biological compartment to another aids in host defense against infectious agents (see below).

Specialized Epithelia

Tissue-specific modifications of polarized epithelial cells produce a wide variety of specialized cell types. An example of this is the retinal pigment epithelium (RPE), which lies beneath the photoreceptors and forms the outermost layer of the retina, i.e. the blood-retinal barrier. Unlike most other epithelial cells, the microvilli on the apical surface of the RPE are not free, but

are interdigitated with photoreceptor outer segments. The RPE supports photoreceptors by processing retinoids, supplying them with nutrients and transporting metabolites out of the retina. Cells of the RPE participate in the circadian phagocytosis of shed outer segment tips of photoreceptors, thus aiding photoreceptor regeneration. Indeed, these cells are the most phagocytically active cells in the body. Dysfunction of the RPE plays a principal role in the pathogenesis of age-related macular degeneration.

Another example of specialized epithelia is the choroid plexus epithelium (CPE), part of the choroid plexus which lies within the ventricles of the [▶brain](#). These cells have tightly packed microvilli at the apical surface and TJs that prevent the paracellular transport of solutes between the blood and cerebrospinal fluid (CSF) i.e., the blood-CSF barrier. In addition to supplying the brain with hormones and nutrients, the CPE is partly responsible for secreting the CSF, which bathes the central nervous system and provides protective mechanical cushioning for the brain through its buoyant action. Polarized secretion of CSF occurs as a result of unidirectional flux of Cl^- and Na^+ , which in turn creates an osmotic gradient that drives the secretion of water. Aquaporin 1, which mediates water transport across cell membranes, is present on the apical surface of the CPE. Impaired choroidal transport may contribute to the pathogenesis of Alzheimer's disease. In contrast to most epithelia where Na^+ , K^+ -ATPase is on the basolateral membrane, both the RPE and CPE express this pump exclusively on their apical membranes. This "reverse" polarity is necessary for maintaining a high Na^+ environment required for photoreceptor function and for Na^+ secretion into and K^+ absorption from the CSF.

Hepatocytes are another type of specialized epithelial cell with a different polarity axis; the canalicular membrane domain, which corresponds to the apical surface in epithelial cells, is enclosed by adjacent cells while the sinusoidal and lateral domains correspond to the basolateral surface of epithelial cells. The apical membranes of hepatocytes line the bile canalicular tract. The sinusoidal membranes face the blood circulation. The sinusoidal and canalicular membrane domains are separated by tight junctions and exhibit distinct lipid and protein polarity as seen in other epithelia. This polarization is necessary for the diverse functions performed by hepatocytes, such as canalicular bile secretion and sinusoidal secretion of serum proteins into the blood. Hepatocellular polarity is disturbed in diseases like cholestasis.

Molecular Interactions

The generation of epithelial polarity in a multicellular organism requires highly coordinated molecular

interactions (3, 4). These interactions function at two focal points: one, the apical junctional complex that initiates intercellular contacts and regulates the identity of membrane domains and two, the polarized sorting and targeting of proteins.

The Apical Junctional Complex

The AJC, which is conserved between *C. elegans*, *Drosophila* and vertebrates, refers to the multi-protein assemblies that make up the adherens and tight junctions. The AJC is a multifunctional apparatus that provides strong adhesion between adjacent cells and forms the diffusion barrier characteristic of epithelia (Fig. 2 and Table 1). In addition, signaling networks that control epithelial cell proliferation, polarity and differentiation converge at the AJC. The constituents of the AJC share a basic structural motif; an integral membrane protein binds intracellular scaffold proteins that in turn bind the actin cytoskeleton and interact with other complexes. Genetic analyses in *Drosophila* and *C. elegans* have identified proteins in AJC sub-complexes that are crucial for epithelial cell polarity: cadherins/catenins, Crumbs (Crb)-Stardust (Sdt)-Patj, Bazooka (Baz/Par 3)-Par 6-atypical protein kinase C (aPKC) and Scribble (Scrib)-Lethal giant larvae (Lgl)-Discs large (Dlg). These protein sub-complexes are functionally integrated into a hierarchical model that regulates the specification of apical and basolateral membrane domains. The Baz-Par 6-aPKC complex initiates the formation of the apical membrane, whose lateral spread is controlled by the Scrib-Lgl-Dlg complex. The Crb-Sdt-Dlg complex is apical to the Baz complex and helps maintain the apical membrane identity. The Scrib-Lgl-Dlg complex establishes the identity of the lateral membrane and is antagonized by the Crb complex. *Drosophila* embryos that lack Crb or Sdt fail to establish a continuous AJ and exhibit lethal defects in cell polarity and tissue organization. Loss of Bazooka or aPKC results in an inability to establish polarity and a failure to form AJs. Defects in the Scrib-Lgl-Dlg complex cause an expansion of the apical membrane into more lateral positions and lead to a multilayered epithelium. In vertebrate TJs, the transmembrane proteins occludin, claudins and the junctional adhesion molecule (JAM) interact with the cytoplasmic PDZ domain-containing proteins ZO-1, ZO-2, ZO-3 and Par3, which serve as scaffolds for other cytoskeletal proteins and signaling molecules.

The [▶Rho-family small GTPases](#) Cdc42 and Rac1 link actin to components of the AJC and regulate actin polymerization with the help of the Arp2/3 complex and other proteins like N-WASP. Cdc42 contributes to microtubule polarization by recruiting IQGAP1, which binds the microtubule tip protein CLIP170 and

promotes microtubule capture. IQGAP1 interferes with homophilic cadherin interactions and reduces epithelial cell adhesion. Cdc42 and Rac1 counter this effect of IQGAP1 by inhibiting the latter's interactions with E-cadherin and β -catenin.

Ezrin, radixin and moesin (ERM) are a family of membrane-associated proteins that link the actin cytoskeleton to proteins on the cell surface. Ezrin is predominantly found in the apical microvilli of polarized epithelial cells while radixin is found in the microvilli of bile canaliculi. By virtue of their interactions with F-actin, ERM proteins participate in maintaining epithelial polarity, membrane transport and signal transduction. In *Drosophila*, moesin localizes with Crumbs and moesin mutants exhibit loss of polarity and disassembled junctions. Recent studies in mice show that ezrin is essential for maintaining the apical terminal web, which anchors the microvilli and stabilizes intercellular junctions. In the absence of ezrin, microvilli are irregular and the apical junctions are elongated.

Polarized Protein Sorting and Transport

As stated previously, short sequences in the cytoplasmic or luminal domains of proteins are thought to dictate their sorting into vesicles destined for transport to the basolateral or apical membrane from the TGN (Fig. 3). Basolateral sorting signals usually contain a crucial tyrosine residue within the sequence NPxY or Yxx ϕ (where x is any amino acid and ϕ is an amino acid with a bulky hydrophobic side chain). Non-tyrosine-based (mono- and dileucine) and dihydrophobic sorting signals have also been identified for some basolaterally targeted proteins. The Yxx ϕ motif and sorting signals with a pair of leucine residues preceded by an acidic cluster bind to tetrameric clathrin adaptor proteins such as AP-1 at the TGN or endosomes. A second type of dileucine signal binds another family of clathrin adaptors called the GGAs (Golgi-localized, γ -ear-containing, ARF-binding proteins).

Once the apical and basolateral membrane proteins are sorted into distinct subdomains, they are packaged into carrier vesicles that bud from tubular extensions of the TGN. Polarized budding of vesicles from the TGN is thought to be regulated by Cdc42. Fidelity of vesicle docking and fusion with the correct membrane domain is ensured by the [▶SNARE complex](#) where cognate vesicle v-SNAREs bind target membrane t-SNAREs. Endogenous t-SNAREs have polarized distributions in epithelial cells; syntaxin 3 is apical while syntaxin 4 is predominantly basolateral. Recent studies in [▶Madin-Darby canine kidney \(MDCK\) cells](#) suggest that a multiprotein complex consisting of mammalian homologs of the yeast exocyst (sec6/8) complex may function in targeting vesicles to the basal-lateral

membrane. During polarization, following cadherin-mediated adhesion, the exocyst is recruited to the apex of the lateral membrane, i.e., the region of basolateral vesicle docking and fusion. The actin cytoskeleton is important for organizing vesicle delivery to the basolateral membrane, while microtubules participate in long-range vesicle transport ([▶Vesicular Traffic](#)) and organize vesicle delivery to the apical membrane (5, 6).

Regulatory Mechanisms

Epithelial Polarity and Neoplasia

Approximately 95% of lethal human carcinomas are epithelial in origin and are characterized by loss of cell polarity. Cells at the leading edge of these tumors undergo an [▶epithelial-to-mesenchymal transition \(EMT\)](#), which makes them less adhesive and more migratory. Structural alterations in tight junctions have been demonstrated in ovarian, liver, colon and breast cancers. Tumor-promoting factors such as tissue plasminogen activator cause leakiness in the TJs and allow the passage of many solutes. Thus, regulation of epithelial cell polarity is tightly coupled to proliferation and invasion. In *Drosophila*, *discs large*, *scribble* and *lethal giant larvae* have been identified as tumor-suppressor genes; *dlg*, *scrib* or *lgl* homozygous mutants exhibit uncontrolled proliferation. Interestingly, human Dlg and Scrib are targeted for proteasomal degradation by oncogenic viruses such as the human papilloma virus, which causes cervical cancer.

Pathogen Entry and Host Defense

Epithelial cells lining the respiratory, gastrointestinal and urogenital tracts are continually challenged by bacteria, viruses and toxins. While tight junctions and the glycocalyx that covers the apical surface provide a barrier to invasion, bacteria and other pathogens have evolved numerous mechanisms to circumvent the epithelial barrier and colonize the host tissue (7). Bacteria such as *Vibrio cholerae* secrete enzymes that break down one or more transmembrane proteins that form the AJC, resulting in loss of barrier function. Others like pathogenic strains of *E. coli* synthesize toxins that activate Rho GTPases Cdc42 and Rac1, leading to cytoskeletal rearrangement and internalization of TJ proteins JAM, ZO-1 and occludin. *Helicobacter pylori* translocates an effector protein CagA into the host cell that forms a complex with JAM and ZO-1 and disrupts the AJC. The diffusion barrier is compromised, resulting in leakage of solutes from the interstitium to the apical surface where the bacteria colonize. For pathogens like *Shigella flexneri* and *Pseudomonas aeruginosa*, loss of epithelial cell polarity is essential for infection.

Epithelial Cells. Table 2 Pathological manifestations of altered trafficking and polarity of membrane proteins

Disease	Defect	Consequences
Cystic Fibrosis	Loss of C-terminal CFTR PDZ-binding domains (apical sorting determinant)	Missorting of CFTR protein; Impaired chloride secretion and lethal alterations in lung epithelial function.
Wilson disease (Copper toxicity)	Mutations prevent sorting of P-type ATPase ATP7B into apically targeted vesicles.	Mislocalization of ATP7B which mediates copper clearance in renal epithelia.
Familial hypercholesterolemia	Mutations affect proper targeting and internalization of the LDL receptor.	LDLr is mistargeted to the canalicular (apical) membrane of hepatocytes instead of the sinusoidal membrane. FH predisposes patients to heart failure and early death.
Nephrogenic diabetes insipidus	Mutations in aquaporin-2 that redirect it to lysosomes for degradation.	Polydipsia, polyuria, renal insufficiency.
Liddle's syndrome	Prolonged stabilization of epithelial Na ⁺ channel on apical membrane caused by a loss of the motif that tags the protein for rapid endocytosis and ubiquitination.	Severe salt-sensitive hypertension; excessive Na ⁺ reabsorption by kidney epithelia.
Polycystic kidney disease (autosomal dominant)	Defective basolateral targeting due to depletion of the exocyst (Sec6/8) complex; aberrant signaling caused by mutant polycystin-1.	Dedifferentiation of kidney epithelia; formation of large fluid-filled cysts in the kidney; loss of renal function.

Epithelia have non-specific mechanisms for host defense including mucus secretions, gastric acid and lysozyme that can neutralize pathogens. Specific defense mechanisms involve immunoglobulins IgA, IgG and IgM, which are secreted by local B-lymphocytes underlying the epithelium and are actively transported across the cell (transcytosis) by specific receptors. They are then secreted into the lumen where they act specifically to prevent infection. IgA and IgM bind the polymeric immunoglobulin receptor on the basolateral membrane of the epithelial cells and the ligand-receptor complex is then endocytosed and transported through a variety of intracellular compartments to the apical surface. The secreted immunoglobulin prevents the interactions of pathogens with the epithelial cell surface by interfering with their motility or by competing with the pathogens for binding sites on the cells (8).

Sorting Defects in Disease

Regulatory pathways that maintain the epithelial phenotype are crucial for the normal functioning of organs such as the liver, intestine and kidneys. Defects in these pathways can lead to mistargeting of proteins

and a loss of polarity and consequently, manifestation of disease (Table 2).

Epithelial-to-Mesenchymal Transition

Definition

Epithelial-to-mesenchymal transition (EMT) (synonym: epithelial-to-mesenchymal conversion) describes a common process during morphogenesis and differentiation. It includes a series of coordinated events that result in cell-cell and cell-matrix interactions and cytoskeletal organization. EMT is a common event in early embryonic development, whereby tightly bound columnar (epithelial) cells lose their intercellular attachments and convert into motile, multipolar (mesenchymal) cells. EMT also accompanies cancer progression from the non-invasive to the invasive state. The process not only comprises of the transition from the epithelioid (e) to fibroblastic (f) morphology, indicating epithelial cell plasticity, but also a change in molecular markers with loss of E-cadherin and gain of vimentin.

ES Cell Differentiation as a Model System for Functional Genomics

KENNETH R. BOHELER

Kenneth R. Boheler, Laboratory of Cardiovascular Science, NIA/NIH, Baltimore, MD, USA
bohelerk@grc.nia.nih.gov

Definition

The pace of sequencing whole genomes has far exceeded our knowledge of gene function, resulting in a set of biotechnological tools consisting of clones, sequence data across genomes and a full catalog of genes from multiple species. Unlike genomics, which is the study of genes and gene function, ► [functional genomics](#) can more aptly be defined as a set of biotechnological tools employed either in the context of an entire genome (e.g., gene trapping) or based on genome-wide information that can be employed to

understand basic mechanisms of gene regulation, structure and function. The development of functional genomics in the context of the latter has specifically led to high throughput assays that permit rapid analysis of a cell's ►**transcriptome** (i.e., entire RNA population in a sample) to elucidate expression patterns of genes (known and unknown) as well as the regulation of gene function. Recently, functional genomics in the context of high throughput assays has been employed to examine ►**embryonic stem cell** lines. These cell lines, derived from the early embryo, retain properties of embryo founder lines, have the capacity to undergo unlimited self-renewal and are capable of multilineage differentiation (►**pluripotentiality**). The specific transcripts/proteins that distinguish ►**stem cells** from non-pluripotent cells remain incompletely known and therefore some mechanisms responsible for self-renewal and pluripotentiality are unknown. Since the identification of signals that regulate the transition from undifferentiated to differentiated cells is fundamental to the understanding of cellular diversity and development, functional genomic approaches have proved critical for defining the molecular basis of multilineage differentiation and to impart the rationale for future hypothesis-driven studies.

Characteristics

Embryonic Stem Cells

Pluripotent stem cell lines derived from early mouse embryos can be maintained as relatively homogeneous stem cell cultures and expanded indefinitely. Three types of pluripotent, self-renewing stem cell lines have been established from mammalian embryos, embryonic carcinoma (EC), embryonic stem (ES) and embryonic germ (EG) cells. EC cell lines are derived from undifferentiated stem cell components of spontaneously arising or experimentally induced germ cell tumors, EG cell lines are derived from primordial germ cells, isolated primarily from the genital ridge and ES cell lines originate from pre-implantation embryos. ES cell lines, in particular, maintain a stable karyotype in culture and retain the character of embryo founder cells. When injected into a blastocyst, ES cells reintegrate fully into embryogenesis, in such a way that chimeric mice contain ES-derived cell progeny among all tissue cell types, including gametes. Undifferentiated ES cells are amenable to genetic engineering *via* random insertion events or homologous recombination, which allows the introduction of precise genetic modifications (knock-ins or knock-outs) in the mouse germ-line.

Embryo-derived stem cell lines (EC, EG and especially ES cell lines) readily differentiate *in vitro* into virtually any cell of endodermal, mesodermal or ectodermal origin. This differentiation process recapitulates many aspects of development, including early but poorly

accessible stages of mammalian embryogenesis. Differentiation of embryo-derived stem cell lines *in vitro* normally (except neurogenesis) requires an initial aggregation step to form three-dimensional spheroid structures, termed ►**embryoid bodies** (EBs) that can differentiate into a wide variety of specialized cell types, including cardiomyocytes, smooth and skeletal muscle cells, hematopoietic cells, cartilage, melanocytes and neurons. Importantly, differentiation of ES cells and formation of EBs can be regulated by the addition of growth factors and additives, the number of starting cells within a developing EB and the time and duration of plating.

Functional Genomics

Functional genomic assays are explicitly designed to generate gene expression profiles and identify gene transcripts that show altered abundance. The assays are not intended to provide mechanistic information, but are intended to provide new information to help explain the physiological role of a given gene-protein in a living organism, a task that has often proven difficult in early mammalian development. The conventional reductionist approach of studying one gene at a time is thus complemented by a more global or integrative approach that considers many genes at once. This ultimately facilitates gene, gene function and pathway discovery. An ideal transcriptome analysis should assay every transcript in a pure cell population prepared or cultivated under standardized conditions. Although the mouse and human genomes have been sequenced, some genes and gene transcripts remain to be identified, precluding an ideal analysis. Embryo-derived stem cell lines that are stable in culture represent an excellent source of cells, but because cell cultivation techniques are not always consistent between laboratories (differences in culturing conditions or reagents, isolation techniques, etc), some variation is expected. Differentiation of embryo-derived stem cells *in vitro* also leads to a heterogeneous population, making interpretation of transcriptome analyses challenging in the absence of complimentary data. Finally, the assumption in performing functional genomic analyses of ES cells during differentiation is that self-renewal and pluripotentiality involve a degree of regulation (e.g., transcriptional, post-transcription) that alters mRNA abundance.

Functional genomic techniques capable of analyzing mRNA transcript abundance include sequencing of expressed sequence tags (ESTs), subtractive hybridization, differential display, competitive PCR, cDNA or oligonucleotide ►**arrays** (►**microarrays**), and ►**serial analysis of gene expression** (SAGE). Only the latter two methods emerge as high throughput technologies suitable for gene expression analysis. Both techniques

are useful for comparisons, but the quantitative nature and uniformity of SAGE greatly facilitates comparative and comprehensive analyses among laboratories, particularly when the datasets are available in the public domain (<http://www.ncbi.nlm.nih.gov/sage/>). SAGE, a sequence-based technique, has the potential to detect and quantify the expression of all cell transcripts (known and unknown), but it is limited by the fidelity and cost of sequencing (1). It is a quantitative sampling technique that is ideal for examining poorly described cell transcriptomes. Two major principles underlie SAGE. First, short DNA sequences are sufficient to identify individual transcripts, and second, concatenation (linking together) of the short DNA sequences (i.e., SAGE tags) increases the efficiency of identifying unique transcripts in a sequence-based assay. The technique generates large numbers of short (e.g., 10 bp) tags, originating from the last (most 3') unique location of an enzyme recognition site in a single transcript. Sequences that satisfy a strict size criterion are analyzed, so that multiple tags corresponding to different transcripts are recognized in a single sequencing run. Currently more than 2,538,124 (476,880 unique) and 534,283 (229,136 unique) SAGE tags of human and mouse origins respectively, have been deposited in the SAGE database (<http://www.ncbi.nlm.nih.gov/SAGE/index.cgi?cmd=printstats>). Within these datasets, many SAGE tags do not correspond to sequences located within currently predicted genes. While some of the mismatches may be due to sequencing errors inherent in the SAGE method, studies utilizing SAGE catalogs have altered the previous estimates of biological complexity and led to the identification of novel genes in mammalian genomes (see below).

► **DNA microarrays**, a hybridization-based technique, permit a systematic and quantitative transcriptome analysis (2). Microarrays can only examine expressed sequences that have already been identified either from clones or previous sequencing assays. This assay is thus limited by the probes present on an array and by signal intensity; poorly expressed transcripts are often not reproducibly quantified by this technique. Specifically, arrays are tools that when employed in hybridization assays, either with radioactive or non-radioactive probes, can assay small amounts of DNA or RNA. Microarray experiments, when compared against other hybridizations performed in a similar manner, permit the elucidation of which transcripts show altered abundance (increased or decreased expression).

Functional Genomics and Application to Embryonic Stem Cells

The identification of signals that regulate pluripotentiality and self-renewal is fundamental to the

understanding of stem cell biology (Fig. 1). The earliest attempt to quantify the functionally active genome of ES cells employed SAGE. Murine R1 ES cells were cultivated under conditions that resulted in a relatively pure cell population while maintaining critical characteristics of undifferentiated ES cells (3). The SAGE catalog contained 44,569 unique SAGE tags, of which 35.2% did not match any sequence previously deposited to any EST dataset. The number of unmatched sequences has now declined to ~10%, but the vast majority (>60%) of transcripts still encodes proteins with only a putative or a completely unknown function. Although SAGE had initially been employed to define the transcriptome of the R1 ES cell line, only a limited number of SAGE libraries were, until recently, available for comparative purposes. This precluded

ES Cell Differentiation as a Model System

for Functional Genomics. Figure 1 Embryo-derived stem cells (ES, EC and EG) are pluripotent stem cell lines that self-renew without apparent limitation *in vitro*. Undifferentiated ES cells on primary cultures of embryonic fibroblasts (feeder layers), when allowed to form cell aggregates known as embryoid bodies, spontaneously differentiate into cells typical of all three primary germ layers (endoderm, ectoderm and mesoderm). Functional genomic high throughput assays (Microarrays or SAGE) generate gene expression profiles and identify transcripts with altered abundance. The results from these assays provide useful information that can be employed to define the molecular basis of pluripotentiality and self-renewal and to provide a rationale for experiments to test newly developed hypotheses.

defining the molecular basis for the embryonic stem cell phenotype.

The analysis did however highlight areas of genomic controversy. Pilot surveys of early mouse embryonic tissues and pre-implantation embryos had suggested that a large number of developmental regulated genes might be expressed only in embryonic tissues. The findings that a large percentage of unknown transcripts were present in R1 ES cells and subsequently in P19 EC cells supported the idea that many genes, known and unknown, are uniquely expressed in pre-implantation embryos. Other groups independently identified SAGE tags that did not correspond to known genes. This led to the use of novel SAGE tags to discover previously unidentified genes in the genome. A systematic large-scale analysis of the genome by SAGE coupled to complementary approaches for gene identification is now envisioned to overcome current computational inadequacies of gene prediction.

SAGE data can also be employed to estimate the total number of transcripts present in ES cells (4). In the R1 ES cell SAGE catalog described above, the number of transcripts increases rapidly (as an inverse-square power law) as the detected transcript abundance is reduced. Although it is difficult, for statistical reasons, to estimate accurately the total number of unique transcripts, a simple correction for sampling and sequencing error indicates that more than 54,000 unique transcripts must be present in this cell population. Since a wide variation in the number of unique transcripts is possible, it is also likely that many very low abundance transcripts have been missed. Monte-Carlo simulations based on the inverse-square model take this latter possibility into account and indicate that as many as 130,000 unique transcripts are compatible with the R1 ES cell sampling profile. Because ~10% of the tags in this SAGE library do not map with any previously described EST dataset, the number of unique transcripts (splice variants or novel gene transcripts) that have not yet been identified remains quite high (~6,000–13,000). This highlights the limited degree of knowledge available to explain the molecular basis of embryonic stem cells.

To define the molecular signature of stem cells, two groups have recently employed microarrays to compare ES cells with adult stem cells of hematopoietic and neuronal origin (5, 6). These analyses identified 216 and 283 transcripts, respectively that were enriched in all three stem cell libraries. When these two datasets were compared, only 5.4% of the factors overlapped, indicating important variations due to culturing conditions, array and hybridization protocols, data analysis and potentially contaminating cells. When the “stemness” transcripts were grouped, however, a more common theme emerged. Stem cells, relative to other

cell types, expressed a large number of transcripts that could be described as signaling factors, transcription/translation factors and proteins associated with DNA repair, protein degradation and protein folding. When compared with differentiated cell types, stem cells expressed a higher number of gene transcripts with unknown function. Some of the “stemness” factors clustered to chromosome 17, suggesting that characterization of the genomic regions that regulate stem cell-associated factors will further our understanding of the regulatory networks required to maintain undifferentiated stem cell populations (5).

Finally, embryo-derived stem cells (EC, ES and EG) *in vitro* readily differentiate to all cell lineages. This is particularly important for the cardiovascular field, where remarkably little is known about the genetic program that directs the differentiation of cardiomyocytes from precursor cells and where the lack of established cardiac cell lines precludes most genetic studies to address this problem. Functional genomic approaches coupled with P19 EC differentiation to cardiomyocytes have therefore been applied to the program of cardiac development. Two independent groups took advantage of the ability of P19 EC cells treated with dimethylsulfoxide (1%) to produce a high percentage of cardiomyocytes *in vitro*, to perform a transcriptome analysis to uncover relationships among known genes and identify novel transcripts that mediate cardiomyocyte differentiation. One group employed cDNA microarrays (7) and the other SAGE (8). The data were remarkably consistent, highly complementary, and revealed that only a small percentage of genes are regulated during the induction of cardiomyocyte differentiation. Although the complexity of differentiation involved a limited number of gene transcripts, the multifaceted results (gene activation, inhibition, bi- and multi-phasic regulation) indicate that the process is more complicated than originally envisioned. Because neither study employed a pure cell population for the transcriptome analysis, it was impossible to identify any factor(s) that specifically controlled cardiac differentiation *in vitro*. These large-scale genomic analyses of gene expression were unable to provide mechanistic information about induction of cardiomyocyte progenitor cells, but the results did provide the rationale and basis for future hypothesis-driven studies. Future studies will require lineage restricted cell surface markers or genetic manipulations (introduction of antibiotic resistance genes or marker genes like the [▶green fluorescence protein](#)) of ES cells coupled with fluorescence activated cell sorting ([▶FACS](#)) and/or antibiotic selection to enhance the isolation of specific subpopulations of ES-derived cell progeny (e.g., subtypes of cardiomyocytes). ES cell differentiation can

thus be effectively employed as a model system for functional genomics to define the molecular basis for multilineage differentiation.

Clinical Relevance

In vivo, stem cells or committed progenitor cells allow organ or tissue self-repair; however, tissue damage or disease (► [Alzheimer's disease](#), diabetes, chronic heart failure, stroke, end-stage kidney disease and ► [cancer](#)) that disrupt cell function require therapy in the form of transplantation or cell replacement. Today's most urgent problem in transplantation is a lack of suitable donor organs and tissues. The recent descriptions of human ES cells suggest that cell replacement therapy is theoretically achievable by the transfer of isolated and defined ES cell progeny to a target organ in sufficient numbers and of good enough quality for them to survive and restore function. To be realized, however, stem cells must exhibit full proliferative potential and *in vitro* differentiation capacity, two of the areas recently evaluated by combining ES cell differentiation with functional genomics. The mechanisms regulating differentiation remain poorly understood and may be influenced by epigenetic or genetic modifications *in vitro*. The identification of signaling molecules that regulate ES cell self-renewal, pluripotentiality and differentiation to specific subtypes should promote our understanding of these processes not only in embryo-derived stem cells, but also in adult stem and progenitor cells. Thus, by continuing basic human and non-human embryonic and adult stem cell research and comparing gene expression patterns and phenotypes, the future application of human stem cells (ES, adult stem and progenitor cells) in clinical settings may become viable. These analyses are critical if we are to demonstrate that ES-derived progeny can be purified, transplanted and lead to normal physiological and functional recovery *in vivo*.

ES Cells

► Embryonic Stem Cell

ESCRT

Definition

The "endosomal sorting complexes required for transport" (ESCRT) is a cellular protein complex involved in the fusion of vesicles to form multi-vesicular bodies. Many enveloped viruses use the complex to complete the process of budding and release from the host cell.

► Retroviruses

ESE

Definition

ESE is the abbreviation for a short regulatory sequence that is located in an exon.

► Alternative Splicing

ESI

► Electrospray Ionisation Mass Spectrometry

ESI-MS

► Electrospray Ionization Mass Spectrometry

Essential Hypertension

►Hypertension

EST

►Expressed Sequence Tags

Estrogen Receptor

Definition

Estrogen receptor (ER) is a transcription factor of the nuclear receptor superfamily which is activated by its ligand, estrogen, and then binds to certain genes containing estrogen responsive elements (EREs) that activate their transcription. ER thus exerts various effects, notably proliferation of mammary epithelial and carcinoma cells.

►Breast Cancer

Etherphospholipids

Definition

Etherphospholipids comprise of a special class of phospholipids, characterized by the presence of an ether-bond at the *sn*-1 position.

►Peroxisomal Disorders

Ethical Issues in Medical Genetics

HANS MARTIN SASS

Kennedy Institute of Ethics, Georgetown University,
Washington DC, USA

sassh@georgetown.edu

Definition

Ethical issues in medical genetics arise from (a) new and previously unknown information on individual and familial genetic heritage and (b) new knowledge in manipulating genetic traits associated with disorder or disease or for enhancement. Moral subjects to make decisions and assess the ethical parameters of new information and knowledge are individuals, families, communities, legal experts, politicians even human-kind; the assessment of who, for a special issue or in a given situation, is or should be the prime moral agent is a highly debated and controversial ethical, cultural and political issue.

Existing and developing knowledge in genetic information and genetic manipulation is a scientific revolution of Copernican dimension and will have far reaching consequences cultural and social consequences in individual and collective attitudes, on values and virtues, lifestyles, hopes and expectations, also in structuring systems of health promotion and disease management.

Characteristics

Towards Risk Factor Health Assessment and Education

New knowledge in science and technology, such as in molecular medicine and new professional and personal applications of new knowledge, such as those in genomics and proteomics, require integrated assessment of values and technology. New knowledge in human genetics and pharmacogenetics will have a great impact on future predictive and preventive health care services, on individualized and more efficacious drug development and prescription, on lay health education in individualized health risk management and in health protection and enhancement, addressing interfaces of physical exercise, nutrition, medication and prudent lifestyle management. The dimensions of those changes cannot yet be described in terms of ►[bioethics](#) and will depend on individual and collective ethical and cultural responses and on regulation in supporting, suppressing or rejecting new fields of research or of transfer of results into medical research, clinical practice and health care management.

Traditional concepts of health may become obsolete together with health policies. In molecular medicine, health cannot simply be understood anymore as 'a state of complete physical, mental and social wellbeing and not merely the absence of disease or infirmity', as the WHO defines, rather as a process of challenge and response, a process of balancing, which needs health literacy, protection, promotion and management by the individual person. Health is not just a status; rather the balanced result of health-literate and risk-competent care of one's own physical, emotional and social

wellbeing and wellfeeling, achieved in competent understanding, modification and enhancement of individual genetic, social and environmental properties, with the support of health care professionals and through equal access to health care services, including information, predictive and preventive medicine. Therefore, a re-evaluation and a re-prioritizing of traditional principles of care, confidentiality, beneficence, ►informed consent and harm will have to occur. Long neglected patient's ethics and health care ethics of the lay person have to become a prime topic for bioethics research, education and application in the clinical, primary care and public health care settings. Future medical ethics will have to focus on modified bioethical principles such as duty to inform, duty to be told and to know, health education, ►health literacy, health care competence, informed request, ►informed contract and the ethics of ►data availability. These new challenges to health care are challenges in health care education of health care experts and of individual citizens, their families and communities. Risk factor medicine will have to focus more on health care ethics of the citizen and the lay person than exclusively on physician's ethics; information and counseling might play a more prominent role in medical education and medical ethics, changing repair mentality in physicians' attitudes and statutory health care systems.

►Carrier Ethics and Family Health Care

New diagnostic knowledge in human genetics and pharmacogenetics make responsibility sharing with citizens as future patients or actual patients possible and ethically mandatory (1). Based on Western and Eastern traditions of responsibility and self-determination within the individual's cultural environment, the obligation to know about one's genetic heritage and its advantages, disadvantages, risks and uncertainties is a precondition for living a self-determined, risk-competent educated life and for enjoying the fullest possible individual quality of life. These dormant cultural and ethical maxims might lead to a new emphasis to inform, to educate, to counsel and to support for the health care experts and to a right to be told and – in those cases, where others are not impacted negatively – a right to either follow or to refuse health care advice. There does not seem to be an obligation to tell, if diagnostic findings cannot result in advice or prescription; but one could make the argument that even in cases of interventional futility citizens have the right to request genetic information for whatever personal reasons. Medical ethics support a right to know and an obligation to tell, if health risks are present or predictable. However, it might not be ethically advisable to call for a legal obligation to follow health care advice; such an obligation might become more pressing if health care costs are shared by insurance.

As genetic diagnosis provides potentially important information for family members in regard to health risk, health status, potentially helpful preventive measures and information essential for individual self-determination and quality of life decisions, each and every person diagnosed will need to consider as part of her or his carrier ethics her or his responsibilities towards family. In modern Western cultures, emphasis is put on privacy of patients or those diagnosed, while traditional Asian professional and family cultures focus more on responsibilities towards family, filial love, parental love and love and obligation within the wider family (2).

As not only severe genetic disorders, but also higher than average risk of hypertension, of cancer and of metabolic disorders may run in families, information about those risks will be influenced by yet to be re-evaluated or newly developed family health care ethics. As a result, family relations will be influenced by new sources of guilt-feelings, shame, accusations, self-denials, maybe divorce, suicide and the breakup or a new bonding-together of families. The golden rule would suggest, not hiding behind traditional attitudes towards secrecy and privacy, but to openly and aggressively inform, educate, teach and support dialogue and discourse in families and in society.

In complex issues of family ethics, privacy, disclosure, right not to know and duty to know, diagnosed carriers would be the prime moral agents to make educated and responsible choices (a) to disclose, (b) to refuse disclosure of all or of some information, (c) to postpone hard choices in informing family members. There will be hard cases, where information might be lifesaving to family members who might be carriers. Proposed WHO guidelines (3) on ethical issues in medical genetics recommend violating the principle of confidentiality in favor of informing and consulting family members; but guidelines of national and professional organizations differ from such a stern position. Additionally, future principles and virtues in responsible parenthood might include decisions whether or not (a) to have children at all, (b) to have prenatal testing and eventually elected abortion following positive testing, or (c) to do nothing and trust in future breakthroughs in medical treatment of as yet untreatable disorders (4).

As molecular medicine will not only allow for better prediction, prevention and management of disorders or diseases, ethical issues of health enhancement such as anti-aging and the improvement of certain physical, intellectual or mental capacities will become an issue of individual choice and of controversy over principles of justice, in particular when not the protection or promotion but the enhancement of health is requested to be paid for by public or insurance funds; definitions of protection, promotion and enhancement of health

will cause public debate and controversies among citizens and ethicists.

Pharmacogenomics and Individualized Drug Treatment

Since the discovery of blood types, reliable diagnosis of blood types, typing and screening has become an essential part of emergency medicine and surgery and has saved millions of lives. For over a century, the ethical and medical benefit of the principle of data availability has been very well documented. Now, molecular medicine demonstrates that we do not differ only in types of blood but in many other individual properties, such as in cytochrome P450 isoforms, controlling drug metabolism, causing non-efficacy, side-effects with nutrition and other medication, even death, in some types of metabolizers (► [Pharmaco-genomics](#)).

When individual pharmacogenetic profiles for medication-typing can be established (5) in the same way that we can easily establish individual profiles in blood-typing, personalized drug delivery is possible and ethically required. The fears that genotyping for drug metabolism will lead to discrimination are not convincing, they are theoretical, ethically unfounded. Blood typing did not lead to discrimination, even though some individuals have blood types, which are rarer, at least in certain populations, and therefore might have less access to blood replacement. Blood profiles and medication profiles do not describe disorders, i.e. an individual aberration from a generic image; rather they constitute different types or variations, none of which is the 'normal' one. We have a model of variation, not one of order and disorder. It would have been a crime against humanity and an unexcusable wrong towards fellow humans if lives had not been saved by technically possible but legally or culturally unaccepted blood transfusion based on proper blood-typing.

Genotyping for drug compatibility causes no significant other ethical concerns than those associated with blood typing, clinical reliability of typing procedures, equal access to typing services, no (medication prescribing) intervention prior to typing. The new scenario of metabolism typing has consequences for the traditional and accepted bioethical setup of vaccine development, clinical trials, prescription procedures and nutritional advice. Given actual pharmacogenetic knowledge, it seems to be unethical not to introduce molecular medicine into drug development and to establish efficacy, dosage and side effects for major types of metabolizers.

Individuals have a civil right to information about their individual proteonomic and enzymatic properties for metabolizing drugs and nutrition. This informational right would best be served by providing individual drug and nutrition cards and access to information and education for professionals and the lay person.

Informational Property Rights and Data Profiling

Personal data, including genomic and proteonomic data on health and health care are the informational property of the individual. In other areas of life we share selected informational properties with others for our own benefit or convenience, such as with credit card providers, supermarkets, libraries, online-merchants and insurers of various kind. But, we rightly worry about protection of private data; we have laws and regulations protecting privacy, which work most, but not all of the time; we accept these risks as we balance risk with benefit. There is no good argument, to treat individual rights on health data differently from other ► [informational property rights](#).

Citizens are informational property owners of data concerning individual health status and health care. It would most probably be in their best interest to have health care cards and to share information with professionals in a protected framework as data availability becomes an important integrated part of data protection. Health care professionals cannot provide quality service if denied access to information necessary for providing safe and efficacious service. Technically, it would be extremely difficult to provide the best possible predictive, preventive and therapeutic service to those who do not share personal health status data with professionals.

Individual health care cards might be an efficacious and just instrument to promote as yet undeveloped cultures and attitudes of individualized health literacy and care. As we as individuals differ in more than enzymes and protein metabolism, it would only be reasonable to allow citizens to have individual health care cards containing information on individual genetic or acquired properties, abilities, disabilities and disorders such as risk of hypertension or diabetes. Data availability is the precondition for good diagnosis and prognosis and subsequently for prevention and treatment.

Research Ethics in Molecular Medicine

Traditional models of informed consent and proband-researcher or patient-physician interactions in communication and cooperation have to be restructured for adequacy in molecular medical research. The soft-paternalism principle of informed consent would be best replaced by a principle of informed contract, detailing for researchers and probandi or patients rights and obligations and liberating probandi and patients from their passive role of just consenting. In particular, this should apply to issues of research in drug metabolism, DNA-sampling and -storing. Moreover, disease-specific research cannot be justified without taking into account the probable benefits to the patient or her or his family. Modern medical research will discover quite a lot of information about pedigree and family members; new ethical issues can rarely be addressed in the old format by simple individual consent.

For genotyping in highly defined populations of patients suffering from certain subgroups of cancer or other diseases and receiving specific medication, it has been debated whether traditional models of informed consent would be enough for multipurpose longterm DNA-banking. Informed consent forms rarely address issues of multipurpose screening and longterm storage. It has been suggested that for genotyping, only specific informed consent should be requested and that further use should be covered by new specific re-consent. Generic consent forms – in particular for prenatal and newborn screening – were proposed, but others criticized such an approach as lowering the standards of informed consent.

As the probability of benefits in cross-purpose genotyping and of future yet to be specified testing and re-testing is of great moral importance for the individual patient, patient groups and the progress of clinical research, a contract model might be more appropriate, describing the obligation of the researchers to inform the patient on all or some of their findings and establishing a contract spelling out the obligations towards the patient and her or his family (6). Within such a contract, patients or their legal representatives must be informed on standard data-protection. In order to solve complex issues of privacy and disclosure, the right not to know and the duty to know, a contract must provide that patients can make their own choices (a) for mandating disclosure of individual predictive, preventive or therapeutic knowledge, (b) for refusal of all or some information and (c) for postponing such a decision for later based on then existing individual circumstances or clinical results. The moral issues of informing and protecting family members will similarly have to be addressed within the contract by allowing the patient to choose among a number of procedures by which family members of various degree may or may not be involved, informed or invited. Such an informed contract model would be based on the stakeholder concept which is usually the preferred scheme for complex management of risk and uncertainties elsewhere. An example of how the ethics of diagnostic research is changing towards a more appropriate appreciation of individual and family health care competence and decision making as partners in research is the HUGO statement (7) on choices in data availability within a firm model of data protection and privacy protection. 'The choices and privacy of individuals, families and communities should be respected. (a) Choices may be with regard to donation, storage and use of samples and the information derived therefrom (e.g. specific, related or other uses subject to authorization by an ethics committee, etc). Informed consent may include notification of uses (actual or future) or opting out or, in some cases, blanket consent. (b) Mechanisms should be established to ensure respect

for such choices. (c) Participants should be informed about the degree of identifiability of their data (e.g. coded, anonymized, aggregate, etc) and the security mechanisms in place to ensure confidentiality. (d) Participants should be told that samples or the information derived therefrom may be shared with other researchers including those from other countries, with commercial entities and through publication and availability on the WEB'.

Individual Values and Cultural Diversities

Modern medicine, including molecular medicine, recognizing the principle of autonomy and self-determination as a most basic human and civil right, allows for clinical research and medical treatment only if the proband or patient has given free and informed consent based on individual concepts of risk, benefit, values, fear and hopes. Global recognition of the informed-consent principle correlates with the vision of universal human rights, as expressed by the United Nations Declaration, 1948 and is a fruit of the processes of enlightenment and emancipation since the European Age of Reason. But many cases have been well documented demonstrating that the principle of autonomy does not work all the time and can be used in an abusive or exploitative manner. (8) If people do not clearly understand risks and benefits associated with research and treatment, oral or written consent is void. (7) If people feel an 'obligation' to sign forms, such consent is not given freely. (4) If researchers cannot or do not adequately inform probands or physicians their patients, signed forms are only a smoke-screen to hide the fact that true informed consent is not given even if the legal requirements seem to be satisfied.

We already see standard deviations, exemptions and modifications form the general rule. (8) Consent for minors is given by their ethical and/or legal representatives, mostly the parents. (7) Competent adults may designate another person to give consent on their behalf, either immediately or under certain conditions in the future. (4) The consent required from psychiatric patients is related to their particular disease and situation at a given time; however, there are well-developed treatment contracts signed by patients and their caretakers for possible future situations known to the patient. Other cultures, even though they might be in transition to being more and more influenced by cultures of individualistic ethics, still have a strong sense of family ethics and family decision making for the good of the individual family member, thus traditionally giving consent for the good of an individual family member as family consent (2). Individualistic European models are seen as an intrusion into a different trust-and-responsibility structure if used only legalistically. Family consent is not without risk. It might be the

elder male or female head of the smaller or larger family accepting responsibility for his or her relatives and having been trusted by them to make those decisions, even far-reaching ones such as those concerning marriage, education or job training. Some individuals or branches of the family might not trust the proxy decision maker; elders might violate the trust with which they are endowed. These are the situations that have led to the rise of emancipation and enlightenment in the Age of Reason. But there are still families and communities around for whom the model of an individual person making autonomous decisions by herself and for herself alone, is considered unethical, not supported by culture and values, actually decadent and perverse.

In order to implement some of the visions and goals of the 'informed consent' principle it might be helpful to at least work with a formula of 'informed consent plus X', X being different supportive features depending on the special cultural and traditional attitudes and modes of decision making, supporting but not replacing individual consent.

Researchers required to inform and educate and to gain consent, would be well advised to use the existing trust-and-responsibility structure for information and education and for contracting with the community and/or families and/or individuals. Benefits for the community, for the families and the individuals should be spelled out in detail (6).

Common sense suggests recognition that probands, even more so patients, expect 'something' in return for their participation; this 'something' can be personal recognition, personal attention, individual or general health care advice, better hygiene, fresh water or nursing care for the community. Recent CIOMS guidelines for medical research in 'populations and communities with limited resources' recommend: 'the sponsor and the investigator must make every effort to ensure that: the research is responsive to the health needs and the priorities of the population or community in which it is to be carried out and that any intervention or product developed or knowledge generated will be made reasonably available for the benefit of that population or community' (8). The Nuffield Council on Bioethics (9) suggests 'that sponsors of research should require that the development of local expertise in healthcare is an integral component of research proposals. Consideration should be given to the extent to which any strengthening of local healthcare facilities can be done in such a way that the changes are sustainable in the local context once the research is over'. Given the diversity of individual and collective cultures in decision-making, one size of consent does not fit all. It seems to be clear, that the classical model of informed consent has outlived its useful life as a general standard

for all, for each and every personal, familial, communitarian, cultural or legal situation. Where the basic cultural attitudes and legal preconditions are not in place to make the classical form of informed consent the preferred and most useful tool, it cannot be made a requirement that medical experts first of all change cultures and attitudes and then proceed with their medical work. It is also not acceptable that medical experts turn a blind eye to the missing of essential prerequisites for making informed consent work. Everyone has to work on implementing human rights and free decision making by competent and risk-literate adults; this task cannot be put on the physicians alone. Also, there might be true ethical situations where coherent trust-and-responsibility structures within families or communities are well developed by cultural or religious tradition and in the history of ideas supported and proven to work well in quite a number of cases. In those situations it would be culturally and ethically insensitive and counterproductive to destroy a working network of trust, hope, responsibility and reliability in order to replace it by a model developed under different cultural and historical conditions.

Models of contract rather than one-sided still soft-paternalistic individualistic consent might work better in those situations, both in medical research and in health care. Of course, all culturally sensitive models need 'escape clauses' or 'conscience clauses' allowing each and every individual to decide for herself or himself on the basis of individual self determination about her or his place in a moral community and in regard to community values and decision making. Molecular medicine will need to be aware of cultural traditions and moral trends among citizens, regulators and bioethicists when developing and offering new options in health care, health promotion and disease management.

Culturally sensitive introduction of new knowledge always was associated with moral and cultural risk and uncertainty. Open and fair discourse, communication and cooperation among all stakeholders in health care will be successful only if personal choices of moral agents at their respective levels are respected. The identification and acceptance of moral decision makers on different levels has yet to be made and will not occur without ethical and political controversy.

Exclusion

Definition

Bacterial plasmids, including those on which the standard cloning vectors are based, have replication systems based on a replication origin counting mechanism. The total copy number of a given origin is regulated and thus multiple clones in the same vector (or more generally with the same replication origin) are not maintained stably in the same cell. Newly transformed cells may contain many plasmids, but individual colonies of their progeny reliably contain one each.

Exocyst

Definition

The exocyst is a multimeric complex of eight subunits (Sec3, Sec5, Sec6, Sec8, Sec10, Sec15, Exo70 and Exo84) which was initially identified in yeast, where it is involved in targeting and tethering of secretory vesicles to sites of polarized exocytosis. Mammalian cells express homologues of all eight yeast subunits. The mammalian exocyst associates with the *trans*-Golgi network and the plasma membrane. In polarized cells it appears to be involved in basolateral traffic.

luini@negrisud.it

Definition

All cells need to secrete a variety of macromolecules in order to modify their environment and to protect themselves. At the same time, cells synthesize new proteins and lipids to replace those that are consumed within the various intracellular compartments. During their synthesis on ribosomes, proteins are either transferred into the lumen of the endoplasmic reticulum (ER) or incorporated into the ER membrane itself and are transported through the several membranous compartments that form the exocytic (also known as the secretory or biosynthetic) pathway. This includes the main secretory/sorting station, the Golgi complex (Fig. 1). After crossing the Golgi complex, proteins are sorted and shipped to their final cellular destinations, such as the apical or basolateral cell surfaces, the secretory granules or the endocytic compartments (1). During this journey through the cell, proteins and lipids are modified by a variety of enzymes, which are located

¹The first two authors contributed equally to this work

²Corresponding principal investigator

Exocytic Pathway. Figure 1 Scheme illustrating the organization and the components of the exocytic pathway.

mostly in the Golgi complex. Glycosylation is the most common and important of these post-translational modifications. With this in mind, it can be seen that the exocytic pathway has two main functions: (i) to transport proteins and lipids to their appropriate cellular compartments as needed and (ii) to complete the protein expression process by adding certain specific chemical elements, which are generally crucial for protein structure and function, to the amino acid backbones of proteins.

Characteristics

The exocytic process needs to be characterized at both the molecular and the morphofunctional levels. While the molecular machineries underlying the main elementary traffic steps (e.g. membrane bending and fusion) are now relatively well understood (1, 2, 3), the overall morphofunctional organization of traffic, in terms of the structures and dynamics of the secretory organelles themselves, remains less clear. However, following the development of new and powerful morphological approaches, this has begun to be unraveled in the last few years. It should be mentioned

here that the traffic model that dominated the field until recently has now become inadequate to explain a number of new observations. This vesicular traffic model, according to which secretory proteins move across successive compartments of the secretory pathway within small vesicles that bud from one compartment and fuse with the next, is now being replaced by different traffic principles that are being tested in several laboratories. The morphofunctional organization of traffic will be the focus of this review.

Exit from the ER

Secretory proteins must travel from their site of synthesis, the ER, to distant cellular sites, one of which is the plasma membrane. The question as to how exit from the ER is organized remains an issue of debate. It is known that exit is mediated by numerous proteins (2, 3), among which the set of **coat proteins** known as COP-II has a prominent role; however, the precise way in which COP-II is involved in the creation of transport carriers remains unclear. According to the original vesicular model, COP-II drives the formation of coated vesicles (of about 70 nm in diameter) at specialized membrane domains that are known as the ER exit sites (2, 3). These vesicles then fuse with each other to form larger (1–5 μm across) pleiomorphic carriers that move to the Golgi complex. According to an alternative and more recent model, however, the secretory proteins are directly incorporated into large transport carriers that emerge from the ER by COP-II mediated *en bloc* protrusion of the ER surface at the ER exit sites (3, 4). While the vesicular model is supported by a large amount of molecular and *in vitro* evidence, it does not easily account for the export of molecular complexes from the ER that are much larger than a vesicle in size, such as procollagen, lipoprotein particles or lipid droplets. These cargoes are abundant and of physiological importance in mammals. Their export is easily explained by the transport carrier model.

After formation and before moving away from the ER, newly formed carriers (Fig. 1) undergo a process of 'maturation', a key part of which is the replacement of the COP-II coat proteins with a different 'coat', **COP-I**. Once COP-I is bound, the carrier proceeds from the peripheral exit sites towards the Golgi complex, which is positioned near to the centre of the cell (4). This centripetal movement is mediated by microtubules and a molecular motor protein, dynein, and is thought to involve the physical detachment of the carrier from the parental ER membranes (4). It is also conceivable, however, that at least in some cases, cargoes might flow towards the Golgi along pre-existing tubular structures (6). Once the cargo carriers arrive at the centre of the cell, they must discharge their contents into the Golgi complex.

The Golgi Complex

The Golgi complex is the central sorting station on the secretory pathway and has been a main focus of research in cell biology for many decades. The Golgi complex receives newly synthesized proteins and lipids from the ER, transports them across its cisternae and then distributes them to the plasma membrane, the endosomal/lysosomal system or the secretory granules (Fig. 1). The Golgi complex also serves as a chemical 'factory' for post-translational modifications of proteins and lipids (mostly by glycosylation). In the lumen of the cisternae of the Golgi complex glycosyltransferases further modify the oligosaccharide chains of secretory proteins (a process initiated in the ER). As well as glycosyltransferases, the Golgi complex contains other enzymes, including pro-protein convertases (such as furin), which cleave protein precursors into their mature forms, and kinases.

From the structural point of view, the Golgi complex consists of a series of 'stacks' made up of 4 to 8 flat cisternae. These cisternae are laterally interconnected by tubular networks (the 'non-compact zones') and together they form a continuous membranous ribbon that is held in the pericentriolar space (5). Despite this complex architecture, the Golgi complex is highly dynamic and can combine enormous rates of membrane flux with the ability to change its shape rapidly and even to disassemble and reassemble, under a variety of physiological and pathological conditions (4).

The glycosylation enzymes reside within the cisternae of the individual stacks. In general, enzymes acting early in the biosynthetic pathway localize to the *cis* and medial portions of the Golgi complex, while the late-acting enzymes reside in the medial/*trans* cisternae. However, quantitative immuno electron microscopy has clearly demonstrated that these enzymes are not restricted to just one or two cisternae; rather, they exhibit concentration gradients through the cisternae of the stacks (6).

Based on these considerations, each Golgi stack is traditionally considered to be composed of three main compartments, the *cis* (entry side)-, the medial- and the *trans* (exit side)-Golgi (5, 6). At the *cis* side of each stack, there is a membrane network known as the *cis*-Golgi network (CGN), which is composed of branching tubules connected with the *cis*-most cisterna (6). The CGN is followed by a number of flat cisternae (Fig. 1). Finally, the *trans* side of each stack, known as the *trans*-Golgi network (TGN), often appears as a network of branching tubules in electron microscopy sections (6). The cisternae usually appear as very flattened and wide sacks or tubules with a narrow (10–20 nm) lumen. This geometry may enhance the efficiency of glycosylation, considering the small volume of the cisternae and the relatively large surface area where cargo proteins can interact with the

glycosylation enzymes (6). Apart from the cisternae, the Golgi has significant tubular and vesicular structural elements.

Vesicles of smaller (50–60 nm) and larger (up to 80–100 nm) diameters are considered to be important elements of the Golgi complex. They depend on the activities of either COP-I or the [clathrin](#) coat machinery (1, 2, 3), respectively.

Arrival at and Transit Through the Golgi Complex

There are two main potential mechanisms for the entrance of cargo into the Golgi. The first involves the direct fusion of ER-to-Golgi carriers with the *cis*-Golgi membranes. The alternative is that the ER-to-Golgi carriers do not fuse directly with the *cis*-Golgi, but instead fuse with each other, thus forming a new *cis*-Golgi cisterna that can then progress through the Golgi stack (by cisternal maturation, see below). Finally, as indicated above, the possibility cannot be excluded that at least in some cases, the cargo may flow along pre-existing tubular structures connecting the ER with the *cis*-Golgi.

After entering the Golgi, the cargo must cross the stack before exiting from the *trans*-Golgi side. The mechanisms behind this intra-Golgi transport remain poorly understood (5, 6, 7). There are three main models for traffic through the Golgi: (i) anterograde vesicular traffic, in which cargo traverses the Golgi stacks *via* COP-I vesicles that bud from donor and fuse with acceptor cisternae (2), (ii) cisternal maturation, in which the cargo remains within the lumen of the cisternae, which themselves mature and progress through the stack (5, 7) and (iii) flow *via* continuities, in which the cargo flows through the stack *via* tubular connections between cisternae at different levels of the stacks (4, 6, 7).

The anterograde vesicular model was favored by the traffic community for a long time, but it no longer appears to apply. In the majority of cases, COP-I vesicles appear to be depleted of most of the secretory cargoes that have been examined, and some cargoes are simply much too large to fit into these vesicles (6, 7). As a result of this and other lines of evidence, the anterograde vesicular model has been all but abandoned, and in recent years, the cisternal maturation model has gained prominence (5, 6, 7). Some aspects of this maturation model remain unclear, however. For instance, according to classical maturation schemes, cisternae containing cargo progress through the stack, while the Golgi enzymes maintain their steady-state positions in the cisternae through their retrograde flow within COP-I vesicles in synchrony with the progression of the cisternae (7). However, most (albeit not all) studies have shown that both cargo proteins and Golgi enzymes are depleted in COP-I-dependent vesicles.

Thus, at least such a ‘classical’ version of the maturation model is unlikely to be valid. In our view, flow *via* continuities is also likely to have a key role in traffic. Indeed, due to the extensive use of electron microscopy tomography, evidence is now accumulating that membrane continuities between heterogeneous cisternae do exist (in contrast to previous beliefs), and that they should therefore have a role in traffic through the Golgi (6, 7). For instance, heterotypic intercisternal connections within the same stack have been seen in actively secreting cells (6). The question as to whether these intercisternal connections can explain antero-grade transport of cargo proteins and/or retrograde transport of Golgi enzymes is an important emerging issue for future research on the Golgi complex.

Exit from the Trans-Golgi

After crossing the Golgi, secretory proteins are ‘packaged’ for their departure to their final destinations. The *trans*-face of the Golgi has attracted the attention of cell biologists since its identification as the exit pole of the Golgi complex. To understand the mechanisms of sorting and exit from the Golgi complex, it was essential to identify the specific compartment in which these processes take place. This compartment is now defined as the TGN, although its precise organization remains under debate. Biochemical and immuno electron microscopy studies have revealed that the TGN is involved in the terminal glycosylation of proteins as well as in cargo packaging into membrane carriers that are destined for the plasma membrane or the endosomal/lysosomal system (6). The TGN has generally been considered to be the *trans*-most cisterna of the Golgi stack, which is seen to continue into a large anastomosing tubular network (6). The morphology and size of the TGN apparently depend on the predominant type and amount of cargo protein leaving the Golgi complex (6).

An alternative view of the organization at the *trans*-face of the Golgi complex comes from studies using electron microscopy tomography (5). Surprisingly, these studies demonstrated a lack of the classical TGN; instead, the three *trans*-most cisternae exhibited tubules that extended into the *trans*-space of the Golgi stacks and frequently had coats on their tips. Each of these cisternae appeared to produce only one type of coated vesicular structure, with only the *trans*-most cisterna having clathrin-coated buds. Thus, this suggests that the three *trans*-most cisternae of the Golgi stacks serve as the classical TGN, and that each of them is specialized in the packaging and export of its own, specific, cargo protein(s).

Given this structure, how does the exit of cargo from the TGN take place? Plasma membrane-directed proteins leave the Golgi within Golgi-to-plasma membrane carriers (GPCs), which at the electron

microscopy level have a complex, tubular-saccular morphology (4, 6) (Fig. 1). Recent work has shown that these carriers form by the fission of complex tubular-reticular membranes from specialized areas of the TGN (the GPC precursors) that are extruded from the Golgi complex along microtubules by the kinesin motors (6). These GPC precursors do not concentrate cargo proteins, do not exhibit visible coated regions and remain in physical continuity with the TGN membranes. They exclude TGN proteins that are directed to the endosomal/lysosomal system, such as mannose 6-phosphate receptor, lamp and furin (6).

What then is the role of coat proteins in this export from the TGN? While, as noted, clathrin and the related adaptor proteins, such as AP-1 and AP-3, are excluded from plasma membrane-directed carriers, AP-based coats are apparently required for the exit of the cargo that is targeted to the compartments of the endosomal system (3, 4, 6). Indeed, endosomal cargoes undergo marked concentration within small clathrin-coated membrane domains before their exit from the TGN (3, 6). The mechanisms by which proteins are selectively targeted to their specific final destinations, which include the apical or basolateral plasma membranes, the endosomal system and the secretory granules, are collectively known as the ‘sorting mechanisms’. The COP and AP proteins have major roles in this sorting and the reader is referred to previous reviews for an exhaustive treatment of these issues (3, 6).

Molecular Interactions

The main traffic molecular machineries and their functions have been admirably reviewed by others recently (1, 2, 3). Coat proteins are thought to be the molecular centerpiece in the exocytic pathway because they allow the selective transfer of macromolecules from one membrane compartment to another by concentrating proteins into specialized membrane patches and then deforming these patches into coated carriers. Furthermore, coat proteins may also participate in the association of these carriers with the cytoskeleton and with acceptor organelles by recruiting cytoskeleton motors and the docking-fusion molecules named ►SNAREs.

Regulatory Mechanisms

Throughout the life of a cell, the secretory pathway must maintain its homeostasis and adapt its level of activity to changing cellular needs. Our knowledge of the mechanisms involved in this regulation is still in its infancy. It is clear, however, that all stages of intracellular traffic are coordinated amongst themselves and with other cellular functions (6). In this context, an important emerging theme is the role of cargo as a

potent determinant of Golgi structure and function. For example, in yeast, cycloheximide treatment (which blocks proteins synthesis, and therefore reduces the secretory load) leads to the complete disappearance of the Golgi complex (6). Similarly, in the primitive eukaryote *Giardia lamblia*, the typical Golgi complex is absent during the proliferative stage, when secretion is very limited. However, the Golgi stacks reappear when the cells begin to secrete the glycans that are needed for cyst formation (6). It can also be seen that the level of cargo traffic influences the organization of the mammalian Golgi complex. Here, blockade of protein synthesis with cycloheximide leads to the formation of very thin cisternae in onion-like Golgi stacks (6). Moreover, when cargo proteins are arrested within the ER, the Golgi structure is all lost within a few hours. In contrast, when cargo influx increases sharply, the Golgi complex immediately grows in size (6). Thus, the Golgi complex tends to disappear gradually in the absence of cargo input even in mammalian cells, where it becomes larger when transport intensifies. This phenomenon has been clearly illustrated by the stimulation and inhibition of prolactin transport in lactating rats (6).

Exon

Definition

An exon is that part of the DNA sequence that is – as part of an eucaryotic gene – transcribed into mature mRNA, which (when positioned 3' to the AUG and 5' to the first ► **stop codon**) can then be translated into protein. This information is interspersed with noncoding sequences which are called introns, i.e. longer or shorter regions of DNA that have no apparent function (non-coding-regions). In order to translate a gene into a protein, the non-coding sequence has to be removed in a process called splicing.

Exon Junction Complex

Definition

Exon Junction Complex (EJC) refers to a complex of at least six proteins that is deposited upstream of exon-exon junctions on RNAs undergoing splicing. The proteins in the EJC have roles in mRNA export, localization and surveillance.

- **RNA Export**

Exon / Intron Junction

Definition

Exon/intron junction denotes a site within the pre-mRNA sequence where pre-mRNA splicing occurs to eliminate intron sequence segments from mature mRNA.

- **Morpholino Oligonucleotides, Functional Genomics by Gene 'Knock-down'**

Exonic Sequence Element

Definition

Exonic sequence element (ESE) refers to a short regulatory sequence that is located in an exon.

► [Alternative Splicing](#)

Exonic Splicing Enhancer/Silencer

Definition

Exonic splicing enhancer/silencers are specific short sequences in an exon that enhance or block pre-RNA splicing, and play important roles in both constitutive and alternative splicing. An exonic splicing enhancer is generally present at a nearby splicing junction. It functions as a cis-acting sequence element with a binding site for serine/arginine-rich (SR) proteins.

Definition

► [Extracellular matrix](#) (ECM) is the name given to the molecular meshwork located between cells in multicellular organisms. It is comprised of sugars and proteins organized into various supramolecular assemblies. Small soluble molecules permanently bound to ECM, such as growth factors, are important constituents of the extracellular microenvironment, but are not normally counted as part of the ECM.

Characteristics

The amount and composition of ECM varies between different tissues. In epithelium or muscle the ratio of tissue volume occupied by ECM to that occupied by cells is less than 1:10, whereas the ratio is more than

10:1 in tendons, cartilage and bone. The ECM provides structural support for cells and also tensile strength, elasticity and compression resistance. Examples include cushioning in cartilage, strength in tendons, elasticity in blood vessels and formation of tissue boundaries and anchorage of cells in epithelial organs. In synergy with growth factors or by themselves, ECM molecules are essential for several signaling events. Thus ECM composition needs to be radically different in different tissues to support these varying functions.

Constituents of the ECM

The molecules comprising ECM can be subdivided into three main categories, proteoglycans, glycoproteins and ► [collagens](#). All morphologically different types of ECM contain some members of these categories. These categories can, in turn, be subdivided based on expression pattern, sugar side chain composition, interactions and typical features of the protein core sequence (1). A recently proposed classification of proteoglycans and glycoproteins (3) is used here. Glycoproteins are divided into glycoproteins of the interstitial connective tissue or ► [basement membrane](#) glycoproteins, whereas proteoglycans are divided into small leucine-rich-, modular nonhyaluronanbinding- or modular hyaluronan and lectin binding-proteoglycans (hyalactans) (Table 1). A few glycoproteins of the interstitial connective tissue, such as fibronectins or fibulin-1 and in disease conditions tenascins are also plasma proteins. Other proteins, more often thought of as plasma proteins, such as vitronectin, fibrinogen, thrombospondin and von Willebrand factor can in their turn be associated with the ECM.

Collagens are a large diverse family of ECM molecules, which account for about one third of the total protein mass in vertebrates. Twenty seven different collagen types have been identified. The many diseases caused by mutations in collagen genes have amply demonstrated their important roles (5). The basic subunits of the collagens are the α -chains. These α -chains contain one or more segments with multiple glycine-X -Y sequence motifs, also known as the collagen sequence. The amino acids X and Y are often proline, hydroxyproline, and hydroxylysine, unique hydroxylated versions of proline and lysine. Three α -chains form the triple helix typical of collagens. Collagens can be divided into fibril-forming and non-fibrillar collagens, but both types consist of homo and heterotrimers of α -chains. In the non-fibrillar collagens these collagen α -helices are often interrupted by non-collagenous sequences. The fibril-forming collagens are synthesized as precursors and processed into mature collagen, followed by fibrillogenesis in which the molecules assemble head to tail and aggregate in a staggered manner into rope-like structures. The non-fibrillar collagens can be divided into microfibrillar

Organization of the ECM

Most structural ECM proteins are chimeric and share similar domains with each other. Many of them form homotypic aggregates to which other proteins bind, thus forming intricate networks. These highly organized polymers do by themselves determine the specific histoarchitecture of tissues, but they also provide cells with information by binding to receptors. Tissue and cell type specific functionality is due to expression of different family members or splice variants.

Morphologically, two main forms of ECM can be discerned, basement membranes and the interstitial ECM. The interstitial ECM can be divided into subforms. Basement membranes underlie epithelial and endothelial cells and surround Schwann, muscle and fat cells. They are composed of two

self-assembling networks of heterotrimeric molecules, collagen IV and laminin. Both these molecules exist as protein families. Thus, several organ or cell-type specific basement membranes are produced. During formation of basement membranes, these networks interconnect through other molecules such as nidogens and perlecan to form the final mat-like structure (4). Basement membrane molecules have been found in all metazoan phyla examined, suggesting that this molecular structure is at least 500 million years old. In contrast, many interstitial ECM components emerged later (2). The evolutionary constancy and genetic data on embryonic development in model organisms strongly suggest that the invention of basement membranes was one essential step for the evolution of multicellular life. Two other collagens, VII and XVII, are associated with specialized structures of basement membranes underlying stratified epithelia, the anchoring fibrils and hemidesmosomes respectively. Mutations in the collagens, the skin basement membrane ► [laminins](#), receptors or intracellular intermediate

filaments connecting to the hemidesmosomes, lead to various forms of skin blister diseases ([▶epidermolysis bullosa](#)).

The interstitium is the space beneath epithelial sheets, and is composed mainly of ECM (Fig. 1). A similar arrangement is seen under endothelial cells. The word mesenchyme is frequently used for embryonic interstitium and the word stroma for interstitium surrounding tumor cells, but these words (interstitium, stroma, mesenchyme) are often used interchangeably. The main constituent in interstitial ECM is collagen I, produced by fibroblasts located within the interstitium. Other major proteins in this meshwork are fibronectin, fibulins and fibrillins (1, 7). Fibronectin mediates a wide variety of cellular interactions and plays an important role in cell adhesion, migration, growth and differentiation. These functions are especially apparent in matrices under reconstruction, such as during wound healing and in development. Fibulins do not form large homotypic aggregates, but can join other supramolecular structures as diverse as basement membranes, elastic fibers, microfibrils and proteoglycan aggregates. To some degree, these structures are thereby stabilized,

but more importantly the biological functions are modified. Mutational studies in mice have revealed that fibulins are essential for the development of larger or smaller blood vessels (7). Mutations in fibrillin-1 lead to [▶Marfan's syndrome](#) in man, which manifests mainly as skeletal abnormalities, ocular changes and cardiovascular problems. The most serious are the cardiovascular problems, in particular the lethal ruptures of the aorta. Marfan's syndrome is the most prevalent hereditary extracellular matrix disorder, with an estimated incidence of 1 in 7000 and an autosomal dominant inheritance with variable penetrance.

A major stromal ECM subtype is produced by cartilage cells, chondrocytes. Cartilage is specialized for a supportive role in the body. Three types of cartilage can be distinguished, articular (or hyaline) cartilage, elastic cartilage and fibrocartilage. Articular cartilage is found on the articulating surfaces of bones and plays a fundamental role in low-friction movement as well as in absorbing and distributing mechanical load. It forms most of the entire appendicular and axial skeleton in the embryo. The cartilage ECM consists of a fibrillar network based on collagen II fibrils dispersed in an environment of highly negatively charged [▶aggrecan](#) molecules that form large supramolecular aggregates. In this fibrous network, large extremely anionic proteoglycans provide a fixed charge density that maintains a high osmotic pressure, thereby promoting water retention. Surrounding the chondrocytes is a thin layer of pericellular ECM containing molecules that signal cells by interacting with cell surface receptors. Further from the cell, a territorial ECM, consisting of molecules with roles in catalyzing and regulating ECM assembly, is found. Still further out, the interterritorial ECM mainly appears to play a role in contributing mechanical properties.

In elastic cartilage there are high levels of elastic fibers composed mainly of fibrillin and elastin, where elastin is laterally packed in thin ordered filaments in the elastic fiber core and fibrillins together with other

Extracellular Matrix. Figure 1 Scheme of the two main extracellular matrix forms, the thin basement membrane and the interstitial ECM. The basement membrane is thin and underlies epithelial cells, whereas the interstitial ECM surrounds cells and occupies much space.

proteins constitute the associated microfibrils. Elastic fibers are otherwise ubiquitous throughout the body. Fibrocartilage shows many similarities to interstitial connective tissue. It is often interposed between other tissues and articular cartilage, tendons or ligaments. The main constituent in this type of ECM is collagen I. A highly specialized form of stromal ECM is found in bone. Bone is a connective tissue with cells and fibers embedded in a hard and largely unbending substance, well suited for supportive and protective functions. The ECM of bone is composed of collagen I fibers and small quantities of sulfated glycosaminoglycans and several glycoproteins produced by osteoblasts. The collagen fibers are organized in spirals around a central canal. These spirals are also arranged at right angles to each other in every second layer. A unique feature of bone is the inorganic phase, the hydroxyapatite crystals, which are deposited in the osteoid structure as slender needles within the collagen fiber network. Other ECM components play important roles in regulating the deposition and organization of hydroxyapatite.

Molecular Interactions

ECM-ECM Interactions

The major basement membrane molecules, the laminins, the collagen IVs, the nidogens and perlecan all bind each other with various affinities depending on isoform. They can also bind to the cell membrane receptors, initializing signaling cascades and cytoskeletal rearrangements. The emerging picture of basement membrane assembly is that laminin binding to cell surface receptors leads to polymerization of the laminins into a network. Then, collagen IV forms a second network, connecting to laminins *via* nidogens. This connection is greatly stabilized by interactions with perlecan.

Perlecan is a large proteoglycan expressed in both cartilage and basement membranes. It interacts with a number of other proteins including ►integrins, ►dystroglycan, collagens and laminins and also sequesters growth factors, particularly those of the fibroblast growth factor family. The majority of perlecan-null mice die due to subtle basement membrane defects during day 10–12 of embryonic development. Basement membranes are formed, but are leaky. Similar leaky basement membranes in the absence of perlecan can be observed in blood vessels after activation of perlecan-degrading proteinases. Surviving mice show extensive chondrodysplasia with abnormal endochondral ossification. Cartilage formation appears normal, but turnover shows major alterations.

In articular cartilage, hyaluronan is the central molecule to which several aggrecan molecules are connected through link proteins. Aggrecan is a large proteoglycan with many sugar side chains. It is linked to other

aggrecan molecules by interactions with fibulin-2. In tissue, collagen fibers can be demonstrated in the interior of the aggregate. Moreover, it has been demonstrated *in vitro* that aggrecan through its keratan sulfate side chains binds tightly to collagen, thus linking the two major molecular aggregates in cartilage to each other. Many molecules interact with collagen and have the ability to modulate fibril assembly. Two examples of collagen binding proteins are thrombospondin-5 and decorin. Thrombospondin-5 is a pentameric molecule with several binding sites on collagen II. However, the molecule is not large enough to span the distance between the binding sites on the same molecule, suggesting that it would link neighboring collagen molecules to each other. The protein cores of leucine-rich repeat (LRR) proteins are multiple repeats of compact horseshoe-shapes, a conformation suitable for protein-protein interactions. The LRR protein decorin can inhibit collagen fibril formation *in vitro*, and decorin null-mice have fragile skin with reduced tensile strength and larger irregular collagen fibrils, suggesting a role in fibril assembly and maintenance of the fibrillar network.

Interactions with Cell Surface Receptors

The integrin family, containing more than 20 members, was the first identified family of ECM receptors. The first discovered integrin bound to fibronectin, but it was soon found that several ECM components bind to similar types of receptors and that several receptors can bind more than one ECM component. All integrins are transmembrane proteins composed of non-covalently linked heterodimers of an α and a β subunit. All integrins containing an α_v or a β_1 subunit bind ECM proteins. Inside the cell, integrins bind signaling molecules and other proteins connecting to actin, thus linking the ECM to the cytoskeleton. The importance of cell attachment to ECM is shown by the prevention of apoptosis in anchorage-dependent cells by integrin $\alpha_5\beta_1$ adhesion to fibronectin. Further examples of the importance of integrin-ECM interactions are bone resorption where osteoclasts bind osteopontin through their integrin $\alpha_v\beta_3$ receptors and integrin binding to laminin isoforms during basement membrane assembly, as occurs during epithelial, endothelial and muscle development (1, 4).

Another group of cell-surface associated receptors, the ►syndecans, are heparan sulfate proteoglycans and act as co-receptors for growth factor receptors. However, they are also known to bind ECM glycoproteins such as tenascin-C, fibronectins and laminins. Intracellularly they are also connected to the cytoskeleton and signaling pathways involving protein kinase C.

The dystroglycan complex (DGC) has emerged as another type of receptor linking the cytoskeleton to the

ECM. The DGC is an important receptor system for ECM in muscle and epithelia. In muscle, mutations in any of the DGC components or in their extracellular ligand laminin $\alpha 2$ chain will lead to different forms of muscular dystrophies. In epithelial development, the main ligand seems to be laminin-1.

Regulatory Mechanisms

Breakdown of ECM by proteinases is an essential step in embryogenesis, tissue remodeling and metastasis. These events are often associated with elevated production and activity of ►[matrix metalloproteinases](#), of which over 20 have been identified. These proteinases can degrade the main components of ECM and can thus profoundly remodel the ECM (6). The positive regulation of ECM has thus far not been extensively studied. However, tissue homeostasis requires a fine balance of catabolic and anabolic signals. A few examples are given.

Epithelial differentiation correlates with increased mRNA expression of laminin-1 and collagen IV. In embryoid bodies, a model system simulating early embryonic development, fibroblast growth factor induced differentiation is followed by activation of PI3-kinase and protein kinase B (Akt/PKB). Among the downstream targets of Akt/PKB are important transcriptional regulators, such as the FOX multigene family and NF κ B. Akt/PKB activation can thus potentially regulate gene transcription. Synthesis of laminin-1 and collagen IV increased markedly in this and other systems with constitutively active Akt/PKB or the catalytic subunit of PI3K, whereas dominant negative Akt/PKB inhibited transcription of laminin $\beta 1$ and collagen IV. Hence, in many cell types, Akt/PKB activation stimulated by receptor tyrosine kinases might be involved in the positive transcriptional regulation of basement membrane components, including laminin-1.

Upon tissue injury, inflammation occurs with concomitant release of cytokines. Transforming growth factor- β (TGF- β) stimulates fibroblasts and other cells to proliferate and synthesize ECM components. This leads to provisional repair, which under normal conditions results in remodeling and regeneration. A balance in the synthesis of ECM proteins, matrix metalloproteinases and tissue inhibitors of these has to be reached. For collagen I, it is known that its two genes are regulated by TGF- β through the TGF- β -activator and the Smad pathways. Many of the provisional or

stromal ECM molecules such as collagen I, fibulins and tenascins are down-regulated by glucocorticoids. Since glucocorticoids also have effects on TGF- β transcription and secretion it is possible that they affect ECM by down-regulating this growth factor. However, ECM synthesis is not only regulated by different growth factors, but also by the mechanical forces, which directly affect transcription by now partially understood mechanisms.

The mineralized part of bone is the inert skeleton that remains after death, but bone is not a metabolically inert part of the living body. On the contrary, throughout life, bone is actively remodeled in a dynamic process. The catabolic phase includes the triggering of osteoblasts to remove the thin layer of osteoid and to condition the bone ECM to recruit osteoclast precursor cells. This activity includes the deposition of osteopontin, a cell-binding ECM protein. The osteoclast precursor cells develop into resorbing osteoclasts, which dissolve the mineral and digest the organic ECM. The resorption pits resulting from osteoclast activity recruit novel osteoblasts essential for new bone tissue formation. An important feature in skeletal biology is a variable mechanical load that induces cellular responses, leading to remodeling.

FAK

Definition

FAK stands for Focal Adhesion Kinase. It is a non-receptor proteintyrosine kinase implicated in signaling pathways involved in cell motility, proliferation and apoptosis. Activated by tyrosine-phosphorylation in response to either integrin clustering induced by cell adhesion or antibody cross-linking, or via G-protein coupled receptor (GPCR) occupancy by ligands such as bombesin or lysophosphatidic acid, or via LDL receptor occupancy. FAK plays a potential role in oncogenic transformations resulting in increased kinase activity.

False Positives/False Negatives

Definition

False positives (or false negatives, respectively) exist when laboratory tests or biometric scans report, incorrectly, that they have found a signal where none exists in reality (or found no signal although one exists in reality). For example, a positive test for AIDS or cancer, when the person was disease free, would be a false positive. In a ►[two-hybrid screen](#), false positives are physiological protein-protein interactions, which cannot be confirmed by another method.

Familial Combined Hyperlipidemia

Definition

Familial combined hyperlipidemia is an inherited disorder of high serum cholesterol and/or high blood triglycerides. Phenotype of IIa, IIb, IV hyperlipoproteinemia (increase in LDL and/or VLDL) is concurrently seen in the same family. VLDL is overproduced and small size LDL are present. This disorder predisposes the person to a greater risk of early coronary artery disease. Frequency of this syndrome is 1:50-1:100 in the general population. Autosomal dominant inheritance is suspected, but the causative gene locus has not yet been determined.

Familial DCM

Definition

Familial DCM refers to an (inheritable) ►[Dilated cardiomyopathy](#) (DCM) caused by an inherited gene mutation.

►[Familial Dilated Cardiomyopathy](#)

Familial Dilated Cardiomyopathy

DIANE FATKIN

Sr Bernice Research Program in Inherited Heart Diseases, Molecular Cardiology Unit, Victor Chang Cardiac Research Institute, Darlinghurst, NSW, Australia
d.fatkin@victorchang.unsw.edu.au

Definition

Cardiomyopathies are diseases of ►heart muscle that are associated with cardiac dysfunction. These disorders are classified on the basis of morphology and function into four categories: hypertrophic cardiomyopathy, dilated cardiomyopathy, arrhythmogenic right ventricular dysplasia and restrictive cardiomyopathy. ►Dilated cardiomyopathy (DCM) is characterized by dilation and contractile dysfunction of the left (± right) ventricles. DCM may result from a variety of conditions that impair cardiomyocyte function or cause cardiomyocyte injury or loss, including myocardial ischaemia, infection, inflammation, increased pressure or volume load, and toxic agents. In approximately 50% cases, an underlying cause is unable to be identified and DCM is termed ►idiopathic. Over the past decade, it has been recognized that genetic factors are also an important cause of DCM. When DCM is caused by an inherited gene defect in families, it is known as ►familial DCM. Studies to date have concentrated on ►monogenic forms of familial DCM that are caused by mutations in a single gene. The extent to which genetic factors may alter the susceptibility to acquired causes of DCM or modify disease ►phenotypes has not yet been elucidated.

Characteristics

Prevalence

The first studies to evaluate the prevalence of familial DCM were based on obtaining a positive clinical history in the relatives of ►probands and had a low yield (<10%). Subsequent studies have systematically evaluated first-degree relatives using physical examination, ECG and transthoracic echocardiography. It is now estimated that at least 20-35% cases of idiopathic DCM are likely to have a genetic basis (1).

Inheritance

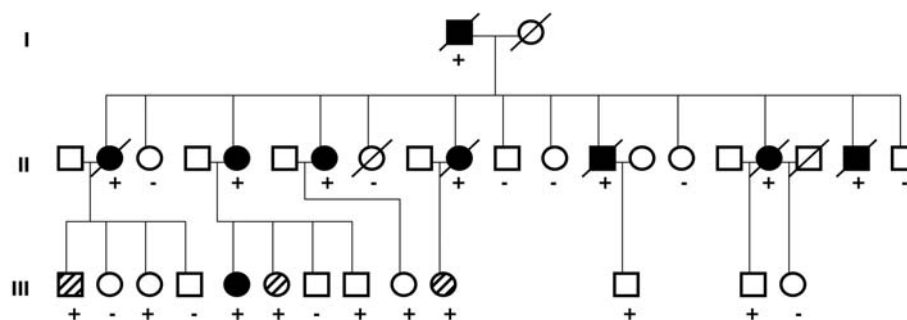

Families with DCM can show autosomal dominant, autosomal recessive, X-linked or maternal modes of inheritance (Fig. 1). Autosomal dominant inheritance is observed most frequently. Several factors may complicate determination of inheritance patterns in familial DCM pedigrees. An apparent absence of disease in younger generations of a family may not necessarily reflect ►genotype status, but rather, the phenomenon of age-related ►penetrance, ie. lack of disease manifestations in genotype-positive individuals until after a certain age (Fig. 2). In autosomal dominant pedigrees, an unaffected individual who has an affected child may be non-penetrant, ie. genotype-positive but phenotype-negative throughout life. Alternatively, DCM in the child may be attributable to a cause other than the familial gene mutation, ie. ►phenocopy. Although

Familial Dilated Cardiomyopathy. Figure 1

Inheritance patterns in families with DCM. Squares denote male family members; circles denote female family members. Clinically affected individuals are shown with solid symbols; clinically unaffected individuals who carry one mutant *allele* are shown by clear symbols marked with a dot. Autosomal dominant inheritance (a) is the most common pattern. In autosomal dominant DCM, affected individuals carry one mutant allele and one normal allele of the disease gene. One mutant allele is sufficient to cause disease. Both males and females can be affected. Each child of an affected parent has a 50% chance of being affected. Autosomal recessive DCM (b) occurs when two individuals who each carry one mutant allele have a child that inherits two mutant alleles. Individuals with one mutant allele are clinically normal and two mutant alleles are required to develop disease. In such a family, each child has a 25% chance of inheriting two normal alleles, a 50% chance of inheriting one mutant allele and a 25% chance of inheriting two mutant alleles. Both males and females can be affected. X-linked DCM (c) results from inheritance of a mutant allele of a gene located on the X-chromosome. If a mother carries a mutant allele, there is a 25% chance of each of four possible outcomes for her children: an affected boy, a normal boy, a carrier girl, or a normal girl. If a father carries a mutant allele, all sons will be normal and all daughters will be carriers.

the traditional view is that female carriers in X-linked disorders remain phenotypically normal, recent observations indicate that these individuals can develop symptoms and signs of DCM from late adolescence to older adult life. Overt expression of disease in female

Familial Dilated Cardiomyopathy. Figure 2 Pedigree of a 3-generation kindred with DCM and conduction-system disease. Symbols with a slash mark denote deceased individuals. Family members with conduction abnormalities without DCM are shown by striped symbols; family members with conduction abnormalities and DCM are shown by solid symbols. The presence (+) or absence (-) of a *LMNA* gene mutation is indicated below each symbol. In generation III, the majority of clinically affected individuals have conduction disturbances with normal left ventricular function. This is typical of the DCM + conduction-system disease phenotype, which is characterized by a prodrome of conduction disturbances from the second to fourth decades with the subsequent development of DCM. In generation III, the absence of clinical manifestations of disease in some of the young genotype-positive individuals can be explained by age-related penetrance. These individuals are at risk of developing overt disease with increasing age.

carriers may mask the presence of X-linked inheritance. Accurate determination of inheritance patterns is important for identification of “at risk” individuals who require cardiac screening, as well as for appropriate genetic counselling, and selection of candidate genes for mutation analysis.

Diagnosis

Familial DCM shows clinical variability. The age of onset and type of symptoms can vary between different families and within members of the same family. Families with DCM can be classified into one of the four phenotype subgroups:

- DCM alone
- DCM with ►conduction-system disease (sinus bradycardia, atrioventricular conduction block, ± supraventricular arrhythmias)
- DCM with skeletal myopathy, ±conduction-system disease
- DCM with other disorders, eg. sensorineural deafness.

Probands and family members should be evaluated by medical history, physical examination, 12-lead electrocardiography and transthoracic echocardiography. Affected individuals in families with the DCM-only phenotype generally present with symptoms and signs of congestive heart failure or cardiac arrhythmias, including dyspnoea, fatigue, palpitations, syncope, pulmonary venous congestion, and peripheral oedema. The diagnosis of DCM is based principally on the findings of increased left ventricular chamber diameters

and reduced fractional shortening on transthoracic echocardiography. In the subgroup of families with the DCM + conduction-system disease phenotype, the majority of affected individuals present with symptomatic or asymptomatic electrocardiographic changes in the second to fourth decades, with the subsequent development of DCM in later life (Fig. 2). Clinical signs of muscle weakness and wasting, and/or elevated serum creatine kinase levels, provide evidence of co-existent skeletal muscle involvement.

Natural History

The natural history of familial DCM is variable, with some individuals having a benign course, while others develop progressive heart failure that may require cardiac transplantation. Sudden death can occur at any age, irrespective of ventricular function. Individuals in families with DCM and conduction-system disease may develop progressive atrioventricular conduction block and require pacemaker implantation. Thromboembolic complications can result from left atrial or left ventricular blood stasis or may be precipitated by cardiac arrhythmias. Genotype-phenotype correlations in familial DCM have not yet been established and will require large populations of genotyped individuals. Although a number of clinical parameters have been proposed as prognostic factors in heart failure populations, it is likely that genotype will be the strongest determinant of outcome in familial DCM.

“Early Disease”

Because of the high prevalence of familial disease, current international guidelines recommend cardiac

screening of all first-degree relatives of probands with “idiopathic” DCM (2). As a result of implementation of screening strategies, a new population of individuals has been identified that have asymptomatic echocardiographic changes that do not fulfil standard criteria for the diagnosis of DCM. Isolated left ventricular dilation is the most common finding, occurring in up to 20% of individuals in families with DCM (3). The significance of these findings is not clear. It has been proposed that left ventricular dilation might represent a pre-symptomatic stage (“early disease”), and that further disease progression would be anticipated. Alternatively, these changes may represent a subclinical form of established disease or be caused by factors unrelated to familial disease. The natural history and optimal management of asymptomatic LV dilation in familial DCM is unknown and requires further evaluation.

Cellular and Molecular Regulation Chromosomal Loci and Disease Genes

Families with DCM have been evaluated genetically using genome-wide linkage analyses in large kindreds and candidate gene screening in small kindreds. Data from these studies have shown that familial DCM is a genetically heterogeneous disorder (4). To date, 32 chromosomal loci and 25 disease genes have been associated with the various forms of inherited DCM (Table 1). The list of gene mutations associated with DCM is already long and is growing rapidly. Surprisingly, very few mutations have been reported in each of these genes. Given the number of individuals in the cohorts screened, it appears likely that these known genes account for only a relatively small proportion of all cases of familial DCM. It is important to note that a number of these genes do not have robust genetic and/or functional evidence supporting disease causality. In some cases, a single mutation has been identified in one family, while in other cases, mutations have been identified in individuals in whom clinical and genetic data from family members are unavailable. Further studies are required to identify additional genes and to establish that putative DCM genes are in fact disease-causing.

Pathogenetic Mechanisms

► **Muscle** contraction is achieved by the sliding movement of thick filaments relative to thin filaments, which is mediated by the cyclical attachment and detachment of myosin cross-bridges. A number of factors regulate actin-myosin interaction, including the calcium-sensitive troponin-tropomyosin complex, intrasarcomeric cytoskeletal proteins and ATP hydrolysis (Fig. 3). Defective generation of contractile force due to mutations in various protein components of the sarcomere has been widely proposed as the

mechanism responsible for familial ► **hypertrophic cardiomyopathy**. Identification of mutations in genes encoding sarcomeric proteins (5), calcium-handling proteins (6) and proteins involved in myocardial energy regulation has indicated that impaired ► **force generation** can also cause familial DCM (Fig. 4). The question of why a number of genes can cause either hypertrophic cardiomyopathy or DCM is intriguing and has yet to be answered, but differences in calcium handling and/or myocardial energetics may be involved.

While some sarcomere protein gene mutations are located in residues involved in actin-myosin interactions, others are located in residues that are predicted to be involved in transmission of generated force to adjacent structures. The cardiomyocyte cytoskeleton provides an intracellular scaffolding that mediates transduction of mechanical force from the sarcomere to the extracellular matrix (Fig. 3). Mutations have been identified in a number of cytoskeletal proteins at various points along this pathway, providing strong support for impaired ► **force transmission** as a mechanism for familial DCM (Fig. 4).

Several studies have highlighted the important additional role of cytoskeletal proteins as determinants of passive myocardial wall properties. For example, titin is an intrasarcomeric protein that contributes to the structural organization of the sarcomere and myocardial elasticity. Mutations in titin are thought to have effects not only on active contraction but also on passive myocardial wall stress and elastic recoil (7). An interacting complex comprised of titin, muscle LIM protein (MLP) and T-cap, that is located at the sarcomeric Z disc, has been proposed to play a critical role in the cardiomyocyte's ability to sense mechanical stretch. DCM-causing mutations in the MLP or T-cap genes are predicted to disrupt this complex and impair stretch responsiveness, resulting in sustained alterations of passive stretch, left ventricular dilation and cell death (8). These remodelling changes reduce the efficiency of contraction and promote left ventricular systolic dysfunction (Fig. 4). Studies in mice suggest that myocardial energetics defects due to mitochondrial dysfunction associated with MLP deficiency could also contribute to contractile dysfunction.

The discovery of mutations in genes encoding the cardiac sodium channel (9), and the SUR2A subunit of the cardiac K_{ATP} channel (10), has recently shown that defective ion homeostasis is yet another disease pathway for familial DCM (Fig. 4). Cardiac K_{ATP} channels are important sensors of metabolic stress within cells. Defective cardiac K_{ATP} channel function compromises stress tolerance and may precipitate intracellular calcium overload and cell death.

Mutations in the *LMNA* gene, that encodes the nuclear lamina proteins, lamins A and C, have been shown to

Familial Dilated Cardiomyopathy. Figure 3 Schematic of cardiomyocyte cytoarchitecture. The cardiac sarcomere is comprised of interdigitating thick and thin filaments. Sarcomeres are linked by a scaffolding of cytoskeletal proteins to the sarcolemma, intercalated discs, and nucleus. Muscle contraction results from the sliding movement of thick filaments with respect to thin filaments that is achieved by the cyclical attachment and detachment of myosin crossbridges. This process is energy-requiring and utilises ATP supplied by mitochondria. The intracellular free Ca^{2+} concentration has a critical regulatory effect on both muscle contraction and relaxation. DHPR, dihydropyridine receptor; RyR, ryanodine receptor. With permission reproduced from: Fatkin D, Graham RM. Molecular mechanisms of inherited cardiomyopathies. *Physiol Rev* 2002; 82:945–980.

cause 9 diverse disorders, including autosomal dominant DCM with conduction-system disease (11). The consequences of *LMNA* mutations and the mechanisms underlying the various tissue-specific phenotypes are not fully understood. Lamin A/C deficiency causes

changes in nuclear shape and size, as well as altered distribution and localization of heterochromatin. Based on these findings, three principal hypotheses for laminopathies have been proposed: altered gene expression, altered protein interactions, and increased

Familial Dilated Cardiomyopathy. Figure 4 Putative pathogenetic mechanisms causing familial DCM.

nuclear fragility and susceptibility to mechanical stress. These hypotheses are not necessarily mutually exclusive and it is likely that a number of factors are involved. The recent identification of mutations in the gene encoding the transcriptional coactivator, Eya4 (12), provides further evidence that altered transcription regulation can underlie familial DCM. The downstream genes involved and the pathophysiological basis for contractile dysfunction have yet to be determined. Although attempts have been made to identify a unifying paradigm for the pathogenesis of familial DCM, current data indicate that the molecular defects that trigger the disease process are quite diverse, with multiple interactions between the various putative disease pathways. In addition to these inherited molecular “triggers”, a number of compensatory and decompensatory responses to the presence of left ventricular dilation and contractile dysfunction can promote further disease progression. These responses include activation of neurohumoral factors, re-induction of embryonic genes, altered calcium homeostasis, apoptosis and left ventricular chamber remodelling. While an inherited gene defect is sufficient to cause DCM in families, a complex interaction of other

genetic and environmental factors are likely to modify the clinical manifestations of disease in individual family members.

Clinical Relevance

Heart failure due to DCM is a major health problem in the developed world. The number of individuals with idiopathic DCM has been estimated to be 5-8 cases per 100,000 per year. The incidence of heart failure increases with age, affecting 10 per 100 individuals aged 65 years and older. Despite advances in medical management, hospitalization rates have risen progressively over the past two decades and the 5-year survival after a diagnosis of heart failure is only 50%. Clearly, new approaches to the treatment of patients with heart failure are required. Studies of single gene defects that cause DCM in families may provide insights into pathophysiologic processes applicable to a wide range of more commonly-occurring, acquired forms of DCM. This information will also facilitate the development of new therapeutic strategies directed towards prevention or attenuation of the disease process itself, rather than alleviation of symptoms. Compilation of a comprehensive list of DCM disease

genes is an essential pre-requisite for understanding the molecular pathogenesis of this disorder and for the development of patient screening strategies. Since each family generally has a unique gene mutation, the coding sequence of all known disease genes needs to be analysed in every new proband. With current techniques, this process is time-consuming and expensive. Rapid, automated methods for large-scale genotyping will be required before molecular genetic information can be incorporated into clinical practice. Ultimately, the ability to genotype populations with familial DCM will enable genotype-phenotype correlations to be performed with determination of “high risk” and “low risk” mutations. This prognostic information will assist physicians in selection of appropriate therapies, timing of follow-up visits, counselling on lifestyle modifications, pregnancy counselling, etc. Genotyping would also enable clinical surveillance of the offspring of affected individuals to be rationalized, so that serial diagnostic investigations need only to be performed in genotype-positive individuals. Importantly, the ability to identify young genotype-positive individuals who are phenotype-negative or those who have early disease, provides the opportunity for preventative interventions, with direct benefits to patient outcome and health-care costs.

Familial Endocrinopathy

Definition

Familial endocrinopathy describes a disorder in the function of an endocrine gland, which affects more members of the same family than can be accounted for by chance.

►Hyper- and Hypoparathyroidism

Familial Exudative Vitreoretinopathy

Definition

Familial exudative vitreoretinopathy (FEVR) is a hereditary ocular disorder characterized by incomplete vascularization of the peripheral retina. Dragged retina, exudation, vitreous hemorrhage, and retinal detachment may develop. One form of FEVR is caused by defects in Frizzled-4 (Fz4), a presumptive Wnt receptor.

Synonyms

Autosomal dominant hypercholesterolemia; Hereditary xanthomatosis

Definition

Familial hypercholesterolemia (FH) is an autosomal dominant inherited disorder of ▶**lipoprotein** metabolism characterized by very high plasma concentrations of low-density lipoprotein (LDL) cholesterol, tendon ▶**xanthomas** and increased risk of premature coronary heart disease (CHD). FH is caused by mutations in the LDL ▶**receptor** gene.

Characteristics

In the late 1930s Müller and Thannhauser recognized an inherited disease with elevated plasma cholesterol, cholesterol accumulation in tendons, and presence of CHD at an early age. Their suggestion that there might be a genetic basis for the hypercholesterolemia was substantiated by several family and metabolic studies during the following years (1). These studies laid the basis for Brown and Goldstein's discovery of the receptor for LDL. This LDL receptor is a cell-surface glycoprotein that plays a pivotal role in the regulation of LDL metabolism (1). For their important and brilliant work Brown and Goldstein were awarded the Nobel Prize for Physiology or Medicine in 1985.

Mutations in the gene encoding the LDL receptor give rise to FH and to date more than 800 pathogenic mutations have been reported (▶<http://www.ucl.ac.uk.fh>; ▶<http://www.umd.necker.fr>). FH is one of the most common autosomal dominantly inherited disorders in humans with an estimated prevalence of heterozygous FH of about 0.2% (1:500) among Caucasians. In contrast, the prevalence of ▶**homozygous** FH is about one in a million. The frequency of heterozygous FH is much higher in certain populations, i.e. one in 67 in the Ashkenazi Jews of Lithuanian descent, one in 100 in the South African Afrikaners, and one in 270 in the French Canadians. These high prevalences are due to ▶**founder gene effects**. Worldwide, an estimated ten million people are afflicted with FH.

In ▶**heterozygotes**, hypercholesterolemia is the earliest manifestation and is present at birth in nearly all subjects. Plasma LDL cholesterol levels are two- to three-fold above normal. Xanthomas especially in the Achilles tendons, in the extensor tendons of the hand, and in the patellar tendons are hallmarks of FH (Fig. 1). They are virtually specific for the disease, and appear with increasing frequency with age. By age 40, approximately 30% of heterozygous FH patients have xanthomas. ▶**Corneal arcus** and ▶**xanthelasmata** are commonly seen but are not specific for FH (Fig. 1).

In untreated FH, premature CHD typically occurs from the third to the fifth decade of life. In a recent

Familial Hypercholesterolemia. Figure 1

Extravascular lipid deposits. (a + b) Tendon xanthomas in the extensor tendons of the hand and in the Achilles tendon, respectively; (c) Corneal arcus; (d) Xanthelasmata.

prospective study, heterozygous FH was associated with a substantial excess mortality from CHD especially in young adults. The data indicate that approximately 50% of FH males and about 20% of females with FH die before age 40. Similar statistics are seen for deaths from all causes because most deaths in FH heterozygotes are due to CHD. Compared to the general population, the coronary standardized mortality ratios are 90 times higher in males under age 40 and 120 times higher in females in the same age group.

The much rarer homozygous condition is particularly severe, with a six- to eightfold increase in plasma cholesterol. These patients develop both cutaneous and tendon xanthomas as well as aortic and coronary atherosclerosis, before the age of 10 years. Typically, they contract CHD in their teens or early twenties.

Genetically determined changes in the ▶**ligands** for the LDL receptor, ▶**apolipoprotein** (apo) B and apoE, may also cause dyslipidemia and premature CHD. Several amino acid substitutions in apoE that prevent normal binding to the LDL receptors result in type III hyperlipoproteinemia which is quite different from FH. In the apoB gene, however, the R3500Q mutation results in a disorder that may mimic FH biochemically and clinically, namely familial defective apolipoprotein B (FDB) (2). The clinical course of FDB, however, is usually milder than that of FH.

Recently, a third locus associated with autosomal dominant hypercholesterolemia, HCHOLA3 at 1p32, has been reported. Two mutations in the gene PCSK9, (proprotein convertase subtilisin/kexin type 9) were identified causing autosomal dominant hypercholesterolemia (3). PCSK9 encodes NARC-1 (neural apoptosis regulated convertase) a newly identified human subtilase that is highly expressed in the liver but the precise implication in cholesterol homeostasis is unknown.

Thus, classical Mendelian inherited elevations of plasma LDL cholesterol may be caused by mutations in at least three different genes, the LDL receptor gene on chromosome 19p13.1-p13.3, the apoB gene on chromosome 2p23-pter and the PCSK9 gene on chromosome 1p32.

A rare **autosomal recessive** form of hypercholesterolemia that clinically resembles FH but is not due to mutations in the LDL receptor gene nor the apoB gene has also been identified (4). The gene locus has been mapped to chromosome 1p35, and a gene encoding a putative LDL receptor adaptor protein has been identified. This adaptor protein contains a phosphotyrosine-binding domain, which in other proteins binds Asn-Pro-X-Tyr motifs in the cytoplasmic tails of cell-surface receptors, including the LDL receptor. Furthermore, the adaptor protein appears to have a tissue-specific role in LDL receptor function, as it is required in hepatocytes but not in fibroblasts.

Cellular and Molecular Regulation

The 5.3 kb human LDL receptor mRNA of which almost half is **untranslated**, encodes a protein of 860 amino acids including an N-terminal signal sequence of 21 amino acid residues which is cleaved from the receptor post-translationally (5). Thus, a mature receptor protein of 839 amino acids is transported to the cell membrane (Fig. 2). The 45 kb LDL receptor gene comprising 18 **exons** and 17 **introns** has been highly conserved through evolution. The regulation of the LDL receptor gene expression is quite complex. Relative to the major transcription start site an 177-base pair fragment of the 5'-flanking DNA has been shown to be sufficient for controlling basal transcription as well as negative feedback regulation by cholesterol and its derivatives. The positive regulatory elements within this region were identified as three GC-rich imperfect 16 bp direct repeats and two TA-rich TATA-like sequences of 7 base pairs each. Repeats 1 and 3 contain **transcription factor** Sp1-binding sites. Interference with Sp1 binding to either repeat severely decreases basal transcription. Regulation of transcriptional activity occurs mainly through a 10-base pair sequence within repeat 2 designated sterol regulatory element-1. When intracellular cholesterol is low, sterol regulatory element-binding proteins bind to the sterol regulatory element-1 and subsequently interact with Sp1 in repeat 3. However, transcription of the LDL receptor gene is regulated not only by cholesterol, but also by nonsterol mediators e.g. hormones, growth factors and cytokines.

Normal function of the hepatic LDL receptor is required for normal levels of plasma LDL cholesterol. The LDL receptor regulates the concentration of plasma LDL cholesterol by internalizing apo

Familial Hypercholesterolemia. Figure 2 Domain structure of the human LDL receptor protein and its relation to the exon organization of the gene. The domains of the 839-amino acid mature protein are shown at the left and the corresponding exons encoding the protein domains at the right. Exon 1 (not shown) encodes a 21-amino acid signal sequence, which is cleaved from the mature protein during synthesis in the endoplasmic reticulum. (From ref. 5)

B-100- and apo E-containing lipoproteins by receptor-mediated endocytosis.

Mutations in the LDL receptor gene are classified into five functional classes as shown in Fig. 3. Class 1 mutations eliminate the synthesis of the LDL receptor. They include mutations in the **promoter**, nonsense mutations and mutations affecting **mRNA splicing** (null alleles). Class 2 mutations, which represent over 50% of mutations causing FH, result in LDL receptors that fail to be transported from the endoplasmic reticulum to the Golgi complex (class 2A) or are transported very inefficiently (class 2B) (transport-defective alleles). Class 3 mutations result in receptors that reach the cell surface but fail to bind their ligands, apoB or apoE (binding-defective alleles). Class 4 mutations generate LDL receptors that are delivered to the cell surface and bind LDL, but fail to concentrate in coated pits thereby leading to defective receptor-mediated endocytosis (internalization-defective alleles). Class 5 mutations result in LDL receptors that bind and internalize ligands normally, but fail to release LDL intracellularly and do not return to the cell surface (recycling-defective alleles).

Familial Hypercholesterolemia. Figure 3

Classification of LDL receptor mutations based on abnormal function of the mutant protein. These mutations disrupt the receptor's synthesis in the endoplasmic reticulum, transport to the Golgi complex, binding of apoprotein ligands, clustering in coated pits, and recycling in endosomes. (From ref. 5)

Clinical Relevance

FH has severe cardiovascular consequences due to the high levels of LDL cholesterol. However, efficient therapy is available in heterozygous FH that may potentially normalize levels of LDL cholesterol. Because target values for LDL-cholesterol are not achieved by dietary changes advised by the European Atherosclerosis Society or the US National Cholesterol Education Program alone, most patients require lipid-lowering drugs. Several studies have shown that hydroxy methylglutaryl coenzyme A (HMG-CoA) reductase inhibitors (statins), which competitively inhibit HMG-CoA reductase and thereby suppress cholesterol synthesis, have a marked effect on elevated plasma LDL cholesterol levels. If necessary, this effect can be enhanced by combining statins with other lipid-lowering drugs such as bile acid-binding resins, niacin and fibrates. It has been documented that intensive combination therapy leads to significant regression of coronary atherosclerosis. Moreover, aggressive statin monotherapy leads to regression of carotid intima media thickness, whereas lower, conventional statin doses do not. No long-term prospective randomized double-blind placebo-controlled studies of lipid-lowering drug therapy, however, have been performed in FH patients to assess the effect on morbidity/mortality. This is because it has been considered unethical to withhold treatment from patients with a diagnosis of FH. However, the Simon Broome cohort of FH patients in the UK showed a decline in relative risk for coronary

mortality in patients aged 20–59 years—from eightfold before 1992 to 3.7-fold post 1992—when statins were introduced (6). Moreover, data from large clinical cholesterol-lowering trials in the general population, strongly suggest that statin treatment will reduce morbidity and mortality in FH subjects. It is therefore, important to identify FH individuals so that appropriate treatment can be offered to reduce the risk of developing premature atherosclerotic cardiovascular disease.

However, even though efficient lipid lowering therapy is available, too few patients with FH have been diagnosed and too few have been put on lipid lowering therapy. In one study it was shown that only 20% of FH heterozygotes had been diagnosed and only 7% were being adequately treated. The main reason for the failure to put FH patients on lipid lowering drugs is assumed to be difficulties in diagnosing FH using clinical criteria. An alternative to a clinical diagnosis of FH is to apply molecular genetic methods to identify a mutation in the LDL receptor gene. However, these analyses are expensive and are only available in a few countries.

Patients with homozygous FH respond poorly to any drug therapy. In these patients non-pharmacological treatment modalities are necessary, preferable selective removal of apoB-containing lipoproteins by LDL apheresis. Although gene replacement therapy has been attempted to restore the function of the defective LDL receptors in patients with homozygous FH, it has met with little success and is still several years away from being a safe and effective treatment.

Fatty Acid Acylation of Proteins

MICHAEL VEIT, MICHAEL F.G. SCHMIDT
Department of Immunology and Molecular Biology,

Faculty of Veterinary Medicine, Free University,
Berlin, Germany
mveit@zedat.fu-berlin.de, schmidt.mfg@vetmed.fu-berlin.de

Synonyms

N-terminal myristoylation, N-acylation, palmitoylation, S-acylation

Definitions

Fatty acid acylation is the covalent attachment of fatty acids to proteins. This distinguishes acylation from other hydrophobic modifications such as “► [glypidation](#)”, ► [isoprenylation](#) and ► [cholesterol modification](#), where either the fatty acids are bound indirectly *via* a glycolipid anchor or where other lipid moieties (isoprenoids, cholesterol) are linked to the protein.

Characteristics

According to the linkage type and the fatty acid species involved in acylation two types of acylation are distinguished: N-terminal myristoylation (► [N-acylation](#)) and palmitoylation (► [S-acylation](#)).

Myristoylation

Myristoylation (1, 2) refers to the attachment of myristate, the 14-carbon saturated fatty acid, *via* an ► [amide-linkage](#) to the amino group of a glycine residue at the N-terminus of eukaryotic and viral proteins. N-terminal myristoylation is an irreversible process, which occurs co-translationally after the initiator methionine has been removed. With a few exceptions (proteins of the retina), fatty acids other than myristate are not transferred to proteins. Myristoylation strictly requires a N-terminal glycine, but not all proteins with such a glycine are acylated. Myristoylation also depends on downstream amino acids. Proteins with a serine or threonine at position six and basic amino acids at position seven are especially preferred substrates. Myristoylated proteins are found in diverse intracellular locations such as the cytosol, the nucleus, the endoplasmic reticulum and the plasma membrane.

Myristoylated proteins are often involved in signal transduction. Protein kinases such as the catalytic subunit of cAMP dependent protein kinase A and kinases of the src-family, the protein-phosphatase calcineurin and most α -subunits of heterotrimeric G-proteins are prominent examples. Myristoylated proteins of viruses are for example the gag-polyprotein precursor of retroviruses and the capsid proteins of

some papova- and picorna-viruses, such as polio- and foot and mouth disease-virus.

Palmitoylation

Palmitoylation (2–8) is the post-translational attachment of long chain fatty acids *via* a ►thioester linkage to cysteine residues. At least in some proteins, palmitoylation is reversible and has therefore the potential to regulate the subcellular localization and function of the

summarizes the main features of myristoylation and palmitoylation: In contrast to myristoylation the molecular signals that direct S-acylation have not been fully identified. However, by comparison of the hitherto identified palmitoylation sites the following conclusions can be drawn:

1. ►Transmembrane proteins are palmitoylated at cysteine residues located at the boundary between the transmembrane region and the cytoplasmic tail.

Protein-species	Membrane	Cytoplasm
Transferrin-Receptor	TGY C ISG S C	RKP KTVNAKTNDANEEDVALKM....NH ₂
CD-4	GIF F C V	R C RHRRRQAERMSQIKRLLSEKKTCQ..COOH
Synaptotagmin 1	VT C C F C V C	KK C LFKKKNNKKGKEKGKNA.....NH ₂
VSV G-protein	LIIGLFLVL	RVGIHL C IKLKRATKKRQIYTDIE....COOH
Influenza virus A Hemagglutinin	AMGLVF I C V	KNGNMR C T I C I -COOH
NDV fusion protein	LSLVLA C YL	MYKQKAQKQTLWLGNNLTLDQ.....COOH

(Palmitoylated cysteine residues are in bold and underlined)

protein. Palmitate (C 16) is often the predominant fatty acid, but other species such as myristate (C 14), stearate (C 18) and even arachidonic acid (C 22:4) have been

In some proteins, e.g. G-protein coupled receptors, the palmitoylated cysteine is found at more distal positions.

Protein-species	Membrane	Cytoplasm
Rhodopsin	NPVIYI	MMNKQFRNCMVTTL C C G KNPLGD...COOH
β2-Adrenalin receptor	NPLIYC	RSPDFRIAFQELL C LRRSSLKAYG.....COOH
Dopamine D1 receptor	NPIIYA	FNADFRKAFSTLL G C Y RL C PAT...COOH

identified in “palmitoylated” proteins. Therefore this modification is also referred to as S-acylation. Palmitoylated proteins are mostly integral or peripheral membrane-proteins present on the cell surface as well as on organelles of the secretory or endocytic pathway. A few palmitoylated proteins have been identified in other organelles such as mitochondria or are even secreted from the cell, for example the surfactant protein C present in alveoli of the lung. The following table

2. Intrinsically hydrophilic proteins, i.e. those without a hydrophobic transmembrane region are palmitoylated in three different regions:

At cysteine residues located near the N-terminus of the protein.

Palmitoylation in this region often occurs after myristoylation of the N-terminal glycine. Such proteins seem to have a characteristic MGC-motif at the N-terminus:

src-family of tyrosine-kinases	α-subunits of heterotrimeric G-proteins
Yes M G C IKSKEDKGPAMKY	α1 M G C TLSAEDKAAVERS
Fyn M G C VQ C KDKEATKLTE	αo M G C TLSAEERAALERS
Lyn M G C IKSKRKDNLDDE	αz M G C RQSSEEKEAARRS

In other myristoylated proteins the palmitoylated cysteine is present at a more distal location:

eNOS **MG**NLKS**VGQEPGPP****C**GLGLGLGLGL**C**GK
 AKAP18 **MG**QL**CC**FPFSRDEGK
 Vac8p **MG****SCCSC**

Other proteins are palmitoylated at cysteines near the N-terminus without prior myristoylation:

Gαq MTLESIM**ACCL**SEEAKEA
 Gα12 MSGVVRTL**SRCL**LPAEAG
 Gα13 MADFLPSRSVLS**VC**FPQ**C**VLN**GEAEQ**QRKSKEIDK**CL**S
 GAP-43 ML**CC**MRRTKQVEKNDD**DQ**KIEQDGI
 PSD-95 MD**CL**CIVTTKKYRYQDE**DTP**

Palmitoylation can also occur at a cluster of cysteine residues located in the middle of the protein.

SNAP-25B NH₂.....EKNLTDLGKF**CGLC****Vc**
 P**c**NKLKSSDA.....COOH
 cysteine string NH₂.....VV**CGLLTCCYCCCC****CCCC**FN
 protein **CCCGKCK**PKA.....COOH

Cysteine residues located near the C-terminus of the protein also serve as palmitoylation sites. In these proteins palmitoylation occurs after isoprenylation of the cysteine within the C-terminal CAAX-box, proteolysis of the AAX and methylation of the penultimate cysteine. This type of palmitoylation has been described for two forms of the ras-protein and the small G-protein rho-B.

Enzymes for Acylation and Deacylation of Proteins

Myristoylation (1)

Myristoylation is catalyzed by a well-characterized enzyme, N-myristoyltransferase (NMT). Genetic studies have established that NMT is essential in *S. cerevisiae* and in *Drosophila melanogaster*. Mammals possess two NMTs, which are both ubiquitously expressed and show the same substrate specificity. Myristoylation is irreversible and thus no enzyme for demyristoylation has been described. In some proteins the myristate may be removed together with neighboring amino acids by proteolytic cleavage.

Palmitoylation (6)

Palmitoyl-acyl-transferases (PAT)

Enzymes that catalyze palmitoylation of proteins have not been identified with certainty. In the test tube some proteins can even be palmitoylated in the absence of any enzyme source with palmitoyl-CoA as lipid donor. This non-enzymatic acylation can occur in stoichiometric amounts and at authentic palmitoylation sites. However, non-enzymatic palmitoylation *in vitro* requires unphysiologically high concentrations of

►Pal-CoA and is therefore believed not to be responsible for palmitoylation of proteins *in vivo*.

Many attempts have failed to purify PAT with biochemical methods, but it is generally agreed that such an enzyme exists on cellular membranes. Enrichment of PAT in membranes such as the ER/Golgi intermediate compartment and the plasma membrane have been reported. Even synaptosomes prepared from neurons and the vacuole of yeast cells contain palmitoylating activity of a protein nature. It is therefore likely that a cell contains different PAT enzymes with different intracellular locations and different substrate specificities.

Using a genetic approach candidates for PAT have been identified in lower eukaryotes:

Skinny Hedgehog

In *Drosophila* the product of the *ski* gene is required for palmitoylation of hedgehog, a secreted protein with a key role in several developmental processes. However, acylation of hedgehog occurs through an amide bond by an unusual mechanism, which makes it unlikely that skinny hedgehog also catalyzes conventional palmitoylation by thioester bonding.

DHHC-CRD Proteins

In *S. cerevisiae* one candidate for PAT is a protein family containing a conserved Asp-His-His-Cys (DHHC) motif within a cysteine rich domain (CRD). One member of this DHHC-DRD protein family (erf2p) catalyzes palmitoylation of yeast ras. A second DHHC-CRD protein (akr1p) palmitoylates a casein kinase. It is not known whether all members of the DHHC-CRD protein family are palmitoyl-transferases with different substrate specificities and if their mammalian orthologues perform the same function.

Thioesterases

Palmitoyl-Protein Thioesterase 1

Palmitoyl-protein thioesterase 1 (PPT-1) has been purified with palmitoylated ras as a substrate. However, its location inside lysosomes suggests that PPT-1 is not involved in depalmitoylation of functional proteins, but is rather required for lysosomal degradation of palmitoylated proteins and peptides (see also Clinical Relevance).

Acyl-Protein Thioesterase -1

Using palmitoylated G-proteins as substrates, a cytosolic deacylating enzyme was purified and designated acyl-protein thioesterase (APT). Peptide sequencing revealed that APT is identical to a lysophospholipase, which is also known to hydrolyze Pal-CoA. APT can cleave fatty acids from several, but not all, palmitoylated proteins. Deletion of the only APT gene in yeast had no obvious effect on the viability of the yeast cells. Thus, the role of APT in the regulated turnover of fatty acids requires further investigation.

Function of Fatty Acylation

Binding of Acylated Proteins to Membranes and to Membrane Subdomains (2, 5)

Attachment of lipids to an otherwise hydrophilic protein increases its hydrophobicity and thereby could facilitate insertion into the lipid bilayer. This has been experimentally demonstrated for the attachment of palmitate to intrinsically hydrophilic proteins, which are thereby anchored to the inner leaflet of the lipid bilayer. In contrast, myristoylation alone can only transiently attach proteins to membranes, probably because myristate is less hydrophobic than palmitate. Therefore a second signal located in the vicinity of the myristoylated glycine is required for permanent membrane anchorage of proteins. This can be a polybasic cluster of amino acids that enhances electrostatic interactions with acidic phospholipids enriched in the inner leaflet of the bilayer. In other myristoylated proteins, palmitoylation of cysteine residues in the vicinity of the myristate group provides the second signal for stable membrane binding.

It is reasonable to assume that protein-bound fatty acids partition into the lipid bilayer for attaching the protein to the membrane. However, membrane targeting based on these lipid-lipid interactions alone would lead to a homogeneous distribution of the modified protein in all intracellular membranes. Therefore additional mechanism must secure the correct intracellular location for acylated proteins. According to the “membrane-trapping model” the location of PAT may determine targeting of a protein to specific membranes. N-terminal myristoylation can attach the protein transiently to various membranes, but only if a PAT is present

is the protein palmitoylated and permanently attached to this membrane. The protein can exit the membrane only by deacylation or by inclusion into budding vesicles mediating intracellular transport, for example from the Golgi to the plasma membrane.

Some palmitoylated proteins are not homogeneously distributed in the plasma membrane, but are enriched in specific subdomains called “lipid-rafts”, or “caveolae” if the palmitoylated protein caveolin is a major constituent. These lipid aggregates are insoluble in non-ionic detergent at low temperature and are characterized by their high cholesterol and sphingomyelin contents. The rafts serve as platforms where specific proteins are concentrated, especially those that participate in protein-protein interactions. The enrichment of palmitoylated proteins in rafts does not depend on the hydrophobicity of the lipid moiety alone, because myristoylated and isoprenylated proteins are not targeted to rafts. Likewise, not every palmitoylated protein is located in ▶“lipid-rafts”, demonstrating that additional signals must exist that regulate the protein composition of “lipid-rafts”.

Release of Acylated Proteins from the Membrane

Some acylated proteins cycle on and off the membrane. Palmitoylation is a reversible process and palmitoylated proteins can be released from the membrane simply by enzymatic cleavage of the fatty acid. This has been shown for ▶peripheral membrane proteins, but not for ▶integral membrane proteins that do not depend on palmitoylation for membrane attachment because their hydrophobic transmembrane region is sufficient for permanent anchorage.

One possibility for releasing a myristoylated protein from the membrane is to quench the second signal required for membrane binding. Phosphorylation of amino acids in the polybasic domain introduces negative charge thereby reducing the interaction with acidic phospholipids in the bilayer. Another possibility for regulating transient membrane interactions of myristoylated proteins is to regulate the surface exposure of the fatty acid. Some myristoylated proteins can occur in two conformations. In one conformation the myristate is sequestered in a hydrophobic pocket within the protein. In the second conformation the fatty acid is expelled and is then available to participate in membrane binding. This “myristoyl switch” is often triggered by binding of a ligand to the protein, for example calcium or GTP.

We have just described the general role of acylation for the attachment of proteins to membranes. In the remaining part of the article we will discuss acylation of specific proteins and their role in cellular functions such as signal transduction, cell transformation and neuronal development and secretion and also in the replication cycle of viruses.

Signal Transduction via G-protein Coupled Receptors, Heterotrimeric G-proteins and Kinases (7)

The role of acylation during signal transduction *via* G-protein coupled receptors (GPCRs), heterotrimeric G-proteins and kinases of the src-family has been intensively studied over the last few years. Myristoylation of the α -subunits of heterotrimeric G-proteins and of tyrosine kinases enhances their subsequent palmitoylation, probably by targeting the acylated α -subunit to a membrane-bound PAT. As already discussed above, palmitoylation then leads to permanent membrane binding and to targeting of the double acylated protein to lipid-rafts. Both myristate and palmitate increase the interaction of the acylated protein with other signaling molecules, in this case between the $G\alpha$ subunit and the $G\beta\gamma$ complex.

Palmitoylation and depalmitoylation are apparently regulated during signal transduction. When a specific signal transduction pathway is activated, increased turnover of protein-bound palmitate can occur both on the receptor (GPCR) and on the downstream G-protein. Deacylation of the G-protein is accelerated and the protein is released into the cytosol or is no longer attached to "lipid-rafts".

Palmitoylation of GPCRs is not essential for membrane binding, but palmitate is thought to insert into the membrane thereby forming an additional cytoplasmic loop. Despite the pronounced structural similarity between different GPCRs, the role of palmitate in the life cycle of GPCRs depends on the individual receptor. Some receptors require palmitoylation for their stable expression on the cell surface. Other receptors are unable to couple to G-proteins without covalently linked palmitate. In yet other receptors, palmitoylation has an effect on desensitization, phosphorylation, internalization and/or down-regulation. Thus, no generalizations can be made and the function of acylation has to be experimentally determined for each signal transduction pathway.

Neuronal Development and Neurosecretion (8)

"Lipid-rafts" are believed to mediate axon targeting of proteins as opposed to dendrites. Dynamic palmitoylation at two N-terminal cysteine residues is required for incorporation of GAP-43 into "lipid-rafts" and for its transport to the growth-cone of developing axons. There it modulates GPCR signaling cascades and regulates neurite outgrowth and path finding. Palmitoylation of GAP-43 decreases in mature axons and disrupting palmitoylation experimentally blocks axon outgrowth, indicating that membrane-bound, palmitoylated GAP 43 orchestrates the molecular machinery for axon extension.

However, not every palmitoylated protein is sorted to axons. PSD-95 is also palmitoylated at two N-terminal cysteine residues, but is transported to dendrites. At postsynaptic densities PSD-95 (together with other scaffolding proteins) regulates clustering of glutamate receptors of the AMPA- and NMDA-type. Certain patterns of synaptic activity reduce palmitoylation of PSD-95. The protein dissociates from postsynaptic sites and the number of glutamate receptors at the synapse is reduced.

Transformation of Cells by the ras Protein (2, 5, 7)

Mutations in the GTP-binding domain of the ras-protein can cause transformation of cells, because downstream signal cascades are permanently activated. To fulfill its function ras must be targeted to the inner leaflet of the plasma membrane. This is accomplished by protein modifications at the ►CAAX-box, isoprenylation, AAX-proteolysis, methylation and (in the case of N-ras and K-ras) palmitoylation. Isoprenylation occurs in the cytosol and targets ras-proteins to the endoplasmic reticulum, where proteolytic cleavage and methylation occur. Palmitoylation is then required for vesicular transport of ras to the plasma membrane and for its association with "lipid-rafts" or caveolae. Isoprenylation is carried out by the well-characterized enzyme farnesyl-transferase. Inhibitors of the enzyme can revert transformed cells to a normal phenotype and are currently being tested in clinical trials for use in cancer patients. Once the enzyme for the palmitoylation of ras has been unambiguously identified, it might also be a promising target for the development of cancer drugs.

Fatty Acid Acylation and the Viral Replication Cycle (3, 5)

Fatty acylation was originally discovered in viral proteins and many investigators have studied the role of myristoylation and palmitoylation in the replicative cycle of different viruses. Disappointingly, no generalization can be drawn from these numerous studies. Poliovirus is a non-enveloped virus that requires myristoylation of its VP4 protein for virus assembly. X-ray structures of whole virus particles show that myristate is an integral part of the virion subunit structure. This also demonstrates that a fatty acid need not necessarily be integrated into a lipid bilayer.

Nef and Gag, two proteins of the AIDS virus require myristoylation plus a polybasic motif for their membrane binding. Blocking myristoylation of the gag-polyprotein disrupts budding of AIDS-virus particles. Many spike glycoproteins of enveloped viruses, often those with membrane fusion activity, are palmitoylated

at cysteine residues in their transmembrane or cytoplasmic region. Although great progress has been made in elucidating the fusion mechanism of these glycoproteins, the role of palmitoylation in membrane fusion is probably quite subtle. The hemagglutinin of influenza virus and gp 160 of the AIDS-virus seem to require palmitoylation for the last step in membrane fusion, the opening or enlargement of the fusion pore. Palmitoylation of viral glycoproteins also effects the release of viruses from the infected cell. Palmitoylated viral glycoproteins as well as internal components of viral particles are often enriched in “lipid-rafts”. This concentration of viral components in membrane subdomains facilitates protein-protein interactions, assembly of virus particles and budding from the cell. Not every viral protein present in lipid-rafts is acylated, but those that are require palmitoylation for raft targeting.

Clinical Relevance

NMT as a Therapeutic Target (1)

Several human pathogens such as *Candida albicans* require a functional NMT for their survival. NMT from humans and from microorganisms both show the same preference for myristoyl-CoA, but have different peptide substrate specificities. Peptide derivatives have been developed that are species-specific inhibitors and show fungistatic or fungicidal activity.

Mutations in PPT Cause a Lysosomal Storage Disease (6)

Infantile neuronal ceroid lipofuscinosis, a lysosomal storage disease, is caused by genetic deficiencies of PPT-1. Pathologically, it is characterized by accumulation of autofluorescent material in the lysosomes of neurons and other cells. The disease is selectively manifested in the central nervous system, so that there is a progressive loss of neurons resulting in dementia and motor problems, epilepsy, blindness and, finally, early death. Cells from patients with the disease accumulate fatty acid thioester peptides derived from palmitoylated proteins.

Definition

The fibroblast has been considered for a long time a relatively static cell fulfilling the function of synthesizing extracellular matrix components, such as collagen. However, during the last few years, new perspectives have opened concerning the biological features, the function and possibly the heterogeneity of this cell; we are now facing a period of intense research concerning new and potentially important contributions of the fibroblast to several physiological and pathological phenomena. In this article, we discuss the role of the fibroblast in contributing to the organization of ► [extracellular matrix](#) and, in particular, the aspects of its biology that open new perspectives in the understanding of connective tissue remodeling in normal and pathological situations.

Characteristics

The morphological features of fibroblasts under normal conditions are very similar in different organs. On electron microscopic examination, they exhibit an oval nucleus and a variably developed endoplasmic reticulum; this is in relation to their synthetic activity (Fig. 1a). The ► [intermediate filament](#) protein typical of fibroblastic cells vimentin.

Fibroblast. Figure 1 (a) Typical fibroblast of the human dermis showing an oval nucleus and a well developed endoplasmic reticulum. (b) typical myofibroblast from an experimental granulation tissue with an indented nucleus, a fairly developed endoplasmic reticulum and many microfilaments (Figure a, from Gabbiani G. et al. *The Journal of Experimental Medicine*, 1972, 135 (4):719–734 with copyright permission of The Rockefeller University Press and Figure B, from Gabbiani G. et al., *Experientia*, 1971, 27:549 with copyright permission of Birkhäuser Verlag AG).

Fibroblasts' Origin

It has been assumed for a long time that in adult mammals fibroblasts are resident mesenchymal cells and that they are renewed locally. This view has not always been predominant. For example, very early work by Connheim (1) suggested that fibroblasts could derive from circulating cells, macrophages in particular. Later, the experiments of R. Ross using parabiotic rats (two rats with the same genetic background, whose circulations have been connected) showed that when a wound was made in one of them, there was no evidence that the fibroblasts of the granulation tissue repairing the wound were derived from the other rat. This established the dogma that the origin of fibroblasts during tissue repair is local (1). However, in the last few years, several observations have challenged this view and convincingly suggested that, at least in part, fibroblasts derive from circulating cells such as

macrophages or more generally stem cells (2). These circulating fibroblasts or fibroblast precursors have been called (somewhat unfortunately from the etymological point of view) fibrocytes (2). Other experiments have shown that if a silicone tube is implanted into the peritoneum of an animal, e.g. a rabbit, the layer of cells surrounding this tube is composed first of macrophages and then of fibroblastic cells that probably derive from these macrophages. The fibroblasts making a capsule around the tube may even transdifferentiate into smooth muscle cells (3). These observations open an important perspective on the characterization of fibroblast precursors that could eventually be used therapeutically during tissue repair and/or tissue reconstruction.

Another interesting new approach concerning the origin of the fibroblast has been the observation that these cells can derive from epithelial cells, particularly in locations such as the kidney interstitium, where the main source of fibroblasts is the epithelial cell from tubules (4) and in the mesothelium of several cavities, where the precursor cell is the mesothelial cell (5). **►Epithelial-to-mesenchymal transition** is an important biological phenomenon for example during development. Taken together these observations show that fibroblasts are more heterogeneous than one would have previously assumed.

Fibroblasts' Heterogeneity

It is intuitively acceptable that fibroblasts present in different organs, although involved in similar functions, e.g. synthesis of extracellular matrix, show different biological features, since some organs are selectively rich in one of the collagen types such as Type I or Type III and may also show different proportions of accumulated connective tissue components. However, for a long time, differences among fibroblastic cells were somehow ignored. During recent years, culturing fibroblastic cells from different locations has indicated that they may behave differently e.g. in the synthesis of collagen types (6), complement fragments (reviewed in 7), cytokines (reviewed in 7) and structural proteins such as α -smooth muscle actin (6), the actin isoform typical of vascular smooth muscle cells that also participates in the force generation by myofibroblasts (see below) in order to produce wound contraction (see below). An interesting recent development is the description of discrimination between two fibroblastic phenotypes using the marker Thy-1, a cell surface protein whose function is at present not known. Using this experimental approach, it has been shown that Thy-1 positive fibroblasts are predisposed to differentiate toward the myofibroblastic phenotype (see below) whereas Thy-1 negative fibroblasts are predisposed to differentiate toward the adipocytic phenotype (7).

Regulatory Mechanisms

It appears more and more clear that fibroblasts can crosstalk with other cells of their microenvironment, through modulation of their phenotype or through production of ►cytokines.

Role of Fibroblasts in Wound Healing and Tissue Remodeling

Perhaps the most important advance in fibroblast biology of recent years is the finding that these cells participate in a crucial way in granulation tissue remodeling and wound contraction (reviewed in 6). When an open wound heals in the skin or in internal organs, the repair is essentially done by connective tissue cells rather than by epithelial cells, since in general mammalian organs do not possess or possess in a very low degree the capacity of regenerating. The process of wound healing starts with an extravasation of blood that coagulates; the fibrin coagulum contains platelets and white blood cells which liberate cytokines and growth factors that in turn play an important role at the beginning of the healing process. Among the actions of these substances, there is a) stimulation of the motility and contractility of fibroblasts and b) stimulation of ►angiogenesis. These actions allow the formation and accumulation of what is called granulation tissue, i.e. a tissue consisting essentially of small vessels, fibroblasts and extracellular matrix components that are synthesized by fibroblasts. Granulation tissue formation is followed by contraction, which is rather a retraction process than a real contraction (see below), which is important for reducing the size of the wound. This process, together with reconstitution of epithelial continuity, i.e. replication and movement of epithelial cells, is essential for the completion of wound healing. During the process of granulation tissue formation, fibroblasts acquire contractile capacity, which is reflected in their neoexpression of bundles of microfilaments (Fig. 1b) that contain contractile proteins such as actin and myosin, the classical molecules that generate force in organs such as cardiac and skeletal muscle. Actin and myosin are expressed as different isoforms (that means similar molecules with slightly different sequences) in different organs. In general fibroblasts do not express actin isoforms typical of muscle cells but granulation tissue fibroblasts, that have been called myofibroblasts, neoexpress α -smooth muscle actin, the actin isoform typical of vascular smooth muscle cells. Hence, fibroblasts not only assume a contractile function during the evolution of granulation tissue but also express proteins typical of a muscle cell. This expression corresponds morphologically to the appearance of cytoplasmic stress fibers (Fig. 2) i.e. bundles of filaments containing actin and myosin and capable of exerting a contractile activity. Stress fibers end at the cell membrane on adhesion

Fibroblast. Figure 2 Three-dimensional reconstruction by means of laserscan confocal microscopy of a myofibroblastic cell present in an epiretinal membrane from a patient suffering from proliferative vitreoretinopathy. The cells have been stained *in toto* by means of immunofluorescence with an antibody against α -smooth muscle actin. The colors change in function of the depth of the section. Myofibroblasts show typical stress fibers. Bar, 10 μ m. (from Serini G. and Gabbiani G., *Experimental Cell Research*, 1999, 250:273–283 with copyright permission of Elsevier Science and Academic Press)

complexes, which connect the cell periphery with the extracellular matrix, allowing the force exerted by stress fibers to be transmitted to the surrounding microenvironment (8). Using these organelles, myofibroblasts remodel the extracellular connective tissue in order to produce reduction of granulation tissue volume i.e. wound contraction. It should be noted that the contractile activity of myofibroblasts is not exerted by means of a mechanism similar to that of striated or smooth muscles, that is always followed by relaxation, but is more the consequence of a long lasting isometric tension that reduces the volume of the surrounding matrix (6). This change in volume is then stabilized by the synthesis of new extracellular components such as collagen molecules and the overall process results in a decrease in the wound area or volume. Recent work has shown that in myofibroblasts actin/myosin interaction in order to produce isometric force is regulated by Rho/Rho kinase mediated inhibition of myosin phosphorylation, a mechanism that is typical of primitive contractile phenomena (6).

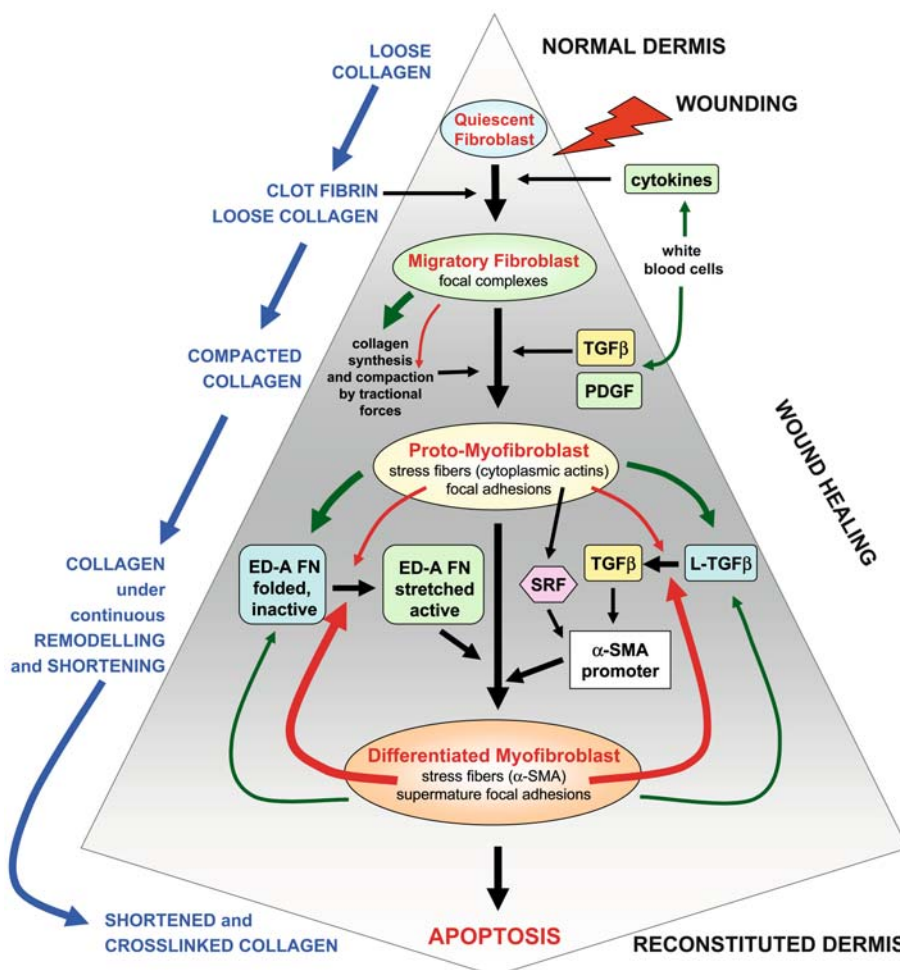

The fibroblast/myofibroblast transition depends on the concerted action of cytokines, such as transforming growth factors β (TGF β) and specific extracellular matrix proteins such as the cellular fibronectin splice-variant ED-A. Recently, acquisition and maintenance of the myofibroblast phenotype has been shown to depend on mechanical tension, which is regulated by the continuous interaction between the rigidity of the

extracellular matrix and the contractile activity of the myofibroblasts (6).

When a wound is reepithelialized and the continuity of the tissue is re-established, myofibroblasts undergo apoptotic phenomena that cause their death, thus provoking the evolution of granulation tissue into scar tissue that is relatively poor in cells. The mechanisms of myofibroblast apoptosis are not very clear but it is established that during pathological wound healing, e.g. hypertrophic scar development, these apoptotic changes do not take place.

Conclusions and Perspectives

The last ten years have seen a profound change in the paradigm of fibroblast biological function with a switch from a static role involving synthesis of extracellular matrix components to a more active participation in tissue repair, remodeling and differentiation. In particular the fibroblast/myofibroblast transition has been established as a key event in wound healing and fibrotic phenomena (Fig. 3). Among the processes that remain to be investigated are the transdifferentiation mechanisms of myofibroblasts from precursor cells located

Fibroblast. Figure 3 Scheme illustrating myofibroblast evolution during dermal wound healing. Stimulatory effects are depicted by black arrows; arrow thickness grossly corresponds to the level of activity. In the mechanically unloaded extracellular matrix (ECM) of normal dermis, fibroblasts are quiescent and do not develop stress fibers or cell-matrix contacts. Cytokines released by blood cells after dermal injury stimulate fibroblasts to form immature focal adhesions and to migrate into the provisional extracellular matrix, where they secrete and remodel collagen. Their tractional forces enhance matrix rigidity and lead to the development of the proto-myofibroblast, which is characterized by stress fibers and mature focal adhesions. Secretion and activation of TGFβ and ED-A fibronectin (ED-A FN) and increased matrix stress induce α-smooth muscle actin (α-SMA) accumulation and formation of the differentiated myofibroblast. When matrix reconstruction is completed, myofibroblasts are removed by apoptosis. PDGF, platelet-derived growth factor; L-TGF, latent transforming growth factor β; SRF, serum response factor (from Hinz B. and Gabbiani G., *Current Opinion in Biotechnology*, 2003, 14 :358–546 with copyright permission of Elsevier Science and Academic Press)

locally or immigrating from the circulation. In fibroblast/myofibroblast modulation, TGF β appears to be a crucial player together with ED-A cellular fibronectin. In addition, the role of mechanical factors such as tissue stiffness and tension is beginning to be elucidated. We are clearly at the beginning of an exciting era that will probably allow definition of the implications of the fibroblast in several important biological phenomena and allow one to influence these phenomena by strategies involving the mechanical or chemical factors modulating fibroblast biology.

Fibronectin is high molecular weight glycoprotein, consisting of two chains (each of 250 kD) linked by

Filaggrin

Definition

Filaggrins are filament-associated proteins that interact with keratin intermediate filaments of terminally

differentiating mammalian epidermis via disulphide bond formation. The proteins are synthesised as large, insoluble, highly- phosphorylated precursors, containing multiple tandem repeats of 324 amino acids, which are not separated by a large linker. The precursor is deposited as keratohyalin granules. Aberrant expression of filaggrin has been implicated in a number of keratinising disorders.

Fingerprint/Fingerprinting

Definition

Fingerprinting refers to a high throughput method in which DNA (of large insert clones) is digested with restriction endonucleases, which results in a largely individual-specific series of bands. The measurement of relative mobilities of the fragments represents a

DNA fingerprint of each clone/individual. This technique enables the identification of other clones that share a large proportion of fragments with the same relative mobilities that represents an overlap of the different clones, thereby constructing a contig. In analogy to DNA fingerprinting, in proteomics the term fingerprint is defined as a series of conserved local sequence alignments, here called motifs, which have been iteratively refined from database searches. The pattern of fragments can be obtained when a protein is digested by a proteolytic enzyme, usually observed following two-dimensional separation by chromatography or electrophoresis.

DNA Fingerprinting has become very popular in forensic laboratories. Scientists have chosen repeating sequences in the DNA, which are present in all individuals on different chromosomes, and are known to vary from individual to individual except in identical twins. By this technique an individual can be identified at molecular level.

FISH

Definition

FISH (Fluorescence in-situ hybridization) is a cytogenetic method of visualizing defined DNA sequences in metaphase or interphase chromosome spreads. It is useful for identifying chromosomes and parts thereof, deciphering chromosomal abnormalities and for gene mapping. A nucleic acid probe labelled with a fluorescent dye is hybridized to chromosomes of suitably prepared cells or histological sections, and the probe is then visualised by fluorescence microscopy and scored for the presence or absence of the signal.

Flow Cytometry

Definition

Flow cytometry (Cytofluorometry) is a method for quantitating components or structural features of cells, primarily by optical means. A suspension of cells or particles is passed through laser light focussed to a beam. As a cell or particle is struck by the beam, it emits scattered light. If the cells have been stained with fluorochromes, they will also emit fluorescence light at levels that directly corresponds to the density of fluorochrome inside or on the cells. The signals are picked up by detectors. Over 1000 cells per second can be distinguished by quantitating biophysical features (size, granularity) and biochemical properties (DNA content, expression of surface markers). These signals are then converted for computer storage and data analysis, and can provide information about various cellular properties. Flow cytometry is often used to characterize blood cells during infection or inflammation.

Many larger flow cytometers can also be used as ► [fluorescence-activated cell sorters](#) (FACS), which sort cells according to selected properties.

Fluorescence Anisotropy

Definition

Similar to excitation, fluorescence emission by the excited fluorophore occurs in a plane oriented parallel to the emission dipole moment. The dipole moments for excitation and emission have a defined orientation with respect to the molecular axes, but can be separated from each other by an angle. During the excited state lifetime, rotation of the fluorophore will depolarize its emission with respect to the excitation polarization history. Fluorescence anisotropy is defined as the ratio of the difference between the emission intensity parallel, and perpendicular to the polarized electric vector of the exciting light in relation to its total emission intensity.

Fluorescence Correlation Spectroscopy

PETRA SCHWILLE

Institute for Biophysics/BioTec, Dresden University of Technology, Dresden, Germany
 petra.schwille@biotec.tu-dresden.de

Definition

Fluorescence correlation spectroscopy (FCS) is a spectroscopic technique based on the laser-induced fluorescence of very small quantities of specifically

labeled biomolecules. Its primary measurement parameter is the spectrally resolved fluorescence intensity from a small spatial element, typically the diffraction-limited spot of a laser beam focused by a high-resolution microscope objective into a low concentration (100 nM and below) solution of fluorescent sample. In contrast to classical spectroscopy, special attention is not given to the average signal, but rather to the resolution of its temporal variations, induced by statistical fluctuations of measurement parameters such as particle number and brightness. Since these fluctuations are mediated by the thermal dynamics of single molecules, FCS is usually subsumed into the family of so-called single-molecule techniques although its standard measurement signal is ensemble-averaged due to comparably long (10–100 s) measurement times. Information that can be revealed by FCS on a single molecule level comprises local concentrations, mobility parameters, rate constants of association and dissociation reactions and time scales of internal fluctuations due to structural or photophysical dynamics. In combination with specific dyes, time scales of internal fluctuations can yield environmental parameters such as pH, ionic strength or oxygen levels. The best performance of FCS is obtained with aqueous solutions of 1–10 nM with average occupation numbers of 1–10 molecules simultaneously present in the measurement volume, which usually has the size of an *E. coli* bacterial cell, *ca.* 10^{-15} liters (femtoliters) and below. Cellular applications are possible, however particles must be sufficiently mobile in order to be successfully analyzed. To study molecular interactions between different molecular species, dual- or multi-color applications such as fluorescence cross-correlation spectroscopy are particularly powerful. During the past years, ► [two-photon excitation](#) has become an attractive alternative for cellular applications, due to the limited cumulative ► [photobleaching](#) and the possibility of exciting more than one fluorescent species with a single (infrared) laser line.

Description History

FCS was conceptually developed in the early 70s, as a special type of ► [relaxation technique](#) (1). The underlying idea is to follow the relaxation of a measurement parameter back to its equilibrium value after a small spontaneous deviation induced by thermal fluctuations. To resolve spontaneous, non-coordinated fluctuations, the size of the measurement system had to be reduced to the single molecule level. Background reduction and sufficient excitation of fluorophores were both optimized by the introduction of the laser-illuminated ► [confocal](#) setup that first allowed single molecule detection and triggered the development of modern

FCS (2) with its high sensitivity and manifold parameters to be analyzed. Since then, FCS has been commercialized and found widespread applications in analytical biochemistry, biotechnology and lately, also cell biology (3, 4, 5, 6).

Theory

► **Correlation analysis** is the mathematical formalism applied to simplify the evaluation of the extremely large numbers of single recorded fluctuation events during a data recording time of seconds to minutes. With a single measured signal, fluorescence ► **auto-correlation** analysis is performed. For two or more measured signals, auto- and cross-correlation functions can be determined. The theory for both modes is outlined in detail in (3). Autocorrelation analysis compares a fluctuating signal with itself at different times and thereby reveals characteristic repetitive time patterns, such as diffusion-mediated single molecule transits through the volume element or internal fluctuations during the residence time of a single molecule. Cross-correlation (4, 6) determines the relationship between different signals due to molecular interactions.

Setup and Data Recording

The setup that is nowadays employed in most FCS measurements is the confocal setup (2). Here, a microscope objective with a high numerical aperture (0.9 or larger) is illuminated through its back aperture by a parallel laser beam of large diameter (ideally the size of the back aperture). The laser is focused to a small diffraction-limited spot of less than 0.5 μm diameter in the sample. Fluorescence excited in this region is collected by the same objective, split from the excitation light by a dichroic mirror and imaged onto the surface of an extremely sensitive, single-photon counting avalanche photodiode. Resolution in the axial direction is enforced by a small (<100 μm) pinhole in front of the detector that can be replaced by an optical fiber of corresponding core diameter. The fluorescence recorded by the detector is coupled into a computer and correlated by hardware or software correlators quasi on-line to follow the correlation curves during the measurement on the monitor. This allows the tracking of artifacts of signal loss during data recording. Dual- or multi-color applications (5) can be employed by superimposing more than one excitation laser line in the focal volume element and by splitting the detection signal by additional dichroic mirrors before directing it to the different detectors. For ► **two-photon excitation**, high performance tunable pulsed laser systems (typically mode-locked titanium-sapphire systems of *ca.* 100 fs pulse width) are employed. In modern commercial systems, FCS units are often built into confocal scanning microscopes to address specific sites

for intracellular FCS applications. The cell is first imaged for identification of interesting measurement locations and the focal spot is then parked at a specific site for FCS recording. Mobile molecules in aqueous solution traverse the fixed volume element on time scales between microseconds and seconds, depending on their diffusional mobility. With measurement times in the seconds to minutes regime, thousands of single molecule transits are usually averaged, which ensures high statistical quality of the signal.

Labeling Dyes

The labeling dyes employed for FCS and other single molecule techniques must fulfill the same requirements as in standard fluorescence applications, such as high ► **absorption coefficients** and fluorescence ► **quantum yields**. Another property of key relevance for these ultrasensitive measurements is however a high photostability, i.e. the potential to withstand the large illumination intensity in the laser focus for a sufficiently long time (at least a single molecular transit time through the measurement volume). Photostability is usually quantified in FCS measurements by the maximum number of photons that can be harvested from a single molecule per unit time. Values of over 100,000 photons/sec per molecule in buffer solutions and at least 1,000 photons/sec per molecule in cellular applications have to be reached to guarantee reliable data evaluation in FCS. Frequently used dyes are several rhodamine derivatives (Rhodamine Green, TAMRA, Texas Red), cyanines (Cy-2, Cy-3, Cy-5), the Alexa dye family (from Alexa-488 in the blue to Alexa-647 in the red) and all ► **GFP** mutants and homologues with emissions larger than 500 nm (BFP and CFP are usually not photostable enough). EGFP and DsRed make very good pairs for intracellular dual-color cross-correlation applications. In buffer, Alexa-488 and Cy-5 are usually combined.

Concentration Range

Above 100 nM, fluctuations are hardly resolved and the signal-to-noise-level in FCS becomes too low. Below 1 nM, measurement artifacts due to fluorescent contaminations of the solvent can become substantial, and special care must be exerted to purify water and buffer components. In principle, there are no lower limits for the detection of fluorescent particles (single molecule aspect of FCS). However, long measurement times are required for subnanomolar concentrations in order to collect statistically relevant data.

Clinical Applications

FCS is a high-performance biophysical technique and has, due to its experimental challenges, not yet found widespread clinical applications, although several medical centers already possess a commercial FCS

instrument in combination with a confocal scanning microscope. The most obvious medical applications of FCS are in diagnostics, where its extreme sensitivity can be utilized. FCS can be employed to detect the specific recognition of ligands by receptors, antigens by antibodies and dimerization or aggregation of molecules at very low (nanomolar and below) concentrations in real time. If specific fluorescent probes are available, FCS can, in principle, facilitate pathogen detection in various body liquids down to pico- and femtomolar concentrations. However, this is only sensible at very low background levels and if additional steps for high sample throughput (beam-scanning or sample flow through a glass capillary) are taken. The most useful biological applications of FCS to date are probably

1. the determination of mobility parameters in living cells that allow probing of the organelle affiliation of proteins (e.g. cytosolic vs membrane-bound) or their specific binding to large or immobilized targets (3, 6)
2. the dynamic co-localization (co-diffusion) of biomolecules in solution, cells or tissue measured by dual-color cross-correlation. Co-diffusion is a valuable means for precisely determining fractions of bound and free partners in recognition and dissociation assays and a powerful complement to the ►FRET measurements that are presently often employed for these purposes (6).

Fluorescence *In Situ* Hybridization

►FISH

Fluorescence Labelling

Definition

Proteins of two different biological conditions are labelled with two different fluorescent compounds, mixed and separated within one 2-DE gel (DIGE, fluorescence difference gel electrophoresis). The fluorescence of a spot is measured at two different wavelengths, and the intensity difference corresponds to the difference of the amount of a certain protein species between the two biological conditions under investigation.

►Two-Dimensional Gel Electrophoresis

Fluorescence Lifetime Imaging

Definition

Fluorescence Lifetime Imaging (FLIM) is a fluorescence microscopy technology, in which image contrast in the fluorescence microscope is derived from the fluorescence lifetime at each point in the image. Biological materials (such as proteins, lipids, nucleic acids, and ions) are labelled with fluorescent dyes. Fluorescence decay times (typically some nanoseconds after excitation) are then measured on a pixel by pixel basis. The lifetime of these fluorophores in the living cell is sensitive to the surrounding intracellular environment, namely ion intensity (e.g. hydrogen ion concentration (pH), Ca^{2+} , Mg^{2+} , Cl^-), hydrophobic properties, oxygen concentration, as well as to molecular binding and interaction. Fluorescence lifetimes are mostly independent of the local probe concentration and photobleaching. Thus, fluorescence lifetime microscopy allows to perform accurate ion concentration measurements. The binding or the interaction between molecules can be measured in combination with FRET (Fluorescence Resonance Energy Transfer).

Fluorescence Microscopy: Single Particle Tracking

ULRICH KUBITSCHKE

Institute of Physical and Theoretical Chemistry,
Bonn, Germany
u.kubitschke@uni-bonn.de

Definition

In single-particle tracking (SPT) high-speed and high-sensitivity video microscopy is employed to trace the movements of single particles – in this context usually single lipid, protein or nucleic acid molecules or single molecular complexes composed of them – on membranes (artificial bilayers or cell membranes) or within the cellular interior. After data acquisition, the respective positions of the single particles are determined by image processing algorithms thus providing a time sequence of positions, which form a pathway or trajectory. Typically, a time resolution of milliseconds and a [localization precision](#) of a few tens of nanometers can be achieved.

Description

Single particle or single molecule tracking is based on the microscopic imaging of single molecules. The molecules in question must be labeled in a specific way. This is usually done by fluorescent tags. A wide range of fluorescent entities are in use, ranging from autofluorescent proteins, which can be genetically coupled to proteins, to fluorescent dyes, which can be coupled covalently to purified material, and to the recently developed quantum dots.

Highly diluted, singled-out fluorescent molecules produce diffraction-limited light spots in the image plane upon efficient excitation. This intensity pattern is formally described by an Airy function, which is very similar to a simple two-dimensional (2D) Gaussian function. The intensity distribution has a full width at half maximum of 250–300 nm, if green light and a high numerical aperture microscope objective lens is used for imaging. Thus, the shape of nanometer-sized objects cannot be recognized. However, the center of

mass of the intensity distribution, which corresponds to the position of the object, can be determined by fitting a two-dimensional Gaussian function to the observed intensity distribution with high precision. This precision depends on the signal-to-noise ratio (SNR) of the image, and the physical stability of the experimental setup employed. Under the sub-optimal conditions in a live cell experiment, where the SNR is hampered by background fluorescence, a localization precision of 20–50 nm can be achieved on a regular basis.

Instrumental preconditions for SPT are the optimization of light detection by carefully adjusting the optical filter systems to the employed fluorescence bandwidth, the utilization of strong excitation light sources usually in form of laser light, the use of [super-resolution](#) and last but not least the employment of sensitive, fast [CCD camera](#) systems. The digital images obtained must be processed after data acquisition by automatic pattern recognition methods and peak finding algorithms. These procedures initially allowed the mapping of single fluorescent molecules in lipid bilayers and later on the surface and within the interior of living cells (1, 2).

The observation of molecules within axially extended systems such as liquids or the interior of living cells is hampered by the problem of an enhanced background due to out-of-focus fluorescence. Only a single plane – the focal plane – is imaged sharply. All fluorescent structures or particles present in the spaces above and below the focal plane do not contribute to a sharp image, but produce an overlaying image blur, which reduces the SNR of the single molecule signals in focus. The general effect is well known from photography, but in microscopy it is more severe due to the small focal length of the microscope objective lens employed. Therefore, a fluctuating background is produced by fluorescent particles, which move around in the out-of-focus space. However, for low enough substrate concentrations the signals from the focal plane still rise high enough above this background to achieve a localization with nanometer precision.

By single particle observation in the cellular interior, the transport pathways of particles such as mobile proteins, molecular motors, molecular complexes or vesicles in intact biological systems can be observed. Conclusions with regard to the underlying cellular architecture can be drawn and mobility restrictions as well as binding processes can be measured. It is easier than with other techniques such as [fluorescence recovery after photobleaching](#) (FRAP) or [fluorescence correlation spectroscopy](#) (FCS) to discriminate different forms of mobility in heterogeneous systems. SPT is especially well suited to analyze slow dynamic processes characterized by diffusion coefficients below 20 $\mu\text{m}^2/\text{s}$. One could designate SPT as a complementary technique to FCS.

The acquisition of image series with high frame rates permits the tracing of single molecule pathways with the mentioned high precision, if the motion of the molecules during image acquisition is negligible. A further requirement is that the molecules remain and move in the focal region of the microscope objective lens. The signals of molecules moving away from the focal plane are quickly dominated by background noise. Hence, single-molecule imaging has an intrinsic three-dimensional (3D) resolution. For immobile or slowly moving molecules the inherent 3D resolution can be used to obtain time series of 3D image stacks (i.e. 4D image data), from which the 3D positions of the single molecules can be determined as a function of time without using confocal optics.

Experimental Setup

Microscopic imaging of single particles or even molecules requires a fluorescence video microscope of the highest optical sensitivity and physical stability. Although different experimental setups can be employed, several general features must be present (Fig. 1). Optimal fluorescence light detection efficiency is of greatest significance. Utilization of at least two fluorescence channels is beneficial. The core of the instrument is often a commercial inverse fluorescence microscope, because these allow a manipulation of biological samples during the experiment. The shape of the point spread function (PSF) produces the intrinsic 3D resolution in single particle imaging, if the probe concentration is low enough. In this context, low means that considerably less than one fluorescent particle should be present within one focal volume element. This corresponds to approximately 0.25 femtoliter when a high numerical aperture objective lens is used and results in a final particle concentration of less than 100 picomolar. Typically lasers are used for fluorescence excitation. The laser light is passed through acousto-optical modulators for rapid intensity switching and is circular polarized by $\lambda/4$ -plates. If several lasers are used, the beams are combined by appropriate beam splitters and passed through an optical mono-mode fiber to the microscope. A collimated light beam exits the fiber and illuminates with a Gaussian intensity distribution a small area of 10 by 10 μm^2 in the object field. The irradiance may conveniently be adjusted using analog acousto-optical modulators (AOMs) or acousto-optical tunable filters (AOTFs). They work as switches to turn on and off the laser irradiation, and define the transmitted power. The irradiance within the sample is thus set to 0.1–2 kW/cm^2 . The emitted fluorescence light is separated from the excitation light by a dichromatic beam splitter, which reflects the excitation lines onto the sample, while the respective fluorescence emission bands are transmitted to the detection system. The fast image acquisition of

scientific-grade CCD cameras is well suited for imaging and tracking of possibly fast moving molecules. If two laser lines are used for excitation of two separate fluorescent dyes, the two fluorescence bands must be separated by an additional dichromatic beam splitter in front of the detection cameras. This allows a simultaneous recording of two fluorescence channels. The insertion of a dichromatic wedge filter at the position of the final dichromatic beam splitter is another solution for obtaining dual or even triple channel detection. It projects two chromatically different and laterally offset images onto a single CCD. Different fluorescence images from an identical object region can be aligned to each other by calibration with images from multicolored microbeads. At the start and the end of the image integration time, the CCD cameras issue trigger signals, which are fed into the drivers of the acousto-optical devices and thereby turn the respective laser illumination on and off. This ensures that the illumination of the sample is kept to a minimum. In general, light integration over 1–50 ms is required to obtain images from single molecules with an SNR, which is sufficient for a nanolocalization with a precision in the nanometer range.

When imaging fast moving objects such as mobile single molecules, a high imaging frame rate is of great importance. Considering the small image integration time, frame rates up to 1 kHz should be achievable. However, in a scientific-grade CCD camera the image readout is rate limiting. For example, the time required to read-out a full image on a chip with 1000×1000 pixels is in the range of 1 s or longer, causing rather low frame rates. A simple method to accelerate the rate is to read out only a subregion of the full frame, which yields a frame rate in the range of 10/s. The frame rate may be further considerably increased by using high-speed imaging techniques. In one technique a mask shields a major part of the CCD from the illumination light. This region of the chip may be used as an intermediate image storage. By direct programming of the chip, several subframes can be acquired rapidly and transferred into this intermediate storage area with high speed before the image series is finally read out. This approach yields high frame rates – but only for about 5–20 images in a succession. A more direct approach to increasing the frame rate is to use a high-speed camera such as an [intensified CCD](#) or an [electron-multiplying CCD](#). These devices combine high sensitivity and high speed in an ideal way, and reach imaging rates that correspond directly to the inverse of the image integration time, i.e. close to 1000/s.

Particle Localization with Nanometer Precision

The image of a particle with a size significantly smaller than light microscopic resolution – like a single

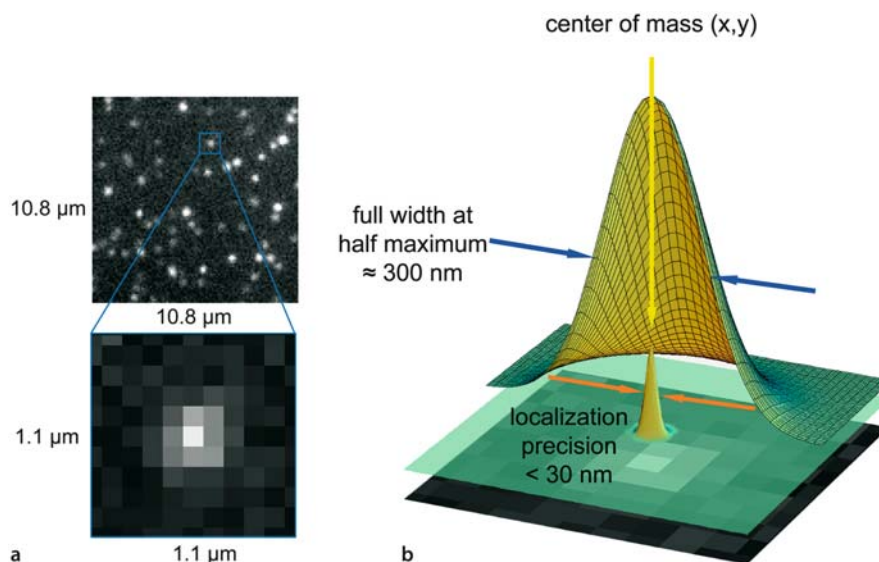

a

Fluorescence Microscopy: Single Particle Tracking. Figure 2 (a) Image of a single fluorescence labeled protein molecule (surface-attached BSA molecules labeled by Oyster565, excitation wavelength 633 nm, emission above 650 nm, irradiance 2 kW/cm²). (b) The 2D-Gaussian function (surface plot) approximating the intensity distribution (grayed image, below) yields the position of the center of mass with a precision (orange arrows), which is significantly smaller than the half-width of the diffraction limited spot size (arrows).

molecule – has a complex intensity profile, which is designated as the PSF. The PSF limits the spatial resolution of a microscope and can be measured by imaging a subresolution object under super-resolution conditions. The experimentally observed PSF can be well approximated by a 2D Gaussian function (Fig. 2). By fitting a 2D Gaussian to the observed intensity profile of a submicroscopic particle, the position of the object center can be determined with a very high precision, which mostly depends on the SNR of the image. This localization precision is usually 10–20× smaller than the width of the PSF. Image acquisition is a stochastic process due to various experimental noise sources. In single-molecule imaging, the inherent photon Poisson noise is inevitable and the camera readout noise is the second important noise source. Therefore the object position that is found by fitting algorithms is merely an estimator for the true object position.

The SNR of a particle image is determined by the brightness of the utilized probe and specific instrument parameters such as the image integration time, detector pixel size, image readout rate, photoelectron conversion factor and laser irradiance. The SNR of a single molecule signal is defined as:

$$\text{SNR} = \frac{I_0}{\sqrt{\sigma_{\text{bg}}^2 + \sigma_{I_0}^2}} \quad (1)$$

where I_0 designates the signal intensity of the maximum of the PSF above background, σ_{bg}^2 the

variance of the background noise and $\sigma_{I_0}^2$ the variance of the maximum signal intensity above background.

An analytical approximation for the localization precision of subresolution objects can be derived (3, 4, 5). An expectation value for the localization precision can thereby be calculated as a function of the SNR, which represents a limit for the experimentally achievable localization precision. For example, an SNR between 10 and 2 corresponds to a localization precision between 10 and 60 nm.

Clinical Applications

Single molecule techniques can be employed for studying basic cell biological systems and processes. Numerous biological processes are initiated by a very small number of effector molecules, e.g. receptor activation as the first step in signal transduction chains or DNA replication or transcription. A detection limit at the single molecule level allows the analysis of the start of such biochemical reaction cascades. Furthermore, important processes within living cells take place on length scales between molecular distances (0.1–1 nm) and the optical microscope resolution limit (≈ 250 nm). Such processes on an “intermediate-sized” length scale usually involve supramolecular complexes containing many nucleic acids and proteins. This makes their reconstitution and study *in vitro* difficult, and their size complicates direct observation and analysis with conventional microscopy. Due to the localization precision in the nanometer range, single molecule

microscopy is well suited for the study of such systems *in vivo*.

In the future a major application for single molecule detection techniques will be the molecular description of individual cells containing or expressing a distinctive collection of receptor molecules. SPT will have an application in all diagnostic situations, where diagnostic information may be derived from a few distinctive molecules on or within a small number of cells. Examples of this are the occurrence of graft *versus* host reactions or graft *versus* leukemia reactions after transplantation or the characterization of success after tumor therapy.

Therapeutic Consequences

In the ideal case, single particle tracking within living cells provides a view of cellular molecular dynamics by directly showing the pathways and activities of intracellular molecular components. It can provide information on molecular mobility thus giving insight into structural determinants of lipid or protein mobility. It reveals information on the assembly sites of protein complexes and ultimately even on interaction topology, loci and partners. A central topic in the current progress of medical research is the search for individual molecular patterns in a single patient's disease to find improved targets for individually fine-tuned therapeutic strategies. SPT provides the means to approach these questions.

Fluorescence Microscopy: Spectral Imaging vs. Filter-based Imaging

M. CRISTINA CARDOSO

Max Delbrueck Center for Molecular Medicine, Berlin, Germany
cardoso@mdc-berlin.de

Definition

In spectral imaging, the entire spectrum of emitted light is utilized by positioning a prism or optical grating device in the emitted light path, which diffracts the light into its spectral components. These can be acquired in a sequential mode or, more efficiently, in parallel detectors. In contrast, optical filters positioned in the light path transmit a selected range of wavelengths with high efficiency while rejecting, through reflection and destructive interference, all other wavelengths.

Description

Light is an extremely versatile tool for studying biological systems and their functions in a non-invasive manner. When light shines upon an object, it can be reflected, transmitted, absorbed or re-emitted. Spectroscopy measures these phenomena to determine the physical properties of the substance being studied. The addition of imaging to spectroscopy aims to provide spatial information to the ability to determine what substances are contained within the object. Our own vision is a form of imaging spectroscopy. The combination of imaging and spectroscopy was pioneered on airborne satellite-based remote sensing, with the aim of determining from a distance the distribution of natural or man-made substances based on their spectral signatures.

Optical imaging combines a wide variety of light sources with non-invasiveness and high spatial and temporal resolution, allowing the investigation of structure-function from the subcellular level up to entire organisms and in real time. Fluorescence is the most rapidly expanding optical microscopy technique in both the medical and biological sciences, which has spurred the development of highly sophisticated fluorescence microscopes. In contrast to other modes of optical microscopy, fluorescence microscopy allows the detection of a single molecular species based on its light emission characteristics. ▶ **Fluorescence** is the process by which an atom or molecule absorbs light at a particular ▶ **wavelength** and subsequently emits light of a longer wavelength (the difference between excitation and emission wavelengths is termed the ▶ **Stokes shift**). Thus, using fluorescence microscopy one can determine with high spatial and temporal resolution, the precise subcellular localization of one or several fluorescently labeled molecules within a living cell. Furthermore, diffusion rates and interactions with other molecules as well as their changes in time and with pathological alterations can be determined. In addition, the fact that fluorochromes are susceptible to environmental influences (pH, oxygen content, ion concentrations, etc.) permits using them as a probe for local environmental characteristics.

The ever-expanding range of fluorescence microscopy applications requires the quantitative analysis of a wide number of fluorochromes at the same time and place within a sample. This requires methods that allow good discrimination of, often spectrally overlapping, fluorochromes. ►**Fluorochromes** (also called ►**fluorophores**) are substances, which fluoresce upon irradiation and are characterized by their excitation and emission spectra. The absorption or ►**excitation spectrum** is obtained by measuring the relative fluorescence intensity at a certain wavelength when the specimen is excited at varying wavelengths. The ►**emission spectrum** is red-shifted (Stokes shift) and results from excitation at a certain wavelength. Most excitation and emission curves overlap to a certain extent (Fig. 1).

The essential feature of a fluorescence microscope is to provide a way of exciting the specimen with a selected wavelength followed by isolating the much weaker fluorescence emission (three to six orders of magnitude less than the excitation) coming from the specimen. The majority of commonly used light sources (natural and artificial) are polychromatic, i.e., emit a broad range of wavelengths that cover the entire visible light spectrum and often extend into the ultraviolet and infrared regions. In order to select the wavelength of excitation from a polychromatic light source, specialized filters are normally used. In addition, filters are also used to discriminate between excitation light and the light emitted by the specimen. This discrimination is possible since the emitted light is of longer wavelength than the excitation light. The choice of filters is of paramount importance in fluorescence microscopy and depends on the spectral characteristics of the fluorochromes used. Filters are constructed in a wide variety of shapes and physical dimensions and can be employed to remove or pass wavelength bands ranging in size from hundreds of nanometers down to a single wavelength. Many filters work by absorbing light, while others reflect unwanted light, but pass a selected range of wavelengths. The characteristics of a filter are seen by its transmission curve. The main types of filters for fluorescence microscopy are interference filters and ►**dichromatic beamsplitters** (3).

►**Interference filters** are glass substrates onto which thin layers of metal salts are deposited. There are different types, named band-pass and short and long-pass interference filters. They operate by transmitting a selected wavelength region with high efficiency while rejecting, through reflection and destructive interference, all other wavelengths. They can be positioned in front of the excitation light source (commonly a mercury or xenon lamp) to select the excitation wavelength or before the detection system (most often

Fluorescence Microscopy: Spectral Imaging vs. Filter-based Imaging. Figure 1 Excitation (solid line) and emission (dashed line) spectra of a fluorochrome.

nowadays a CCD camera) to select a range of emitted wavelengths.

Dichromatic beamsplitters reflect light of wavelengths shorter than the specified wavelength and transmit light of longer wavelengths. The dichroic beamsplitter is positioned at a 45-degree angle to the optical axis of the illumination path and reflects the exciting rays into the objective in an epi-illumination setup where the objective serves as condenser. Light emitted by the sample is collected by the objective, traverses the dichroic filter and is further selected by the emission (interference) filter.

A typical filter set configuration for fluorescence microscopy consists of an excitation (interference) filter, a dichromatic beamsplitter and an emission (interference) filter mounted in a cube as shown in Fig. 2. The individual filters can also be positioned each separately into the light path as part of rotating filter wheels, which permit different combinations of the three basic components to be chosen in a more flexible way. The filters in a configuration should be chosen so that the wavelength range transmitted by the excitation interference filter matches the reflection range of the dichroic. In that way, the excitation light is effectively directed onto the sample. In addition the emitted light from the specimen must match a high transmission range from the dichroic in order to pass through to the detector. The emission filter, albeit less relevant, still imposes further constraints onto the light that reaches the detector.

Even in perfect combinations of filters there is always some crossover or bleedthrough of light between the

Fluorescence Microscopy: Spectral Imaging vs. Filter-based Imaging. Figure 2 Separation of excitation and emission using a classical filter set configuration. Polychromatic light (yellow light beam) is selected (green light) by the excitation interference filter and reflected onto the specimen by the dichroic beamsplitter. Fluorescence emission of longer wavelength from the sample (red light) is transmitted through the dichroic and further selected by the emission filter before it reaches the detector.

filters. Furthermore, the more discriminating a filter set is, the less light it passes and with increasing numbers of fluorochromes used in a single sample the more difficult it is to find filters which fit all the fluorochromes one needs. Moreover, the strongly overlapping emission spectra of commonly used fluorescent dyes and proteins severely limit their combined use in multicolor imaging using optical filters. A better solution is to have systems where the selection of wavelengths is flexible, in particular at the detection side or the entire range of emitted light (spectrum) is detected and resolved into the individual components. In recent years, several commercial manufacturers have started to implement both these solutions, in particular into their laser scanning confocal microscopes where the excitation light source is monochromatic.

Flexible selection of wavelength can be performed using tunable filters, in particular ▶[acousto-optical filters](#). These are electro-optical devices that allow the modulation of the light intensity as well as wavelength. Light penetrating the optical crystal is deflected depending on its wavelength and the wavelength of the ultrasonic field applied to the crystal. These filters do not have the mechanical limitations, speed

constraints and vibrations associated with the rotating filter wheels. Furthermore, they offer far greater flexibility and durability as compared to interference filters upon exposure to heat and high intensity light. In order to remove the constraints of filters on the detected range of wavelengths, spectral detectors can be used. The light emitted by the specimen consists of mixtures of wavelengths, due to autofluorescence and excitation crosstalk (excitation of multiple fluorochromes with overlapping absorption spectra) as well as the broad range of wavelengths emitted by single fluorochromes (represented in its emission spectrum). A prism or optical grating device positioned in the emitted light path diffracts this light into its spectral components, which can subsequently be acquired in a sequential mode or, more efficiently, in parallel detectors (Fig. 3). In order to select a particular range of the emission spectrum, a motorized slide aperture can be positioned before the detector, letting only a particular wavelength range of the spectrum pass. Alternatively, the entire spectrum can be detected and the contributions of the different fluorochromes calculated based on their spectral signatures. For this unmixing of the spectral signatures, the relative contributions of each of the fluorochromes into each

Fluorescence Microscopy: Spectral Imaging vs. Filter-based Imaging. Figure 3 Spectral detection of emitted light. Fluorescence emitted by the sample (arrows), consisting of a mixture of wavelengths, is dispersed *via* a prism and the entire emission spectrum gets projected onto the detection system.

detection channel are first recorded as reference spectra. The latter are used to build up a matrix of fluorophore specific weight for the calculation of an individual fluorophore's contribution to each pixel. By applying this matrix to the spectral image acquired, one can determine the contribution of the individual fluorophores at every pixel in the image and effectively separate their signals. This mathematical operation is called **linear unmixing**. In principle, any fluorescent contribution can be calculated back and this can even be used to subtract the contribution of background fluorescence from an image. The combination of spectral detection with linear unmixing analysis (1,4) allows the simultaneous use of highly overlapping fluorescent molecules, which has thus far been a major limitation in multicolor imaging. Moreover, since most of the emitted fluorescence is recorded, greatly increased sensitivity is attained as compared to classic filter-based systems.

The information summarized here focuses on commonly used fluorescence microscopy systems in biomedical research. Additional information on spectral imaging can be found elsewhere (2).

Fluorescent Proteins

Definition

Naturally occurring proteins with an intrinsic fluorophore generated by an autocyclization reaction of

neighboring aminoacids. The ►[green fluorescent protein](#) is derived from the jellyfish *Aequorea victoria*. Several variants with different spectral properties have been generated (enhanced green, cyan and yellow fluorescent proteins) by combinatorial mutagenesis. A novel class of fluorescent proteins has been isolated from reef corals (red FPs such as DsRed and HcRed). ►[In Vivo Imaging of Transgenic Mice with Fluorescent Protein Expression](#)

Fluorochrome

A natural or synthetic dye or molecule that is capable of exhibiting fluorescence. Fluorochromes (also termed fluorescent molecules, probes or fluorescent dyes) are usually polynuclear heterocyclic molecules containing nitrogen, sulfur, and/or oxygen with delocalized electron systems and reactive moieties that enable the compounds to be attached to a biological species.

5-Fluoroorotic Acid

Definition

5-Fluoroorotic acid (5-FOA) is a toxic analog of orotic acid, and is the most widely used negative selection marker in yeast. Yeast cells with the functional URA3 gene are sensitive to this drug, since they convert it into a product that is toxic to the cell. This negative selection system can efficiently be used to select for a specific protein-protein interaction in yeast, or to characterize drugs that specifically inhibit a protein-protein interaction.

Definition

The integrity of an organism depends on adhesion of cells to their immediate vicinity formed by a network of extracellular matrix or a neighboring cell (Fig. 1). Cells produce adhesion molecules, the ► [integrins](#), which link the intracellular cytoskeleton to the extracellular environment (Fig. 1). Strength of cell adhesion can be achieved by grouping individual integrins in clusters,

Focal Adhesions. **Figure 1** Photograph of an adherent migrating cell. Integrins (β3 chain linked to EGFP shown in green) are organized in focal adhesions adhering to vitronectin. The actin-cytoskeleton is labeled with rhodamine in red. Ribs of bundled actin filaments ending in focal adhesions form the lamellipodium. The intracellular thin network of actin filaments exists but is difficult to visualize at the resolution shown.

the so-called focal adhesions. The formation of focal adhesions involves several steps, including integrin activation and recruitment of cytoskeletal adaptor proteins (1).

Characteristics Integrin Activation

Integrins are a family of heterodimeric receptors binding to ligands only when an activated conformation is formed (2). The ligand-binding domain of integrins consists of a headpiece in which α and β chains meet (Fig. 2). In its inactive conformation, this headpiece cannot bind to ligands and is bent towards the cell membrane through a domain called genu (hinge). Activation of the bent integrin involves a separation of the two integrin chains and opening of the molecule like a switchblade, making the headpiece available for ligand binding (3). This mechanism increases the affinity for binding to an individual ligand. However, integrins usually act in clusters and this increases the avidity for groups of integrin ligands such as extracellular matrix components. Clustering of integrins needs lateral mobility. A cascade of events and molecules induced by **▶receptor tyrosine kinases** (RTKs) or **▶G-protein coupled receptors** leads to unfolding of integrins and increased lateral mobility allowing clustering. Among the many molecules involved in integrin activation, a selected number of important ones is described here (Fig. 2).

Molecular Interactions Rap1 and Rap-Ligand

Rap1, Rap2 and their splice variants are four **▶small GTPases** of the Ras protein family that play a pivotal role in mediating inside-out signals to activate the integrins (4). They cycle between an inactive GDP-bound form and an active GTP-bound form. Guanine nucleotide exchange factors such as Epac and C3G regulate Rap1 conversion (Fig. 2). Cells transfected with constitutively active Rap1 adhere and migrate without requiring a G protein signal. Spa1 or RapGAPII are Rap specific GTPase-activation proteins that inactivate Rap1 by modifying the GTP bound into the GDP bound form. Transfection of Spa1/RapGAPII blocks integrin mediated cell adhesion and migration. In cells of hemopoietic origin, activated Rap1 binds the Rap1-ligand RAPL and this complex activates the integrin through binding to the **▶GFFKR domain** of the integrin α chain. Over-expression of RAPL can activate integrin mediated cell adhesion but expression of a RapL mutant, which is incapable of Rap1 binding, inhibits adhesion. So, cell surface receptor induced activation of Rap1 seems to be key in the signal transduction pathway that activates integrins and cell adhesion.

Talin

Talin is a cytoskeleton protein with a globular head and a rod-like domain. The head domain contains a FERM (ezrin, radixin, moesin) domain which binds to the non-phosphorylated **▶NPxY/F motif** of the β integrin chain and activates the integrin, probably by keeping the cytoplasmic tails of the α and β integrin chains at a distance allowing unfolding of the extracellular, ligand binding domains (5). The regulatory link of RTK and G protein mediated integrin activation through talin binding is not clear but talin is required for integrin activation downstream of several physiologically relevant signaling pathways. In a resting cell, talin is present in an inactive, folded conformation with masked integrin binding the FERM domain in its globular head. One way to regulate talin-integrin interactions occurs through binding of **▶PIP2** (phosphatidylinositol 4,5-bis-phosphate), which leads to a conformational change of the talin FERM domain and increases the binding affinity of talin for the integrin β chain. Interestingly the PIP2 producing enzyme type I γ -90 phosphoinositol phosphate kinase (PIPKI γ -90) can also bind to talin, which then produces its "own" localized PIP2. Unfortunately, PIPKI γ -90 binding to talin competes with talin binding to the integrin, which creates a negative loop of regulation. Another way of activating talin is its cleavage into a head and a rod domain by the protease calpain. The separated talin head domain has a six fold higher affinity for integrin β chain than does the intact molecule and hence it is a more efficient integrin activator than the intact talin. Interestingly, phosphorylating the tyrosine residue of the NPxY/F talin-binding motif of the integrin by Src-family kinases can block talin binding to the integrin. Thus, talin is a general regulatory molecule for integrin activation and there are several mechanisms to control talin binding to the integrin.

Atypical ζ PKC and Integrin Clustering

The atypical protein kinase C ζ (ζ PKC) is associated with a protein complex that regulates cell polarity. Recently it has been found that cell activation by G proteins activates the kinase activity of ζ PKC by its interaction with phosphatidyl inositol 3- phosphate kinase PI(3)K and brings the enzyme to the plasma membrane, where it leads to increased mobility of integrins. This effect is needed to allow clustering of activated integrins and achieve the highest level of integrin **▶avidity**.

Formation of Focal Adhesions

Activated integrins bind to their ligands. The intracellular tail of integrins then interacts with adaptor proteins and the actin cytoskeleton. Clustering of these complexes leads to the formation of focal adhesions (Fig. 3).

Integrin Activation

Focal Adhesions. Figure 2 Integrin activation. Receptor mediated signaling through receptor tyrosine kinases (RTK) and G-protein coupled receptors activates two major intracellular signaling pathways. First, Rap1 GTPase is activated by the cAMP dependent GTP exchange factor Epac or C3G and will then bind to RapL forming a complex that targets the cytoplasmic domain of the α subunit of integrins. At the same time the cytoskeletal linker protein talin is activated by calpain, which cleaves the talin head from its tail, or by binding of PIP2 (phosphatidylinositol 4,5-bis-phosphate) to the talin head domain. This results in recruitment of talin to the cytoplasmic domain of the β integrin subunit. Both Rap1/RapL and talin head domain binding will induce an allosteric switch in the integrin heterodimer creating high affinity binding to integrin ligands (affinity switch). The induction of the small GTPase Rac downstream of PI3 kinase leads to integrin clusters, which have an increased avidity for multimeric or clustered integrin ligands (avidity switch).

Rac1

One of the first steps in focal adhesion assembly is the activation of the small GTPase Rac1 (Fig. 2). GTP-bound Rac1 induces the polymerization of an actin network at the periphery of the cell, the ►**lamellipodium**. Within this network, the adaptor protein vinculin binds PIP2 and recruits it to the plasma membrane.

Vinculin

Vinculin activation by PIP2 leads to interaction with the Arp2/3 complex. This induces nucleation and polymerization of actin at the plasma membrane. The nascent fibers emanating from the vinculin/Arp2/3 complex can now interact with the major F-actin binding site of talin. It is thought that this interaction recruits activated integrin into nascent focal adhesions.

This complex can be reinforced by the integrin-linked kinase (ILK).

Integrin-linked Kinase

ILK interacts with two adaptor proteins PINCH and parvin and forms a trimeric linker between actin filaments in focal adhesions and the plasma membrane (6). The structural importance of ILK is best illustrated in ILK deficient animals, which suffer from severe cell adhesion defects. In *Drosophila*, ILK deletion results in an embryonic lethal muscle defect, disrupting the actin cytoskeleton from the integrin and the plasma membrane.

Conclusion

Two classes of focal adhesion adaptor proteins provide the physical link between the ECM and the actin

cytoskeleton. The first class consists of structural proteins such as talin, filamin and α -actinin, which crosslink the actin cytoskeleton to the cytoplasmic tail of integrins. The second class of adaptors is formed by regulatory proteins such as the trimeric ILK-PINCH-parvin complex (Fig. 3).

Regulatory Mechanisms

Dynamics and Regulation of Focal Adhesions

Focal adhesions can be distinguished according to their size, shape and location within the cell and have been named focal complexes or focal contacts respectively. During cell migration, small point-like focal complexes form in the leading lamellipodium whereas large, elongated focal contacts form in the central and posterior parts the cell. Focal complexes appear in response to Rac1 activity; focal contacts require RhoA signaling and evolve by maturation from focal complexes mediated by actomyosin tension (Fig. 4) (7).

A Role for RhoA and Rac1

RhoA is a member of the small GTPase family inducing the formation of actin stress fibers and focal contacts. The two Rho effectors Citron and ROCK are kinases acting on the **actin cytoskeleton** by phosphorylation of myosin light chain. The phosphorylated **myosin light chain** then interacts with myosin and induces intracellular contractility and the formation of focal contacts. As another target, ROCK inactivates the myosin light chain phosphatase leading to the maintenance of focal contacts. Rac1, another GTPase family member counter-balances the effect of RhoA. It blocks myosin light chain kinase *via* its downstream effector PAK (p21-activated kinase).

FAK/Pyk2

The tyrosine kinases **FAK** (focal adhesion kinase) and Pyk2 are involved in G protein-induced cell adhesion and migration. These are proline-rich molecules with 45% homology to each other. FAK and Pyk2 bind to the cytoskeleton protein paxillin and are recruited to clusters of integrins. In FAK deficient cells, focal adhesions form more slowly but are more stable, resulting in an immobile phenotype. This suggests that FAK signaling is important for focal adhesion remodeling and cell migration. Similarly, cells from Pyk2 deficient mice fail to migrate in response to chemotactic signals.

Paxillin

Paxillin, a 68 kD focal adhesion adaptor protein exhibits multiple protein-recognition motifs and is recruited to nascent focal adhesions. It directly binds to the cytoplasmic tail of integrin and the structural focal adhesion protein vinculin. It also binds and recruits signal-transducing molecules, such as the kinases FAK,

Focal Adhesions. Figure 3 The structural and regulatory link between the substrate and the actin cytoskeleton. Integrins are activated by intracellular adaptor molecules such as Rap1/RAPL or talin that bind to the α -subunit (blue) or the β -subunit (red) respectively. As soon as the high affinity form of integrin (open configuration) is attached to immobilized substrate (orange), the docking of the vinculin/Arp2/3 (red/blue) and ILK-PINCH-parvin (yellow) complexes stabilizes the initial integrin-substrate contact and reinforces the connection of the integrin to the actin cytoskeleton (dark-blue). This structural link now recruits focal adhesion adaptors (pink) that either serve to further stabilize focal adhesions, or in contrast, lead to their remodeling or dispersal (for explanation of the respective roles of the regulatory adaptors see text).

Src and ILK and the phosphatase PTP-PEST to focal adhesions. Vinculin regulates cell motility by reducing the interaction of paxillin with FAK and vinculin deficient cells are highly motile. Thus paxillin-FAK interaction controls cell adhesion and migration. Accordingly, paxillin null cells show reduced focal adhesion kinase (FAK) phosphorylation and delayed **spreading** and migration.

Protein-Tyrosine Phosphatase-PEST

PTP-PEST is a cytosolic protein-tyrosine phosphatase that dephosphorylates focal adhesion adaptor proteins

Focal Adhesions. Figure 4 Differential remodeling of focal adhesions during cell migration. Cell migration is driven by Rac1-dependent actin polymerization in the advancing lamellipodium. Integrins that are incorporated into nascent focal complexes exhibit low density and slow turnover rates, resulting in stationary focal adhesions that firmly anchor the actin network to the substrate. Under the influence of RhoA signaling, stationary focal complexes mature into focal contacts that are linked to actin stress fibers. The integrin cluster density increases with the applied intracellular actomyosin tension and the integrin exchange rate increases, leading to focal contacts, which can be remodeled. The plasticity of focal contacts due to intense remodeling is best illustrated during the retraction of the cell tail, where focal contacts undergo a polarized renewal, which results in sliding.

such as paxillin and signal adaptor proteins leading to activation of Rac1. Over-expression of PTP-PEST reduces cell spreading due to interference with Rac1 activity. In contrast, fibroblasts lacking PTP-PEST spread normally but form increased numbers of focal adhesions and do not migrate.

MEK Kinase 1

The activation of the dual specific MEK kinase 1 (MEKK1) is a critical event in the dynamic remodeling of focal contacts during cell migration. MEKK1 acts downstream of the receptor tyrosine kinase pathway and signals to Jun kinase (JNK) and stimulates the activity of the Ca^{2+} dependent intracellular protease calpain. Calpain cleaves various focal contact components such as talin, filamin and β -integrin tails and its

absence alters the actin cytoskeleton and reduces cell migration.

Jun Kinase

JNK stimulates the detachment of focal adhesions by the phosphorylation of serine 178 of paxillin. Small focal adhesions in fast migrating cells such as fish keratinocytes are transformed into larger immobile focal adhesions by the expression of the S178A paxillin mutant.

Visualizing the Formation of Focal Complexes and Focal Contacts

The attached movie summarizes integrin activation, the formation of focal complexes at the front of an adherent migrating cell, cytoskeleton and adaptor protein

organization, the building of focal contacts and their resolution at the tail of the migrating cell.

Förster Resonance Energy Transfer

MARTIN BEUTLER, RAINER HEINTZMANN
Randall Division of Cell and Molecular Biophysics,
King's College, London, UK
martin.beutler@kcl.ac.uk
rainer.heintzmann@kcl.ac.uk

Definition

Förster resonance energy transfer (FRET) is a distance-dependent quantum mechanical process that occurs between chromophores. In a FRET-pair, an excitation energy exchange of the electronic states takes place *via* a dipole-dipole coupling mechanism. The ►donor in a FRET pair is a fluorophore in its electronic excited state, passing the energy to another chromophore, the ►acceptor. This process, however, can only occur if the donor ►fluorescence emission and the acceptor excitation spectra show a spectral overlap. The efficiency of FRET is dependent upon the distance and relative orientation between donor and acceptor. Typically, quantification of FRET requires a mutual distance of fluorophores in the range of 1nm to 10 nm. This distance sensitivity makes it an important method for investigating a variety of biological phenomena showing changes in the proximity, mutual orientation or rigidity of proteins and other macromolecules. FRET is used in microscopy, flow cytometry and spectroscopy to analyze interaction between or conformational changes in donor and acceptor molecules (e.g. proteins, ligands, lipids) even in living cells. In practice, two molecules of interest are modified to fluoresce in order to investigate their interaction or even to determine the sub-cellular localization of their interaction.

Description Theory

FRET was first described theoretically by Theodor Förster in 1948 (1). Ever since, investigation of this phenomenon has been applied to establish now routinely employed methods in cell and protein

biology. This development has been reviewed and discussed in depth (2, 3), but methodological progress is still being made.

For FRET in a pair of molecules to occur, the donor first requires excitation, e.g. by absorption of a photon (Fig. 1). The excited donor can then de-excite thermally, emit a photon as fluorescence or transfer energy to the acceptor *via* electrical dipole-dipole coupling (in contrast to Dexter type energy transfer the electrons are not exchanged). For FRET, it is not necessary for the acceptor to be able to emit fluorescence, but in most FRET experiments fluorescent acceptors are nonetheless employed. However, for some applications dark acceptors are advantageous (2). The transfer efficiency is influenced by the spatial distance between the donor and acceptor molecules and is given by an inverse sixth power law in dependence on the donor acceptor distance (Equation 1 and Fig. 2). This fact is a consequence of the dipole-dipole interaction. FRET can therefore be employed as a molecular ruler (4).

$$E = \frac{1}{1 + (r/R_0)^6} = \frac{R_0^6}{R_0^6 + r^6} \quad (1)$$

with E being the energy transfer efficiency, R_0 the radius of 50% transfer efficiency (Förster radius) and r the donor-acceptor distance.

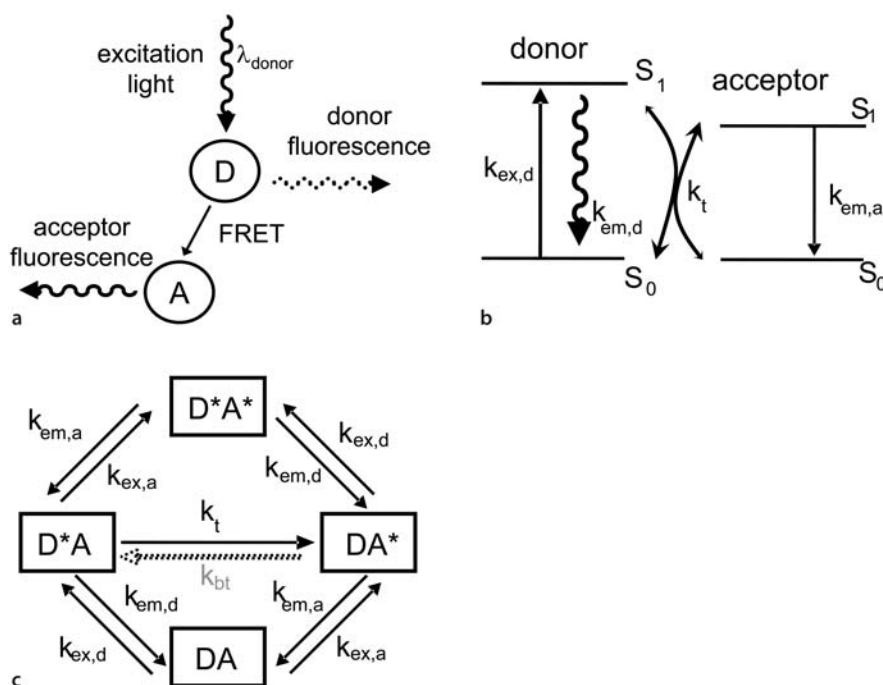

The Förster radius R_0 is proportional to the spectral overlap integral of the normalized donor emission spectrum and the acceptor absorption spectrum (J) (Equation 2) and depends on the relative orientation of the molecules and the refractive index (n). Figure 3 shows their spectra and their spectral overlap region. The Förster radius is computed as

$$R_0 = 0.211(\kappa^2 n^{-4} Q_D J(\lambda))^{1/6} \quad (2)$$

$$J(\lambda) = \int \varepsilon A(\lambda) \varepsilon m D(\lambda) \lambda^4 d\lambda$$

where κ is the orientation factor representing the directions of the emission dipole of the donor with respect to the acceptor excitation dipole. For randomly orientated molecules, κ^2 can be assumed as 2/3. n is the refractive index of the medium and Q_D is the quantum efficiency of the donor. The emission spectrum of the donor (with its integral normalized to one) is given by $\varepsilon m D(\lambda)$, and $\varepsilon A(\lambda)$ denotes the wavelength-dependent acceptor extinction coefficient.

In microscopy, flow cytometry or spectro-fluorometry, the most often desired parameters are the concentration of FRET pairs, the concentration of free donor ("free" means no acceptor in proximity to the donor) and free acceptor, as well as the distance (given by the FRET efficiency) between donors and acceptors in pairs or the

Förster Resonance Energy Transfer. Figure 1 (a) The donor molecule absorbs light energy. It can emit the energy by fluorescing (emission of a photon) or alternatively transfer the energy to the acceptor molecule, which, if fluorescent, could then itself emit a photon. (b) Energetic state model: before light absorption, the donor molecule is in its ground state denoted as S_0 . After the up-take of a photon ($k_{ex,d}$) it transits to the first excited singlet state S_1 . From here it can de-excite via light emission (fluorescence, $k_{em,d}$) or radiationless excitation (k_t) of the acceptor molecule (this process is, to some extent, reversible, especially when donor and acceptor are molecules of the same type). The acceptor changes from the ground state to the first excited state and de-excites ($k_{em,a}$) by light emission (if fluorescent) or heat emission. (c) Energy state diagram of the acceptor-donor system (DA) for defining differential equations. $*$ indicates an excited state of donor (D) or acceptor (A). Rate constants are the same as in (b) (10).

orientation of donor to acceptor. In most cases, not all of the parameters can be determined simultaneously. Often some of the desired parameters can only be retrieved by other calibration experiments or must be assumed as *a priori* known constants.

Organic dye molecules have been widely used both as acceptors and donors in FRET experiments. They are often covalently coupled to target molecules, exhibit a high ►fluorescence quantum yield (which means an easily detectable signal) and are small in size, a fact that diminishes perturbation of biological systems. Recently, quantum dots have been employed as donors in FRET experiments (5). These are minuscule semiconductors with a diameter of a mere few nanometers. Their properties are similar to single fluorophore molecules, but they offer a rather broad excitation spectrum (“free” choice in excitation wavelength), relatively monochromatic emission (width ~ 30 nm) and a high quantum yield. In addition, quantum dots are highly photo-stable, allowing for longer measuring periods than with ordinary dyes.

Methods

Sensitized Emission

Many FRET measurements are based on spectral methods, i.e. sensitized emission measurements (6). They can be used stand-alone, but may also be combined with any of the methods described below. A method-sensitized emission exploits the fact that donor and acceptor molecules absorb and emit light energy at different wavelength regimes (Fig. 3). Therefore, in donor and acceptor pairs that show very little spectral overlap, the fluorescence of donors can be detected by performing excitation at the donor excitation wavelengths and measuring emission at the donor fluorescence emission wavelengths (Fig. 3). Acceptor fluorescence can be detected in an analogous manner. The sensitized emission (sometimes termed “FRET channel”) can be measured by excitation at a wavelength range within the donor excitation spectrum and detection of the acceptor emission within its emission spectrum. Ideally, this signal depends only on the concentration of FRET pairs and the FRET

Förster Resonance Energy Transfer. Figure 2 FRET transfer efficiency in dependence on the donor-acceptor distance. 50% transfer efficiency is achieved at the Förster radius, R_0 . This example shows a Förster radius of 6.31 nm, calculated for the FRET pair Alexa 488-Alexa 546.

Förster Resonance Energy Transfer.

efficiency. However, many FRET pairs that are suitable for biological experiments (e.g. green fluorescent protein and its spectral derivatives) show substantial spectral overlap (7). In other words the donor also fluoresces in the wavelength range of the acceptor emission channel (“donor crosstalk”) and the acceptor is directly excited at donor excitation wavelengths (“direct excitation”). These effects can be corrected mathematically (“spectral unmixing”) by careful calibration,

using the respective individual fluorophores (7). A problem occurs in FRET experiments if not all of the donors find a binding partner or the affinity of the binding is low. In these cases, many free donors and acceptors are present that do not show FRET. However, they exhibit fluorescence in the respective detection channels. In this case, additional measurements are required (see methods further below) in combination with sensitized emission to achieve reasonable estimates of the concentration of the two species and the FRET efficiency of the interaction. Depending on the investigated molecules, it may be debatable whether a fixed FRET efficiency can be assumed for bound pairs.

Acceptor ► Photobleaching

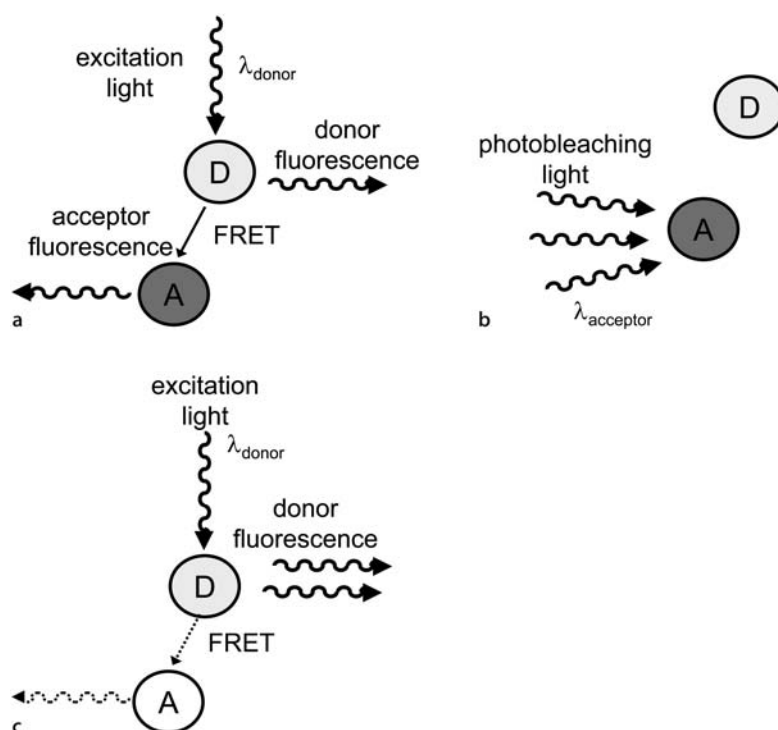

Photobleaching techniques are widely used because they can be performed easily and yield relatively robust estimates of FRET (8). In acceptor photobleaching approaches, the acceptor of a FRET pair is illuminated with intense light of wavelengths strongly absorbed by the acceptor but as little as possible by the donor. The acceptor then undergoes a photochemical destruction process with a substantial change in its absorption cross-section at the donor emission wavelength. After this, FRET cannot occur any longer and the donor fluorescence increases, as it is no longer quenched by energy transfer to the acceptor. The amount of donor fluorescence before and after the photobleaching procedure can be used to estimate the FRET efficiency (E):

$$E = 1 - I_{bb}/I_{ab} \quad (3)$$

with I_{bb} being the donor fluorescence intensity before and I_{ab} being its intensity after photobleaching

For the principle underlying the acceptor photobleaching measurement see Fig. 4. An experimental example obtained with a confocal microscope is shown in Fig. 5. Problematic cases for this method include incomplete bleaching of the acceptors, non-zero extinction coefficients of bleached acceptors in the donor emission spectrum and photodestruction of donors during acceptor depletion.

Alternatively, FRET efficiencies can be estimated by careful investigation of the time traces of bleaching experiments (2, 3) specifically targeted at bleaching the donor. A donor molecule displaying FRET exhibits an improved resistance to bleaching in comparison to “free” donors. From the analysis of fluorescence decay time constants, the FRET efficiency can then be calculated. One evident major problem in the above approaches based on photodestruction is that the experiment cannot be repeated after bleaching. These techniques are therefore not well suited to time-resolved FRET studies. In addition, excessive photobleaching is often lethal to live samples such as cells.

Förster Resonance Energy Transfer. Figure 4 Acceptor photobleaching approach. (a) An intact FRET pair is illuminated by excitation light—FRET does take place. (b) The sample is exposed to intense light at acceptor excitation frequency causing photodamage to the acceptor. (c) Measurement of a FRET pair with a photo-damaged acceptor. FRET transfer is decreased to a minimum and the donor fluorescence increased due to de-quenching of the donor.

► Fluorescence Lifetime Imaging (FLIM)

Each excited state of a molecule or fluorophore has a decay time called its fluorescence lifetime. The lifetime is usually stated as the time span a given excited state population requires to de-excite to $1/e$ (~ 0.37) of the original population. After exciting a population of fluorophores with a light pulse, the fluorescence emission intensity decays (often exponentially) as the number of excited molecules decreases over time (6). If a donor transfers its energy efficiently to an acceptor, the lifetime of the donor excited state is decreased when compared to the unperturbed donor. There are several ways to determine fluorescence lifetime experimentally (2, 6). FLIM is a rapid, robust and non-destructive method for FRET estimation. FRET efficiencies as well as the number of FRET pairs can be estimated, when combined with spectral analysis (9).

Fluorescence Anisotropy

In FRET measurements that employ ► fluorescence anisotropy or fluorescence polarization, the donor is excited with polarized light (2, 3). Polarized excitation predominantly excites molecules whose excitation dipole moment is collinear to the polarization of the

excitation light (“photoselection”). If the rotational correlation time of the donor is long in comparison to its fluorescence lifetime, the emission of the donor signal will be partially polarized. Light emission after energy transfer that originates from a randomly oriented acceptor will not be polarized. However, due to the dependence of κ on the mutual orientation of the molecules, the effect of this method is often only a further reduction in the degree of polarization. FRET can occur between two fluorophores of the same type (e.g. donor and acceptor are both GFP), providing they meet the FRET criteria outlined above. FRET between molecules of the same type can then be used to quantify the formation of homo-dimers and higher oligomers of the same protein. This method cannot predict a change in lifetime or a massive spectral change, since the acceptor signal is not spectrally separated from the donor signal and both molecules have similar properties.

Photochromic FRET (pcFRET)

In pcFRET, a recently applied technique, photoswitchable acceptors are employed (2). These acceptors can be switched between two states by ultra-violet illumination. One state is capable of absorbing the

Förster Resonance Energy Transfer. Figure 5 Donor (CFP) dequenching under acceptor (YFP) depletion. (a) Donor (left) and acceptor (right) before bleaching. (b) Donor and acceptor after intense illumination at acceptor wavelength of a sample-region (as indicated in a) leading to its photodestruction. These are CHO cells transfected with protein kinase C reporter (CKAR construct, kindly provided by Alexandra C. Newton) in the non-phosphorylated (closed) state. All images are acquired under illumination at donor excitation wavelength (458 nm) and detection with a bandpass (480/20 nm) for CFP and longpass (>545 nm, 545 dichroic and LP 505) for YFP. Note the increase in donor fluorescence (left b) after photo-destruction of the acceptor. The data were kindly provided by Elena Kardash.

donor fluorescence, whereas the extinction ratio of the other state is substantially reduced. This switching of states is reversible. In comparison to the photobleaching approach, which is not a reversible process, fewer quanta are necessary to cause the desired state transition, which has obvious advantages in speed and cell viability.

Outlook

In addition to various combinations of the approaches described, there are other promising approaches for FRET estimation, such as saturation approaches in which donor or acceptor molecules are driven into excited state saturation by intense excitation light (2, 10). At low light intensities, the fluorescence emission of a fluorophore population is proportional to the excitation intensity. When exposed to higher excitation light intensity, more and more fluorophores are driven

into the excited state. In extreme cases the fluorescence intensity finally reaches a limit as defined by the radiative rate. In this limiting case, all fluorophores are in the excited state since a fluorophore is immediately re-excited after fluorescence emission. At less extreme but high intensity, the proportionality between excitation intensity and fluorescence emission is violated, with many molecules being in the excited state at all times. In some systems, excited molecules are unsuitable for absorption in the wavelength range required for FRET. If the acceptor in a FRET pair is saturated by high light intensities within its direct absorption spectrum, the donor becomes de-quenched, since less acceptor molecules are now available in the singlet (non-excited) state. Related approaches are based on an increased excitation intensity required for saturation in the presence of the acceptor. When combined with spectral methods, this approach may

deliver FRET efficiencies as well as donor and acceptor quantities.

Acknowledgements

We thank Thomas Jovin and Stephan Hoepfner for critical reading of the manuscript. We also thank Elena Kardash for the supply of the data in Fig. 5 (all from the Department of Molecular Biology at the Max Planck Institute for Biophysical Chemistry, Göttingen). The CKAR construct (Fig. 5) was kindly provided by Alexandra C. Newton. M. Beutler was financed by DFG Project HE 3492/2-1, SPP 1128.

Forward Genetics

Definition

Forward genetics comprise of genetics techniques (e.g. knockout or transgenic studies) that aim to identify genes/mutations that produce a certain phenotype. A mutagen is very often used to accelerate this process. Once mutants have been isolated, the mutated gene can be molecularly identified. Once the sequence of the gene has been identified, the mutant phenotype can assign its function with nearly absolute certainty.

Fourier Transform Ion Cyclotron Resonance Mass Spectrometer

Definition

Fourier transform ion cyclotron resonance mass spectrometer is an instrument to measure mass-to-charge ratios dependent on the principle of an ion orbiting in the presence of a strong magnetic field. While orbiting in this field, the ions are excited by a radio frequency signal, which produces a detectable image current. The time-dependent image current has to be subjected to Fourier transformation to obtain the component frequencies of the ions, which can then be correlated to their mass-to-charge ratios.

Synonyms

Fragile X Syndrome; Martin Bell Syndrome; Marker X Syndrome

Definition

► [Mental retardation](#) manifests during the developmental period and causes children to have educational problems. They learn and develop more slowly than a typical child of the same age and have certain limitations in intellectual functioning and adaptive behaviour, i.e. in skills such as communication, taking

care of him or herself and social performance. Intellectual functioning is measured by an ►IQ test. The average score is 100. People scoring below 70 are thought to be mentally retarded. Adaptive behaviour is measured by comparing what a child can do in comparison to other children of the same age. About 3% of all children in the population have mental retardation. The most common causes are problems during pregnancy (e.g. rubella infection, alcohol or drug abuse by the mother) or during birth (e.g. oxygen deficiency of the baby), health problems (e.g. infectious diseases such as measles or meningitis, extreme malnutrition, exposure to poisons), and genetic conditions. One of the most common forms of inherited mental retardation, besides ►Down syndrome and phenylketonuria, is fragile X syndrome.

Characteristics

The name of the syndrome derived from the “fragile ►X chromosome” that is seen in affected males and females (Fig. 1). Under normal circumstances each somatic cell contains twenty-three pairs of ►chromosomes harbouring the genetic material (►DNA). Twenty-two pairs are morphologically the same in males and females. The remaining two chromosomes (X and Y) are the sex chromosomes. They determine whether a person is male (XY) or female (XX). A fragile X chromosome carries a particular ►fragile site (designated ►FRAXA) that is prone to breakage when cells are cultured under certain conditions outside the body (*in vitro*). Thereby the fragile site becomes visible under the microscope. At the molecular level, i.e. in the DNA of the X chromosome, the FRAXA site represents an abnormally expanded segment of a particular gene, designated ►FMR1 (fragile X mental retardation 1).

Common Symptoms

The common symptoms of fragile X syndrome include intellectual, physical and behavioural characteristics. The most significant feature is developmental delays ranging widely from ►learning disabilities to severe mental impairment. Learning disabilities are often accompanied by delays in speech and communication skills. There can also be delays in gross and fine motor skills. Some people with fragile X mental retardation have a long face, large ears that stick out from the head, connective tissue weakness leading to floppy muscle tone and flat feet, hyperflexible joints and large testicles ►Mitral Prolapse and High-pitched Speech. About 25% are affected by seizures. The behavioural characteristics include a tendency to anxiety and unstable mood, to trouble coping with sensory stimuli and to autistic like behaviours such as hand flapping, avoiding eye contact, saying or doing the same thing

over and over and disliking change in routine. Many have ►attention deficit hyperactivity disorder (ADHD) showing poor concentration and poor social skills. Some experience tantrums and emotional outbursts. Boys are typically more severely affected than girls. Most boys have mental retardation but only about one-half of girls have significant intellectual impairment while the rest share either normal IQ or learning disabilities. Emotional and behavioural problems are common in both sexes.

Treatment

There is currently no cure for fragile X syndrome. But specialist therapies, targeted education and medication can help maximise the potential of each child and to improve the quality of life. However, most boys and girls remain significantly affected throughout their lives. Because of speech and language delay and because of their poor concentration, the children may seem hard to educate. However, the child may have more ability than he or she can demonstrate, e.g. good copying skills, excellent long-term memories, good senses of humour, and often good vocabulary and reading skills.

Researchers are currently investigating two main strategies of causal treatment.

Fragile X Mental Retardation Syndrome. Figure 1

The fragile X chromosome at mitosis, and the FMR1 gene. The fragile site (FRAXA), located at the FMR1 locus (arrow), shows a break leading to dislocation of a small part of the chromosome's long arm. The chromosomal fragile site corresponds to the gene's CGG trinucleotide repeat (CGG) situated between the promoter (P) and the region encoding the FMR protein (coding region). Transcriptional activity (symbolised by angled arrow at the beginning of the transcribed gene region) is usually lost upon expansion of a premutation to a full mutation coinciding with methylation of the promoter region (hatched symbol). For further explanation see text.

- 1) Gene therapy by inserting functional copies of the *FMRI* gene into ►neurons of ►*FMRI* knockout mice to refine techniques for achieving consistent delivery of genetic material into humans.
- 2) Gene repair to restore the normal function of a mutated *FMRI* gene whose coding sequence is normal but which is not expressed because the gene is turned off.

Genetics

Fragile X mental retardation syndrome is caused by the absence of functional FMR protein (►FMRP), encoded by the fragile X mental retardation gene, *FMRI* (Fig. 1). This gene was discovered in 1991 when the FRAXA site was isolated by molecular cloning. The fragile site turned out to be a CGG ►trinucleotide repeat, i.e., a stretch of DNA containing a repeat sequence of C, G, and G nucleotides that reads CGG-CGG-CGG, etc. (1, 2). Fragile X syndrome is the first human disease identified to be caused by an unstable DNA sequence. The CGG repeat is situated in the *FMRI* gene but does not contribute to biosynthesis of the FMR protein. The repeat varies in length from one person to another, ordinarily falling within a “normal”-range (5 to 58 trinucleotides). In most individuals who have fragile X syndrome the stretch of CGGs is expanded to several hundreds of CGGs (>220). This large expansion is called a “►full mutation”. In this situation the gene usually becomes heavily modified by ►DNA methylation and is shut down.

Inheritance

Fragile X syndrome is inherited. The mutated gene is transmitted by female or male individuals who are “carriers” (Fig. 2). The fully mutated *FMRI* gene of affected children is always received from a carrier mother. She may carry a full mutation herself but mostly she has a “►premutation”, i.e. the length of her CGG repeat is between the normal and the full mutation range (59 to 200 CGGs). The majority of female premutation carriers did not receive the gene from their mothers but from the fathers. In this case, the father is a carrier male passing the premutation to all his daughters but none of his sons, who inherit the Y chromosome. Carriers of a premutation do not typically have symptoms of fragile X syndrome, but the premutated CGG repeat is “unstable” in that it is prone to further expansion when passed from a mother to her children. A full mutation male may also have children, but he only passes a premutation to his daughters.

Timing of Full Mutation

Expansion of a premutated CGG repeat to a full mutation allele probably occurs when the ►oogonia in the ovary of a female premutation carrier reproduce by

Fragile X Mental Retardation Syndrome. Figure 2 Fictitious pedigree of a family with fragile X mental retardation syndrome resulting from expansion of the CGG trinucleotide repeat in the *FMRI* gene. Females are symbolised by circles, males by squares. Filled symbols indicate affected individuals who have a full mutation. Male and female carriers of a premutation are indicated by a dotted symbol.

mitotic cell divisions before they enter ►meiosis to become egg cells that can be fertilised by sperm. The full mutation allele, that a fragile X embryo receives only through an oocyte, is probably not methylated initially, and is mitotically unstable in that cells with different lengths of the CGG repeat are generated upon continual mitotic activity. The unstable behaviour results in a mosaic of cells with different CGG repeats. Methylation of full mutation alleles only occurs at a later stage of development. The methylated CGG repeats then acquire mitotic stability by an unknown mechanism (3, 4).

In the testis of a fragile X male, premutated CGG repeats may also expand in dividing ►spermatogonia. But, in the absence of the normal *FMRI* gene in the male, cells with larger repeats produce less FMR protein and reproduce more slowly than cells with a short repeats. After a history of mitotic cell divisions that is much longer compared to that of oocytes, adult fragile X males, no matter if they are a carrier of a pre or a full mutation, have only premutations in their sperm.

Genetic Testing

The CGG repeat sequence is used to identify those who carry a pre or a full mutation and those who do not. According to the guidelines accepted by informed professionals, genetic testing of any individual requires genetic counselling and her or his informed consent. The DNA test for fragile X is offered by specialised laboratories and is quite accurate. It usually takes about two weeks to get the results.

Cellular and Molecular Regulation

Fragile X mental retardation syndrome is genetically caused by mutations that change the DNA sequence

of the *FMR1* gene. Most of these changes do not allow for the production of ►messenger RNA (►transcription) that is normally translated into protein (►translation). The normal *FMR1* gene is only transcribed when the ►promoter region, that is located “before” the CGG repeat (Fig. 1), is open to ►transcription factors, i.e. proteins that bind to the promoter DNA to initiate or regulate transcription.

In full mutation fragile X patients (98% of the cases) the promoter region is closed. The DNA of sufficiently large CGG repeats probably folds abnormally and thereby attracts an enzyme that methylates the triplet repeat and the nearby promoter region as well. Next, the methylated DNA binds to specialised proteins and enzymes that modify the ►chromatin of the *FMR1* promoter. The modified chromatin is remodelled and becomes so dense that the promoter is no longer accessible to transcription factors.

In about 1–2% of all fragile X cases, a portion of the *FMR1* gene including the promoter and the CGG repeat is lost. Changes of the genetic code may also be a genetic cause of fragile X syndrome but have been found only rarely. All but one of these changes generated one or more premature termination signals, because the genetic code was read through an altered frame, and thereby caused degradation of the aberrant messenger ►RNA by a cellular mRNA surveillance system.

In one exceptional case, a severely affected male showed normal quantities of abnormal FMR protein with one of the amino acids exchanged by a “missense” mutation. This change probably interfered with the ability of the protein to interact with other molecules to form a messenger ribonucleoprotein particle (mRNP). These particles contain messenger RNA (mRNA) and a number of previously identified proteins interacting with normal FMRP and with each other. The FMR protein has RNA binding domains and selectively binds to its own and to several other messenger RNAs in a highly specific manner.

High quantities of FMR protein are produced in all cells when they reproduce by mitotic division and in some non-dividing cells including neurons in several regions of the brain. While the function of FMR protein in dividing cells is less well understood, the protein’s normal role in brain is to help shape the synaptic connections of neurons that underlie learning and memory.

The vast majority of ►synapses receiving signals from other neurons sit on the heads of tiny protrusions of the ►dendrites. These protrusions are known as spines. Tens of thousands of spines can coat a single neuron making the dendrite look spiny, like a rose. In the normal brain, FMR protein is also produced near synapses and its level increases when the synapse is stimulated by nerve impulses. High-frequency

stimulation of a synapse increases its sensitivity and the efficiency of synaptic transmission over a long period of time. This phenomenon is called ►long term potentiation (LTP). It contributes to the formation of memories on which learning depends. LTP coincides with a controlled synthesis and activation of “key-” proteins at the synapse.

In the absence of FMR protein, i.e., in fragile X patients and in knockout mice lacking a functional *FMR1* gene (5), the density and shape of dendritic spines is abnormal, resembling the immature state of the early period of brain development when the number of spines with immature synapses is highest, before experience acts to mould brain organisation by selecting which synapses mature and survive and which fail to mature and consequently degenerate (6). In the absence of FMR protein, the level of several synaptic key proteins is significantly higher compared to the normal brain, where the translation of the corresponding messenger mRNAs is down-regulated by FMR protein functioning as a specific repressor of translation (7). Together with those mRNAs that are regulated by FMRP the protein is bound to a synaptic repressor complex (Fig. 3). This particle differs both structurally and functionally from the FMRP-containing mRNP outside the brain.

Fragile X Mental Retardation Syndrome. Figure 3 Translational regulation by FMR protein (FMRP) at the synapse. Interacting with known and unknown protein partners (symbolised by elliptic figures), FMRP binds to BC1/BC200 in a specific messenger ribonucleoprotein particle (mRNP). Direct interaction between BC1/BC200 RNA and a regulated mRNA is thought to bring the mRNP complex in the vicinity of the site where translation is normally initiated by binding of a ribosome, but is blocked by the FMRP complex. CBP, “Cap-binding protein” bound to the first nucleotide base of the mRNA, interacting with “Poly(A) binding protein” (PABP) that coats the mRNA’s tail formed by a series of A nucleotides.

The specificity of the synaptic mRNP complex is probably determined by the “▶[small dendritic RNA](#)” (▶[BC1/BC200](#)) that is included in the complex. BC1/BC200 RNA, also known as brain cytoplasmic RNA 1 (▶[BCYRN1](#)), is localised at synapses, does not encode a protein, but has been suggested earlier to be engaged in the regulation of ▶[dendritic protein biosynthesis](#). BC1/BC200 binds directly to FMR protein, and is also able to undergo base-pairing interaction with the mRNAs that are regulated by FMRP. There is some evidence that the FMRP mRNP represses translation of its target mRNAs in the initiation phase by blocking their binding to the ▶[ribosome](#) (5).

Thus, fragile X mental retardation is probably caused by synaptic dysfunction due to loss of appropriate regulation of dendritic protein biosynthesis in the absence of FMR protein.

Clinical Relevance

The identification of expanded triplet repeat sequences as the underlying cause of genetic disease has been a fascinating new development in human genetics. In fragile X mental retardation, expansion of a premutated CGG trinucleotide repeat in the *FMR1* gene on the human X chromosome to a full mutation upon maternal transmission sets off a molecular pathway leading to functional loss of the FMR protein that eventually results in a synaptic dysfunction phenotype. Investigation of the pathogenetic mechanisms in fragile X syndrome has already rendered valuable insights into complex processes of molecular genetics and cell biology, such as DNA synthesis and repair, DNA methylation and gene regulation. Research on fragile X syndrome is now beginning to significantly improve our knowledge of translational regulation at synapses, one of the key processes in the biochemistry of learning and memory.

Fragile X Syndrome

▶[Fragile X Mental Retardation Syndrome](#)

Fragile X(A) Syndrome

Definition

Fragile X(A) syndrome is an X-linked mental retardation syndrome associated with ‘fragile X phenotype’ (as detectable after specific cell culture treatment for chromosome preparation; nowadays molecular genetic diagnosis of repeat expansion mutations in the ▶[fmr1](#) gene). The syndrome is characterized by moderate to severe mental retardation, dysmorphic signs (large ears, increased size of testicles, prominent jaw, joint hypermobility, chest deformity, ▶[mitral valve prolapse](#)) and high-pitched speech.

Fragment-Based Ligand Design

Definition

Fragment-based ligand design describes a method used to identify ligands for a target protein by building up potent ligands in a modular way, starting from small fragments.

▶[NMR-Based Screening](#)

Frame (+1 Frame/−1 Frame)

Definition

With respect to an open reading frame on an mRNA, +1 frame is the translational reading frame consisting of codons shifted one nucleotide downstream (toward the 3' end of the mRNA). −1 frame refers to a reading frame to which codons are shifted one nucleotide upstream (towards the 5' end of the mRNA).

► [Translational Frameshifting, Non-standard Reading of the Genetic Code](#)

Frameshift Suppression/Suppressor

Definition

Frameshift suppression is a mechanism of translational termination suppression, used by some retroviruses. The process allows ribosomes to read (at a low frequency) through a frameshift mutation, producing the normal protein despite the genetic alteration. Translation can proceed from ► [gag](#) or pro into ► [pol](#).

► [Retroviruses](#)

Frameshift (Mutation)

Definition

Frameshift means the programmed shift of the reading frame during translation, which leads to a protein that differs in sequence from the sequence predicted from the mRNA on the basis of the standard genetic code, and is required to obtain functional protein. In most cases, the reading frame is shifted by one base in a +1 or −1 direction. Frameshifting frequently depends on the presence of particular structural elements (hairpin, pseudoknot) in the mRNA downstream of the shift site. The nature of the shift sequence is such that it provides a sufficiently stable base pairing between codon and anticodon, after the anticodon has shifted by one base. Frameshift mutations alter the reading frames of the corresponding messenger RNAs, so that codons downstream from the mutation site are out of register and are not translated properly. If the resulting protein is expressed, a frameshift mutation generally results in a truncated protein with an abnormal C-terminus.

Definition

► [Photobleaching](#) is the irreversible photo-induced destruction of the fluorescent properties of a fluorophore. While the loss of ► [fluorescence](#) can be problematic in fluorescence microscopy imaging experiments, photobleaching can be exploited in live cell imaging experiments to reveal information concerning the kinetic properties and environment of fluorescently labeled molecules in cells. Four different photobleaching applications (FRAP, FLIP, selective photobleaching and IFRAP) are described below. The different methodologies are illustrated in Fig. 1.

FRAP (Fluorescence Recovery After Photobleaching)

Fluorescent molecules in a small ► [region of interest](#) (ROI) of the cell are rapidly and irreversibly photobleached using a ► [confocal laser scanning microscope](#) (CLSM) with a high-powered laser beam. Subsequent

Frameshift Stimulator Sequences

Definition

Frameshift stimulator sequences refer to sequences found near to sites of programmed translational frameshifting, which have the effect of increasing the frequency of frameshifting.

► [Translational Frameshifting, Non-standard Reading of the Genetic Code](#)

movement of surrounding nonbleached fluorescent molecules into the photobleached ROI is imaged and quantitated using an attenuated light source (Fig. 1A). FRAP can reveal information concerning a protein's mobility and association with complexes and the protein's environment.

Selective Photobleaching

This method is similar to FRAP, but is generally used to characterize and quantitate nondiffusive movement of fluorescently labeled molecules. Specifically, a fluorescently labeled compartment or ROI is discretely photobleached using a CLSM to visualize and measure nondiffusive transport into and between discontinuous

compartments (e.g. trafficking between the endoplasmic reticulum to the Golgi complex).

IFRAP (Inverse FRAP)

Everything outside a fluorescently labeled compartment or ROI is selectively photobleached and a CLSM is used to follow loss of fluorescence from the ROI (Fig. 1B). IFRAP complements selective photobleaching experiments and can potentially be used to study bind and release kinetics of proteins.

FLIP (Fluorescence Loss in Photobleaching)

Fluorescence in a discrete region of the cell is repeatedly bleached while images of the entire cell

FRAP

IFRAP

FLIP

FRAP and Other Photobleaching Methods. Figure 1 Kinetic microscopy techniques. (a) In FRAP, a region of the cell (black dashed line box) is selectively and intensely irradiated to photobleach fluorescent molecules. The return of fluorescent molecules into that region is assessed quantitatively to determine diffusion coefficients and mobile fractions. (b) In IFRAP, the entire cell is photobleached except for one of two discrete structures (black dashed outline). The exit of fluorescent molecules or carriers from the unbleached region is assessed quantitatively to measure transport kinetics or bind and release kinetics. In addition, dim fluorescent carriers and their trafficking to other structures can be better visualized. In the example, fluorescent molecules have trafficked in vesicles from the unbleached structure to the photobleached structure. (c) In FLIP, a region of the cell (black dashed line box) is repeatedly photobleached. Movement of fluorescent molecules into the photobleached ROI results in loss of fluorescence from areas outside the box and can be used to determine the boundaries for a protein's diffusional movement within a cell. Loss of cellular intensity can be monitored in a separate region of interest, marked "M."

are monitored (Fig. 1C). In this photobleaching technique, the rate of loss of fluorescence rather than fluorescence recovery is monitored. FLIP can probe the extent of continuity of various intracellular membrane systems.

Description

Cellular proteins can freely diffuse, be immobilized to a scaffold or be actively transported. These dynamic properties influence what function a protein serves within the cell. Photobleaching can reveal a protein's diffusional properties, movement between compartments within cells and life history.

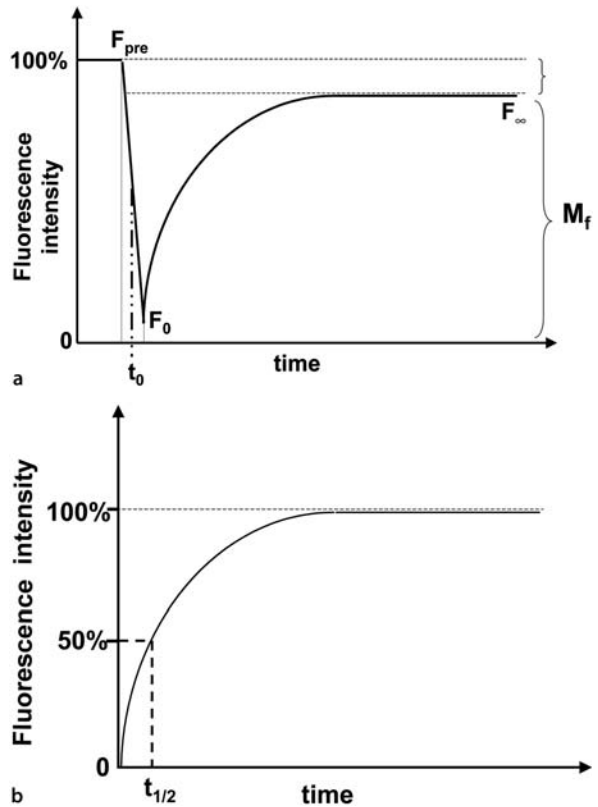

Photobleaching techniques depend on the availability of fluorescently labeled molecules such as fluorescent dyes and their labeled antibodies. ►GFP chimeras have become a popular method of fluorescently labeling proteins in living cells. An important property of GFP is that it can be photobleached without detectable damage to the surrounding environment. This is presumably because the GFP's cage-like structure, which surrounds a small cyclic peptide fluorophore (5), shields the external environment from any damaging effects caused by reactive photobleaching intermediates. These characteristics of GFP-chimeras make them ideal reagents in photobleaching experiments.

Fluorescence Recovery after Photobleaching

Several forms of FRAP or FPR (fluorescence photobleaching recovery) have been described. Popular methods include spot photobleaching, pattern photobleaching and strip bleaching. Spot photobleaching (1) can be performed on custom microscopes and some commercially available CLSMs. The strip photobleach method is suitable for commercially available CLSMs. Strip photobleaching permits imaging of the whole cell, while monitoring the fluorescence recovery into the photobleached ROI. This allows information concerning the changes in the spatio-temporal distribution of fluorescence to be readily determined.

The kinetic parameters that can be determined from FRAP experiments are the ►mobile fraction (M_f) of the fluorescent fusion protein and its ►diffusion coefficient (D). M_f and D are distinct parameters. D is a characteristic of the mobile pool of fluorescent proteins. A typical FRAP curve, which provides this information is shown in Fig. 2a. The M_f is the fraction of fluorescent proteins capable of diffusing into the photobleached region during the time course of the experiment. M_f is determined by calculating the ratio of the final to the initial fluorescence intensity in the bleached region, corrected for the amount of fluorescence removed during photobleaching.

D reflects the mean squared displacement that a protein explores through a random walk over time and has

FRAP and Other Photobleaching Methods. Figure 2 Plot of fluorescence intensity in a ROI versus time after photobleaching a fluorescent protein. (a) The prebleach (F_{pre}) is compared with the asymptote of the recovery (F_{∞}) to calculate the mobile and immobile fractions. Information from the recovery curve (from F_0 to F_{∞}) can be used to determine D . (b) The data plotted in part A can be transformed into a new scale in which F_{∞} represents 100% of the recovery and F_0 is 0% recovery. The time at which 50% of fluorescence has recovered into the photobleach ROI is the $t_{1/2}$. This analysis is useful for quantifying complex diffusion and nondiffusive processes.

units of area per time (usually $\text{cm}^2 \text{s}^{-1}$ or $\mu\text{m}^2 \text{s}^{-1}$). All proteins undergo this type of diffusive movement if they are not immobilized or experiencing active transport. The diffusion constant, D , is obtained by plotting the recovery of relative fluorescence intensity within the bleached region as a function of time and fitting this recovery curve with various equations. Several equations and simulations are available for calculating D for spot and strip photobleaching. For more information concerning FRAP theory and techniques see (3, 6).

Changes in M_f can reveal new information. A decrease in M_f indicates that the protein could be binding to fixed molecules or forming immobile aggregates or that

the protein is confined to a compartment and cannot contribute to fluorescence recovery in a separate disconnected compartment. When the M_f increases, the protein has been released from either a restricted compartment or a fixed macromolecular complex.

Changes in D and deviations from the predicted D value can reveal important information about the environment and size of the fluorescently labeled molecule. For example, a D significantly lower than a predicted value (indicating slower diffusion) suggests that a fluorescent protein could be incorporated into an aggregate or a large complex, because D is inversely proportional to protein size. Alternatively, the environment of a protein could be notably more viscous than expected or the protein could be interacting transiently with large or fixed molecules. By contrast, if D is significantly higher than predicted (indicating faster diffusion), the protein might be showing nondiffusive behavior such as ►flow or directed movement by motor proteins or the viscosity of the environment might be decreased. Given that there are many ways to interpret the D and M_f values for different proteins, combining FRAP data with biochemistry and cell biology is essential for determining the correct interpretation of the data.

The theoretical D for a protein is related to the molecular radius of the protein, the viscosity of the medium within which it is diffusing and whether the protein is soluble or integrated into a membrane. Membranes have a much higher viscosity than cytoplasm, so the lateral diffusion of an integrated membrane protein is considerably slower than that of a soluble protein and this is reflected in a lower D value. For a soluble spherical protein, an eightfold increase in size will lead to a twofold decrease in D . The relative insensitivity of D to small changes in molecular radius makes FRAP a poor method for detecting dimerization or other subtle changes in size.

The mobilities of several proteins are complicated by behaviors such as protein-protein interactions or binding to a matrix that might slow or immobilize a protein or populations with multiple D s. Such conditions complicate the analysis of D and may prevent fitting of data by traditional diffusion analysis. When a diffusion equation or simulation is unable to fit the fluorescence recovery data, the $t_{1/2}$ measure can be used to compare relative recovery rates between samples. The $t_{1/2}$ is the time required for the fluorescence intensity in the photobleach ROI to recover to 50% of the recovery asymptote fluorescence intensity (Fig. 2B). Other processes that lead to recovery into the bleached area (including vesicle transport or flow based movement) also may be quantitated and studied by this method. Though $t_{1/2}$ can be a useful tool, it is only relevant for the user's system and conditions.

Selective Photobleaching

Within cells, some proteins are transported between compartments within membrane-bounded vesicles moving along cytoskeletal fibers. It is difficult to gain insight into the rate of this movement in cells by only observing GFP chimeras at steady state. By selectively photobleaching the donor but not the acceptor compartment (or *vice versa*), vesicle transport of GFP-tagged cargo can be monitored by recording the rate of fluorescence recovery in the photobleached compartment. Data obtained from this type of experiment can be used to model kinetically the flux or cycling rates of the protein between compartments or to determine rate constants and residency times for proteins in distinct compartments. An additional application of selective photobleaching is to enhance the imaging of dim structures in cells or in areas of the cell next to very bright objects (i.e. photobleaching of Golgi fluorescence to visualize cargo delivery to this organelle).

Inverse FRAP

To probe the behavior and rates of trafficking of fluorescent proteins moving out from a structure, IFRAP can be performed. IFRAP essentially follows the FRAP protocol. However, instead of a strip, the investigator creates a photobleach ROI including the area of the entire cell, but excluding the organelle or structure of interest. For example, the Golgi complex (4) can be photobleached and then fluorescence recovery of either fluorescence into the photobleached organelle or fluorescence trafficking out of the unbleached organelle into the photobleached area surrounding the organelle can be imaged for both qualitative and quantitative analysis.

FLIP (Fluorescence Loss in Photobleaching)

FLIP is similar to FRAP in that an ROI is photobleached with a high power laser, but in FLIP the ROI is repeatedly photobleached over time to examine the behavior of the entire fluorescent pool. If fluorescent molecules within a cell are mobile and can diffuse into the photobleach ROI, the entire fluorescent pool of a compartment will be photobleached. Results from FLIP experiments can provide information about the connectedness of structures and organelles. For example, GFP-fusion proteins localized in the ER membrane show complete loss of fluorescence upon FLIP of a small area in the ER indicating that the luminal spaces of the ER are normally continuous throughout the cell (2). In addition, FLIP experiments can address whether a protein can diffuse uniformly across a compartment or whether there are regions of restricted mobility.

Frasier Syndrome

Definition

Frasier syndrome describes a rare disorder which is characterized by the presence of an XY sex chromosome constitution, and undermasculinized external genitalia that may range from ambiguous in appearance to normal-looking female genitalia. There is also kidney disease (glomerulosclerosis) and an increased risk of gonadal tumors (gonadoblastoma). Mutations in the donor splice site in intron 9 of the Wilms' tumor (WT1) gene have been shown to cause Frasier syndrome

Free Energy

Definition

Free energy defines a fundamental thermodynamic state function taking into account both energy and entropy. The free energy change for a reaction (or a transition between two states) is a measure of how far the reaction is from equilibrium. It determines whether and in which direction the reaction can occur.

► [Molecular Dynamics Simulation in Drug Design](#)

Free Energy Change (dG)

Definition

Free energy change (dG) describes a thermodynamic state function that represents the work, at constant pressure, necessary to achieve a given state from the reference state. The Gibbs free energy change (dG) provides a measure of the stability of the thermodynamic state.

► [Thermodynamic Properties of DNA](#)

Free Energy Perturbation

Definition

Free energy perturbation describes a statistical thermodynamical method to calculate the free energy difference between two systems A and B by generating an ensemble using one of the two potential functions and evaluating an ensemble-average expression that depends on the difference between the two potential functions. The two systems should be sufficiently similar, so that one may be regarded as a “perturbation” of the other.

Free Radicals

LEOPOLD FLOHÉ, HEIKE BUDDE
MOLISA GmbH, Magdeburg, Germany
l.flohe@t-online.de

Definition

In chemical terms, free radicals are molecules with an uneven number of electrons. More precisely, free radicals are molecules that contain one or more unpaired electrons and thus are paramagnetic. This physicochemical definition includes a large number of highly diversified natural compounds, such as enzymes containing transition metals or catalyzing univalent redox-transitions, cofactors of the respiratory chain like ubiquinone, intermediates in various catalytic processes, and finally low molecular weight compounds such as molecular dioxygen (O_2), endothelium-derived relaxing factor (EDRF; $\cdot NO$) and the superoxide anion ($\cdot O_2^-$). In cell biology, however, the term “free radical” is used in a narrower definition to describe small, highly reactive oxygen-, nitrogen-, sulfur-, or carbon-centered radicals that are implicated in oxidative or **▶nitrosative stress**, respectively.

This article will focus on radicals produced enzymatically such as $\cdot O_2^-$ and $\cdot NO$ and “reactive oxygen species (**▶ROS**)” derived therefrom. It has, however, to be stressed that the terms “oxygen-centered free radical” and “ROS” are not identical. The latter includes aggressive species such as H_2O_2 , alkylhydroperoxide, singlet oxygen, hypochlorite and peroxy-nitrite that are not radicals but are formed from, or may initiate, free radical reactions.

Characteristics Chain Reactions

A common feature of free radicals is their ability to initiate, propagate or terminate free radical chain reactions (1). If a free radical is formed (chain initiation), it tends to react with any kind of electronically saturated molecules. The product thus formed is inevitably a radical that may react with another molecule to create a new radical (chain propagation). Only if the reaction partner of a radical is a radical itself, can the free radical chain reaction be terminated by forming a product with an even number of electrons (chain termination). In such free radical chain reactions, labile intermediates are often formed that decompose with formation of two radicals, each being able to initiate a new chain reaction (chain branching). If not balanced by free radical scavengers, this leads to an uncontrolled situation, known by the term “**▶oxidative stress**” (1).

Phagocytic Killing, a Superoxide-driven Free Radical Chain (1, 2)

A typical free radical process in biology is the “killing reaction” of phagocytes, which is an indispensable component of the innate immune response but, if unbalanced, causes oxidative tissue damage as, e.g., in septicemia. Herein, a free radical chain is initiated by **▶NADPH oxidase**, a transmembranal cytochrome b-containing flavoprotein ($gp91^{phox}$). It separates the electron pair of NADPH to form two $\cdot O_2^-$ radicals.

The superoxide radical anion, $\cdot O_2^-$, is not a particular aggressive radical. It is a weak base that associates to the superoxide radical ($\cdot O_2H$) with a pK of 5. At the low pH of the phagocytic vacuole it dismutates spontaneously according to Eq. 2 or 3:

At neutral pH, the $\cdot O_2^-$ anions require enzymatic catalysis to dismutate. These reactions seemingly terminate the radical chain, since O_2 , although a biradical, is less reactive than $\cdot O_2^-$ and H_2O_2 is no longer a radical. H_2O_2 and other hydroperoxides ($ROOH$), however, can re-initiate radical chains in different ways. They may decompose according to 4 and 5 to form hydroxy ($\cdot OH$) or alkoxy radicals ($RO\cdot$).

According to Eq. 4 the chain termination according to (2) and (3) leads to chain branching. A variety of other chain branchings and/or propagations, which differ between tissues, appear to be physiologically more important.

In general, H_2O_2 decomposes in the presence of Fe^{2+} ions with formation of $\cdot OH$, as has been known for a long time from Fenton chemistry (Eq. 6).

The Fe^{2+} thereby consumed can be regenerated by $\cdot O_2^-$ (or other reductants; Eq. 7):

Summing up reaction (6) and (7) reveals a continuous production of $\cdot OH$ from $\cdot O_2^-$ and H_2O_2 as long as catalytic amounts of transition metals are available:

This special case of Fenton chemistry is also called the Haber-Weiss reaction. It is a major source of the hydroxyl radical. The latter reacts with all kind of SH groups, polyalcohols and aromatic compounds with diffusion-limited rate constants near $2 \times 10^{10} \text{ M}^{-1} \text{ s}^{-1}$ and accounts for most of the toxicity attributed to superoxide-driven free radical chains.

In activated Polymorphic Clear Lencocytes (PMNs), the myeloperoxidase uses the ►respiratory burst-derived H_2O_2 to produce hypochlorite, a non-radical but equally aggressive oxidant (Eq. 9):

Hypochlorite according to Eq. 10 and 11 is in equilibrium with chlorine molecules and chlorine atoms. The latter, as radicals, re-initiate and branch the radical chain:

Hypochlorite and H_2O_2 further generate singlet oxygen ($^1\Delta_g \text{O}_2$), a non-radical excited form of molecular dioxygen.

$^1\Delta_g \text{O}_2$, commonly obtained by UV light, is the reactive form of O_2 that, e.g., readily oxidizes unsaturated lipids.

Particularly in macrophages, the production of $\cdot\text{O}_2^-$ may occur simultaneously with that of $\cdot\text{NO}$. These two radicals instantly react with each other to peroxynitrite:

Again a non-radical but highly aggressive oxidant is generated, which is implicated in bacterial killing, protein nitration and nitrosation. Moreover, peroxynitrite under acid conditions decomposes with formation of two radicals $\cdot\text{OH}$ and $\cdot\text{NO}_2$, and thus re-initiates two radical chains:

While $\cdot\text{NO}$ itself is a fairly inert and, in physiological terms, often beneficial radical, the peroxynitrite-mediated reactions tend to account for pathological phenomena subsumed under the term nitrosative stress. Any of the $\cdot\text{O}_2^-$ derived radicals (Eq. 1–13) may initiate chain reactions in lipid phases by hydrogen abstraction from unsaturated lipids. Carbon-centered radicals thus formed add O_2 to yield lipidperoxy radicals, $\text{ROO}\cdot$ that are reduced by lipid-soluble antioxidants, e.g. tocopherols, to lipidhydroperoxides. If not enzymatically

reduced by any of the ►glutathione peroxidases, these may, in analogy to Eq. 4–6, decompose to $\cdot\text{OH}$ and/or alkoxy radicals ($\text{RO}\cdot$), which sustain the radicalic “►lipid peroxidation”.

Molecular Interactions (1, 3, 4)

Apart from the nonspecific interactions of radicals with each other and other susceptible molecules implicated in oxidative stress, both primary biological radicals, $\cdot\text{O}_2^-$ and $\cdot\text{NO}$, have their specific targets that mediate either their decomposition or specific cellular responses.

$\cdot\text{O}_2^-$ and $\cdot\text{NO}$ have pronounced affinity to heme proteins. The reduction of cytochrome c by $\cdot\text{O}_2^-$, which is used for routine $\cdot\text{O}_2^-$ determination, may be quoted as an example. Similarly the formation of nitroso hemoglobin by $\cdot\text{NO}$ can be used analytically and is a physiological scavenging mechanism. Moreover, $\cdot\text{NO}$ binding to heme proteins is the chemical basis of its role as signaling molecule (see below). Both radicals modify protein thiols. The relative specificity of thiol modifications is due to the molecular environment of the SH groups, which have to be exposed and dissociated. The chemistry of such protein modification is complex and in most cases the radicals are not considered to be the proximal reactants. Oxidation of protein SH to SOH followed by disulfide formation is rather due to H_2O_2 or ONOO^- than to $\cdot\text{O}_2^-$. S-Nitrosation, i.e. the formation of R-SNO, is also not directly achieved by $\cdot\text{NO}$ but by the nitroxyl cation, NO^+ , which is formed from $\cdot\text{NO}$ and O_2 via N_2O_3 . Since nitrosothiols readily react with free thiols, nitrosation represents an alternative route to protein mixed disulfides.

Nitration of proteins at tyrosine residues under conditions of $\cdot\text{NO}$ generation often occurs in a rather specific manner. Again, not $\cdot\text{NO}$ itself, but $\cdot\text{NO}_2$ that is generated from peroxynitrite is the immediate reactant. While specific enzymatic routes to degrade $\cdot\text{NO}$ are unknown, $\cdot\text{O}_2^-$ is eliminated at almost diffusion-limited rates by ►superoxide dismutases (SOD), which are metalloenzymes of three distinct protein families, containing Fe, Mn or Cu as catalytic transition metal. The SODs acting with copper contain Zn as additional metal cofactor for structural stabilization. The unusually high rate constants of the Cu/Zn SODs ($2 \times 10^9 \text{ M}^{-1} \text{ s}^{-1}$) are explained by an electrostatic gradient that draws the negatively charged $\cdot\text{O}_2^-$ into a tunnel of increasing positive charge with the complexed Cu^{2+} ion at its bottom. The catalytic mechanism is otherwise simple. A first $\cdot\text{O}_2^-$ delivers its unpaired electron to the Cu^{2+} , a second one picks it up again. An analogous redox shuttling of the transition metal takes place in the Fe- and Mn-SODs.

Regulatory Mechanisms

Regulation of Radical Production (2, 4, 5)

For obvious reasons the formation of free radicals is strictly controlled. $\cdot\text{O}_2^-$ production by phagocytes is triggered by a receptor-mediated phosphorylation cascade that leads to an association of the cytosolic components p47^{phox} , p40^{phox} , p67^{phox} and the GTP binding proteins Rac 1/2 to the catalytic transmembranal flavocytochrome $\text{gp91}^{\text{phox}}$ and to p22^{phox} (2). Formation of the active complex is associated with a massive oxygen consumption ("respiratory burst") and release of $\cdot\text{O}_2^-$ into the phagosome or the extracellular space. Typical activators of the respiratory burst are microbial structures (e.g. formyl peptides) and numerous inflammatory mediators such as anaphylatoxins, platelet activating factor, TNF α , leukotriene B $_4$, and interleukins. The ability of calcium ionophores and phorbol esters to induce a respiratory burst suggests an involvement of PKC-type enzymes in the initial steps of signaling. The relevance of the system to host defense is evident from mutations in any of the system components that all result in defective bacterial killing (Chronic Granulomatous Disease).

Many variations of this theme have meanwhile been detected in other cell types (3). Either the activating components or the catalytic entity itself may be changed. The flavocytochrome $\text{gp91}^{\text{phox}}$ (Nox 2) may be replaced by any of the homologous Nox proteins. In contrast to Nox 1–4, Nox 5 has a calcium-binding domain attached; the Duox proteins, in addition, contain an intracellular peroxidase domain. Although less efficient, the $\cdot\text{O}_2^-$ producing systems of non-phagocytic cells are also discussed in the context of innate immune response. In particular cases, alternative roles are obvious. In the thyroid gland, e.g., a Duox 1/2 system, *via* $\cdot\text{O}_2^-$ production, probably provides the H_2O_2 required for thyronine synthesis. In nematodes, Duox systems are implicated in oxidative cross-linking of cuticular proteins *via* dimerisation or trimerisation of tyrosine residues. It remains to be worked out which of the system variants is responsible for growth factor-induced ROS formation, which is also believed to result from an initial $\cdot\text{O}_2^-$ synthesis by any of the $\text{gp91}^{\text{phox}}$ -related proteins.

$\cdot\text{NO}$ is generated in mammals by three distinct, though homologous, NO synthases (NOS) from arginine, NADPH and oxygen (3, 4). The neuronal form, nNOS, which is predominantly, but not exclusively formed in the nervous system, and the endothelial form, eNOS, are low output enzymes that are primarily regulated at the protein level by the Ca^{2+} /calmodulin system. They require free Ca^{2+} for activity, while their activity is reduced by serine/threonine phosphorylation by Ca^{2+} /calmodulin-dependent PK II, PKA, C or G, and other protein kinases. Of the NOS-bound cofactors, which

are FAD, FMN, heme and tetrahydrobiopterin (BH_4), the last deserves particular interest, since suboptimum saturation changes the NOS reaction specificity towards that of an $\cdot\text{O}_2^-$ producing system. Regulation of nNOS and eNOS at the transcriptional level, e.g. by sex hormones and corticosteroids, has also been observed but only modulates the, in essence, constitutive expression (for more details see 2). In contrast, the high-output "inducible NOS", iNOS, is primarily regulated at the expression level (3), while little is known about regulation of the enzyme itself apart from inhibition of (activating) dimerisation by kalirin in the nervous system and by NAP110 in macrophages. The pattern of inducers/inhibitors, the signaling pathways and affected promoter sequences vary substantially between cell types (3). Most consistently, the iNOS promoter is positively affected by NF κB , octamer factor (Oct), interferon regulator factor-1 (IRF-1), C/EBP, HIF-1, estrogen receptor- β , pregnane X receptor (PXR), antioxidant-responsive element binding protein, nuclear factor- Jl6 (NF- Jl6) and Krüppel-like factor 6 (KLF6). Interestingly, there is a considerable, although not strictly conserved, overlap between the cytokines and signaling pathways leading to iNOS induction and those triggering oxidative burst. This implies that iNOS induction can in most cases be rated as an inflammatory or stress response and that, under these conditions, excessive amounts of $\cdot\text{NO}$ and $\cdot\text{O}_2^-$ are produced simultaneously, a situation that inevitably results in peroxynitrite formation.

Regulation by Free Radicals

$\cdot\text{O}_2^-$ formation upon receptor stimulation by, e.g., EGF, PDGF or insulin is considered to positively influence signal transduction and, accordingly, the radical is often described as a second messenger (3, 4). In view of the fast enzymatic dismutation and the multiple possible interactions of the radical with other cellular components it is, however, almost impossible to attribute the physiological consequences to $\cdot\text{O}_2^-$ itself. Cautious interpretation attributes the observation to "ROS" (4) and there is ample evidence that $\cdot\text{O}_2^-$ -dependent modulation of signaling is achieved through protein thiol modification by H_2O_2 . In addition, alkylhydroperoxides directly formed by lipoxygenases may contribute to enhancement of signaling. In line with this view, exposure to cell-permeable thiols and overexpression of GPx- or Prx-type peroxidases usually dampen or even block such signaling cascades. In most cases of redox-regulated signaling cascades, however, the molecular targets of ROS still remain as unclear as the reacting oxidant species and the nature of target modification.

Much better defined is the regulatory role of $\cdot\text{NO}$. By binding to the heme moiety of soluble guanylyl cyclases

it enhances the formation of cyclic GMP. This appears to account for many of the specific $\cdot\text{NO}$ effects such as modulation of cGMP-regulated ion channels, phosphodiesterases and protein kinases. A direct binding of $\cdot\text{NO}$ to heme moieties is also discussed as a mechanism to induce $\cdot\text{O}_2^-$ formation in the mitochondrial respiratory chain and is implicated in triggering apoptosis. The effect of $\cdot\text{NO}$ on GTP-binding proteins involves nitrosation of cysteine residues and thus is not a direct effect of $\cdot\text{NO}$. Similarly, the effects of $\cdot\text{NO}$ on MAP kinase and other signaling cascades are often not mimicked by cGMP. They rather resemble the effects of ROS and might involve peroxynitrite-dependent oxidations or nitrosations.

Full-Length cDNA

Definition

Full-length cDNA is defined as a cDNA that contains the sequence information of the whole original mRNA it derives from. However, cDNA is frequently defined as being full-length if it covers the complete protein

coding part of the original mRNA (some sequence of the 5' UTR may not be present). While the latter cDNA is still useful to express the encoded protein, the identification of the transcription start site and all sequence motifs that had been present in the 5' UTR of the mRNA is not possible.

Definition

► [cDNA](#) is a 'complementary' or 'copy-DNA' that is generated *in vitro* from cellular ► [mRNA](#) (messenger ► [RNA](#)). ► [Full-length cDNAs](#) contain the complete sequence information of their respective mRNA templates. This information is determined by full-length cDNA sequencing and provides knowledge of the protein encoded by the original mRNA and, in addition, of the untranslated regions (► [UTR](#)) of this mRNA. The so called open reading frame (► [ORF](#)) specifies the protein sequence that is encrypted in the mRNA while the UTR frequently contain sequence elements, e.g. regulating mRNA stability or localization.

Characteristics

RNA is an Intermediate between DNA and Protein

mRNA is an intermediate between DNA (the gene) and the encoded protein (Fig. 1) and is one of several RNA species that are present in cells. DNA stores the genetic information, and proteins are the molecules executing most cellular processes. Most genes are present in one or two copies in the chromosomes and alterations in the copy number mostly result in disease (e.g. trisomy 21 causes ► [Down syndrome](#)) or death. The genome needs to be stable over generations. In contrast, the amount of mRNA that cells produce from these genes can vary over several orders of magnitude to allow for a rapid and fine-tuned expression of these mRNAs and the proteins. RNA is generated exclusively as required and quickly degraded when no longer necessary. The expression of mRNA is often tissue specific or occurs only in defined developmental stages.

In addition, genes in eukaryotes are mostly structured in ► [exons](#) and ► [introns](#). To produce mRNA, introns

Full-Length cDNA Sequencing. Figure 1 From DNA to protein. *In vivo*, protein is generated from the DNA (genes) with the help of an intermediate messenger or mRNA. RNA can be isolated and copied *in vitro* into cDNA with the help of the enzyme reverse transcriptase (dotted line to from mRNA to cDNA). By determining the sequence of cDNA, the gene and the sequence of the encoded protein are identified. A cDNA can also be used to translate the encoded protein *in vitro* (dotted line from cDNA to protein).

Full-Length cDNA Sequencing. Figure 2 From the gene to the mRNA. The genome (on top) contains genes, which have a promoter region and other elements regulating the amount of RNA that is transcribed. In eukaryotes, most genes consist of exons (boxes) and introns (thin lines). The exons contain the information needed to make protein or a functional RNA. The functions of introns are not completely clear yet; however, they are frequently involved in the regulation of transcription, in alternative splicing and in evolutionary processes. First the gene is transcribed by DNA-dependent RNA-polymerase (transcription) into a perfect copy (hnRNA = heterogeneous nuclear RNA - center) of the gene, although omitting the promoter region. The following maturation of the RNA consists of processes during which a stretch of A-residues is polymerized at the 3' end (poly A tail) and the introns are removed by splicing. In the end, the exons are lined up in a non-interrupted order. All these processes, starting from transcription and ending with the mature mRNA happen in the nucleus.

are removed in a natural process named **▶splicing** to yield the protein coding part in a non-interrupted fashion (Fig. 2). The mature mRNA is transported into the cytoplasm of cells, where the encoded protein is translated with help of ribosomes.

cDNA is Synthesized from RNA

Unfortunately mRNA degrades very easily and cannot be manipulated e.g. cut with restriction enzymes.

Consequently, the mRNA must be converted into more stable DNA before analysis. This reaction, which is called reverse **▶transcription**, is catalyzed by the enzyme reverse transcriptase (1) and produces cDNA (Fig. 1). Since cDNA normally descends from mature mRNA, it contains the protein encoding part of the original gene in non-interrupted order. cDNAs are also a means for the identification of alternative splice forms (**▶Alternative splicing**), when different sets of exons are used *in vivo* to assemble the template mRNA. The cDNA can additionally be used to express the encoded protein *in vitro* (Fig. 1).

This DNA is cloned into vectors that can be propagated and amplified in bacteria to produce cDNA libraries (2). In analogy to a book library, which consists of a large collection of different books, cDNA libraries should contain representatives of, ideally, all mRNAs that were expressed in the tissue from which the RNA was isolated.

When cDNAs are generated and cloned to make cDNA libraries, mRNAs expressed at low levels are usually underrepresented, whereas highly expressed mRNAs lead to high numbers of cDNA clones in these libraries (Table 1). The different abundances of cDNA species impose difficulties, both in gene discovery and in full-length sequencing projects. New genes or targets for full-length sequencing are commonly identified by random sequencing of cDNAs on a large scale. mRNAs present in high and medium abundance are quickly identified by this approach. However, mRNAs expressed at low levels often escape identification. One effect of this problem is that the complete number of human genes is still unknown, despite the genome sequence being fully determined.

Full-Length Cloning and Sequencing vs. Gene Discovery

1. The sequencing of cDNAs can be carried out to obtain two levels of information (Fig. 3). The full-length sequencing of cDNAs is performed to determine the complete sequence of the protein coding as well as the non-coding parts of the mRNA in question. Splice variants of mRNAs often lead to variant proteins with different functions or activities (see clinical relevance) and are also identified by full-length sequencing of cDNAs. In addition, the cDNAs are physical resources, i.e. DNA clones, suitable for experimental exploitation (e.g. expression of proteins).
2. The sequencing of **▶ESTs** (expressed sequence tags) has proved valuable in the discovery of genes. ESTs are sequence information generated from cDNA clones; however, only the ends of the clone-sequences are determined (Fig. 3). This short stretch (tag) of sequence is still sufficient to identify the gene this cDNA represents (3). Note that the

Full-Length cDNA Sequencing. Table 1 mRNA abundance classes. The amount of specific mRNAs in cells is highly variable. While some genes are expressed at high levels, resulting in large amounts of a specific mRNA (copies of mRNA per cell), other mRNAs are expressed in very small quantities. Most mRNAs are present in low or intermediate abundance.

Abundance Class	Copies per Cell	Abundance of each mRNA
Low	5–15	<0.004%
Intermediate	200–400	<0.1%
High	12,000	3%

terms “cDNA” and “EST” need to be clearly distinguished. While a cDNA is a physical resource (clone), an EST is a piece of sequence information that is generated from a cDNA.

Large-scale projects aiming at the full-length sequencing of cDNAs were initiated considerably after the production of ESTs had become fashionable. Most (human) genes are believed to be represented by one or more EST-sequences in public databases, however, a significant fraction of the respective genes is not (yet) covered by full-length cDNA clones and sequences.

Model Organisms (Human, Mouse, Rat, Others)

With improved sequencing and ►cDNA library technologies available, the number of full-length cDNA sequencing projects and the organisms analyzed has grown over the years. The first human full-length cDNA analysis project was established in 1994 in Japan (4). Long human cDNAs were generated and sequenced at the Kazusa DNA Research Institute. Since then, a small number of large-scale projects have evolved in Japan (5), Germany (6) and in the USA (7) with the focus on human and mouse cDNAs. The overall goal of these projects has been to generate full-length cDNAs for all genes contained and expressed in the respective species. For human over 50% of the expected genes are available as full-length sequences, for most of them the cDNA clones are also made available.

The number of species analyzed by full-length cDNA sequencing is low compared to the large number of organisms that have been sequenced at the genome level. This is partly due to the high variability of mRNA levels in cells and tissues (Table 1) and also because of the different sequencing set-up necessary to analyze cDNAs, compared to genome sequencing. An up-to-date list of individual projects is available at the National Center for Biotechnology Information (NCBI) in the USA (► <http://www.ncbi.nlm.nih.gov/genome/flcdna/>). Most organisms that are currently analyzed in full-length cDNA sequencing projects are important in

Full-Length cDNA Sequencing. Figure 3 EST vs. Full-length sequencing. A cDNA is cloned into a plasmid vector, amplified in bacteria and then purified. Using vector primers, the terminal sequences of the cDNA insert are determined at the 5' and 3' ends (in the direction of the original mRNA), which produces ESTs (expressed sequence tags). These sequences are error-prone since they have been determined analyzing only one of the two DNA strands (ESTs drawn as single lines). In full-length sequencing, the sequence of the cDNA is determined by analyzing both DNA strands (drawn as a double line). An increase in accuracy is reached by analysis of the two DNA strands compared to the relatively poor quality obtained in EST sequencing. A cDNA ideally contains the 5' UTR and 3' UTR (un-translated region), and also, in the case of protein-coding cDNAs, the non-interrupted ORF (open reading frame), where the protein is encoded.

cell biology (e.g. *Drosophila*, *Xenopus*) and medicine (e.g. human, mouse, zebrafish).

Clinical Relevance

Full-length sequences and clones serve at least two functions with clinical relevance.

1. Identification of the full-length mRNAs and encoded proteins is essential in disease gene identification and for the identification of splice variants associated with disease (clotting factor VIII in haemophilia A, presenilin in Alzheimer). The full-length sequences then form the basis for the functional characterization of the proteins and for the development of diagnostic tools.
2. Full-length cDNAs can be used to produce the proteins encoded by the cDNA. For example, human clotting factor VIII is commonly expressed in bacteria using a full-length cDNA as starting material. The factor is purified and used therapeutically in the treatment of haemophilia A patients. Thus, full-length cDNA can also serve as a basis for therapeutics.

With the genome being sequenced, and growing information on genes and gene products becoming available, the importance of full-length cDNAs in functional genomics, proteomics and medical sciences will further increase.

Functional Assays

JEREMY C. SIMPSON

Cell Biology and Biophysics Programme, European Molecular Biology Laboratory (EMBL), Heidelberg, Germany
simpson@embl-heidelberg.de

Synonyms

Functional assays are encompassed within the terms high-throughput screening and high-content screening.

Definition

One goal of current proteomic approaches is to provide a listing of all the proteins present in either an

organelle, cell type or whole tissue at a particular point in time. Although such data are extremely valuable, this is only one step towards our understanding of global protein function. Once a particular set of proteins has been identified, methodologies must be applied to screen these proteins for their cellular role. In this regard, functional assays can be defined as systematic *in vivo* experiments that are designed to determine the involvement of each protein in a particular cellular pathway or biological process. This approach provides both the first clues to the cellular role of individual proteins and a means to classify the proteome into functionally related groups. In keeping with this definition, the term functional assays is not used here to describe general enzymatic activities such as phosphorylation or glycosylation. The readout from functional assays can be obtained in a variety of ways, but the description given here will use the paradigm of microscopy-based methods to identify proteins that are involved in intracellular transport.

Characteristics

In multicellular organisms, biological function is ultimately determined at the cellular level. Although the human body is composed of at least 250 cell types, some of which perform specialised functions, a large number of biological processes are common to nearly all cells. These include cell division, the ►secretion of various proteins or macromolecules, the uptake of nutrients and the cell's response to external stimuli. A large part of the proteome in any cell type is dedicated to these processes and the challenge is to correctly assign proteins to these as a first step towards a full understanding of their individual role. To reconcile such large lists of proteins with a putative function therefore requires the application of systematic and directed assays, which can be characterised by certain features:

1. methodology that allows testing of individual proteins in turn,
2. criteria to choose which proteins are appropriate for which assay,
3. clear and reliable readouts from the experiment, preferably quantitative,
4. the potential for scaling up to thousands of samples,
5. easy adaptability as requirements change.

The purification of every protein from the human proteome is still technically unachievable and furthermore, since it requires their removal from the normal cellular environment, it may be considered an inappropriate means to determine their *in vivo* function. Consequently, functional assays must adopt an approach whereby each protein under investigation can be easily identified while still in its cellular context. This has now become possible due to the complete

sequencing of the genomes of a number of model organisms. Such sequencing projects not only provide a means of identifying all the possible proteins in an organism, they also provide a physical resource of many thousand clones and ►[open reading frames](#) (ORFs) that encode the proteins (1). The availability of large clone collections provides an excellent tool for functional assays, as these can be taken, genetically tagged and then reintroduced into cells in appropriate ►[expression vectors](#). The tag enables the protein to be specifically localised within the cell and the effect of the over-expression of individual proteins on a given process can be monitored. Since the introduction of a number of recombination-based cloning systems, many thousand ORFs can be subcloned rapidly into these expression vectors without having to take account of their individual restriction enzyme sites. The advantage of this whole approach is that tagged ORFs can be easily introduced into model cell systems using either plasmid or viral vectors. Simple plasmid vectors are easy to prepare and propagate and indeed a wide variety are available for use with recombination cloning strategies. However, when used in transient ►[transfection](#) experiments, it is inevitable that not all of the cells receive the DNA for over-expression. This is generally not a problem with viral vectors, but their preparation is more labour intensive and the viral infection itself can induce cellular changes. The design of functional assays around any type of expression vector does however have one major caveat; in order to see a phenotypic effect, it is assumed that the over-expressed protein of interest is present in sufficient amounts to titrate out its interacting partners. In this way, over-expression experiments attempt to override the normal operation of a particular process by upsetting the equilibrium of the endogenous factors involved.

The choice of tag is important when designing functional assays. Many ►[epitope tags](#) are now available, such as haemagglutinin, hexahistidine, V5, FLAG and so on, and these have the advantage of being relatively small (a few amino acid residues) compared with the size of the final expressed protein. This means that generally, the function of the tagged protein and its interactions are preserved. However, the disadvantage of these epitope tags is that they can only be visualised (for example using antibodies) after the cells have been fixed. Another type of tag makes use of entire proteins that have fluorescent properties. The most frequently used of these is the ►[green fluorescent protein](#) (GFP). As GFP fluorescence still occurs when appended to another protein and without the need for co-factors, it is a marker that can be utilised in living cells from many organisms. Although it is significantly larger than an epitope tag, it folds into a compact barrel-shaped structure and studies indicate that the functionality of

the protein to which it is attached is retained in the majority of cases. In addition, GFP-tagging allows the protein under study to be visualised in real time in living cells, potentially allowing more information to be retrieved from the functional assay.

Having generated a comprehensive set of appropriately tagged ORFs encoding proteins to be assayed, it may be necessary to first choose appropriate subsets of proteins for screening. There are a number of possibilities here, again depending on the assay in question. For example, since bioinformatic analysis is available for every predicted ORF, the assay could be designed around a subset of proteins that contain a particular ►[protein domain](#). Work by Cesareni and colleagues provides such useful information for the SH3 protein recognition domain (2). Their analysis has highlighted the presence of over 1500 SH3 domain-containing proteins, with functions in totally diverse processes. They have further suggested a sub-classification of these domains, thereby providing a potential starting point from which to screen a realistic number of proteins in any functional assay of interest. Such a strategy is potentially applicable to proteins containing any domain, such as those annotated in the ►[SMART databases](#) and ►[PFAM databases](#).

Another possibility for identifying an interesting subset of proteins for a functional assay is to screen and classify them according to their subcellular localisation. Indeed, researchers are making significant efforts to determine this information for every protein. Most recently, this has been achieved on a genome-wide scale in the yeast *Saccharomyces cerevisiae* (3) and it is inevitable that this will be extended to mammalian systems. Numerous projects have localised the products of hundreds of human ORFs and this information is already proving useful in determining subsequent strategies for characterising the proteins (4). Pre-screening proteins according to their localisation undoubtedly helps to make any functional assay more efficient. For example, if one were interested in identifying all the proteins involved in the ►[endocytosis](#) of nutrients from outside the cell, it makes more sense to assay those proteins that localise to the plasma membrane than those that localise to the nucleus. As more localisation projects come to fruition, functional assays will become increasingly focussed according to these results, in such a way that candidate proteins for the process of interest can be more rapidly identified. A functional assay in which individual, tagged proteins are over-expressed should not only provide clear, interpretable results, but it should also be possible to distinguish the results obtained from individual cells. Such a readout on a cell-by-cell basis is crucial if one is using transfection techniques to over-express a protein of interest. In this scenario, not all the cells in a well or dish will be transfected and correspondingly will not all

display a phenotypic effect in the assay. Therefore, taking a measurement from the entire well or dish will result in an erroneously high 'background' reading from the non-transfected cells, which could mask the phenotype of the cells that have been transfected. In order to make the data acquisition more reliable, it is therefore preferable to take measurements from individual cells. This has the advantage that the results will be more accurate and furthermore, allows the direct comparison of transfected and non-transfected cells under the same conditions. Microscopy-based data acquisition systems are ideally suited to this use because the two cell types can be easily distinguished and quantitative measurements of fluorescence can be made. Again, if we take the example of a functional assay designed to assess the endocytosis of a ligand into a cell, the protein under test could be tagged with GFP and the ligand, such as transferrin, could be labelled with a red fluorophore such as rhodamine. On addition to the culture medium, the labelled transferrin would be internalised by the cells and over a period of time degraded. Such an assay could therefore provide information about the uptake and degradation (loss of rhodamine fluorescence) of the ligand at various time points and allow a comparison of these measurements between transfected and non-transfected cells to be made.

Such cell-based functional assays can therefore be envisaged for any cellular activity of interest and could be applied to any fraction of the proteome. However, in order to do this for a large set of molecules, a certain degree of automation is required. Such automation can be at the level of sample preparation – namely the use of a pipetting robot – but it can also be at the level of data acquisition and analysis. For example, we have recently developed a screening platform, the central component of which is an automated microscope that is capable of acquiring images from multiple colour channels and from a variety of plate formats, including 96-well plates (5). As this system also contains an autofocus feature, an entire 96-well plate can be assayed without manual intervention. To demonstrate this platform, a functional assay to assess the secretion of a transmembrane marker protein was carried out. Such systems will inevitably become more widespread and more sophisticated, so that functional assays will become possible on a proteome-wide scale.

The approaches described here largely relate to experiments that utilise protein over-expression as a means to screen for function. However, as a result of the relatively recent discovery and application of **small interfering RNAs** (siRNAs) to effectively down-regulate proteins in mammalian cell systems, functional assays can now be used to screen cells that are depleted in specific proteins. Furthermore, if fluorescently labelled siRNA molecules are used, it is

again relatively easy to adapt the screening platform to specifically detect those cells that received the oligonucleotides. Although not all siRNA oligonucleotides are effective at down-regulating their target protein, combinations of siRNAs have been shown to have a greater efficacy and may ultimately provide the possibility of genome-wide knockdown screens.

Finally, it is worth considering the practicalities of routinely performing functional assays on the entire proteome of an organism. In order to undertake such a task, it is necessary to go beyond assays in plates and instead carry them out in a microarray format. ORFs and siRNAs can be spotted on to glass slides, then overlaid with cells that subsequently take up the nucleic acids in the presence of appropriate transfection reagent (6). The resulting highly localised transfected areas within a lawn of cells mean that functional assays on hundreds of proteins can be carried out on a single glass slide. Furthermore, since such nucleic acid spotting requires only small amounts of material to create many identical arrays, the assays should be highly reproducible. Arrays representing the human genome are already commercially available, and so it is only a matter of time before this is also the case for arrays of tagged ORFs, which are more suited for functional assays.

Clinical Relevance

Currently the application of functional assays to biological problems remains in the research laboratory. This is primarily because at this time most of the proteome is still uncharacterised and also because the development of robust large-scale functional assays is still in its infancy. However, as more diseases become associated with specific protein dysfunction, the need for established functional assays to assist clinical work will increase. In the field of intracellular protein transport, which encompasses both secretion and endocytosis, a whole variety of diseases can now be attributed to defects in a variety of transport machinery molecules (7). Assays that address such fundamental biological processes should prove essential to reconcile the results from proteomic projects with further understanding of the molecular biology of disease. Ultimately this is the purpose of primary biomedical research.

Functional Group

Definition

Functional group refers to a defined arrangement of atoms that recursively occurs in molecules and stands for particular properties of these molecules. For example, carbonic acids possess a carboxylate group as functional group ($-\text{COOH}$) that can release a proton and form polar or hydrogen-bonding interactions.

Functional imaging represents a range of microscopic techniques in which the aim is to extract quantitative information about structure and physiological function from image based fluorescence data. Using ► [confocal laser scanning microscopy](#) (CLSM) the dynamics of molecular mobility, protein protein interactions, processes of signal transduction and structural characteristics of cell surfaces can be examined.

Description

Use Of Caged Compounds

Caged compounds are an elegant means of producing rapid jumps in the concentration of chemical messenger molecules inside cells. These compounds are photolabile, inactive derivatives of biologically active molecules, whose biological activity has been disabled by a photoprotecting or caging group. Caged compounds can be applied to cells under steady-state conditions without evoking biological responses. The biologically active substance is rapidly released by a

photochemical reaction. Flash photolysis using near-UV light cleaves the modifying group and rapidly generates the biologically active molecule (1). For many applications, it is useful to determine quantitatively the degree of photolysis of the caged compound inside cells. In a few cases this has been possible by rather complicated calibration of the cellular reaction. With novel caged compounds this quantitative determination is feasible by measurements of fluorescence (2).

Fluorescence Photobleaching Techniques

Fluorescence recovery after photobleaching (FRAP) and the related FLIP technique (fluorescence loss in photobleaching) are popular methods that utilize changes in the recovery of fluorescence after local bleaching events to measure the dynamics of 2D or 3D molecular mobility, e.g. diffusion or transport of fluorescently labeled molecules in membranes or inside living cells (3). Fig. 1 shows the schematic of both procedures. FRAP enables the measurement of the relative mobility and the fraction of mobile fluorophores. With FLIP it is possible to measure the continuity and transport between two populations of fluorophores. Fig. 2 shows the relative fluorescence intensity within the bleach region plotted as a function of time. Some methods calculate the effective diffusion coefficient D_{eff} directly from the time ($t_{1/2}$) to reach half final intensity I_H . But to calculate D_{eff} as accurately as possible, I must be corrected for the background intensity and the amount of total fluorescence removed by the bleach.

Very recently, another FRAP related method was described (4) and named FLAP (fluorescence localization after photobleaching). In this type of experiment, the molecule of interest is labeled with two fluorophores, e.g. CFP and YFP, one to be bleached and the other to act as the reference label. This combination permits the monitoring of the localization of the bleached molecules themselves as the FLAP signal is

Functional Genomics, the Systematic Analysis of the Function of All Genes and Gene Products in Parallel

H. LEHRACH

Max Planck Institute for Molecular Genetics, Berlin, Germany

lehrach@molgen.mpg.de

Definition

Functional genomics is the systematic study of gene products and their functions in biological processes. Functional genomics deals with gene knockouts and their phenotypic characterization, gene expression profiles (mRNA or protein levels) in different tissues of an organism, the sub-cellular location of proteins, three-dimensional protein structure, post-translational modification and processing of proteins, protein-protein interactions, and many more functional aspects of gene products that can be assayed systematically and at high throughput.

► **Structural Genomics: Structure-to-Function Approaches**

Introduction

In a sense, life can be considered a ‘computational’ process: The organism ‘computes’ its phenotype from the information in its genome, modulated by the environment as well as by some random components. This ‘computation’ is carried out by a complex network of processes, involving many of the genes and gene products of the organism. These networks have evolved over billions of years, translating the information in the genome into the phenotype. Selection of phenotypes therefore selects the genome, driving evolution.

Diseases are disturbances in these networks, usually caused by some combination of genetic and environmental factors. Understanding the disease mechanism will therefore require an understanding of both the underlying network in its normal, healthy state and the exact disturbance leading to the disease. To understand such complex processes, we have, in the past, tried to subdivide the processes into individual segments, which could then be analyzed by small labs working in (relative) isolation. This approach has clearly been very successful in identifying many of the basic biological mechanisms, but has given us less than sparkling progress in solving other areas of major importance to us all. Little progress has, for example,

been made in improving the rates of cure of many common cancers.

The Limits of Classical Biology

This slow progress in many important areas could very well be due to very basic limitations in our current approaches to understanding biology. It is, for example, not proven (and in my view not even likely), that all important problems in biology can be effectively approached by the divide and conquer strategy we have been using up to now. Biological processes, like neural networks, have evolved without any regard to the ease with which they can be subdivided and therefore effectively studied by our current strategies. Neither neuronal networks, nor many problems in mathematics (e.g. the traveling salesman problem), can be effectively subdivided in this way. Are we reaching the limits of our current strategy (as well as the organizational structure science has developed to implement this strategy)?

Functional Genomics, a Major Step Forward

In functional genomics, the systematic analysis of the functions and interactions of the genes and gene products encoded by the genome, we do have a key new tool in hand to put biological research on a new basis. Functional genomics is however also a key to progress in many of the real world problems we are facing. Like the situation in an analysis of a neural network, we will probably have to identify and analyze essentially all components of the complex processes we are investigating, rather than being able to concentrate on a few ‘interesting genes’ supposed to carry out the key steps of a process.

To try to understand the functions of all the genes of the organism, we have to be able to analyze the entire flow of information from the gene to the effect changes in the gene have on the phenotype of cells and ultimately of the organism, covering essentially all the types of analysis that have been traditionally used to try to understand the function of a single gene in classical (molecular) biology.

Since the function of a gene cannot be separated from the analysis of its expression pattern (transcriptomics) or the analysis of the structure and function of its protein product (proteomics) or even the analysis of the metabolic changes caused by e.g. the inactivation of a gene (metabolomics), these (and other -omics approaches) are all legitimate parts of functional genomics (proteomics is however covered in a separate article in this book and will therefore not be treated in this review).

Such an identification and analysis of thousands or tens of thousands of components (genes, gene products, metabolites etc.) can be carried out most easily by

systematic, highly automated procedures, incorporating mechanisms to control the processes carried out, to track samples and results and to eliminate errors as much as possible. Since functional genomics relies much more on systematic, automated data production, it is in many respects more efficient than the normal, manual strategy of producing data in biological research. Systematic data generation makes it much easier to standardize conditions and materials used and, since automated procedures are typically easier to control, data will often be of higher quality and will generally be more easily accessible, since they can be more easily submitted to the corresponding databases. The function of each gene can however be defined on many (at least three) levels. It can for example be defined in molecular terms (e.g. protein kinase), in the context of the cell (e.g. cell-cycle regulator) or in the context of the entire organism (e.g. recessive embryonic lethal). It is therefore very difficult to define the function of a gene in a straightforward fashion. To make the situation even more complex, it is highly likely that each gene has multiple functions on each of these levels, making it even more difficult to assign a clear function for each gene. In a sense, we might therefore most easily describe the function of any gene implicitly by computer models (of a complexity approaching the complexity of the organism itself (systems biology) of the processes in which it (and its gene products) are involved. The ultimate goal of functional genomics can therefore be defined as being able to compute the phenotype of organisms from their genomic sequence (as well their environment). In this sense, functional genomics will be a core research activity for many decades (if not centuries). Only after this goal has been achieved we can really argue that we have entered the 'post genomic' phase of biological research.

Genomic Tools

The primary information about the genes in an organism is provided by the sequence of its genome. If this information is not available, the analysis of expressed sequences can provide information on the most abundantly expressed genes. Gene identification can be carried out by a number of techniques.

The first phase of this work, the determination of the genomic sequence of many of the key organisms, provides an essential background to any of this work. The sequence of the human genome (1), as well as of the genomes of many other organisms including mouse (2), rat (3), chicken, *Fugu* (4), *Ciona* (5), *C. elegans* (6), *Drosophila* (7), *Arabidopsis* (8), *S. cerevisiae* (9) and *S. pombe* (10) to name a few (see also ►<http://www.ensembl.org/> or ►<http://genome.ucsc.edu/>), have been determined. In addition, a

number of other systematic analyses have been carried out at the transcript level [German cDNA sequencing consortium (11), FANTOM encyclopedia of mouse genes (12), IMAGE consortium (13), TIGR gene indices (14)]. These analyses have given us information on many of the basic components (genes, transcripts, proteins) of a large number of organisms.

Gene Predictions

To identify the functions of all genes, we first have to be able to identify them within the sequence of the genome. This problem is fairly straightforward for a subset of the genes, namely those coding for proteins. This is partly due to the improvements in informatics tools available, with Genscan being probably the most widely used program (15). Basically, all prediction methods are combinatorial approaches based on, e.g. splice site detection, multimer and motif statistics etc. together with artificial intelligence (AI) techniques like neural networks or HMMs.

Important roles are however also played by the results of sequence comparisons and the large amount of information from the analyses of expressed sequence tags (ESTs) available for a large number of organisms. Based on different types of information, our estimates for the number of protein coding genes in the human genome has continued to decrease, from initial estimates of 100,000 or higher to current estimates of between 20,000 and 25,000. Information on the current best estimates of the identity and structure of these genes is available for many organisms with completely sequenced genomes from the ENSEMBL project (www.ensembl.org) and the UCSC bioinformatics center (►<http://genome.ucsc.edu>), both based on an automated analysis pipeline. For selected organisms (*D. melanogaster*, *C. elegans*, yeast etc.) species specific databases, which tend to be hand curated, are generating additional information (www.flybase.org, www.wormbase.org), which in turn enters the automated annotation systems.

Recently, a very interesting experimental approach to gene prediction was introduced. A high-resolution oligo chip covering specific regions of the human genome was shown to be able to detect many novel loci with potential transcriptional activity (16).

Evolutionary Analysis

One of the most important sources of information on the functional importance of specific segments of a gene or of a specific element in the genome is provided by its evolution. Regions that are functionally important tend to be more conserved than those that have no clear function. On the other hand, genes that are under strong positive selection can be evolving faster than regions without any discernable function. In

protein coding genes, this can, for example, be recognized by comparing the rate of evolution of nucleotide positions that do not lead to a change in the amino acid of the protein (e.g. many changes in the third base of a codon), kS, with the rate of evolution of those that do change the amino acid, kN, of the encoded protein (kS/kN). Especially for closely related species like human and chimp, a detailed analysis by genome-genome comparison can deliver deep insights into the evolutionary dynamics (17), e.g. the unexpectedly high mutation rates in 5' UTRs of protein coding genes in humans compared to the chimp. Evolutionary analyses are getting more straightforward, as more and more genomes are completely sequenced and analyzed and can provide insights into the mechanisms of evolution by comparisons even between distant genomes (e.g. *C. elegans*, *D. melanogaster*, and vertebrates like mouse, man, etc.). Based on the genome and transcript/protein sequences of several invertebrate and vertebrate species, two independent studies (18,19) recently provided new arguments for a genome-wide duplication event at the transition from invertebrates to vertebrates, which could be dated to around 600 million years ago (under the assumption of a molecular clock model).

Identification and Analysis of Transcripts

Transcript Identification

A major effort has been invested world wide in cDNA analysis projects in order to gain an overview of a major fraction of the genes of an organism, to analyze the structure of the transcript or transcripts produced from each gene and to gain some insights into the abundance of transcripts in different tissues and at different stages of development. ► **Expressed sequence tags** (ESTs) have been generated for many organisms, many tissues and many stages of development. For instance, there are 149 species for which EST projects have been initiated, for which dbEST, the data base of expressed sequence tags (► www.ncbi.nlm.nih.gov/dbEST), contains over 10,000 entries per species (Release 092404; Sept. 24th, 2004). The six top species (number of ESTs in brackets) are human (5.9 Mio), mouse (4.2 Mio), *Ciona intestinalis* and rat (684000 each), zebrafish (575000) and wheat (561000). To shortcut the procedure of generating comprehensive gene catalogues for selected species, alternative techniques have been developed and used in an attempt to generate sufficient sequence information to recognize each transcript at lower cost than *via* the sequencing strategy.

As an example, oligonucleotide fingerprinting has been used in a number of projects to identify new genes as a powerful means to reduce complexity prior to sequencing (20), e.g. in *Amphioxus* (21), sea

urchin (22), zebrafish (23), mouse, medaka and sugar beet (24). Since the information generated covers the entire transcript, this procedure should, in principle, also be better at identifying specific splice forms than the EST strategy.

Other procedures have attempted to identify short sequence elements (sequence tags) within each transcript in order to be able to quantify the abundance of transcripts in different materials. Examples of such approaches are ► **serial analysis of gene expression** (SAGE) (25) and massively parallel signature sequencing technology (MPSS) that involves microbead arrays (26).

Alternative Splice Products

Alternative splicing contributes significantly to human proteome complexity and allows large proteomic complexity from a limited number of genes. It explains to some extent the difference between the low number of human protein-coding genes and the number of human proteins. Annotation of the human genome shows that alternative splicing is a major cause of transcriptome diversification.

The bulk of intron-containing transcripts are alternatively spliced. A single primary transcript yields different mature RNAs leading to the production of proteins with diverse functions.

More than 45% of the genes in the human genome have alternative transcripts ranging from two to 40. 50% of these genes have alternative promoters. The human genome is currently annotated with 23,245 gene loci (NCBI Build 34). For these loci over 43,000 transcripts are known. Despite an early report that most alternative splices occur within the 5'untranslated region, recent studies indicate that 70–88% of alternative splices change the protein product. The majority of these changes appear to be functionally interesting, such as replacement of the amino or carboxy terminus, or in-frame addition and removal of a functional unit.

Bioinformatics studies have reported that about 25% of genes have alternative polyadenylation forms (mRNAs that are cleaved and polyadenylated at different sites). In addition 6,418 of the annotated loci have two or more promoters. These numbers show that most of the genes are highly flexible entities with regard to transcripts and regulation. It has been estimated, that 15% of the point mutations that cause human genetic disease affect splicing (27). Alternatively spliced exons are typically identified by aligning EST clusters to reference mRNAs or genomic DNA. A high rate of false negatives is the greatest disadvantage of methods that require mapping ESTs to the genome sequence. This approach is not useful for genomes that lack robust EST coverage.

Non-messenger RNAs

For a long time non-messenger RNAs (nmRNA) were regarded as a somewhat exotic class of RNAs with very few members known. The most prominent ones were structural RNAs (tRNA, ribosomal RNA, snRNA) and a handful of classic examples like Xist (28) (X inactivation) or H19 (29) (tumor suppressor RNA). Only recently has the detection of the micro-RNAs and small interfering RNAs (siRNAs) (30) produced remarkable scientific and technical interest in the fundamental roles of nmRNAs, which is, for example, reflected in the repeated election of small nmRNAs as “Molecule of the Year” or runner-up in Science Magazine (31).

In the last few years, several large-scale studies gave rise to the question as to whether the number of nmRNAs active in regulation, suppression and modification of mRNAs and their protein products hadn't been notoriously underestimated. Recently, Affymetrix scientists (16) tested the transcriptional activity in the human genome. A novel high-resolution chip covering the entire human chromosomes 21 and 22 with evenly spaced oligonucleotides revealed a ~10-fold higher proportion of non-genic transcribed regions, many of which could be verified by subsequent experimentation. Analysis of the mouse FANTOM cDNA collection published by members of the RIKEN consortium resulted in the surprising detection of at least several thousand large RNAs that exhibit features of mRNAs, but do not contain any significant open reading frames (32).

It may be speculated that the increased complexity of higher vertebrates as compared to invertebrates (e.g. *C. elegans*) cannot be explained by a mere 1.5-fold increase in protein-coding genes, but might be based on a complex network of non-protein coding sequences (33).

Analysis of Transcript Levels

Sequence identifiers are used to analyze transcript abundance in ‘electronic Northern’. As data continue to increase, the reliability of the information is similarly increased. A significant difficulty in establishing these ‘electronic Northern’ is, however, the accurate description of the material used to make the library, the need to eliminate normalized libraries from the analysis and the complex relationships between the different descriptions.

The use of DNA or oligonucleotide arrays to probe the abundance of transcripts has constituted a revolution, since it allows the large-scale analysis of the transcriptome level of tens of thousands of genes in parallel within one single hybridization experiment. Originally based on the DNA and clone array format developed by us in 1987 (22, 34, 35), it has

been extended later to a number of other formats. The main differences in the formats arise from the nature of the DNA probes, the labeling procedures and the material of the solid array surface. A particularly useful variant has been oligonucleotide chips (36, 37, 38) with (typically short) oligonucleotides either synthesized *in situ* by a variety of techniques or (longer oligonucleotides, e.g. 70 mers) spotted after synthesis. A number of successful commercial formats are available (for example Affymetrix, Agilent). Furthermore, more and more chromosomes are mapped to so-called tiling arrays that represent the entire (non-repetitive) genomic sequence of the chromosome by oligonucleotides, which has contributed additional information on transcripts outside the canonical gene set (16, 39).

For all these analyses significant amounts of material (typically in the range of micrograms of total RNA) have to be generated. The development of amplification procedures has contributed to a decrease in the requirement for material and has, for example, allowed the analysis of material microdissected from tissue sections. This application is particularly important in the analysis of cancer tissue containing many different cell types (40). Though these types of microdissection and similar procedures have contributed to increasing the anatomical resolution achieved, this is nevertheless the weak point in most of the techniques that analyze the expression levels of many genes in parallel.

In situ hybridization techniques, in contrast, are typically only able to analyze the expression level of a single gene at a time, but can achieve very high anatomical resolution. They are therefore much better in the identification of spatial expression patterns. Such analyses have, for example, been carried out systematically in the mouse using the whole mount *in-situ* hybridization technique (41, 42). Even higher anatomical resolution, down to the single cell level, can be achieved using *in situ* hybridization to frozen sections (43).

A weak point in all these analytical techniques is still the identification of the expression patterns of different splice forms, since this type of hybridization will typically score the overall abundance of different exons, which can, however, be parts of alternatively spliced transcripts. For this, additional techniques will have to be developed.

The chip-based analyses are still error prone and the correlation between different platforms is rather low. Thus, they require verification with independent techniques at the single gene level, mostly performed by RT-PCR or Taqman analysis.

Other techniques, which have been quite popular for some time, are now being used less often. An example

of this is the technique of differential display, based on the selective amplification of sequences by short oligonucleotides. Similarly, differential cloning is now being used rarely in those systems for which an abundance of information is available (man, mouse, rat). It is, however, still useful for organisms for which gene sets are not well defined and genomic sequence is not available.

Proteomics

Since the function of many genes is to code for proteins, proteomics, the systematic analysis of the structure and function of proteins, is an essential component of the functional genomics of protein coding genes. This topic is covered in detail in [►Proteomics – from Proteins to Disease Mechanisms and the Development of Novel Therapeutic Strategies](#).

Analysis of Gene and Protein Function in Cells

A number of aspects of gene (and protein) function can be most easily studied in cell systems. Examples are localization in the cell, the effect of protein over-expression or elimination of a protein by [►RNA interference](#) (RNAi) on a cell phenotype and the analysis of protein-protein interactions in mammalian cells. The analysis can be carried out on the microtiter plate scale, using automated equipment to handle the large number of plates that have to be analyzed in any realistic experiment. Some types of analysis can also be carried out on a smaller scale (cell chips), considerably reducing the effort involved in the analysis of many samples in parallel.

Protein Localization

The intracellular localization of the gene product can provide important information about its function, due to the high degree of compartmentalization of the cell. Most protein activities can be assigned to particular cellular compartments. Moreover the interactions of the proteins within regulatory networks rely to a large extent on proper localization of their components. Together with other functional data such as the sequence of the gene, its expression profile and the expression, modification and interaction of its product with other proteins, information about the distribution of the protein within the cells contributes significantly to integrative functional characterization of the gene. Until recently protein localization studies have been limited to a particular gene of interest. Accomplishment of the mouse and human genome project resulted in a vast number of sequences of unknown function. As a result the demand for a high throughput functional genomics solution has been growing. Hitherto functional analyses of genes have been performed on an individual basis, thus creating a

bottleneck for analysis of gene expression data. Recently several attempts at genome-wide functional analysis have been made in budding yeast (44, 45) and, to a lesser extent, man (46).

In addition to micro-well based assays, transfected cell arrays offer a robust platform for protein localization studies, allowing the simultaneous screening of a large number of novel genes, thereby reducing the amount of reagents (antibodies and dyes for counterstaining for particular organelles) and cells per assay (see section Cell Arrays below).

RNAi, Morpholinos, Antisense Constructs

RNA interference (RNAi) is the post-transcriptional silencing of gene expression that occurs in response to the introduction of double stranded RNA into cells. Application of RNAi in experimental systems has provided a quantum leap in the elucidation of gene functions.

In this approach, short, double stranded RNA molecules are used to trigger a cellular response, leading to the destruction of the corresponding transcripts. For short lived proteins and for rapidly dividing cells, this will lead to a reduction in the concentration of the corresponding protein, reaching, in some cases, an almost complete elimination. A number of strategies have been developed for use in mammalian cells, using short chemically synthesized oligonucleotides, short double stranded RNA products generated *in vitro* from longer ds RNA generated from appropriate DNA constructs *in vitro* or vector systems able to produce short double stranded RNAs *in vivo*.

To facilitate large-scale functional genomics studies using RNAi, several high throughput approaches have been developed based on microarray or micro-well assays. The recent establishment of large libraries of RNAi reagents combined with a variety of detection assays further opened the door for genome-wide screens of gene function in mammalian cells. For many systems this new strategy has replaced similar strategies developed earlier (the use of morpholino containing oligonucleotides to block translation, the use of antisense oligos or RNAs).

Protein Over-expression

The influence of specific genes on cellular phenotypes can be most easily studied by either reducing or eliminating the protein (e.g. by RNAi) or by increasing its level (e.g. by transfecting the coding sequence under the control of a strong promoter). The effects of over-expressing a gene on the phenotype of a cell can be analyzed by a range of cell biological assays. Changes in cellular localization patterns as determined by immunofluorescence techniques or the

effect of each gene on, for example, cell-cycle or apoptosis can be determined in micro-well based assays or in high throughput assays such as transfected cell arrays.

Cell Arrays

A recently described, novel cell-based microarray system, called the transfected cell array (TCA) (47) paved a way for high throughput gene analysis in the field of functional genomics. The principle of the TCA technique is based on the transfection of DNA or RNA molecules immobilized on a solid surface into mammalian cells with subsequent detection of the physiological effects caused by the introduction of the foreign nucleic acid in these cells. Briefly, full-length open reading frames of genes inserted in expression vectors are printed at a high density on a glass slide along with a lipid transfection reagent using a robotic arrayer. When the microarray of DNA constructs is covered with a monolayer of adherent cells, only the cells growing on top of the DNA spots become transfected, resulting in the expression of specific proteins in spatially distinct groups of cells. The phenotypic effects of this reverse transfection of hundreds or thousands of genes can be detected using specific cell-based bioassays. Cell arrays can be used for the large-scale analysis of protein-protein interactions (mammalian two-hybrid), gene silencing (siRNA, double stranded "decoy" oligonucleotides, morpholinos), promoter activity and the subcellular localization of proteins.

Analysis of cell arrays is restricted to those phenotypes that can be easily scored under a microscope and can be analyzed effectively in spite of the fact that typically only a fraction of cells take up the DNA or siRNA (fluorescent assays, other easily detectable phenotypes like apoptosis etc). However there are a number of advantages in using cell arrays as compared to functional assays performed on mammalian cells in micro-well plate format. The array approach requires fewer cells per number of genes tested. This is especially relevant for human primary cells (cells recently isolated from organs or tissues) since only small numbers of these cells can be isolated out of a tissue and the *in vitro* expansion of these cells is rather limited. Although primary cells are notorious for their low capacity to be transfected, reverse transfection of these cells is possible, but it requires careful optimization of the experimental conditions for each cell type tested (48). Transfected cell arrays also require far less DNA/RNA as well as transfection and signal development reagents as compared to assays performed in microwell plate format. Since in the case of high throughput technologies the cost of the single sample analysis must be reduced to an

absolute minimum, cell arrays are at the moment the most effective functional genomic tool available.

Cell arrays (47) offer a particularly efficient route to analyzing the effects of many genes on specific phenotypes of the cell. In this approach, DNA constructs, siRNAs or other effectors are spotted on glass arrays in some matrix (e.g. gelatin plus lipofection reagents). The chips are then covered with appropriate indicator cells and the effect of the reagent on the phenotype of the cell is observed. Since thousands of constructs can be analyzed on a single chip using this approach, this procedure offers a chance to analyze the effects of most or all of the genes of the genome on a particular phenotype. The analysis is however restricted to a number of phenotypes that can be scored easily under a microscope and can be scored effectively in spite of the fact that typically only a fraction of the cells take up the DNA or siRNA (fluorescent assays, other easily scoreable phenotypes like apoptosis etc). Other phenotypes will therefore have to be converted into phenotypes scoreable in this format, e.g. by introducing an appropriate indicator construct that translates the primary phenotype into a fluorescence signal.

The transfected cell array can be regarded as a sophisticated protein expression system where location of particular proteins on the slide can be identified by the coordinates of the arrayed cDNA. Cell arrays can, for example, be used for identification of disease related proteins by analyzing the binding of patient sera on arrays of expressed cDNA libraries, leading to identification of molecular diagnostic markers. Furthermore, the cell arrays are also well suited for screening of small molecules such as G-protein-coupled receptors for their ability to interact specifically with protein targets. Again, cell microarrays present a more advanced alternative to standard protein arrays, since in TCA the proteins are synthesized *in situ* in the physiological environment of the cells, thus enabling proper post-translational protein folding and glycosylation. Furthermore, cell arrays represent a powerful functional genomics tool for target gene identification. Through the accurate selection of cell line properties and signal detection assays, usage of cell arrays on a genome-wide scale can rapidly lead to identification of target genes related to particular diseases.

Analysis of Gene Function in the Organism

Ultimately the function of each gene has also to be studied in the organism itself, work that is typically being carried out in model organisms. The mouse especially has been an incredibly effective system for this type of analysis, due to the genetic resources and the highly developed tools to manipulate the mouse

genome. We will particularly focus here on approaches to identifying the phenotype associated with a specific gene or a specific set of genes (gene driven approaches). In addition, there are many types of analysis that start from a phenotype, aiming to identify the gene or genes involved (phenotype driven approaches). While in man for obvious reasons only phenotype driven analyses are possible, model organisms typically allow both gene driven and phenotype driven approaches.

Transgenic Animals

For a number of different model organisms (mouse, rat, zebrafish, ►*C. elegans*, ►*D. melanogaster*) genes can be efficiently introduced into the germ line, allowing detailed analysis of the function of a single gene. Use of tissue specific or inducible promoters allows the analysis of gene function in only a single tissue or after addition of an appropriate inducer (or withdrawal of an inhibitor).

Homologous Recombination

For the analysis of the function of a single gene, homologous recombination offers the possibility of introducing very specific changes in the genome. This technique works exceedingly well for a number of lower eukaryotes (e.g. *S. cerevisiae*, *Physcomitrella*), but has also become the main tool in analyzing gene function in the mouse. Mutations are introduced by homologous recombination into the genome of an embryonic stem (ES) cell and then introduced into the germ line (49,50), allowing detailed functional analyses by standard mouse genetic techniques. Changes introduced can range from the exchange of a single base pair to the introduction of large-scale rearrangements or deletions in the genome.

Gene Traps

A high throughput alternative for the analysis of gene function in the ES cell or the organism is provided by the gene trap system, based on the random insertion of DNA sequences into the genome of a mouse ES cell (51). The gene trap vector is designed so that a reporter/selection cassette (b-Geo) can be spliced onto an endogenous gene transcript if the construct inserts into an intron of an actively transcribed gene in the appropriate orientation. An internal ribosome entry site (IRES) allows expression of the reporter/selection cassette independently of the reading frame of the endogenous transcript. This comparatively rare event can therefore be selected (for neo/G418 resistance) and analyzed further to determine in which gene and in which position of this gene the insertion has taken place. Insertions can either be obtained by transfection of DNA fragments or by the use of appropriate

retroviral constructs. A number of efforts to construct complete gene trap libraries have been performed and have resulted in a large library of ES cell lines carrying insertions in defined genes (52). Several additional modifications of this principle have been designed (poly A trap, trap vectors enriching for secreted proteins, insertions generating conditional mutations etc.).

Chemical Mutagenesis, Tilling

An additional approach to generate mutations in the genome, particularly useful for organisms, for which no equivalent to the mouse ES cell system exists, takes advantage of the high mutagenic potential of some chemicals (e.g. ethylnitrosourea, ENU). After treatment of the male with high doses of ENU, a high frequency of mutations can be generated. In combination with high throughput screening systems able to identify point mutants or deletions within a specific gene, this can be used to identify a set of animals carrying mutations within the gene of interest or in a specific gene region (53). A related strategy has, for example, been used to generate the equivalent to a knockout mutation in the rat, in which the standard knockout procedure is not possible (54). Other successful examples are archives of small genomic deletions in *C. elegans* (55, 56), and phenotype-based mutagenesis screens in mouse (57, 58), zebrafish (59) and medaka (60). Chemical mutagenesis can also be applied to mouse ES cells (61, 62), holding great promise for the construction of allelic series within the genes of interest (63).

RNAi Constructs

RNAi has been used very successfully to degrade specific transcripts in a number of organisms. While the largest screens have been carried out in *C. elegans*, using a number of different approaches, an analogous strategy is increasingly being used in mouse ES cells or mouse embryos. In this case, specific vectors have to be constructed that are able to produce a primary transcript that can be processed to give the appropriate interfering RNA *in vivo*. Compared to most of the other systems (gene traps, knock-outs, ENU mutagenesis), this strategy has the enormous advantage of being able to produce dominant mutants, since a single copy of the construct will typically be able to inactivate the transcripts from both chromosomes. Most vector systems used contain a RNA polymerase III promoter driving the synthesis of short hairpin RNAs (shRNA) in mammalian cells. These are then processed intracellularly into siRNA-like molecules. ShRNAs turned out to be as effective as siRNA and moreover can exert their silencing effect over longer periods of time. Alternatively, two tandem pol III promoters have

been used to obtain sense and antisense siRNA sequences from expression constructs (convergent transcription). The silencing effect can be further extended using adenoviral, retroviral or lentiviral RNA expression vectors. Greater versatility and more refined applications will become possible with the development of cell- and tissue-specific RNAi expression constructs. Although most of the RNAi inducing systems were used for the specific silencing of a limited number of genes, large siRNA expression libraries in high throughput RNAi screens would allow for the identification of new genes involved in different cellular processes. In fact, efforts are underway to develop larger siRNA expression libraries and use of these libraries in cell-based RNAi screens is already generating important results.

Databases, Systems Biology

Databases

The collection and use of information from functional genomics approaches represents a major challenge to bioinformatics/computational biology. In contrast to sequence databases, which are restricted to a single data class, data from functional genomics experiments can be extremely complex and are typically only useful if a large amount of information on the experiment, the materials used, the exact experimental conditions etc is provided. In addition, many experiments are technically only feasible (or at least possible) in particular species. It is therefore essential to combine functional genomics information across many organisms, based on the orthology between the genes in the different species.

A number of relevant databases have been developed. Expression data, for example, have dedicated databases (ArrayExpress ►<http://www.ebi.ac.uk/arrayexpress/>, Gene Expression Omnibus ►<http://www.ncbi.nlm.nih.gov/geo/>, GenomeCubeTM Express ►<http://www.rzpd.de/asearch/>), in which expression data following the MIAME standard (Minimum Information About a Microarray Experiment, ►<http://www.mged.org>) can be deposited. There are a number of databases for protein interactions (Biomolecular Interaction Network Database (BIND) ►<http://www.bind.ca/>, Database of Interacting Proteins ►<http://dip.doe-mbi.ucla.edu/>, Grid ►<http://biodata.mshri.on.ca/grid/>, Protein-Protein-Interaction (PPI) ►<http://mips.gsf.de/proj/yeast/CYGD/interaction/>, Worm Interactome (64) ►<http://vidal.dfci.harvard.edu/>), protein structure (Protein Data Bank (PDB) ►<http://www.rcsb.org/pdb/>), gene traps (German Genetrap Consortium (GGTC) ►<http://tikus.gsf.de/>, Sanger Institute Gene Trap Resource (SIGTR) ►<http://www.sanger.ac.uk/PostGenomics/genetrap/>, BayGenomics ►<http://baygenomics.ucsf.edu/>, Soriano gene trap lines ►<http://www.fhcrc.org/labs/soriano/trap.html>)

and many other aspects of functional genomics. In addition to these databases centered around the type of information they store, there are many organism specific databases, (Mouse Genome Informatics (MGI) ►<http://www.informatics.jax.org/>, Rat Genome Database (RGD) ►<http://rgd.mcw.edu/>, WormBase ►<http://www.wormbase.org>, FlyBase ►<http://flybase.bio.indiana.edu>, the Zebrafish Information Network (ZFIN) ►<http://zfin.org>, etc.) in which all data on the genes of a specific organism are usually stored, typically in curated form. Access to this information is however typically focused on gene-by-gene queries and is therefore not optimal for the display of information on thousands of genes at a time, typical of functional genomics problems.

This has been the main driving force behind the development of GenomeMatrix (www.genome-matrix.org), a database/data base interface system developed by us. In this, information on the different genes in the different organisms is displayed in the form of a matrix of colored rectangles, with each column representing one gene (and its orthologs in the other organisms displayed), while each row corresponds to one particular type of information relevant to understanding the function of the genes.

As far as possible, the information on one particular data type for one particular gene is represented by the color of the box (usually possibly for scalar information). The color of the box can for example identify the function of the gene (GO annotation), represent a quantitative measure (normalized expression levels for a gene displayed on a red-green or yellow-blue scale) or simply indicate that there is information of one particular type for this particular gene available (e.g. an X ray structure of a protein, a picture showing a developmental phenotype of a mouse knockout strain, a RNAi phenotype in *C. elegans* etc.). Clicking on the boxes then displays the information available, stored either locally or in a database or website anywhere in the world. Since this system has a very low overhead, it is easy to adapt to changes in the many databases holding the primary information, a feature required for any realistic system attempting to keep track of the multitude of relevant data produced worldwide.

Systems Biology

Ultimately any display of information will be useful to identify unexpected correlations, formulate hypotheses and plan new experiments. It will, in itself, not be sufficient to be able to use the information to make quantitative predictions from the enormous amount of data available (in the future possibly even on every single patient). This is the domain of systems biology. Here we do not only have the possibility of representing our entire knowledge of biological

objects, their interactions, their function etc. in a formalized language, these systems also allow us to make quantitative predictions, which can be verified or refined by further experiments in an iterative process and which can be used in many practical applications to guide e.g. the treatment of individual patients. This approach offers the possibility of testing a hypothesis in the computer before expensive developments, e.g. the development of a new drug. In a sense, functional genomics, the systematic generation of data on the function of all the genes of an organism only covers the aspect of producing the information required. Systems biology is the component that is essential to make this information useful and to enable us to use functional genomics to solve the many problems, which affect our daily lives.

Acknowledgements

represented by a simple difference image (unbleached fluorophore – bleached fluorophore). FLAP is therefore comparable with methods of photoactivation or uncaging fluorescent probes, but avoids exposing the living cells to harmful UV irradiation and takes advantage of the fluorescent proteins that can be expressed in living cells.

GFP (green fluorescent protein) fusion proteins are excellent reagents for use in photobleaching studies, because GFP inflicts much less photodamage on its surrounding environment than do other fluorophores (5). Either technique benefits from excellent confocal microscopy technology, which allows the monitoring of the dynamics not only of one fluorescent tag, but also of two or even more spectrally overlapping labels.

Fluorescence Resonance Energy Transfer

Fluorescence resonance energy transfer (FRET) is the non-radiative transfer of photon energy from a donor fluorophore to an acceptor fluorophore when both are located within close proximity (1–10 nm). Fig. 3 shows the scheme for this process. FRET can be used to reveal interactions between proteins or structural changes within a molecule (6). The method is very sensitive to

the distance between the fluorophores and thus can serve as an indicator of close proximity.

There are only certain pairs of fluorophores suitable for FRET experiments, since besides other prerequisites the donor emission has to overlap the excitation spectrum of the acceptor. Fluorescent proteins such as the green fluorescent protein (GFP) are very suitable for FRET experiments. They can be genetically fused to proteins of interest and expressed in cells, making them an excellent reporter system for gene expression and protein localization in living cells. Several enhanced fluorescent protein variants with different spectral properties are available. The cyan-colored CFP as donor and the yellow-colored YFP as acceptor are best suited for FRET experiments in living cells.

Fluorescence Correlation Spectroscopy

► **Fluorescence correlations spectroscopy (FCS)** is based on measurements of the fluorescence emitted from a small open observation subregion of the sample (7). This method uses statistical fluctuations in the intensity of the small illuminated sample volume to obtain information about the process that provokes these fluctuations. FCS is difficult to apply to cells but can provide important complementary information in

Functional Genomics, the Systematic Analysis of the Function of All Genes and Gene Products in Parallel.

Figure 2 The idealized plot of fluorescence intensity (I) as a function of time (t) shows the parameters of a quantitative FRAP experiment. The bleach region is monitored during a pre-bleach period to determine the initial intensity I_i . The region is bleached using high intensity illumination from time t_b to t_0 , and the recovery is started at t_0 with the intensity I_0 . The fluorescence intensity increases during recovery to the intensity I_F . I_H is the half final intensity $((I_F - I_0)/2)$, and $t_{1/2}$ the half life.

some circumstances. The measured quantities include translational diffusion, rotational motion, chemical kinetics, the fluorescence lifetime of the excited state, diffusion and interactions between molecules, and aggregation and self-association. So FCS can be used, e.g. to study interactions of ligand with its target

molecules/receptor, antibody/antigen interactions on the surfaces of prokaryotic or eukaryotic cells, interactions of antisense oligonucleotides or regulatory proteins with target DNA or RNA or enzymatic activity. To reduce background noise, two-photon excitation has been applied to FCS (8).

Functional Genomics, the Systematic Analysis of the Function of All Genes and Gene Products in Parallel.
Figure 3 The principle of fluorescence resonance energy transfer (FRET). ex_D —excitation of the donor; em_D —emission of the donor; em_A —emission of the acceptor; D_{max} —maximum of the fluorescence of the donor; A_{max} —maximum of the fluorescence of the acceptor.

Functional Genomics, the Systematic Analysis of the Function of All Genes and Gene Products in Parallel.
Figure 4 The principle of the atomic force microscope.

Fluorescence Lifetime Imaging Microscopy

In the fluorescence lifetime imaging microscopy (FLIM) method, image contrast in the fluorescence microscope is derived from the fluorescence lifetime at each point in the image. FLIM has the advantage of providing 2-dimensional maps of the fluorescence lifetime with high spatial and temporal resolution. Importantly, FLIM measurements are independent of probe concentration and photobleaching. FLIM also provides an opportunity to study the dynamics of the environment surrounding the fluorophores, using time resolved emission anisotropy. Fluorescence lifetime probes already exist for the measurement of e.g. oxygen concentration, Ca^{2+} , Mg^{2+} , Cl^- , pH and K^+ .

Scanning Force Microscopy

Scanning force microscopy (SFM), or atomic force microscopy (AFM), represents a unique approach to detecting structures and forces in the nanoscale range (9). Its major advantage is that it can produce high-resolution topographic images of the surfaces of biological samples in aqueous and physiologically relevant environments without the need to stain the specimen. The principle of this method is shown in Fig. 4. The potential to measure ultralow forces enabled detection of specific interaction forces on the single molecule level. Molecular recognition of a single ligand-receptor pair can be observed in its native environment. The interaction forces between the ligand-receptor combinations biotin-avidin, antibody-antigen, sense-antisense DNA, cell recognition proteins and NTA (nitrilotriacetate) -His6 (histidine 6) were thus quantified in recent years. In combination with a confocal microscope, it is possible to examine the cellular topography in contact imaging mode simultaneously with fluorescence detection (e.g. for the cytoskeleton) in living cells.

Functional Magnetic Resonance Imaging

Definition

Functional magnetic resonance imaging (fMRI) is a non-invasive technique used to visualize brain function. Changes in chemical composition of brain areas or changes in the flow of fluids that occur over timespans of seconds to minutes can be monitored.

► [In Vivo Imaging of Transgenic Mice with Fluorescent Protein Expression](#)

Functional Proteomics

Definition

Proteomics, the large scale identification of proteins by 1-D and 2-D gel-electrophoresis and mass spectrometry, is traditionally divided into two main areas: expression proteomics and functional proteomics. Functional proteomics comprises the analysis of the function of each protein encoded by the genome.

Functional Studies

Definition

An all-encompassing study of the function of an organism's genes and gene products, including transcriptional regulation, post-transcriptional processing, translational regulation, protein modification, protein interactions, etc. to understand basic mechanisms of gene regulation, structure and function. Functional studies often involve analyzing the effects of the

perturbation of normal gene/protein function (Mutational studies, overexpression/misexpression, knock-down/knockout studies, etc.).

Furin

Definition

Furin is a membrane-associated, calcium-dependent, serine protease that belongs to the subtilisin-like prohormone convertase (PC) family. Members of this family of cellular enzymes cleave most prohormones and neuropeptide precursors. Numerous other cellular proteins, some viral proteins, and bacterial toxins that are transported by the constitutive secretory pathway are also targeted for maturation by PCs. Retroviruses use furin to process the mature Env protein complex (by cleavage of SU from TM).

► **Retroviruses**

Fusion

Definition

Fusion characterizes a process which describes the merging of two originally separated membranes. Fusion plays an essential role in intracellular vesicular transport between organelles. Fusion also occurs at the level of cell-cell interaction. For example, during myogenesis myoblasts fuse to form myotubuli. Release of the genetic information of enveloped viruses such as influenza virus and Human Immunodeficiency Virus (HIV) into the host cells, requires the merger of the viral envelope membrane with the host target membrane. Fusion of biological membranes is a local process regulated by specific proteins.

► **Biological Membranes**

Fusion Domain

Definition

Fusion domain describes a hydrophobic region near or at the N-terminus of the retrovirus ► **TM** (transmem-

brane) protein, which is exposed to interact with the target cell membrane following interaction of the retroviral ► **SU (surface)** protein with the receptor.

► **Retroviruses**

Fusion Proteins

Definition

Fusion proteins are two proteins or protein fragments which are fused into one by means of recombinant DNA techniques.

► **Protein Tags**

► **Two-Hybrid System**

Fusion Tag

Definition

Fusion tag is a peptide or protein, capable of being detected experimentally, which is fused to one end of a protein of interest, via expression from recombinant DNA vectors, in order to analyze the expression of the protein of interest.

► **Immunochemical Methods, Localization**

Fyn

Definition

Fyn is a Src-family kinases and is implicated in the control of cell growth.

Gain-of-Function Screens

Definition

Gain-of-function screens are mutational screens based on the over- or misexpression of genes, aimed at detecting genes that may show no loss-of-function effect. Ectopic expression of an endogenous transcription unit adjacent to the 5' end of the randomly integrated P element is dependent on the expression of the GAL4 gene (*Drosophila melanogaster*), and thus may be spatially and temporally controlled.

- [Drosophila as a Model Organism for Functional Genomics](#)

GAL4–Expression System

Definition

The GAL4–expression system is a method for directed gene expression that can be used to misexpress genes in specific cell types, or tissues, at different times of development. This system relies on the generation of transgenic lines that carry “activator” or “effector” constructs. Activator lines express the yeast transcription factor, Gal4, under the control of a desired promoter, whereas effector lines contain DNA binding motifs for Gal4–(UAS) linked to the gene of interest.

Gamma Rays

Definition

Gamma rays are an energetic form of electromagnetic radiation produced by radioactivity or other nuclear or subatomic processes such as electron-positron annihilation. Gamma rays are often defined to begin at an energy of 10 keV, although electromagnetic radiation from around 10 keV to several hundred keV is also referred to as hard X-rays. Gamma rays are a form of ionizing radiation; they are more penetrating than either alpha or beta radiation (neither of which is electromagnetic radiation), but less ionizing.

► [Molecular Imaging](#)

Gammaretroviruses

Definition

Gammaretroviruses refers to the genus of simple retroviruses that includes murine and feline leukemia viruses. Many species contain oncogenes and cause leukemias and sarcomas.

► [Retroviruses](#)

Gammaretroviruses IN (Integrase)

Definition

Gammaretroviruses IN (integrase) is the retrovirus virion enzyme, and is a product of the pol gene.

► [Retroviruses](#)

Gamma-Secretase (Complex)

The γ -secretase (complex) is a multimeric complex that is composed of at least four different transmembrane proteins (presenilin 1 or presenilin 2 (► [PSEN1/PSEN2](#)); (► [APH-1](#)); nicastrin; PEN-2). The last step of ► [amyloid](#) generation from amyloid precursor protein (► [APP](#)) is performed by the γ -secretase complex. The γ -secretase is also important in other pathways, as for example in the cleavage of ErbB4, intra cellular domains of Notch, and similar types of proteins.

Gap

Definition

A space introduced into an alignment to compensate for insertions or deletions in one sequence relative to another.

► [Protein Databases](#)

Gap Junctions

W. HOWARD EVANS

Medical Biochemistry and Immunology, Cardiff University School of Medicine, Cardiff, Wales, UK
wmbwhe@cf.ac.uk

Definition

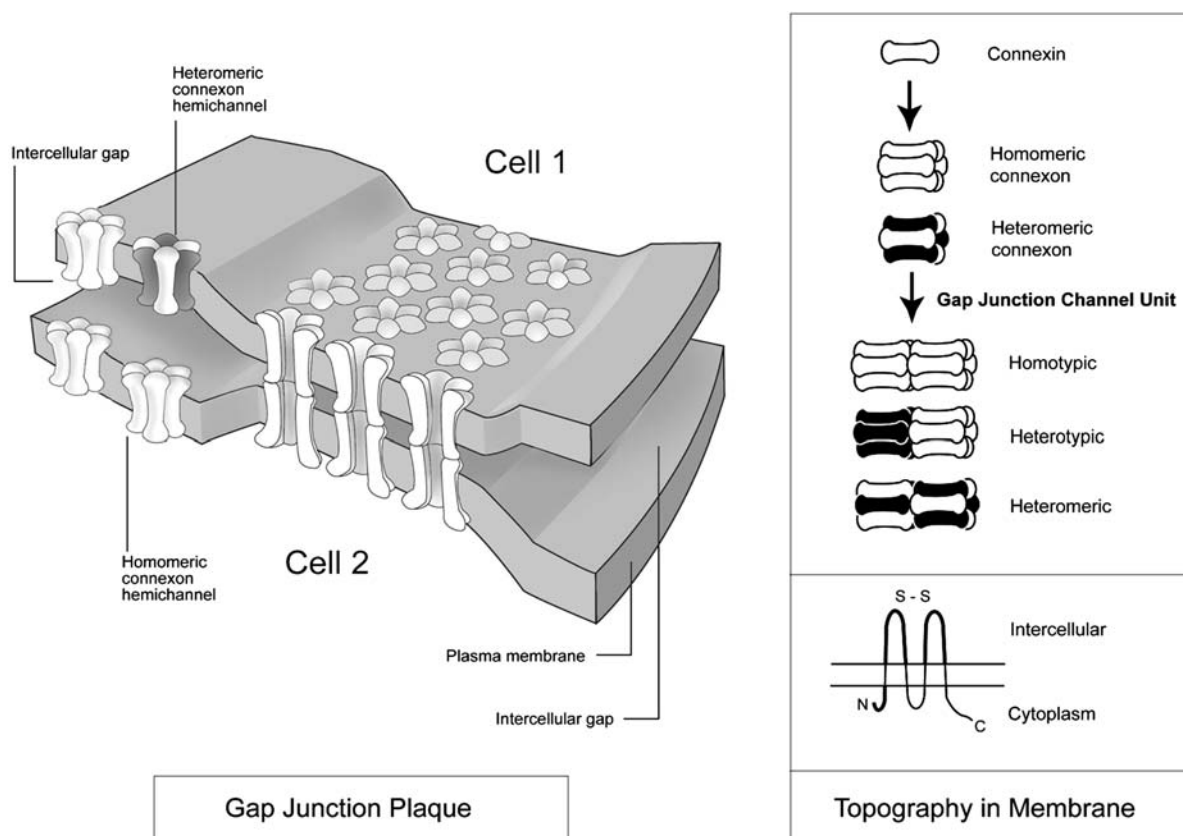

Gap junctions comprise minute regions of the cell's plasma (surface) membrane containing arrays of closely packed membrane channels. These channels traversing two aligned membranes separated by a 2–3 nm intercellular gap provide a communication pathway that directly connects cell interiors (Fig. 1). Communication across gap junctions enables single cells to co-ordinate, integrate and summate their metabolic and electrical interactive activities but also results in some loss of independence. Co-operation and harmonisation of cellular activities in tissues and organs is vividly illustrated by the ordered contraction of heart muscle, made possible because the beating of individual cells is synchronised and summated to the organ level by interactions facilitated by gap junctions. Indeed, each cardiac myocyte can communicate with about a dozen or more surrounding partner cells. In the brain, gap junctions enable the synchronisation of the electrical coupling of neuronal cell networks. In non-excitabile cells, small signalling molecules below 1200 daltons are exchanged across gap junctions. All animal cells communicate directly with each other across gap junctions, except striated muscle where the cells have fused, spermatozoa and non-nucleated erythrocytes and platelets (1).

Characteristics

Gap junctions are built from one of three biochemically different families of proteins.

► [Connexins](#)

In vertebrates, gap junctions are constructed from ► [connexin](#) protein units (Fig. 1). Over 20 different

Gap Junctions. Figure 1 A gap junction plaque showing diagrammatically the arrangement of paired connexon hemichannels in the membrane. These dock to generate a channel directly joining two cells. Connexons attach to the edges of plaques, but they may also function as hemichannels in their own right. In the top box, the oligomerisation of connexins into hexameric connexons and the various types of gap junctions formed are illustrated. In the lower box, the topography of a generalised connexin in the lipid bilayer is shown. Bold line indicates sequences with high homology.

connexins have been found in humans and rodents and various tissues synthesise different and often overlapping types of connexin (Table 1). They constitute a family of proteins displaying about 40% overall amino acid sequence identity. A widely adopted method of naming individual connexins uses the abbreviation Cx followed by the predicted molecular mass in kD. Increasingly, a prefix may be added to indicate the species e.g. h, human; m, mouse; zf, zebra fish, etc. When the molecular mass of the connexins is similar, a decimal point is added e.g. mCx 30.2, mCx 30.3 and mCx 31.1. However, although there is often little size variation between species, e.g. mCx36 and fish (skate) Cx35, there is sometimes greater disparity in the molecular sizes of functionally similar connexins, e.g. rat Cx46, bovine Cx44 and chicken Cx56 and clearly this nomenclature is not entirely satisfactory. Mouse and human connexins have been classified phylogenetically as follows: Group 1 or beta: Cx26, Cx30.3, Cx31, Cx31.1, Cx32; Group 2 or alpha: Cx33, Cx37,

Cx38, Cx40, Cx42, Cx43, Cx50, Cx56; Group3 or gamma: Cx45, Cx47 and an uncategorised group: Cx25, Cx29, Cx30.2, Cx36, Cx39, Cx40.1 and Cx58. Cx43 is by far the most widely distributed connexin (1). In heart ventricles, myocytes express Cx43 exclusively but myocytes in the atrium and Purkinje fibres also express Cx40. Endothelial cells lining the vascular wall express Cx37 in addition to Cx43, which is also expressed by the smooth muscle cells controlling the contraction of arteries. Cx36 is expressed by neurons in the retina, whereas in the brain astrocytes express mainly Cx43 and oligodendrocytes Cx32 and Cx47. Cells comprising the various layers in the skin express a range of connexins, especially Cx26, Cx30, Cx31, Cx32, Cx40, Cx43 and Cx45. In liver, hepatocytes express Cx26 and Cx32, with their relative abundance varying between species. Lens fibre cells express Cx46 and Cx50, but epithelial cells enveloping the lens capsule express Cx43. Up to 196 permutations of homologous and heterologous connexin based gap

junction interactions are possible when cells express two or more different types of connexins (Fig. 1). The relative amounts of each connexin in cells also varies during embryonic and tissue development.

Connexins span the membrane lipid bilayer four times and in an alpha helical conformation (Fig. 1). The protein's amino terminus (a highly conserved sequence of 21 amino acids) and carboxyl terminus (a highly variable number of amino acids as described below) and a single intracellular loop face the inside of the cell (Fig. 1). Two highly conserved amino acid sequences forming a loop (twenty in the first and forty amino acids in the second) project in a beta sheet conformation from the cell surface into the extracellular space; these loops contain three cysteine residues that are invariable in all connexins discovered and they are linked to each other by intramolecular disulphide bonds. These extracellular loop interactions are crucial for they provide a scaffold that aligns and extends the transmembrane [hemichannel](#) domains across the intercellular gap. The amino acid sequences in these two loops also set the rules governing the compatibility of interactions between various connexins. For example, cells with gap junction channels made from Cx32 and Cx26 communicate but cells making Cx32 do not communicate with those making Cx43. The types of connexin synthesised by cells thus dictate whether homo- or heterophilic gap junction channels are generated, with different channel pore characteristics and molecular selectivities. The third transmembrane domain and parts of the first and second transmembrane domains contribute the

wall of the overall channel. The greatest differences in amino acid sequences between connexins are found in the intracellular loop projecting into the cytoplasm and consisting of 30 amino acids in the smaller connexins, 50–55 amino acids in Cx33, Cx37, Cx40, Cx43, Cx46, Cx50 and Cx57, 80 amino acids in Cx45 and 100 amino acids in Cx36. The carboxyl terminal tail, often referred to as the regulatory domain, varies in length from 16 amino acids in Cx26 to 75 in Cx32, 156 in Cx43 and 275 in Cx57. Larger connexins are post-translationally modified by phosphorylation of several serine and threonine residues on the carboxyl tail. The functional consequences of phosphorylation of connexins remain to be defined as well as the key protein kinases and phosphatases involved in regulating gap junction channels. Connexins are not glycosylated, but are ubiquitinated and acylated.

The genes encoding mouse and human connexins are located on different chromosomes (Table 1). The general organisation of connexin genes is similar, and connexin phylogenetic trees indicate that connexins are likely to have arisen by gene duplication. Most connexin genes have a first exon containing 5' untranslated sequences and a large second exon containing the complete coding region as well as untranslated sequences. In contrast, the Cx32 gene contains two alternative first exons and their expression is tissue specific. Connexin 36 contains two exons both with translated and untranslated sequences with the coding region interrupted by an intron. The Cx45 gene has three exons, with most transcripts containing only

Gap Junctions. Table 1 Properties of some major mouse/human connexins

Connexin type	Chromosome mouse	mRNA (kb)	Cells/tissues where present	Disease involvement
Cx26	14	2.4	Mammary gland, liver, skin, cochlea	Deafness, palmoplantar hyperkeratosis
Cx30	14	20.23	Skin, cochlea	Deafness, ectodermal dysplasia, hair loss
Cx31	4	1.9, 2.3	Skin, cochlea, uterus	Deafness erythrokeratoderma variabilis
Cx32	X	1.6	Liver, oligodendrocytes	Peripheral neuropathy
Cx36	2	2.9	Neurons, retina	Visual defects
Cx37	4	1.7	Endothelium ovaries	bleeding
Cx40	3	3.5	Heart, endothelium	Atrial arrhythmia
Cx43	10	3.0	Diverse	Cardiac malformations
Cx45	11	2.2	Heart, brain thalamus, bladder	
Cx46	14	2.8	lens	cataract
Cx50	3	8.5	lens	cataract

exons 2 and 3. Cx40 also has three exons with the third containing the complete coding sequence. mRNA encoding connexins is subject to transcriptional control and tissue specific promoters (acting *via* multiple exons) account for hormonal and pharmacological regulation of expression. This is important, for example, in the contraction of uterine muscle during birth when gap junction numbers composed of Cx43 are regulated by oestrogens whereas gap junctions in the heart are not. Post-transcriptional regulation of mRNA levels is especially evident with some connexins, for example Cx32 and Cx26 in liver.

How are connexins organised into gap junctions? A hexagonal arrangement in which six connexins interact and surround a central pore of 2 nm was suggested by the regular packing of the presumed channel units in liver gap junctions stained with heavy metals as well as by atomic force microscopy. The most up to date structure is based on a three-dimensional electron crystallographic analysis of gap junctions prepared from cultured cells over-expressing recombinant Cx43. This model (2) shows the alignment of two composite hexameric connexin hemichannels at a resolution of 0.7 nm in the membrane plane and 2.1 nm in the vertical plane and it confirms independent biochemical and physical chemical studies showing the presence of 24 transmembrane alpha helices in each connexon hemichannel unit. The hemichannel unit has a dumb-bell shape and is 7 nm wide at the cytoplasmic aspect, narrowing to 5 nm at the extracellular aspect. The aqueous channel narrows from 4 nm diameter at the cytoplasmic entry point to 1.5–2.5 nm depending on the calcium concentration at the extracellular region where it becomes continuous with the partner hemichannel of a neighbouring cell. The arrangement of the connexin subunits in the gap junction ensures that the intercellular channel is completely insulated from the extracellular 'gap'.

► Innexins and ► Pannexins

Arthropod and vertebrate gap junctions differ in their overall thickness. Invertebrate gap junctions are constructed of a biochemically unrelated class of proteins called innexins. There is no amino acid sequence homology with connexins, but innexins adopt a similar topography in the membrane with four transmembrane domains and cytoplasmically oriented amino and carboxyl termini. Innexin transcripts expressed in *Xenopus* oocytes form functional gap junctions displaying typical channel gating characteristics. The *Caenorhabditis elegans* genome contains as many as 25 innexin genes, with single cells in this worm expressing more than one innexin transcript. Innexins are also present in *Drosophila* fruit flies where they feature in the development of the nervous system and intestine. Innexins have also been identified

recently in *Annelida*. The biochemical characterisation of innexins is awaited.

Pannexins are electrical junctions in vertebrates that are related to innexins. Pannexin 1 and 2 genes are abundantly expressed in the central nervous system, especially the hippocampus, olfactory bulb and cerebellum; pannexin 1 is confined to white matter. As with innexins, expression of pannexin transcripts generates intercellular channels with similar electrical characteristics to vertebrate gap junctions constructed of connexins. Their biochemical characterisation is awaited.

Assembly and Breakdown of Gap Junctions

Connexins are rapidly degraded; the half-life in heart and other cells is around two to four hours, a figure about 10–20× faster than most membrane proteins. Connexins are co-translationally inserted directly from ribosomes into the endoplasmic reticulum, threading four times into the membrane bilayer to achieve the typical connexin topography (Fig. 1). Connexins show a proclivity to oligomerise into hexameric hemichannels that exit the endoplasmic reticulum and enter the Golgi apparatus. The hemichannels are maintained in a closed configuration to limit continuity between cytoplasmic and luminal environments since ionic gradients allow cell-signalling responses. The hemichannels are then trafficked in membrane vesicles to the cell's plasma membrane and attach to the periphery of pre-existing gap junction plaques, a process that occurs simultaneously with their docking and alignment with hemichannels in the adjacent cell (Fig. 1). Connexins can be tagged at the carboxyl terminus with auto-fluorescent proteins such as green fluorescent protein or short tetracysteine-containing amino acid motifs to which arsenic-containing chemicals that fluoresce at different wavelengths will bind. These approaches have elegantly demonstrated in living cells how connexin hemichannels are moved to the plasma membrane and accrete into gap junction plaques and how gap junction units are internalised (3). Connexins are transported on 0.5 µm vesicles to the plasma membrane guided by a microtubular scaffolding and are removed from the central area of gap junction plaques as larger vesicles that correspond to annular gap junctions observed in the electron microscope. Gap junction plaques are built from up to thousands of paired hemichannel units that cannot be peeled apart once formed. Therefore, plaques are internalised into partner cells as complete units and are ultimately degraded in phagosomes or lysosomes. In contrast, incorrectly folded or mutated connexins are transferred directly from the endoplasmic reticulum for degradation in proteasomes.

Gap junctions are frequently located next to other adhesive junctions and it is not surprising that their

assembly by cells is closely co-ordinated. Connexins interact *via* their carboxyl tails with zona occludens 1 and occludin, two proteins associated with tight ►intercellular junctions, with tubulin, the major constituent of microtubules and with catenins, a further class of proteins associated with adhesive junctions. Specific connexins are also detected in ►lipid raft membrane microdomains where they associate with caveolins.

Regulatory Mechanisms

Gap Junction Channels

Measurements of electrical currents across gap junctions in paired *Xenopus* oocytes synthesising various recombinant connexins have shown that opening and closing (gating) of gap junction channels is determined mainly by a voltage difference between the paired cells and features amino acid sequences in the first to second transmembrane regions. In larger connexins, a second mechanism is identified involving a “ball and chain” type interaction between amino acids in the intracellular loop and the carboxyl tail. This chemical gating is mainly a function of pH with channels closing as pH drops (4). Gap junctions constructed of different connexins vary in their gating characteristics. Calcium ions also regulate gap junctional communication. Elevation of calcium in cells generally closes gap junctions. Cell signalling responses such as an increase in cytoplasmic calcium induced by mechanical aggravation of cells or release of inositol phosphates are propagated across gap junctions to neighbouring cells thus generating a calcium wave. The biochemical nature of the signal transmitted is not known for sure but one suggestion is that intercellular transmission of calcium waves involves the passage of inositol triphosphate through the gap junction channel. Calcium waves are also propagated between cells across connexin hemichannels. Here, ATP is released across the hemichannel and then binds in a paracrine fashion to purinergic receptors on neighbouring cells. In contrast, progress in establishing the biochemical nature of molecules/ions transmitted across gap junctions has been slow, probably because its direct nature has made their interception difficult. All that can be said is such entities are likely to be 1.2 Kd or less and with an ionic radius of below 1 nm. Gap junctions should not be regarded as nonselective pores joining cells, for the molecular selectivity for a range of permeants in the context of charge and size is a function of the connexin makeup of the channel. For example, gap junction channels distinguish between the passage of cAMP and cGMP.

Hemichannels

Unopposed connexin hemichannels in non-junctional regions of the plasma membrane (Fig. 1) were

previously thought of as biogenetic precursors of gap junctions. However, evidence is building up that they are regulatable entities in their own right, with functions influenced for example by calcium levels inside and outside the cell. These unpaired connexin hemichannels were first observed in the horizontal cells of catfish retina and their operation has now been studied extensively (5). Their presence in mammalian cells was demonstrated on the basis of passage of small dyes across the channels or the detection of electrical currents crossing them. Cells tolerate small numbers of open connexin hemichannels on the plasma membrane but the presence of larger numbers is often a pathological consequence of a metabolic insult such as in ischaemia, when cells release ATP across the open hemichannels in cardiac myocytes or glutamate in astrocytes. Importantly, hemichannels provide a second mechanism for connexin-dependent intercellular propagation of calcium waves that complements the calcium signalling occurring directly across gap junctions.

Modifications in Disease

Changes in gap junctional communication and especially mutations in connexin genes have been shown to correlate with a number of human diseases. Mutations in Cx43 are extremely rare and diseases in tissues expressing this connexin mainly involve modifications in the abundance of functional gap junction channels and the remodelling of pre-existing gap junctions as seen in cardiac hypertrophy and infarction and in endothelial dysfunction in arteries. In contrast, about 200 Cx32 mutations have been detected in the X-linked form of ►Charcot-Marie-Tooth Disease, a demyelinating syndrome that leads to degeneration of peripheral nerves. The channels constructed of Cx32 are located mainly in the paranodal loops and Schmidt-Landermann incisures of myelinating Schwann cells and provide a direct radial diffusion pathway that is about 300-fold shorter in distance than a circumferential route. Many missense, frameshift, deletion and nonsense mutations lead to a loss of function, many caused by failure of Cx32 to oligomerise correctly into hemichannels and to be targeted in a precise manner to the plasma membrane. Sometimes, gap junctions are formed by these mutated connexins but their operation is faulty. Gap junctions constructed from Cx32 in the liver and pancreatic acinar cells (Table 1) are unaffected. Surprisingly, myelination by oligodendrocytes in the central nervous system is unaffected. Mutations in Cx26 and Cx30 in the human inner ear are associated with congenital deafness, a disorder present in 1 in 1,000 births. Over 50 Cx26 mutations are known, with one common recessive mutation resulting in a severely truncated Cx26 protein. Many other site-specific mutations result in trafficking/►channel

assembly deficiencies. Gap junctions in the inner ear function in K^+ circulation from the interstitial space and through the cochlear supporting cells, a mechanism confirmed in mice in which the Cx26 gene was inactivated. Mutations in Cx26, Cx30 and Cx31.1 are also associated with disorders of the skin.

Mutations in Cx50 and Cx46 genes are associated with lens transparency and are prevalent in humans with inherited zonular pulverulent cataract. As with Cx43 in the heart, gap junctional communication is important in cell migration during organ growth and development. Knowledge gained by studying genetic mutations in the laboratory by functional expression in model cell systems has been extended and complemented in transgenic mice with single or double gene connexin “knockouts” and “knockins”. These approaches have added important inputs to our understanding of the physiological, pathological and developmental roles of individual connexins. The knowledge base will expand with the application of RNA interference techniques to silence connexin genes simultaneously *in vivo*. Further research aims will be to identify functions that can be attributed to individual connexins or specific combinations of connexins assembled into heteromeric channels. Higher definition molecular models will help explain how gap junction channels operate. The molecular basis of the specificity of transfer of signals between cells across gap junctions and the way they are interpreted will continue to be major foci for research.

GenBank

Definition

GenBank, the NIH genetic sequence database, is an annotated collection of all publicly available DNA sequences, located at <http://www.ncbi.nlm.nih.gov>. It is part of the International Nucleotide Sequence Database Collaboration, which is comprised of the DNA DataBank of Japan (DDBJ), the European Molecular Biology Laboratory (EMBL), and GenBank at NCBI.

► [Protein Databases](#)

Gene

Definition

Gene refers to a segment of DNA coding for a polypeptide chain of amino acids. A gene includes untranslated regions before and after the coding region

and intervening (intronic) sequences. Nomenclature: Human genes are abbreviated using italic capital letters and numbers without spaces, dashes etc. according to the approved gene symbols listed in the Human Gene Nomenclature Database (<http://www.gene.ucl.ac.uk/cgi-bin/nomenclature/searchgenes.pl>). Nomenclature for murine gene symbols underlies the same rules, but uses lower case letters after the first letter. Example: *PSEN1* = human gene for PS1; *Psen1* = murine gene for PS1.

Gene Annotation in Plants

Department of Plant Systems Biology, University of
Ghent, Ghent, Belgium
pierre.rouze@psb.ugent.be

Synonyms

Just as for gene and genome annotation in any other organism, gene annotation in plants makes use of algorithmic approaches based on statistics, artificial intelligence and machine learning, recently complemented with homology based approaches depending on the

availability of sequence data, whether related genomes, complete cDNAs or expressed sequence tags (ESTs).

Definition

All prokaryotic and eukaryotic organisms encode their genetic information in their genome, built up from DNA. The process of genome annotation consists of finding and decoding the information encrypted on the DNA molecules into known conceptual objects related to biological entities and functions. In general, annotation is mostly focused on finding genes, defining their structure and assigning a function to the product and the process resulting from the expression of each gene. But annotation is not restricted to genes, as non-coding RNAs, transposable elements, promoters and enhancers also make up the genome and are essential to an understanding of the organization and the various functions encoded by or embedded in genomes.

Characteristics

Gene annotation in plants is in essence not different from gene annotation in human or mouse, except that each genome although constituted by the same DNA has its own style that needs to be captured by the models used by the different prediction programs. Anticipating which are the genome specific characteristics, e.g. codon usage, gene density, length and composition of introns and intergenic sequences, as well as conservation of signals such as splice sites (Table 1) are all important for building adequate algorithms and for their proper training.

Gene Annotation in Plants. Table 1 Splice site prediction programs

Program	Organism	Method
GeneSplicer (152)	<i>Arabidopsis</i> , human	HMM + MDD

HMM, hidden MM; MDD, maximal dependence decomposition; NN, neural networks

The effort undertaken by several laboratories worldwide to sequence the *Arabidopsis thaliana* genome led, by the end of 2000, to the first full catalogue of genes present in a plant. This work also revealed that plants have about the same number of protein gene loci as vertebrate genomes (27,000 for *Arabidopsis*) but also that about 5,000 genes remained unknown, showing no homology to any known sequence in databases (1). These genes could only be predicted using *ab initio* prediction programs and need further experiment to prove that they truly exist, which has since been done for a number of them.

Genome annotation can be subdivided in two steps; structural annotation will provide gene structures and functional annotation as an as accurate as possible prediction of the function of each gene. To acquire structural annotation two main approaches are combined, intrinsic and extrinsic methods. Intrinsic (or *ab initio*) methods are all those methods that decipher genome content based solely on statistical/lexical models built by using human-curated data sets of sequences from the organism under investigation. The algorithms used for intrinsic approaches can be subdivided into signal sensors or content sensors. Signal sensors are algorithms that focus on the retrieval and identification of functional sites such as e.g. splice and translation initiation sites, transcription and polyadenylation signals and include methods such as position weight matrices, neural networks and support vector machines. Content sensors recognize regions along a sequence that have local characteristics differing from the surrounding sequence, include mainly methods such as Markov models and all their variants and are broadly used to distinguish coding from non-coding regions.

The purpose of the multiplicity of methods used is to decompose the problem of gene annotation into key components and achieve the best results on each component, which can thereafter be reassembled towards a whole gene structure (2).

Extrinsic or comparative approaches on the contrary rely on the availability of sequences from other genomes and proteins, where regions that show enough similarity between genomes are believed to have the same biological meaning, as a result of common ancestry. The advantage of comparative methods to predict genes is that it allows the revealing of small and novel genes without ambiguities and, more importantly, enables the detection of non-coding features that can hardly be detected otherwise. One needs nevertheless to be careful as to the choice of organisms used for comparative methods to achieve good results. Too closely related genomes might not reveal the information hidden in the genomes, as regions larger than coding sequences will remain conserved, making the delineation of gene structures impossible. If on the

other hand genomes are too distantly related, only a few genes will keep significant similarity to be correctly modeled or even be found. For plants, genome sequences of one dicot, *Arabidopsis*, and one monocot, rice are presently available. Unfortunately they diverged some 200 million years ago and are therefore too divergent for comparative annotation. Other genomes that are currently being sequenced, poplar, *Medicago* and *Lotus* for dicots, maize for monocots will soon fill this gap.

Besides experimental approaches, functional annotation can only be achieved through comparative methods where the knowledge of genes from one organism can be transposed to the genes and the genome of the organism concerned. To achieve this, homology searches and alignment programs are the main algorithms used (Table 2). The quality of the databases providing the data is of primary importance and is currently the main limitation. The homology searches are performed against protein, domain and motif databases using BLAST or FastA or by using hidden Markov profiles that show a better sensitivity and specificity. One point that needs to be stressed is the importance of consistency in genome annotation across species. The gene ontology (GO) project is an attempt to achieve this goal, through a hierarchical description of the genes in a genome according to the functions of their products at the various biological levels, from the molecules to the biological processes and cellular components with which they are associated. The classification and standardized terminology of GO (gene ontology) has been initiated in the annotation of the *D. melanogaster* genome and it is hoped that GO will become a community-curated entity, providing a central frame and vocabulary for annotation.

Many gene prediction programs are publicly available; many of them are referred to on the web site maintained by W. Li (<http://linkage.rockefeller.edu/wli/gene/programs.html>). Several reviews are available on this topic too, among which that of Mathé et al. (2) is more specifically oriented towards plants. The large variety of gene prediction programs have the drawback that one does not necessarily know which program to use in which situation and which performs best depending on the organism of interest. The issues of specificity, or the ability to predict only real genes and sensitivity, or the ability to predict all the genes present in a sequence, have been addressed by Burset and Guigo (3), Rogic et al. (4) and in the specific case of plants by Pavy et al. (5). In those publications it has been made clear that programs rarely performed well enough to be able to predict all the genes and that 30–40% of the genes were likely to be wrongly predicted even by the best intrinsic methods. In addition, it is clear that the more extrinsic data (of high quality) become available, the better the annotation will be.

The above described programs are different from annotation platforms, which do not attempt to make predictions themselves, but present the results from different prediction programs graphically and thus have to be seen as complementary tools that facilitate human driven annotation.

Clinical Relevance

The use of plants for medical purposes dates back thousands of years and was part of the magic exerted by medicine man, sorcerers and druids. Even now many pharmaceutical compounds that are commonly used are or were once extracted from plants. Genetic engineering

of plants to produce biopharmaceuticals is much more recent. Identification and mining of genes involved in the metabolism of such compounds in medicinal plants and in model systems is then an important issue. Gene annotation is the basic step for it, and its high quality can speed up and better focus the research on genes of potential pharmaceutical importance, especially the ones involved in secondary metabolism.

Besides being a source of pharmaceuticals, plants are also seen as a convenient and inexpensive way to produce proteins and other molecules of medicinal interest, a practice often referred as “pharming”. Most genes can indeed be expressed in a wide range of organisms. Therefore expression systems need to be tested for efficiency, cost and the biological activity of the products as the demand for high production levels at low cost is important to make modern medicine available for an ever expanding world population. Modified mammalian cells are in that respect valuable as far as the biological activity is concerned but their use is limited because of expensive culturing and difficult scaling up. The advantage of microbial organisms is that as well as the easier modification of the organisms, larger quantities can be manufactured using industrial bioreactors. Their disadvantage is that proteins do not become correctly glycosylated for usage in humans and that some proteins lack the proper folding and disulfide bridges. Plants on the other hand,

have many potential advantages for the production of recombinant proteins and the engineering of pharmaceuticals. First, growing plants is more economical than industrial facilities with bioreactors. Second, starting from plant material is already documented. Third, purification is not required when the therapeutic product can be administrated as food. Fourth, plants can be directed to target proteins into organs and intracellular compartments that confer better and more stable conservation (e.g. seeds). Fifth, the production levels that can be reached using modified plants approaches industrial scales. Last, the risk of human health threats due to contamination is reduced to a minimum.

The first recombinant therapeutic proteins, successfully produced in tobacco plants were different forms and parts of immunoglobulin (Ig), making plants virtually unlimited sources of inexpensive monoclonal antibodies. Ig produced in plants can effectively prevent infectious diseases and cancers in the mouse model or be used for *in vivo* tumor imaging. None are available commercially yet.

Glycosylation of proteins though remains a potential problem, as N-glycans in plants are structurally more diverse with a majority of oligosaccharides having β -(1,2)-xylose and α -(1,3)-fucose linked to the Man₃-GlcNAc₂ core. These are not found in mammalian N-glycans, while plant engineered proteins are lacking the sialic acid that represents 10% of the mouse sugar

content. These differences appear to have no influence on the binding affinities of Ig *in vitro*, however, there is some concern about the immunogenicity and allergenicity of plant engineered proteins. To circumvent this problem, proteins have been made edible, suppressing the problem since plant materials are ubiquitous in the human diet, the rationale being that plant engineered proteins can trigger a mucosal immunity. A high dosage is needed to maximize the chances of the protein reaching the gut intact. Therefore high expression levels in the plant tissues must be achieved. If annotation proper is not giving an answer to this issue, taking into account the features selected for making efficient, *ab initio* prediction software can be used as a guide. This tells us what makes a gene most adapted to its genome style and in turn most expressed. The latest approach to achieving high expressions levels was to express the proteins in the chloroplast. Expressing proteins in chloroplasts is an alternative for high expression with some advantages such as the absence of silencing of the engineered gene and the environmentally friendliness of the process, as spreading of chloroplast-targeted genes to other plants becomes very unlikely (6, 7).

Gene Chip Technology and Its Application to Molecular Medicine

HEIKE ZIMDAHL, NORBERT HÜBNER

Max Delbrück Center for Molecular Medicine (MDC),
Berlin, Germany
nhuebner@mdc-berlin.de

Definition

DNA ▶**microarrays**, or DNA chips consist of thousands of individual DNA sequences arrayed at a high density on a single matrix, usually glass slides or quartz wafers, but sometimes on nylon substrates. Probes with known identity are used to determine complementary binding, thus allowing the analysis of ▶**gene expression**, DNA sequence variation or protein levels in a parallel format.

Description

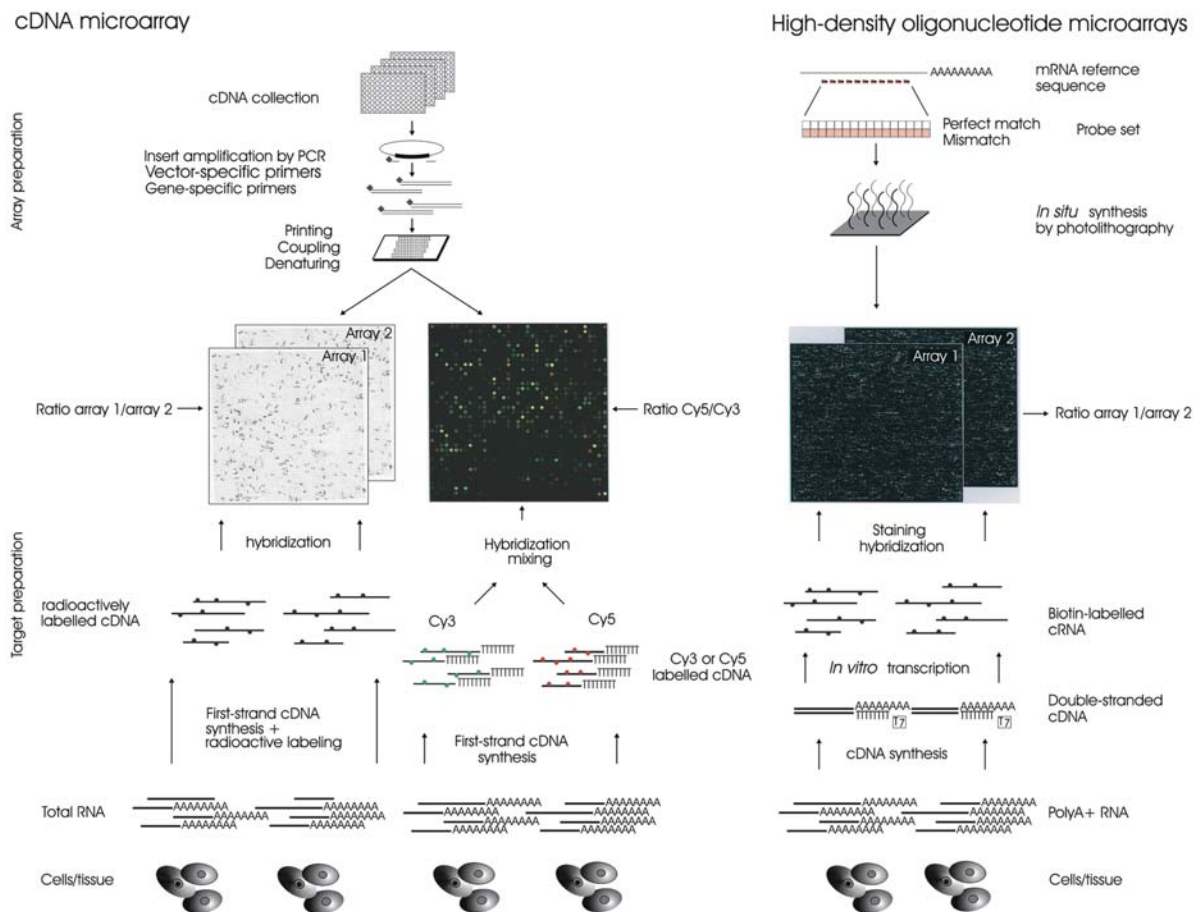

The analysis of gene expression levels in a certain tissue, cell type or stage of development provides essential information for any attempt to understand biological processes and to isolate differently regulated genes associated with a disease phenotype. Gene expression profiling may allow linkage of specific genes to disease susceptibility and drug response and the identification of genes and components of complex molecular pathways.

Various methods are available for detecting and quantitating gene expression levels, e.g. Northern blot, RNase protection assay, differential display, representational difference analysis (RDA) and serial analysis of gene expression (SAGE). For the high throughput analysis of gene expression on a global level, the microarray has emerged.

Microarrays usually contain thousands of arrayed ▶**cDNAs** or ▶**oligonucleotides**.

After completion of the human genome sequencing, the estimated number of human genes is ~30,000, but there are more ▶**mRNA** species that arise e.g. by ▶**alternative splicing**. Most investigators use in their experiments arrays comprising a substantial subset of the entire transcriptome. Gene expression analysis arrays are commercially available for a number of organisms, e.g. *H. sapiens*, *M. musculus*, *R. norvegicus*, *Arabidopsis*, *C. elegans* and *Drosophila*.

Expression profiling using microarrays represents the most efficient way of measuring gene expression – alterations in transcript levels in tissues or entire genomes can be simultaneously assayed (1-3). In addition to the capacity for parallel analysis of thousands of genes with a minimal amount of sample,

Gene Chip Technology and Its Application to Molecular Medicine. Figure 1 Schematic representation of the experimental strategy of cDNA and oligonucleotide arrays (modified according to Schulze A, Downward J, Nat Cell Biol 2001; 3:E190-E195(36)). cDNA arrays: For the array preparation, inserts from cDNA clones (libraries) are amplified and PCR products are spotted onto glass slides or nylon membranes at specific positions using arraying robots. Target preparation: RNA from the two tissues or cell populations under comparison is used to synthesize cDNA in the presence of either radioactively labeled nucleotides or nucleotides labeled with two different fluorescent dyes, Cy3 and Cy5, during cDNA synthesis. Samples labeled with two different fluorescent dyes are mixed and are hybridized to the array, whereas samples labeled radioactively (or with one fluorescent dye) are hybridized to separate arrays. Signal intensity ratios are obtained by comparing either two different signals (Cy5/Cy3) on one array or by comparing signals of genes represented on two arrays (array 1/array 2). High-density oligonucleotide arrays: For the array preparation sequences of 16–20 short oligonucleotides (typically 25mers) are chosen from the mRNA reference sequence of each gene. Light-directed, *in situ* oligonucleotide synthesis is used to generate high-density probe arrays, usually containing over 300,000 individual elements. Target preparation: polyA⁺ RNA is prepared from different tissues and used to generate double-stranded cDNA carrying a transcriptional start site for T7 DNA polymerase. During *in vitro* transcription, biotin-labeled nucleotides are incorporated into synthesized cRNA molecules. Each cRNA sample hybridizes separately to the array. Target binding is detected by staining with a fluorescent dye coupled to streptavidin. Signal intensities on different arrays are used to calculate relative mRNA abundance for genes represented on the array.

other advantages include the high sensitivity, the economy of size (miniaturization) and the use of non-toxic chemicals.

Despite the enormous potential of the technology a number of issues attenuate the power of microarrays, e.g. the control for biological and environmental factors and fluctuations, the validation of data, the need for

computational tools to analyze the vast amount of data and to enable comparisons between arrays and finally the high costs of commercial microarrays.

Conceptually different approaches to the development of microarray technology have resulted in the generation of two different array formats, oligonucleotide and cDNA ('targets') arrays (Fig. 1). The 'target'

cDNAs (or oligonucleotides) are immobilized on nylon membranes or glass slides. cDNA arrays are generated by arraying PCR products of ►cDNA libraries or clone collections usually onto glass or nylon substrates. cDNA arrays offer flexibility in the choice of arrayed elements and lower costs, particularly for the preparation of smaller, customized arrays for specific investigations of a small number of genes. In addition, arraying of unsequenced clones from cDNA libraries can be useful for gene discovery.

The advantage of the *in situ* synthesized, high-density oligonucleotide arrays (Affymetrix, www.affymetrix.com) is the high reproducibility of *in situ* synthesis on oligonucleotide chips, allowing an accurate comparison of signals generated by samples hybridized to separate arrays.

Microarray Fabrication

The concept of being able to characterize large numbers of clones by ►hybridization analyses of high-density arrayed cDNA libraries was established more than a decade ago (1).

In general, arrays are described as macroarrays or microarrays, the difference being the size of the sample spots and size of the array. Macroarrays are usually printed on nylon membranes, contain sample spot sizes of about 250 microns or larger and can easily be imaged by existing gel and blot scanners. The sample spot sizes in microarrays are typically less than 200 microns in diameter and probes are attached onto glass-like substrates. Depending on the arrayed material, the most commonly used array platforms are cDNA arrays and oligonucleotide arrays (►<http://www.gene-chips.com/>). For the generation of a cDNA microarray (4), cDNA clones representing as many unique transcripts as possible are either selected within ►EST data (►<http://www.ncbi.nlm.nih.gov/> UniGene and ►<http://www.tigr.org/tdb/tgi/hgi>) or tissue-specific cDNA libraries are constructed or ordered (www.rzpd.de). The cDNA clone inserts are PCR amplified from plasmid DNA or amplified from bacterial cultures. In high-throughput applications the amplification of clones in cultures stored in 384-well plates is more cost efficient and less labor intensive than amplification from plasmid DNA. PCR products can be purified to remove unincorporated nucleotides and primers, e.g. by filtration using silica systems. Amplified PCR products are spotted, usually in denaturing or high-salt buffer, onto glass slides or nylon membranes using robotic systems. Spots are typically 100–300 µm in size and are spaced about the same distance apart. Using this technique, arrays consisting of more than 30,000 cDNAs can be fitted onto the surface of a conventional microscope slide.

Commercially available cDNA arrays consisting of thousands of distinct sequence-verified genes are

provided by companies, like Clontech, Agilent, Incyte Genomics, Invitrogen (Research Genetics) or non-profit, public, limited institutions like the German Resource Center (►www.rzpd.de).

For oligonucleotide arrays, short oligonucleotides from 20–25 mers (Affymetrix) up to 60mers (Agilent Technologies) are usually synthesized *in situ*, either by photolithography onto silicon wafers (high-density oligonucleotide arrays from Affymetrix) or spotted by ink-jet technology (e.g. Agilent Technologies). Alternatively, presynthesized oligonucleotides can be spotted onto glass slides or glass-like matrices. Oligonucleotide arrays have certain advantages over cDNA arrays, namely high reproducibility and the facts that the sequence information (usually EST sequences) alone is sufficient to generate the DNA to be arrayed. Furthermore the oligonucleotide arrays can be designed to allow both ►SNP and alternative splicing analysis and do not require amplification and purification of cDNA fragments (5).

Since short oligonucleotides may result in less specific hybridization and reduced sensitivity, the arraying of presynthesized longer oligonucleotides (50–100 mers) has recently been developed to counteract these disadvantages. However, the high costs of commercially available, *in situ*-synthesized oligonucleotide arrays and their accessories (spotters, scanners, analysis software) as well as the time-consuming design of oligonucleotide sets may limit their use for academic laboratories.

Affymetrix has pioneered the oligonucleotide array technology and generated a number of different commercially available arrays for various organisms (►www.affymetrix.com).

The Microarray Experiment

Careful experimental design of the microarray will ensure the maximal potential gain in efficiency and is particularly important if the resulting experiment is to be maximally informative, given the effort and the resources.

There are many protocols and different types of systems available; the basic procedure for a large-scale measurement of gene expression involves the preparation of total or mRNA from the biological sample(s) under investigation (e.g. ‘candidate’ organ) and the hybridization of copied ‘labeled’ RNA to the array (Fig. 1).

In most cases, the extracted mRNA is converted to cDNA (►reverse transcription), labeled and hybridized to the DNA elements on the array surface of the array. In some cases (e.g. hybridization of Affymetrix chips) the cDNA is labeled during *in vitro* transcription and ►cRNA is hybridized. To ensure a high reproducibility, fluctuations in sample preparation and hybridization need to be reduced to a minimum. Major sources of

random fluctuations to be expected are in probe, target and array preparation, e.g. in mRNA preparation, reverse transcription, labeling, target volume, hybridization parameters, overshining effects, non-specific background, variations in pin geometry during spotting of cDNA, slide inhomogeneities and image analysis (6). Replicates of each experiment should be used in order to reduce variability and to differentiate between experimental variation and real expression differences. Suitable internal controls ensure quality control measurements for samples and array. After the hybridization process, intensity signals from the hybridized RNA samples are detected by phosphoimaging or fluorescence scanning and independent images are generated.

Analysis and Data Management

Microarray experiments generate large and complex data sets, e.g. lists of spot intensities and intensity ratios. Basically, the data obtained from microarray experiments provide information on the relative expression of genes corresponding to the mRNA sample of interest. Computational and statistical tools are required to analyze the large amount of data in order to address biological questions.

Once images of hybridized microarrays are processed, arrayed spots are identified, relative signal intensities for each spot are measured and background intensity is subtracted. Signal intensities are usually normalized to compensate for experimental variability and to 'balance' the signals from the two samples being compared (7). All normalization techniques assume that all or a subset of spots (e.g. genes) on the array have an average expression ratio equal to one. The normalization factor is then used to adjust the data (signal intensities) from the two samples and to ensure that the total quantity of RNA hybridized to the array is the same. Finally mean spot or transcript intensities are calculated and ratios of intensities are used to account for relative expression differences. In a simple pairwise comparison of gene expression between two samples, the results can be shown in plots of the intensities or the log of the intensity ratios. Scatter plots are widely used to make the observed differential expression visible.

A variety of software tools utilizing different mathematical algorithms to perform microarray image analysis are available; a detailed discussion of the analytical tools is beyond the scope of this article (see reviews 8, 9).

The first information obtained after data analysis and extraction of gene expression analysis is identification of those genes with significant differential expression in two samples or in a time series after a given treatment. To address the full potential of genome-scale experiments a ►cluster analysis is performed to analyze the entire repertoire of transcripts. Basically,

cluster analysis uses a standard statistical algorithm to arrange and organize genes according similar patterns of gene expression (10).

The data management is of particular importance for further downstream analyses. Databases are an important resource for storing and retrieving the vast amount of data generated in a microarray experiment. A number of gene expression databases have been generated and are accessible to the public (e.g. Gene Expression Omnibus at the National Center for Biotechnology Information, www.ncbi.nlm.nih.gov/geo and ArrayExpress at the European Bioinformatics Institute, EMBL-EBI www.ebi.ac.uk/arrayexpress/). Due to the experimental variation inherent in microarray experiments, the validation of the results by alternative techniques, such as quantitative real-time PCR or Northern blotting is advisable.

The most challenging part is "making sense" of the complex data retrieved, including to distinguish, whether the gene's expression change is part of the etiology of the disease or part of the pathology of the disease. The first task is the identification of the relevant gene(s), the prediction of protein function and the identification of the genetic variation that modulates gene expression, including the number of loci involved, the effect of each single locus and the interaction between loci.

Clinical Applications

Microarrays certainly have multiple applications many of which will develop and evolve over time. Although the first application of microarrays was in monitoring gene expression, the strategy of using arrayed biomolecules to examine a biological sample is generally applicable, e.g. for mutation screening, ►polymorphism analysis, mapping and other applications. An increasing number of human diseases result from alterations in DNA sequence and/or altered gene expression patterns. Therefore, information about up- and down-regulation of multiple genes is important for identification of disease genes, understanding of gene function and for potential therapeutic and/or diagnostic applications. The first clinical application may be the use of microarrays for the molecular classification of cancer (see disease diagnosis).

Although gene expression analysis is a powerful approach to identify characteristics of disease states or signaling pathways, it should be noted that gene expression levels often represent complex, quantitative phenotypes, influenced by environmental and genetic factors and the regulation of mRNA levels is only one aspect of biological control. Protein levels are also controlled at several post-transcriptional steps and protein activity is controlled by post-translational modification. A complete picture may be obtained by studying the global level of cellular proteins by proteomics (e.g. protein microarrays).

Disease Diagnosis

The real promise of the examination of gene expression using microarrays is to identify genes, which are consistently up- or down-regulated and play significant roles in the development and progression of disease. For example, the over-expression of certain genes is correlated with a certain type of cancer. By monitoring expression a new generic approach for cancer classification has been established and a comprehensive and commonly accessible catalog of gene expression profiles will make an accurate multiclass cancer classification feasible. Improvement in precise, objective and systematic tumor classification at the molecular level will advance cancer treatment (3, 11).

Pharmacogenomics

The information about gene expression and sequence variation will also have an impact on many aspects of the drug discovery process and on drug efficacy (12). Use for prognostic markers or to identify therapeutic targets has great potential.

Microarrays are used at specified steps in the process of drug development:

- Target discovery, to identify genes or pathways with altered expression in diseased human tissues or in animal models of disease.
- Target validation, to determine that a gene product is causative of disease symptoms or that activation of the target protein ameliorates disease symptoms. An agonist/activator or an inhibitor, which may be therapeutic, could be identified using microarrays.
- Compound optimization, to screen a series of therapeutic drug candidates to find the compounds that are most specific for the target protein and those that cause unintended effects.
- Drug metabolism, to predict whether a drug candidate will cause drug–drug interactions.
- Drug efficacy, to identify the individual mode of action or adverse effects of a given drug.
- Microarrays should therefore prove useful in understanding the mechanistic basis of action of many drugs.

Toxicological research: Toxicogenomics

Toxicogenomics is concerned with the identification of potential human and environmental toxicants and with finding correlations between toxic responses to toxicants and changes in the genetic profiles of the objects exposed to such toxicants through the use of genomics resources. DNA microarrays allow the identification of highly sensitive and informative markers for toxicity, by monitoring the expression levels of thousands of genes simultaneously.

Therapeutic Consequences

It has been suggested that microarrays will be routinely used not only in the selection, assessment and quality control of the best drugs for pharmaceutical development and for disease diagnosis, but also for monitoring disease status and the outcomes of therapeutic interventions (11–15). Microarrays may be of great benefit with respect to personalized medicine, i.e. to select the most likely effective drug, to individualize dosing and to minimize the safety risk for cost effective health care management. Microarrays may also be useful to identify bacterial strains that are resistant to known antibiotics to avoid a lack of response in certain patients.

One important aspect is to find a correlation between therapeutic responses to drugs and the genetic profiles of patients to address questions, such as why do some drugs work better in some patients than in others and why some drugs may even be highly toxic to certain patients?

Additionally to gene expression profiling, microarrays are especially suited for high-throughput genotyping to examine sequence variation, i.e. to screen SNPs (single nucleotide polymorphisms). An individual's genotype or genetic profile may allow 1. determination of disease association and assessment of disease risk and 2. determination of dosage and type of drug. This will enable the selection of the most appropriate and efficient drug and reduce chances of an adverse drug reaction (16, 17).

To realize the potential of microarrays, it will be a challenge to develop a cooperative framework that meets the requirements of basic research and clinical medicine.

Gene Cluster

Definition

Gene cluster refers to a set of co-regulated genes, presumably belonging to the same functional class.

► [RNAi Interference in Mammalian Cells](#)

Gene Conversion

Definition

Gene conversion refers to a non-reciprocal, limited transfer of sequence information from one chromosome to another, or from one chromosome region to another region, of the same chromosome. The donating sequence is copied to the receiving chromosome, which is thus “converted”. The donating sequence remains unchanged.

sebastian.shimeld@zoo.ox.ac.uk

Synonyms

segment duplication, chromosome duplication, ► [trisomy](#) and polyploidy. Sister genes separated by duplication are referred to as paralogues.

Definition

The term gene duplication describes a situation where a single ancestral gene has been copied such that two (or more) copies of that gene now exist in a single genome. Gene duplications are saltatory events in genome evolution in that the change occurs in one generation, with the parents having one copy while the offspring have two copies. Therefore, as with other genetic changes, gene duplications typically first exist in one individual. Whether they spread to become fixed in a population or are purged will primarily depend upon the effect they have on the organism's ► [fitness](#). At a practical level, gene duplications that have become fixed within a taxon are recognised retrospectively by the presence of homologous genes within one genome. These are best known in the context of gene families, groups of genes of related sequence inferred to have originated by repeated gene duplication from a single ancestral gene.

Characteristics

The Origin of Duplicated Genes

The prevalence of gene families in eukaryotic and prokaryotic genomes suggests gene duplication has played a prominent role in evolution. How do gene duplications occur? Probably the most common event is tandem duplication, as evidenced by the prevalence of homologous genes situated in tandem in most genomes. Tandem duplication probably occurs most frequently due to mis-recombination at ► [meiosis](#),

although other factors might also be important. Repeated tandem duplication without purging of duplicated genes results in ►**gene clusters**, that is a group of related genes situated next to each other in the genome. Such gene clusters can be evolutionarily ancient (for instance the ►**Hox gene cluster**), but are more commonly of relatively recent origin, for example the cluster of zinc finger genes on chromosome 19q12. Genes can also duplicate in other ways. Single genes can be duplicated elsewhere in the genome by several potential mechanisms, including *via* piggybacking on adjacent active retrotransposons or insertion of a reverse transcribed mRNA into the genome by a viral reverse transcriptase. Several mechanisms allow multiple genes to be duplicated simultaneously. Sections of DNA containing multiple genes can duplicate either in tandem or elsewhere in the genome (for example by transposition). Evidence suggests that recently duplicated segments form an estimated 5% of the human genome, suggesting this is a frequent and ongoing process (1). These are also known as segmental or block duplications. Duplication of an entire chromosome with all its incumbent genes can also occur. Although this is strongly selected against in humans and typically unviable (an exception is trisomy of chromosome 21), some other lineages appear to be able to tolerate such duplications more easily and aberrant chromosome numbers are especially common in flowering plants. Finally, there is evidence that whole genome duplication has occurred in several lineages, including in yeast, plants and salmonid fish (2). There is also evidence that genome duplication occurred early in vertebrate evolution and therefore that all vertebrates including humans are ancestrally polyploid. Duplication of an entire genome includes duplication of all its incumbent genes.

The Fate of Duplicated Genes

When examining the genomes of living organisms, we infer the presence of previous gene duplications by the existence of genes with homologous sequences. By their nature, these represent gene duplications that have become fixed within a population such that all members of a species (or higher taxonomic division) possess both copies. The route from the initial gene duplication to ►**fixation** or loss is affected by several factors. Some gene duplications confer an obvious ►**selective advantage** and spread rapidly through a population, for example the tandem amplification of esterase genes in mosquitoes can confer a degree of resistance to specific pesticides. Conversely, fixation of a duplicated gene within a population is by no means certain. Many gene products are required at a specific dosage and duplication disrupts this balance. This is likely to reduce the fitness of the individual carrying the gene duplication, leading to it being rapidly purged from the population.

For many genes, however, it is likely that duplication has little or no effect on fitness and is effectively neutral. A common way to view the fate of duplicated genes in this context was as a race between the accumulation of mutations that eventually silence one gene (turning it into a ►**pseudogene** which would accumulate more mutations over evolutionary time and eventually become unrecognisable) and the acquisition of divergent functions by the two duplicates and hence the necessity for an organism to maintain both. Empirical data does not support this model, however, suggesting a high rate of retention of duplicate genes (3).

More recently, a modified form of this model has been proposed. Many genes, particularly in multicellular organisms, are multifunctional, either at the biochemical level or in terms of regulated expression in different organs or cell types. This creates the possibility of duplicated genes diverging by subfunctionalisation, which implies that duplicate genes diverge by maintaining separate functions that were all initially maintained by the single gene ancestor. An organism must maintain both copies in its genome or lose one of the functions, providing a selective reason for gene duplicates to be retained in a population. Genes whose expression in multiple tissues is regulated by separate ►**enhancers** may be particularly prone to subfunctionalisation, as mutations in different enhancers of two duplicate genes would necessitate the retention of both, even if the encoded amino acid sequences were identical. This provides a potential explanation for the apparently high retention rate of duplicate genes, at least in multicellular organisms (4).

A corollary of duplicate gene divergence is redundancy and compensation. Mutational analysis of families of homologous genes often reveals a degree of redundancy, such that the phenotype of a ►**double mutant** is more severe than the sum of the phenotypes of each single mutant. This implies the genes are partially redundant and that one gene can in part compensate for the lack of the other, due to co-expression in the same tissue and a similar biochemical function.

Evolutionary Implications of Gene Duplication

Gene duplication has the potential to provide a lineage with 'new' genetic material, in that one copy of the gene is, in principle, free to evolve new functions, while the other maintains existing functions. This concept has led to the suggestion that gene duplication and entire genome duplication may play an important role in evolutionary innovation. However direct experimental support for this suggestion is lacking and some evidence suggests that, contrary to the above, both duplicate copies experience purifying ►**selection** following duplication (5). Nevertheless, it is commonplace to find gene family members that have undoubtedly evolved by duplication playing different roles in

the development, biochemistry or physiology of an organism. This implies that some degree of evolutionary innovation frequently follows gene duplication. A second possible evolutionary consequence of gene duplication is the disruption of successful interbreeding between populations in which different genes have duplicated. This suggests gene duplication might be a powerful force behind the evolution of reproductively isolated populations, and therefore of new species (6).

Clinical Relevance

The phenotypic effect of chromosomal aberrations involving duplication of segments of DNA or the possession of extra chromosomes is due to the imbalance of gene products deriving from the duplicated genes. ►[Down syndrome](#) (trisomy of chromosome 21) is probably the best-known case involving an entire chromosome, as, unlike most trisomies in humans, embryos carrying an extra chromosome 21 are viable. There are numerous other syndromes involving the duplication of specific chromosomal regions (7). Incomplete gene duplications may also result in the fusion of two genes at the boundary between the original and duplicated DNA. This can result in novel gene products with deleterious properties.

Gene Expression

Definition

Gene expression describes the process by which a gene's coded information is converted into the

structures present and operating in the cell. Expressed genes include those that are transcribed into mRNA and then translated into protein, and those that are transcribed into RNA but not translated into protein (e.g. transfer and ribosomal RNAs).

►[Microarrays in Colorectal Cancer](#)

Gene Expression Data Analysis: Classification

Definition

For classification, algorithms such as weighted-voting, k -nearest-neighbor classifiers, support vector machines and artificial neural networks can be applied to the set of genes selected using supervised analysis of gene expression to build models capable of predicting the class of a particular sample. To test the robustness of classification, these methods are often coupled with a leave-one-out cross-validation analysis, in which one of the samples from the original 'training' set is withheld and a class prediction is made on the withheld sample. For complete validation, gene lists should be tested on a second 'test' set of samples that were not used to derive the discriminatory gene list.

Gene Expression Data Analysis: Supervised Analysis

Definition

Using this method, one searches for genes whose expression patterns correlate with an external parameter. The most commonly used 'supervising' parameters are clinical features such as survival, presence of metastases and response to therapy. Many statistical metrics have been used successfully in 'supervised' analyses, including the standard t -test, permutation-based tests, and signal-to-noise ratios.

►[Microarrays in Colorectal Cancer](#)

Gene Expression Data Analysis: Unsupervised Analysis

Definition

No external feature is used to guide the analysis process of gene expression. The data are used to search for patterns without any *a priori* expectation concerning the number or type of groups that are present. The most common ‘unsupervised’ analysis method is hierarchical cluster analysis, based on similarity metrics.

► [Microarrays in Colorectal Cancer](#)

Gene Expression Data Matrix

Definition

Gene expression data matrix refers to a table where each row represents a gene, each column represents a particular sample, or a particular experimental condition, and each position contains a number or a set of numbers characterising the expression level of the particular gene under the particular experimental condition.

Gene Targeting

Definition

Gene-targeting describes the production of a modified allele of a gene by the process of homologous recombination between a modified exogenous DNA

molecule with its endogenous counterpart (target). In transgenic technology, it is used to introduce a targeted mutation into the genome of mouse embryonic stem cells (►ES-cells). When injected into blastocysts, mutant ES-cells contribute to all tissues of the embryo, including germ cells. Once the mutant gene has entered the germ line, mouse strains heterozygous and homozygous for the mutated gene can be bred and analysed.

Genetic Algorithm

Definition

Genetic algorithm is a statistical/mathematical term/method that is aimed at finding the optimal solution to a question. The process is the same as natural selection: (1) selection of the strongest individuals/solutions, (2) production of new organisms/new solutions, by mixing the previously selected elements, and (3) mutations, which are accidental changes in the organisms/solutions. The process is reiterated until no more improvement can be done. The last solution is taken as the final one.

Genetic Background

ROBERT GERLAI

Psychology Department, University of Toronto at Mississauga, Mississauga, Canada
robert_gerlai@yahoo.com

Synonyms

Host genotype; host genome

Definition

Genetic background represents all the genes in the ►genome. The effects of “background” genes are often considered with regard to their ability to influence or modify the effects of ►mutations artificially generated by the experimenter in model organisms such as the mouse. Mutations may be induced or introduced using targeted mutagenesis (►Targeted Gene Disruption), for example by ►homologous recombination in ►embryonic stem cells in the mouse or by using random mutagenesis with chemical mutagens including ethyl nitroso urea ►ENU. These mutations interact with the genetic background and will express their effects at the phenotypical level in a manner modulated and modified by the genetic background, a phenomenon called ►epistasis. The present essay will focus on the genetic background from this perspective. It will explain the complications associated with epistasis and with genetic linkage using examples of ►knock out (or ►null mutant) mice developed for the analysis of molecular mechanisms of mammalian brain function and behavior. The issues raised in this essay, however, are general and will be valid for several other genetic manipulation approaches and for all fields of biology.

Characteristics

►Gene targeting allows to create null mutations in mice and to analyze how the mutant organism responds to the lack of the product of a ►single gene. This has facilitated the molecular dissection of such complex traits as mammalian brain function and behavior. However, numerous problems have been pointed out (2, 4, 5, 6) with regard to the interpretation of the phenotypical changes observed in null mutant mice. Briefly, the most controversial issues stem from the fact that scientists overlooked the influence of the genetic background. These issues can be divided into two main categories, both of which have general importance in genomics. The first is a cluster of problems associated with compensatory mechanisms. This problem is rather difficult as there is no general solution to avoid it. The second problem is associated with genetic linkage (the

so called flanking region problem). Practical solutions to this problem exist and will be presented. While the examples will be drawn mostly from the field of behavioral neuroscience, the points illustrated are valid for any biological trait.

The Complicating Effect of Compensatory Mechanisms

With gene targeting one can knock out a gene *in vivo* and create a mutant organism that lacks the gene product. The promise of gene targeting has been to reveal the *in vivo* function of the gene of interest. However, the functional relevance of gene targeting has been questioned [reviewed in (3)] because the mutation may lead to an avalanche of compensatory processes (e.g. up- or down-regulation of other genes) and resulting secondary phenotypical changes. Compensation may be due to ►genetic redundancy. Genetic redundancy in this context means that putative “helper” genes take over the function of the targeted one, e.g. become up-regulated and compensate for the absence of the product of the targeted gene. Although labor intensive, proper analysis of compensatory changes may allow one to reveal how biochemical pathways interact. For example, Chen et al. (1) showed that although a null mutation in protein kinase C γ subtype (PKC γ) in mice resulted in an apparently normal long-term depression (LTD) in the cerebellum of the mutants, LTD could be blocked by a PKC inhibitor only in control mice but not in the null mutants, suggesting that LTD was mediated, at least partly, by non-PKC dependent processes in the null mutant mice. “Compensatory” processes, however, can also induce phenotypical changes. For example, assume gene α serves hypothetical function ‘A’. Also assume that targeted gene α is compensated for by gene β in the genetic background; gene β becomes up-regulated in response to the absence of α gene product. The excess of gene β product is able to compensate for the lack of gene α product and no change is observed in function ‘A’ at the phenotypical level. However, over-expression of gene β may have some pleiotropic effects, i.e. may affect functions other than ‘A’, similarly to the way over-expression of genes alters the phenotype of transgenic mice. These functional alterations when observed by the investigator will be assigned to gene α . Although they are indeed due to the introduced mutation of gene α , they need not reveal the function of this gene *per se* because they are related to this gene only indirectly. This example is not hypothetical. Empirical evidence for similar situations can be found in the literature (2).

Teasing out the direct and indirect effects of the mutation is not trivial and dissection of the molecular mechanisms underlying complex phenotypical traits will require meticulous studies in which numerous factors need to be controlled. Lathe (6) discusses

several confounding factors. Instead of reiterating his arguments, the reader's attention is now drawn to what is proposed to be the main issue, the necessity of a "systemic approach" view in gene targeting (5) (also see ► [Phenomics](#)).

The Need for a Systemic View

The principal problem in genomics is a systemic one that concerns biological organization and the functional units of this organization. From a geneticist's viewpoint the units of biological organization are the genes and their function is to encode particular proteins. However, when it comes to the question of phenotypical effects, genes may not be the units and the definition of their function may be complicated. Clusters of genes in the genetic background defined by higher organizational level phenomena, including developmental, physiological or even behavioral, may represent the functionally relevant unit. Disruption of a single gene may alter a biochemical cascade within the functional gene cluster. Expression levels of the genes belonging to a functional cluster may change in concert. Investigation of such changes may reveal the biological organization of the organism. The boundaries of putative gene clusters may not be sharp. Some genes may belong more, others less, to a specific functional gene group. This also implies that the gene group organization may not be orthogonal, i.e. some genes may belong to more than one functional group. Functional groups may be hierarchically organized. A smaller number of genes may define subgroups that may make up groups that in turn may be organized into super-groups, etc. Disrupting single genes will perturb the organism and will force it to respond in a way inherent in its biological organization. The phenotypical changes one observes are the reflection of this organization. Instead of looking for the function of single genes, it is proposed that investigators should take a systemic organizational view into consideration, an approach conceptually similar to metabolic control analysis employed in biochemistry.

In summary, the effects of genetic manipulation must be investigated at all practically feasible levels of biological organization, including gene expression patterns, protein-protein interactions and a broad spectrum of phenotypical traits that may be affected by the direct and indirect effects of the mutation.

Polymorphism in the Genetic Background May Make the Results of Gene Targeting Studies Difficult to Interpret

Assume that knock out of gene α leads to differential expression of alleles b vs. B of gene β , and a regulatory change of gene β leads to different phenotypical effects depending on which allele (b or B) is present in the α null mutant mouse. Consequently, ► [polymorphism](#) in

the genetic background will not allow one to conclude with certainty that a particular phenotypical change observed in the null mutant was due to the null mutation or to the genetic background. This issue is especially problematic if the genetic background of the null mutant animals is different from that of their wild type control counterparts, which is a typical problem in a large number of gene targeting studies.

Null Mutant Mice of Gene Targeting Studies Are Often the F2 Offspring of Two Mouse Strains

The genetics of the breeding strategy usually employed to generate null mutant mice is explained in Fig. 1. The figure also depicts why the hybrid genetic background leads to complications.

The Flanking Allele Problem

The F2 population is a segregating population in which mice have recombinant genotypes derived from the two parental mouse strains (Fig. 1). The difficulties arising from this are threefold. First, the recombination pattern, i.e. which locus contains strain 129 and which B6 alleles and whether in a homozygous or heterozygous form, may be different between littermates. Thus not even wild type littermates of their mutant counterparts represent an appropriate control, since their alleles could be different from those of the mutants not only at the locus of the gene of interest but also at other loci. This may lead to false positive results. Second, due to the genetic variation resulting from the hybrid segregating background, detecting significant effects of the mutated gene may be difficult, which leads to false negative results. These two problems can be alleviated by measuring larger numbers of animals, i.e. by increasing the power of statistical comparisons and decreasing the possibility of sampling error. Increasing the sample size, however, will not solve the third problem, which is associated with genetic linkage. If the targeted mutagenesis is conducted in ES cells from strain 129, the chromosome with the targeted locus will carry alleles of genes of 129-type. The probability of genetic recombination is generally inversely related to the distance between the loci of the genes (linkage). Thus, the 129-type alleles of the genes whose loci are close to the locus of the mutated gene will remain together with the mutated allele of the gene of interest (Fig. 1). In other words, any time the mutation is detected in a mouse, e.g. by ► [Southern blotting](#) or PCR, that particular animal will also carry the linked 129-type genes with high probability. Conversely, a non-mutant control, animal will not carry these 129-type alleles and will have B6 alleles with high probability if the 129-ES cell chimera was crossed to B6. In effect, the mutation can be seen as a ► [marker](#) for the 129-type genes linked to the locus of the targeted gene. Consequently, any phenotypical differences

Genetic Background. Figure 1 The genetic background of mice generated by gene targeting. Most gene targeting is carried out in cultured embryonic stem (ES) cells derived from one of the substrains of mouse strain '129'. The 129-type ES cells carrying the targeted mutation are introduced into a blastocyst and the surviving chimeric embryos develop to term, are raised to adulthood and are mated to "wild type", i.e. non mutated, mice. ES cells originating from mouse strain 129 carry one *chromosome* (white) with the disrupted allele (double lines) of the targeted gene. If these ES cells populate the germ-line in the chimeric mice, the mutation will be transmitted when the chimera is mated. A cross between a germline transmitting chimera and a C57BL/6 (B6) mouse (black chromosomes (a) will produce an F1 population (b) in which 50 % of the animals will have one copy of the mutant allele (heterozygous mutants) and 50% of them will have no mutant allele (wild type animals) at the targeted locus. Using Southern blotting or PCR (*polymerase chain reaction*) one can detect the presence of the mutant allele and identify the heterozygous mutant animals. If these animals are mated with each other, according to Mendel's law, homozygous mutant (two mutant alleles), heterozygous mutant (one mutant and one wild type allele) and wild type (two wild type alleles) animals will be obtained. It is also important to remember, however,

observed between mutant and control littermates of the hybrid genetic origin may be due either to the introduced null mutation or to the background genes linked to the targeted locus. Thus, one may find false positive results [for experimental examples see (3)].

Solutions to the Flanking Allele Problem

In order to decrease the probability of contribution of variable background genes, one could backcross the mutant hybrid animals for several generations to the strain of choice, e.g. to B6, and create a **congenic strain** that carries the mutation on the desired genetic background. However, complete elimination of 129-type genes that surround the locus of the gene of interest is not practically possible. For example, even with 12 generations of backcrossing (approximately 2 years of breeding) to B6, the length of the 129-type chromosome segment introduced to the B6 genome

how genes at loci other than the targeted one will be inherited. Crossover events during the meiotic process of gametogenesis will "shuffle" the alleles of these background genes and will create recombinant chromosomes (c), which will characterize the genotype of the sperm and the egg of the F1 mice. The genotype of an F2 individual, therefore, will be represented by a pair of such recombinant chromosomes. For example, a homozygous null mutant mouse may have chromosomes a and b, a and c, or b and c; a heterozygous mouse may have one of the recombinant chromosomes with the null mutation (a, b, or c) and another without the null mutation (d, e, or f); whereas a wild type control mouse may have chromosomes d and e, d and f, or e and f. Panel C shows that the null mutant allele of the targeted gene will be surrounded by 129-type genes, however, the wild type allele of the gene will be surrounded by B6 type genes. This *linkage disequilibrium* is simply due to the fact that the null mutant allele came from a strain 129 genetic background. In an animal produced from mating such F2 mice (F3 or the following generations), the null mutant allele could be surrounded by B6 genes only if, during the meiotic processes of gametogenesis, crossovers occurred precisely flanking both sides of the targeted gene, events whose combined probability is infinitesimally small. (d) shows the probabilistic distribution of 129 (white) vs. B6 (black) alleles in an F2 segregating population. The depicted chromosomes thus represent the genotype "average" of the F2 population. Note that in mice carrying the null mutation (chromosome 'a'), the probability of finding 129 alleles on the mutant chromosome increases the closer a given locus is to the locus of the targeted gene. However, in mice carrying the wild type allele of the targeted gene (chromosome 'b'), the probability of finding 129 alleles decreases the closer a given locus is to the locus of the targeted gene. Also note that as the distance increases from the locus of the targeted gene, the probability of the presence of 129 vs. B6 allele approaches 50-50%. (Modified from (3))

would be, on average, about 16 centiMorgans (cM) representing about 1% of the genome, i.e. about 3–400 genes. But if no alternatives are available, backcrossing is recommended because it stabilizes the genetic background of the mutant line by reducing the variation in recombination patterns across generations. Other, more complicated breeding strategies have also been proposed [reviewed in (3)]. They represent better solutions than simple backcrossing but they do not completely eliminate the flanking allele problem. Additional suggestions have also been made [for review see (3)]; rescue experiments may rule out the potential effects of linked 129-type genes and generation of “knock in” mice may be a control for the null mutant gene “knock out” animals. Furthermore, inducible knock out techniques, e.g. tetracycline transactivator systems, are recommended because comparison of pre- and post-induction phenotypes represents appropriate within subject control. Finally, generating null mutant mice with a pure genetic background is known to be the perfect solution for the problems associated with the genetic background, but up to date, this has not been preferred because most ES cells are derived from 129 type mice and these animals are not good breeders.

Clinical Relevance

Numerous genetic models of human diseases have been and will be created. However, the genetic manipulation is expected to lead to complex phenotypical changes that are influenced by a large number of genes in the genetic background as well as by environmental factors. Understanding compensatory mechanisms and systemic responses to the induced mutation and eliminating or addressing the confounding effects of background genes are important steps forward that will facilitate the modeling and ultimately the understanding of human diseases.

Genetic Code

JEAN LEHMANN

Theoretical Biophysics, Department of Physics,
Royal Institute of Technology, Stockholm, Sweden
jean@theophys.kth.se

Definition

The genetic code is the set of correspondences between the codons of mRNAs and the amino acids of the proteins produced on the ribosomes through the ►translation of these mRNAs. This set also includes “stop” codons without an amino-acid assignment, which specify the termination of translation.

Codons are the units of information in mRNA. They are made up of three consecutive ►nucleotides, each of which can be one of the four bases U, C, G or A. Sixty-four different codons result from all the combinations. Twenty amino acids are coded through the phenomenon of translation. A twenty-first, selenocysteine, is coded in some organisms in particular situations (1, 2) and a still very rare twenty-second (pyrrolysine) has recently been discovered (2).

The set of correspondences between the codons and the amino acids is highly conserved in all organisms. The most common one is called the canonical genetic code, previously also called the universal genetic code before deviations were found in different ►taxa. It is usually depicted in a table with three entries (Fig. 1).

Since the sequences of mRNAs can be different from those of the genes for proteins from which they are transcribed, the coding rules are generally only valid for the mRNAs prior to translation. These differences arise from modifications on mRNAs through ►maturation processes occurring before translation (observed however almost only in Eukaryotes).

Characteristics

Main Molecular Processes Involved in Decoding

The coding rules are the outcome of extremely sophisticated molecular processes. Basically, the translation system converts genetic information contained in genes into functional proteins. The information is always processed in the form of an mRNA. In Eukaryotes, the latter can be the outcome of a complex maturation process from its primary transcript(s), which can involve several genes. In Eubacteria and Archebacteria, it is generally translated during or immediately after its ►transcription from a gene without any rearrangement. It may also come from the genome of an invasive entity (virus).

A start codon upstream of the mRNA signals the place of the beginning of translation. This codon is almost always AUG, but is also sometimes GUG (very rarely

Genetic Code. Figure 1 The canonical genetic code table. The codonic positions are arranged from left to right of the table, corresponding to the reading direction of the mRNAs (5'–3'). Each of the sixty-four possible codons code for a particular amino acid or the stop function, which binds a release factor RF1 or RF2 at the end of translation. The amino acids are abbreviated to their three-letter notation.

UUG or CUG). Any of these codons can bind the initiator tRNA coding a modified methionine, N-formylmethionine. The start codon also positions the sequence into the correct **▶reading frame**. The process generally ends at a stop codon (UAA, UAG or UGA in the canonical genetic code), which binds a release factor RF1 (UAA, UAG) or RF2 (UAA, UGA).

The path leading a free amino acid to incorporation into a coded protein involves three main steps (Fig. 2):

1. **▶Activation** of the amino acid by the corresponding aminoacyl-tRNA synthetase (aaRS) through hydrolysis of a molecule of ATP.
2. The aaRS subsequently binds the amino acid to a cognate tRNA. Prior to translation, a complex made up of an **▶elongation factor** Tu (EF-Tu) and GTP binds the amino acid at the 3' end of the tRNA, giving it a much higher affinity for the ribosome.

3. During translation, occurring on the ribosomes, the successive codons of a particular mRNA are tested by the incoming tRNAs through anticodon-codon associations. A proofreading mechanism is preceded by hydrolysis of the GTP of the complex at the 3' end of the tRNA. Anticodon-codon complementarity is the decisive factor leading to the formation of the peptide bond between the last amino acid of the nascent protein and the amino acid carried by the incoming tRNA.

Accuracy of the Coding Rules

The reliability of the coding rules thus depends on the accuracy of two major processes of molecular recognition:

- a) Binding of both an amino acid and a tRNA by an aaRS (steps 1–2).
- b) Binding of the anticodon of a tRNA by a codon of an mRNA through base pairing (step 3).

The first process (a) constitutes a textbook case of RNA-protein recognition (3) and has been referred to as the second genetic code; as soon as a particular aaRS has bound an amino acid to a cognate tRNA, the code is virtually already established since the anticodon-codon associations occurring in (b) follow relatively strict base-pairing rules.

Each of the (generally) twenty different aaRSs thus recognizes both a tRNA and an amino acid. The recognition elements on the tRNAs are mainly situated in the acceptor stem and anticodon domains, which constitute the two major spatial regions of that molecule. Both positive and negative elements are used by the aaRSs to identify their associated tRNAs, and differentiation between two tRNAs can sometimes depend on the identity of only a few bases (3). Since more than one tRNA molecule is often necessary for the translation of the whole set of codons belonging to a particular amino acid, in several cases an aaRS must be capable of recognizing different tRNAs, which implies that the anticodon is sometimes not used as a discriminatory element (e.g. for ser-, leu- and ala-accepting tRNAs). The aaRSs are among the most studied enzymes, and their structural analyses have given important clues on the evolution of the genetic system (4).

The second process (b) involves an initial selection and a proofreading mechanism that are used by the ribosomes to discriminate between correct and incorrect anticodon-codon associations (5). These coupled mechanisms, separated by GTP hydrolysis, ensure a very low error frequency which in *E. coli* has been estimated as being between 6×10^{-4} and 5×10^{-3} . The initial selection step occurs when an incoming tRNA charged with its cognate amino acid (combined with EF-Tu and GTP) binds the ribosome and tests the

Genetic Code. Figure 2 The main molecular processes involved in the assemblage of free amino acids into proteins according to the rules of the genetic code. Three sets of molecules participate in the translation of the mRNAs: the encoded amino acids (20 different kinds), the aminoacyl-tRNA synthetases (aaRSs) (at least one for each encoded amino acid, not all shown here) and the tRNAs (at least 22 but often more than 30 different kinds, not all shown here). The example shows the events leading to the translation of a CUU codon of an mRNA. First, a leuRS binds a leucine and subsequently catalyses its activation through the hydrolysis of a molecule of ATP, resulting in an aminoacyl-adenylate (leu ~ AMP) and ppi [reaction (1)]. As soon as the leuRS recognizes a cognate tRNA (in this case, a tRNA with an anticodon GAG), the aminoacylation reaction occurs and the tRNA is thus charged with the amino acid [reaction (2)]. The AMP molecule is then released. After the [EF-Tu + GTP] complex has bound the amino acid at the 3' end of the tRNA (not shown here), the latter can participate in translation, occurring on a ribosome. In accordance with the wobble rules (Table 1), it can successfully bind the CUU codon, thereby enabling the formation of the peptide bond between the incoming leucine and the nascent protein [reaction (3)]. The previous tRNA (with the anticodon AAG) then leaves the ribosome. Note that the codons read from 5' to 3' (thus from right to left in the figure) and the anticodons from 3' to 5'. The arrow above the mRNA shows the starting place of translation, while the cutting of the strand into codons is indicated by small dots. For clarity, details on structures and events are omitted at the level of the ribosome.

codon at the point of being translated. At this stage, most of the non-cognate tRNAs are rejected. However, in addition to cognate tRNAs, some near-cognate tRNAs (whose anticodons can form partial base-pairs) may also cross this first stage, associated with the hydrolysis of the GTP. This hydrolysis results in a [▶conformational](#) change of EF-Tu, which subsequently leaves the 3' end of the tRNA. The amino acid is then free to move to the [▶peptidyl-transferase center](#) of the ribosome where peptide bond formation can take

place. Before that event however, almost all remaining near-cognate tRNAs are rejected (proofreading) (5).

Caveat

The standard rules of the genetic code can be altered during translation events that have been referred to as “recoding” (1). These alterations are specific to individual mRNAs, and involve three possible kinds of event, [▶programmed frame shifting](#), [▶translational bypassing](#) and [▶redefinition of codons](#). Albeit not

common, it is thought that any of these events may occur in all living organisms (1). They serve notably as control mechanisms of gene expression.

Order in the Genetic Code Table

Degeneracy

Since most of the amino acids are coded by more than one codon, the genetic code is degenerate (Fig. 3). The degeneracy is connected with the base in third position of the codons, which often has only a small influence on the nature of the encoded amino acid. A particular codon generally belongs to one of two major categories, the four-fold and the two-fold degenerate families. In two cases, the latter family is further split into individual codons, each with a specific assignment. The presence of a degeneracy symmetry over the entire table, appearing when the succession [U, C, G, A] (or its inverse) is used to write the table, shows that the splitting into four-fold and two-fold degenerate families is conditioned by the nature of the bases in the first and second positions of the codons (Fig. 3).

The origin of the degeneracy stems from the existence of wobble rules in the base-pairing of the third position of the anticodons that can be specific to the type of family (four-fold or two-fold degenerate), and which are controlled by the ribosome (Table 1). Thus, in the case of mitochondrial and chloroplastic systems where wobble rules are the most extensive, a tRNA with U in the third position of the anticodon can translate any of the four codons of the corresponding four-fold degenerate family, while a tRNA with U (G) in the third position of the anticodon can translate any of the two codons with G or A (U or C) in the third position of the anticodon of the corresponding two-fold degenerate family. As a result, only 22 different tRNAs are necessary in some systems (in which also the AGR family is reassigned to stop; see next subsection) in order to read all the codons for amino acids. The wobble rules are, however, generally less extensive and in most systems more than 30 kinds of tRNAs are used for the translation of all the codons. Moreover, the tRNAs often have modified bases in the third position of the anticodon (e.g. I, Q), each with particular matching properties (Table 1).

An important consequence of this wobble phenomenon, enabling a limited number of different tRNAs to cope with the whole set of codons, is an improvement in the efficiency of translation.

Moreover, some amino acids are present in more than one codon family. Thus, leu, ser and arg are coded by a total of six codons in two codon families in the canonical genetic code.

Reassignments

Although the general organization of the genetic code is conserved over all living organisms, many variants

Genetic Code. Figure 3 Degeneracy in the canonical genetic code table. Two families of degeneracy are mainly present in the table: the four-fold degenerate families (gray rectangles) and the two-fold degenerate families (squares). In two cases (AUR and UGR), the latter type of degeneracy is further split into individual codons. The succession [U, C, G, A] used to write the table highlights a degeneracy symmetry over entire the table (dashed line), highlighting the fact that simple rules based on the nature of the bases in the first and second positions of the codon account for the distribution of the two main families in the table:

Four-fold degenerate families		Two-fold degenerate families	
1st pos.	2nd pos.	1st pos.	2nd pos.
(W)	(Y,S)	(W)	(Y,W), (R,S), (R,W)
(S)	(Y,W), (Y,S), (R,S)	(S)	(R,W)

where the following categories are used to differentiate the bases: S (strong matching) = G or C; W (weak matching) = A or U; R (purine) = A or G; Y (pyrimidine) = C or U

Main source: ref (6). N = U, C, G or A; R = A or G; Y = C or U. Mt. = mitochondria; ch. = chloroplasts

have been discovered in different taxa. In addition, the organelles (mitochondria and chloroplasts) have their own translation systems with specific variants of the canonical genetic code (Fig. 4).

An examination of all the variants discovered so far indicates that some codons are more prone to reassignment than others (6). The stop codons constitute a typical example; the two-fold degenerate family UAR is frequently reassigned to gln in the nuclear system, while UGA almost always codes for trp in mitochondria. This particular versatility may be explained by the rarity of these codons, which implies that their reassignments might not cause catastrophic disturbance. Another interesting change concerns the AUA codon, which often codes for met in the mitochondria. As a result, the degeneracy symmetry pointed out in Fig. 3 is entirely valid for the

mitochondrial systems that also have UGA coding for trp. These changes imply that the wobble rules can be altered within the codon families concerned.

Furthermore, it has been observed that all codons that have been reassigned in the nuclear systems have also been subject to reassignment in the mitochondria, while no codon has been reassigned in the nuclear systems only (6).

Some codon families seem to be excluded from any reassignment procedure. This is especially the case for all codons with G in first position, corresponding to the amino acids val, ala, gly, asp and glu, as compared with the codons with U, C or A in this same position, for which at least four changes have been reported (Fig. 4). Moreover, all these amino acids are only present in this part of the table in the canonical genetic code. This particularity shows that the genetic code has a core.

Genetic Code. Figure 4 Reassignments and parameters of order in the canonical genetic code table. The numbers refer to reassignments that have been reported so far [main source: ref (6)]: ¹ thr, ² ser, ³ met and unassigned, ⁴ stop, ⁵ trp and cys, ⁶ unassigned, ⁷ ser, gly, stop and unassigned, ⁸ ser, gly, stop and unassigned (⁷ and ⁸ changes are independent), ⁹ leu, ala and gln, ¹⁰ tyr, gln and glu, ¹¹ asn. Unassigned means that the codon(s) disappeared in the entire genome. Changes that have been reported in mitochondria only are indicated by an asterisk (*). The gray area within the table points out all codon families with G in first position, for which any reassignment has been reported so far. The corresponding amino acids generally constitute more than 97% of the amount of all amino acids produced in experiments thought to reproduce the conditions of the early Earth (the results however differ slightly depending on the hypothesized conditions). The hydrophobicity parameter is shown on the top of the table. It is connected with the 2nd anticodonic position (overdrawn above the codonic one), the succession [A, G, C, U] ranking the bases in decreasing order on the hydrophobicity scale. The hydrophobicity correlation between the base at this position and the amino acids result in most of the hydrophobic amino acids being on the left of the table, while most of the hydrophilic ones are on the right.

The Core of the Genetic Code

As revealed by statistical analyses of coding sequences, all codons of the genetic code do not occur with equal probability. Some codons occur very rarely while others

are frequent. Many factors can affect their distribution, but a general trend connected with the organization of the genetic code, which is independent of the organism or the genes under consideration can be highlighted.

The most general pattern occurring in coding sequences is GNN, meaning that the codons with G in first position are overrepresented in comparison with those with U, C or A at this same position (N stands for any nucleotide).

These codons code for the amino acids val, ala, gly, asp and glu, which display the simplest side chains of all the amino acids of the genetic code. This can explain their relative abundance in the proteins of which they constitute the scaffold.

One can, furthermore, connect this abundance to the observed stability of their assignment (see previous section). Changing the signification of any of the corresponding codons may cause malfunctions in some proteins, resulting in disturbances in biochemical processes (it has, however, been experimentally shown that an organism such as *E. coli* can survive treatment of this kind).

Interestingly enough, this set of amino acids generally constitute more than 97% of the total quantity of all amino acids found in the so-called prebiotic synthesis experiments (Fig. 4). It thus seems likely that the primitive code was limited to the use of these amino acids, which were only assigned to the codons with G in first position for physico-chemical reason. Later, more codons and more amino acids were added, eventually constituting the genetic code as we know it in present-day organisms.

A Hydrophobicity Parameter in the Table

Correlation studies on physico-chemical properties of the constituents of the genetic code have revealed that the **hydrophobicity** of the base in the second position of the anticodon is positively correlated with that of the encoded amino acid. It has also been established that the succession [A, G, C, U] ranks the bases from the most hydrophobic (A) to the most hydrophilic (U). Thus, Fig. 4 naturally arranges the amino acids into the genetic code table with regard to hydrophobicity; the most hydrophobic amino acids are mainly on the left of the table while the hydrophilic ones are on the right.

This order in the genetic code table is noteworthy since the hydrophobicity of the amino acids has a major influence on the folding of the proteins of which they are the constituents. Thus, an analysis of coding sequences based on this correlation can provide information on the structure of the corresponding encoded proteins (7).

Clinical Relevance

Since the aaRSs are responsible for the reliability of the coding rules, genetic diseases affecting these proteins can create important disorders in the organism.

Autoantibodies to five aaRRs have been described, and each is associated with a syndrome of inflammatory myopathy with interstitial lung disease and arthritis (8). At the level of the ribosome, antibiotics such as paromomycin and streptomycin can significantly affect the fidelity of translation. Paromomycin stabilizes the tRNAs irrespective of whether the codon-anticodon pair is cognate or near-cognate and hence increases amino acid misincorporation (5).

Genetic Counselling

Definition

The following definition of genetic counselling was adopted by the American Society of Human Genetics: “Genetic counselling is a communication process which deals with the human problems associated with the occurrence or the risk of an occurrence of a genetic disorder in the family. This process involves an attempt by one or more appropriately trained persons to help the individual or family to (1) comprehend the medical facts including the diagnosis probable course of the disorder and the available management; (2) appreciate the way heredity contributes to the disorder and the risk of recurrence in specified relatives; (3) understand the

alternatives for dealing with the risk of occurrence; (4) choose the course of action which seems to them appropriate in view of their risk their family goals and their ethical and religious standards to act in accordance with that decision; and (5) to make the best possible adjustment to the disorder in an affected family member and/or the risk of recurrence of that disorder.”

Genetic Distance

Definition

Genetic distance describes the linear distance between genes on a genetic map, measured in Morgan (=100 centi-Morgan); a genetic distance of 1 centi-Morgan between two loci entails that they are expected to be involved, on average, in one recombination per 100 meioses.

Definition

Genetic epidemiology is the scientific discipline concerned with the causes and distribution of human diseases in groups of relatives and with the inherited predisposition to disease in populations. In many ways, genetic epidemiology is an interdisciplinary science that has more aspects of population and evolutionary genetics to it than of classical epidemiology. Only recently has the discipline changed its focus to target diseases that are characterized by the small-to-moderate relative risks that are usually the objective of conventional epidemiological research. So far however, genetic epidemiology has been most successful in elucidating the genetic basis of so-called “monogenic” disorders, including cystic fibrosis, Huntington disease and Duchenne muscular dystrophy (Table 1). The

OMIM: Entry number in "Mendelian Inheritance in Man Online" at ► <http://www.ncbi.nlm.nih.gov/omim/>

approach taken to detect the genetic variants responsible for these diseases is generally known as "positional cloning". Instead of relying upon prior knowledge about the disease-causing biochemical defect(s), positional cloning utilizes the segregation pattern of genetic markers (e.g. SNPs, microsatellites, RFLPs) in affected families to localize the genes involved in a given phenotypic trait ("linkage analysis"). The more often the trait and a particular marker allele are co-inherited by family members, the stronger the evidence that a gene in the vicinity of the marker influences the trait, i.e. that marker and disease gene are linked.

Characteristics

Gene Mapping and Meiotic ► Recombination

Formally, linkage analysis involves the assessment of the recombination fraction θ between two genetic loci like, in the context of genetic epidemiology, a marker and an unknown disease gene. Parameter θ equals the rate at which children receive from a given parent either the grand-maternal allele at one locus and the grand-paternal allele at the other or *vice versa*. Assuming Mendelian inheritance, $\theta = 1/2$ for a pair of genes located on different chromosomes. For two loci residing on the same chromosome, meiotic recombination is only possible *via* "► crossing-over", signifying the breakage and re-union of homologous, non-sister chromatids during the metaphase of meiotic division I (Fig. 1). Indeed, it can be shown mathematically that θ equals exactly half the probability of at least one crossing-over occurring between the two loci in question, provided that some critical assumptions about the randomness of crossing-overs are correct.

In any case, one corollary of the above is that θ represents an increasing function of the physical distance between two loci and therefore provides a key parameter for gene mapping. Unfortunately, θ is not an additive measure of distance since it can never exceed $1/2$. In order to facilitate gene mapping, θ

therefore has to be transformed into a linear "► genetic distance" $d(\theta)$ by some ► mapping function (the most widely used being $d(\theta) = 1/2 \ln(1-2\theta)$, proposed by British geneticist J.B.S. Haldane in 1919). Genetic distance is measured in units of Morgan (M) in order to honour T.H. Morgan, the American Nobel prize-winning biologist who first discovered the role of chromosomes in heredity. One centi-Morgan (cM) roughly corresponds to one expected recombination per 100 meioses.

Parametric Linkage Analysis

Linkage analysis has two major objectives, namely (i) to clarify with some statistical confidence whether $\theta = 1/2$ or $\theta < 1/2$, and (ii) to estimate θ in the latter case. Both goals are easily achieved in laboratory animals where controlled breeding can be performed such that, after a few generations, recombinants and non-recombinants can simply be counted. In humans as well as in animals with longer generation times however, linkage analysis has to fall back upon family data. How such data can be used to draw statistical inferences about linkage depends upon their complexity, i.e. on how much prior knowledge is available about the genetic, environmental and stochastic nature of the phenotypes of interest.

For the simple genotype-phenotype relationships encountered with most monogenic disorders, family data can be analysed by explicitly modelling the co-inheritance of the disease and marker in a family, based upon the underlying genotype frequencies and ► penetrances ("parametric linkage analysis"). In such cases, the likelihood L of a given recombination fraction θ_0 between disease gene and marker is a computable function of the phenotypic data D observed in the family. This leads to the definition of $z(\theta_0) = \log_{10} \{L(\theta = \theta_0|D)/L(\theta = 1/2|\Delta)\}$.

Quantity z , termed the "► lod score" and introduced by N.E. Morton in 1955, is used as a sequential statistic to

Genetic Epidemiology. Figure 1 Process of crossing-over during germ cell development. The two nearly duplicated chromosomes align during the late metaphase of meiotic division I, where an overlap and breakage of their constituent non-sister chromatids may occur (red: maternal chromosome, blue: paternal chromosome). Re-annealing and re-synthesis by the cellular repair mechanisms leaves two chromatids with genetic material flanking the site of crossing-over that is not of the same parental origin (i.e. the resulting chromosomes would represent recombinants with respect to the two loci shown).

test whether $\theta < \frac{1}{2}$, and to quantify the evidence in favour or against θ_0 . When $z(\theta_0) > 3$, then linkage between disease gene and marker locus is regarded as being proven and θ is estimated by that recombination fraction that yields the highest lod score. This procedure is exemplified in Fig. 2 for a large family affected by an autosomal dominant disorder. The results of a linkage analysis are usually presented in the form of lod score tables or graphs (Fig. 2b) where *ceteris paribus*, studies of independent (i.e. unrelated) families can be aggregated by summation of the family-wise lod scores. If a disease gene is to be integrated into a pre-existing map of linked markers, then this is most efficiently performed by parametric multi-locus linkage analysis, which has been shown to be up to twice as accurate as the pair-wise approach, measured in terms of the variance of the ensuing recombination fraction estimates.

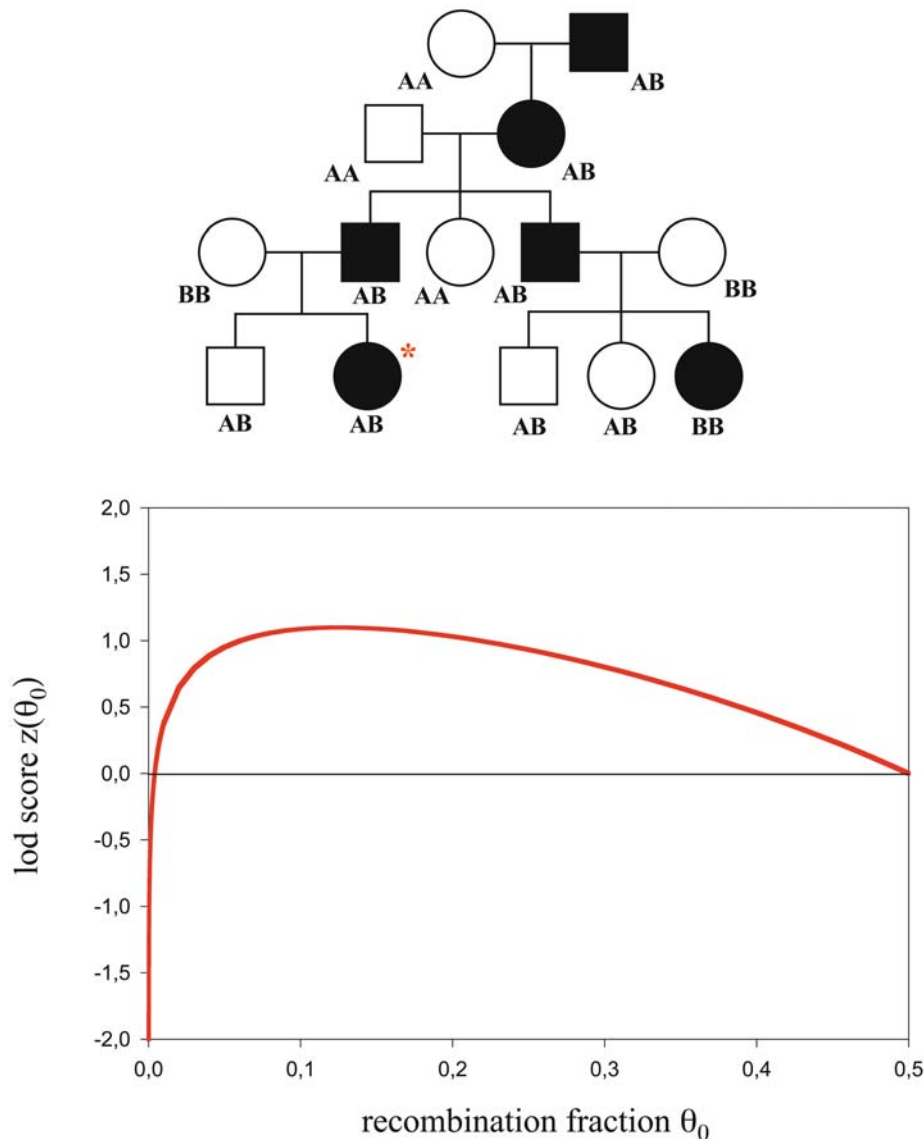

Non-Parametric Linkage Analysis of Complex Diseases

Increasingly, the major challenge to genetic epidemiology is being posed by so-called “complex” diseases, which comprise conditions such as diabetes, heart disease, cancer and psychiatric illness. When compared to monogenic disorders, this category of disease is characterized by

- a substantially higher population frequency,
- the involvement of multiple genes, most probably interacting with one another,

- relatively minor effects exerted by individual variants and
- an important modifying role of environmental factors.

Since no prior information is usually available as to how genetic variation at a given locus modifies the risk for a complex disease (i.e. the genetic model of the disease is unknown), gene mapping for complex diseases has to adopt robust, albeit less powerful, “non-parametric” or “model-free” linkage analysis such as, for example, the study of pairs of relatives. The idea underlying this approach, which is both simple and intuitively appealing, goes back to a 1935 paper by British medical geneticist L.S. Penrose. The number of sib-pairs, out of a total of n independent pairs, who share k parental alleles of an autosomal locus identical by descent (“ibd”) follows a multinomial distribution with parameters z_k , $k = 0, 1$, or 2 (Fig. 3). Under the null hypothesis of no etiological connection between marker and disease, the inheritance of a marker can be assumed to follow Mendelian rules and to be independent of the disease status of the siblings. This implies that, irrespective of whether the sibs are concordant or discordant, $z_0 = \frac{1}{4}$, $z_1 = \frac{1}{2}$ and $z_2 = \frac{1}{4}$. Any test for a deviation from these proportions represents a test for linkage between the marker and a putative disease gene. In its original form, the affected sib-pair test required that the ibd status at each marker be determined unequivocally for all sib-pairs.

Genetic Epidemiology. Figure 2 Linkage analysis of a family affected by an autosomal dominant disease. (a) shows the pedigree with patients marked by black symbols. Genotypes observed for a biallelic marker locus with alleles “A” and “B” are displayed alongside each individual. (b) is a graphical display of the lod scores as calculated from the family data, assuming full penetrance and lack of *de novo* mutation. The lod score at $\theta_0=0.00$ equals minus infinity owing to a recombination that has occurred during the paternal meiosis leading to an affected girl in the most recent generation (marked by *).

However, a number of derivatives of the test have since been developed which incorporate posterior distributions on k (as inferred from other relatives), utilize relatives other than sibs or are based upon identity-by-state (“ibs”) rather than ibd allele sharing. In general, these methods are less powerful than the original test, but can extract mapping information that would otherwise not be used.

Quantitative Phenotypes

Non-parametric methods have also been devised for the genetic analysis of quantitative phenotypes which, in many instances, may be more powerful than the consideration of dichotomized disease outcomes (“affected” vs “non-affected”) derived from them. The idea underlying the concept of quantitative trait mapping is nevertheless the same as for qualitative characters in

Genetic Epidemiology. Figure 3 Level k of autosomal identical-by-descent (ibd) allele sharing between two sibs. For each value of k (i.e. $k=0, 1$, or 2), shared alleles are marked in red for the second sib.

Genetic Epidemiology. Table 2 Haplotype frequencies of two biallelic loci

Marker 2	Marker 1		Total
	allele 1A	allele 1B	
allele 2A	a	b	a+b
allele 2B	c	d	c+d
Total	a+c	b+d	1

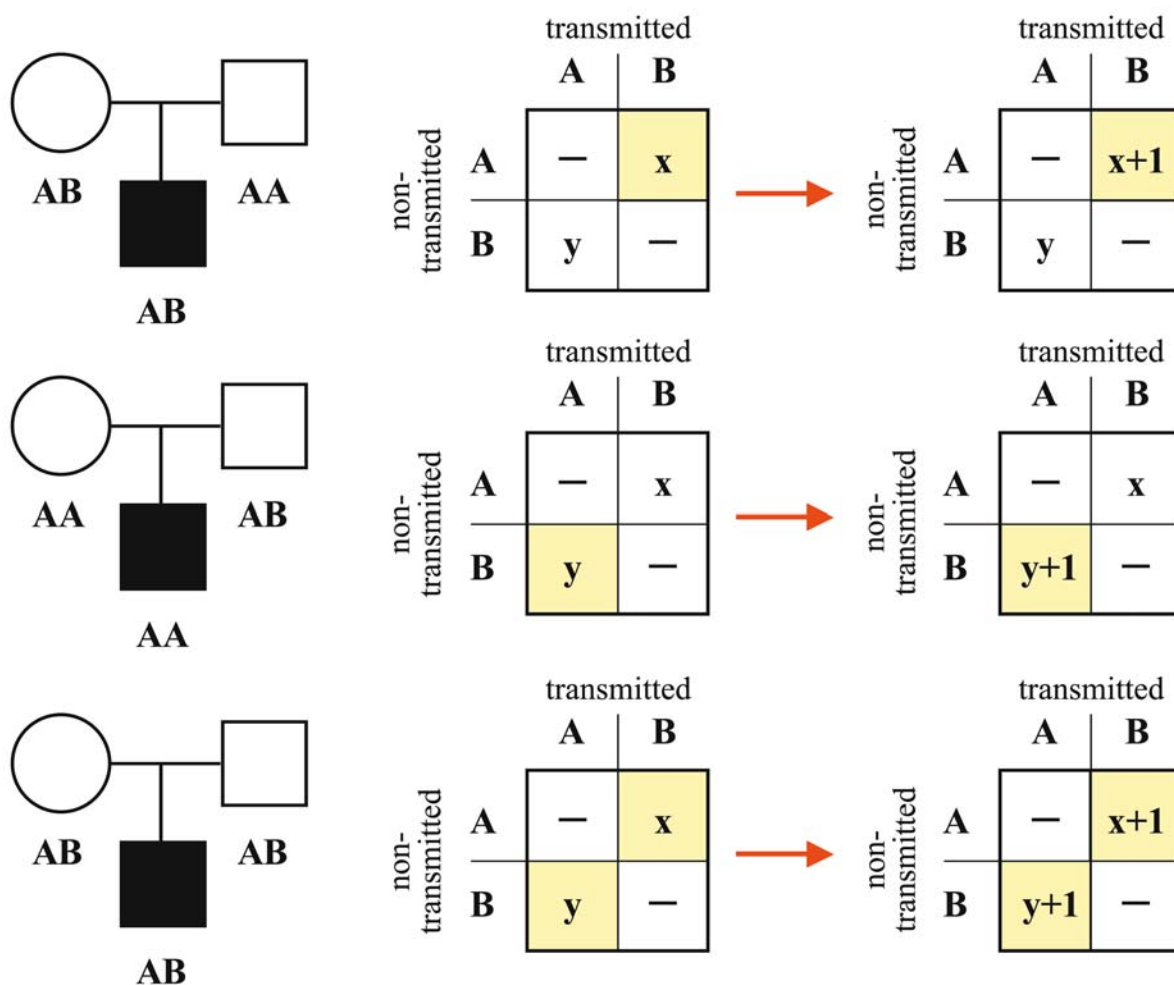

Linkage disequilibrium (LD) is usually measured by $D=ad-bc$. However, since D depends upon the marginal sums (i.e. the allele frequencies), LD is often quantified by $D'=D/D_{\max}$ instead. Here, D_{\max} denotes the maximum absolute value of D that is possible for the same allele frequencies. If $D>0$, then $D_{\max}=\min\{(a+c)(c+d), (a+b)(b+d)\}$; if $D<0$, then $D_{\max}=\min\{(a+b)(a+c), (b+d)(c+d)\}$.

that the observed level of marker ibd sharing between relatives is compared to their phenotypic similarity. If a marker is linked to a gene that influences the trait, then sibs with similar phenotypes, for example, will tend to share more than $1/2$ of their marker alleles ibd whereas dissimilar sibs will not. A formal test for this effect was proposed by American statisticians J.K. Haseman and R.C. Elston in 1972. For each sib-pair, the squared difference Y of their phenotypic values is calculated, and the number π of their ibd marker alleles determined (or estimated). A linear regression analysis of Y on π then reveals (i) whether the two variables are correlated and (ii) whether a significant relationship, if found, is a biologically plausible indication of linkage. The Haseman-Elston approach has since been expanded and refined, for example by considering the mean-corrected product of the sib-specific phenotypes instead of Y , so as to increase informativity about linkage. An alternative method aims at decomposing the variance of the phenotype into components that are due to genes which are either linked to the marker, or not ("variance component analysis"). For a marker

linked to a gene of strong effect, the phenotypic covariance among relatives should be positively related to their degree of marker ibd sharing, and this relationship translates into larger estimates of the corresponding variance components.

► Linkage Disequilibrium

Intervals of 1 Mb are generally regarded as the limit of mapping resolution that can be achieved using (family-based) linkage analysis, and more precise mapping of disease genes can only be expected from population-based association studies, exploiting linkage disequilibrium (LD). The most general definition of LD is the condition that the alleles of linked loci do not occur statistically independent on the chromosomes observed in a population. In the simplest case of two biallelic loci, haplotype frequencies can be arranged in a two-by-two table with cell probabilities a, b, c and d (Table 2), and LD is meaningfully quantified by the cross product $D = ad - bc$. When a new allele first arises in a population by either mutation or migration, it occurs as a single copy that resides on a certain haplotype background, together with certain alleles of other loci. Only in later generations will the allele become more frequent through either selection or genetic drift or both. In any case, chromosomes carrying the new allele will recombine with chromosomes carrying other haplotypes so that the strong original LD will erode with time. This loss of LD will be slower for closely linked loci and, under some simplifying assumptions about mutation rates, migration and mating patterns, D can indeed be shown to decrease by a factor of $1 - \theta$ in each generation. Therefore, strong LD is an indication of close linkage and assessment of LD between a marker and putative disease gene can be regarded as linkage analysis in a super-pedigree tying all analysed individuals together. In principle, any kind of genetic marker can be employed in disease association studies provided that (i) the marker mutation rate is low and (ii) the density of markers chosen for analysis is high enough to ensure

Genetic Epidemiology. Figure 4 Transmission disequilibrium test (TDT) of disease-association for biallelic marker genes. The sampling units of the TDT are nuclear families comprising both parents and an affected child ("trios"). Only transmissions from heterozygous parents to their children are evaluated (cells x and y in the table shown). The TDT statistic equals McNemar's $(x-y)^2/(x+y)$, which follows a χ^2 distribution with 1 degree of freedom under the null hypothesis of no association.

sufficiently strong LD with disease gene(s). Empirical data and theoretical considerations suggest that a sensible marker density should be no lower than approximately 1 in 50,000 nucleotides. Ideally, association markers should be chosen from within genes that represent biologically plausible candidates for an involvement in the disease of interest. The chance of detecting association would then be increased further if marker alleles were themselves of functional significance by altering, for example, the protein product or a regulatory sequence.

Family-based Association Studies

The simplest form of a population-based association study is that invoking a case-control design. As in classical epidemiology, relative risks or odds ratio of particular marker genotypes or haplotypes can be

estimated from the respective frequencies in patients and unrelated healthy controls. However, concerns have arisen over the potentially confounding effects of ethnic, social or geographical population stratification that would generate systematic differences between the genetic characteristics of the two samples, unrelated to disease. To solve this problem, family-based association designs have been proposed of which the transmission disequilibrium test (TDT) is the most widely used. A TDT is basically a McNemar test for preferential transmission of particular marker alleles from heterozygous parents to their affected offspring (Fig. 4). Any deviation of the transmission to non-transmission ratio from the expected 1:1 is indicative of both linkage between marker and disease gene in the presence of LD and of LD in the presence of linkage.

Since chromosomes of close relatives act as internal controls in the TDT and similar tests, it has become almost paradigmatic for the genetic epidemiology of complex disease that family-based association studies are superior to case-control designs. However, family-based designs also have disadvantages that might not always be fully outweighed by their apparent robustness. For example, gene-environment interactions cannot be analysed in family-based studies since no genuine controls are available for comparison to patients. Furthermore, parental genotypes are required for the TDT and these may be difficult to obtain for late-onset disorders. The use of other family members as surrogates to try to reconstruct parental genotypes with some certainty has been suggested in such instances. However, such methods are usually costly, inaccurate and inefficient. On the other hand, possible confounding of data by population stratification can be avoided in case-control studies through careful matching by ethnic and geographic origin. Furthermore, if a sufficiently large set of genetic markers is available that is not itself tested for association, then these markers can be used to estimate the level of population stratification and to correct the employed test statistic accordingly. Finally, although population stratification may represent a theoretical possibility, empirical evidence for its practical importance as a confounding factor in genetic epidemiology is still lacking.

Clinical Relevance

The reasons for the apparent lack of success that plagues genetic studies of complex disease are manifold and the most critical issue is probably the reduction in power caused by genetic heterogeneity. Genetic heterogeneity can occur at two levels, either within genes ("allelic heterogeneity") or between genes ("locus heterogeneity"). In order to increase the power of genetic studies of complex diseases, the major goal in their planning and performance is thus to control for genetic heterogeneity at all levels. First and foremost, this requires a careful choice of the population under study. Ideally for a disease association to be detectable, all copies of the predisposing allele should be *ibd* in patients. The best populations to analyse for LD are therefore those that have been small and isolated for most of their history or that have undergone recent expansion from a small number of founders. Not surprisingly, genetic epidemiology has been particularly successful in Finland and some inward breeding communities in the USA (e.g. Amish, Hutterites, Ashkenazim). In addition to population genetic issues, an appropriate definition of phenotypes, a breakdown by sub-phenotypes and the use of sensible covariates to define etiologically homogeneous sub-populations can help to reduce genetic heterogeneity further. Finally, genetic epidemiology

is a constantly evolving scientific discipline so that improved power may also arise from the development and application of new analytical tools that take genetic and etiological heterogeneity into account (e.g. multi-locus statistics, time series analysis).

Complex human diseases are typically common and have a substantial economic impact upon national health systems. The resulting public interest renders disorders such as cancer, heart disease and diabetes particularly attractive for genetic research and a large number of studies into these diseases are often being performed in parallel. On the other hand, for the reasons mentioned above, the prior probability of successfully mapping and characterizing genes for complex diseases is comparatively low and usually unknown. Even with high significance levels imposed, most positive gene mapping results may therefore be wrong. This implies that genetic epidemiological research will almost inevitably continue to be driven towards the generation of false positive results. Claims as to the elucidation of a disease predisposition should therefore always be received with some caution and judged as preliminary until confirmed by controlled replication, meta-analysis or independent laboratory experiments.

Genetic Map

Definition

Genetic map (also known as a linkage map) is a map of a genome, which shows the relative positions (order and distances) of the genes and/or markers on the chromosomes. The map is based on pairwise coinheritance (linkage) of markers. Genetic maps are generally composites of data from many experiments.

► [Chromosome 21, Disorders](#)

Genetic Modification

Definition

Genetic modification describes the introduction of a new nucleic acid into a cell, organism or micro-organism. In the context of clinical gene transfer, the term is used in conjunction with the transfer of a nucleic acid. This can be achieved by either introducing an expression construct or by modification of cellular nucleic acid e.g. by revision of a point mutation. Nucleic acids used (e.g. for triple helix formation or RNA with ribozyme function that is not part of a transgene) are not meant to lead to genetic modification as far as the term is used in the context of clinical gene transfer.

► [Clinical Gene Transfer](#)

Genetic Polymorphism

Definition

Genetic polymorphism is the presence of multiple inherited forms of a gene with at least an allele frequency of 1% within the population.

Genetic Predisposition to Multiple Sclerosis

ALASTAIR COMPSTON

University of Cambridge Neurology Unit,
Cambridge, UK

alastair.compston@medschl.cam.ac.uk

Definition

► [Multiple sclerosis](#) is a typical complex trait. There is an increased familial recurrence risk and evidence from ► [linkage](#) and ► [association](#) studies for functional ► [polymorphisms](#) that increase disease susceptibility but without Mendelian patterns of inheritance. There is epidemiological evidence for the role of environmental factors in determining the distribution of the disease.

Characteristics

Familial Multiple Sclerosis

Multiple sclerosis has a familial recurrence rate of approximately 15%. Overall, the reduction in risk changes from 3% (relative risk 9) in first-degree relatives to 1% (relative risk 3.4) and 1% (relative risk 2.9) in second and third degree relatives, respectively, compared with a population lifetime rate of 0.3%. At one extreme, the risk of multiple sclerosis is 35% for the monozygotic twin partner of an affected proband, or the children of parents who are both affected (► [conjugal pairs](#)), compared to 0.3% for individuals related by adoption to a proband. Familial clustering is therefore genetically determined.

Cellular and Molecular Recognition The Analysis of Complex Traits

Two methods—linkage and association—underpin the analysis of complex traits. Linkage has low statistical power but operates within families across relatively large genetic distances. Association has high statistical power but is only informative within the boundaries of

►linkage disequilibrium present in the population under study. In founder populations, polymorphisms that increase susceptibility to disease are necessarily located within a large group of linked genes. This block is subject to recombination during subsequent meioses and is gradually whittled down until there is no residual linkage disequilibrium. It seems that genetic factors determine susceptibility and, to some extent, also shape the clinical course. The choice of markers has been driven either by *a priori* guesses on the nature of susceptibility (►candidate genes) or systematic screening of the genome. Candidates selected because they map within linked regions combine both strategies. Markers are analyzed individually (single point analysis) or corrected for information available from their neighbours (multipoint analysis). The cumulative probability that a given marker or region of interest is linked or associated with multiple sclerosis can be formally tested by ►meta-analysis of available studies. The lesson learned thus far is that no one gene makes a major contribution to susceptibility although collectively they determine a relative risk (for siblings) of around 20.

Candidate Genes in Multiple Sclerosis

Much effort has gone into the assessment of candidate susceptibility genes chosen on the basis of prevailing ideas concerning the pathogenesis of multiple sclerosis. Population studies comparing unrelated cases and controls show an association between the class II ►major histocompatibility complex alleles DR15 and DQ6 and their underlying genotypes (DRB1*1501, DRB5*0101 and DQA1*0102, DQB2*0602). This is seen in almost all populations (Caucasian, Oriental, Arab, Hispanic, Finnish, Russian and Jewish) although the strength of the association differs. Even those ethnic groups in which the frequency of multiple sclerosis is low, or the phenotype distinct from that usually observed in northern Europe, are now acknowledged to be primarily DR15 associated with one exception. In Sardinians, the association is with DR4 (DRB1*0405-DQA*0301-DQB1*0302). In some other Mediterranean populations (Canaries and Turkey), the association is with DR2 (DRB1*1501, DQA1*0102, DQB1*0602) and DR4 (DRB1*04, DQA1*03, DQB1*0302). Most investigators assume that—based on the genetics and obvious candidature through its role in restricting the immune response—DR (or DQ) is itself the susceptibility gene encoded at 6p21.

Outside the major histocompatibility complex, many candidates have been screened. The case made on the basis of ideas concerning the pathogenesis of multiple sclerosis is much strengthened by prior knowledge that the candidate gene also maps to a region already implicated by linkage studies (positional candidates). The range of candidates now studied includes adhesion

molecules, immune receptors, accessory molecules, cytokines, chemokines and their receptors or antagonists, structural genes of oligodendrocytes or myelin, and molecules regulating cell death and survival. In a small and regionally restricted population of Finns, multiple sclerosis is associated and linked to the gene for myelin basic protein, encoded on chromosome 18. The effect can be traced to a subset of families with common ancestry and does not hold up in the larger cohort. It is the nature of screening so many potential effects that a proportion will appear to be associated or linked but by chance. Equally, it would be difficult to show unambiguously that one or more genes exerting a small biological effect is making a contribution to susceptibility in a single study. That said, some plausible associations or linkages have been provisionally reported, although no one of these has yet stood up to repeated replication. These mainly involve factors that appear to increase susceptibility to multiple sclerosis, but there is provisional evidence for primary effects on resistance and effects on severity or clinical features of the disease.

DR15 is associated with younger age at diagnosis and female gender but does not distinguish features relating to disease course, outcome, specific clinical features or paraclinical investigations. This suggests that DR15 exerts its effect on susceptibility rather than modifying the course of multiple sclerosis. Loci apparently associated with disease protection are FAS-670, IL-12p40, FcR and MCP-3. Genes that may influence the course or phenotype of multiple sclerosis include CTLA4, IL-1Ra/IL-1B, IL-2, CCR5, oestrogen receptor, CNTF and Apo-E and mutations of mitochondrial DNA.

Linkage Genome Screens

The dividend from attempting to fast-track the solution to susceptibility in multiple sclerosis by the candidate gene approach has been small but the problem is also not solved by the nine whole genome linkage analyses using variable numbers of families from the United States, Canada, United Kingdom, Finland, Sardinia, Italy, Turkey, Scandinavia and Australia. These screens have involved between 21–225 families each typed for 257–443 microsatellite markers chosen to provide an average spacing of around 10 centiMorgans. Although several new genomic regions of interest were revealed, many are false positives. These whole genome screens have been used to explore regions of interest in more detail hoping to consolidate their status based on mapping but without picking out positional candidates. Linkage on chromosome 17q is supported by additional positional screens from Denmark, Canada, and Finland. There is collateral support for the involvement of chromosomes 5p, 7p and 12q based on direct evidence and synteny with genes determining susceptibility to experimental forms of demyelination.

Meta-analysis has been deployed in the expectation that this will reduce the evidence for false positive peaks and strengthen the candidature of those which are genuine providing the best guide to shared regions of interest as the map is serially up-dated. This was last completed in 2005.

Whole Genome Association Screening

Until recently, whole genome linkage disequilibrium mapping was considered impractical and dependent on chance co-localisation of susceptibility genes and markers applied randomly and at low density. This situation changed with the increased availability of widely distributed microsatellite markers and is set to increase further with the identification and mapping of [▶single nucleotide polymorphisms](#). A first pass at screening the genome for association was completed in 2003 based on a 0.5 cM map of microsatellite markers and using DNA pools derived from cases with multiple sclerosis and unrelated controls. Individual results provided provisional evidence for associations based on linkage disequilibrium outside the major histocompatibility complex on 6p21. The number of micro-satellite markers used necessarily made this a low-density screen, especially since the number of informative markers was less than the full set of 6000 used in this Genetic Analysis of Multiple sclerosis in EuropeanS (GAMES). With considerable variation depending on the stochastic nature of linkage disequilibrium on individual chromosomes in European populations, it may only have covered 10% of the genome in detail and another 20% in part, leaving much yet to be explored. Perhaps its main value lies in the exclusion of many microsatellite markers lying in blocks of linkage disequilibrium of varying size rather than in the provisional positive associations. New screens based on single nucleotide markers present on individual chips, and at a much higher density are now in progress.

Future Strategies for Identifying Susceptibility Genes

Once regions of interest are mapped, the next aim is to move from whole genome screening to the identification of functional polymorphisms which condition one component or another of the disease process and determine variations in the clinical course and features. How to reach that position is less clear and several parallel strategies have been suggested. One is to add incrementally to the number of available families until thresholds for linkage are reached for the identification of secure loci using statistical criteria for genome wide significances. An alternative is to accept that the combination of linkage and association now available is sufficient to concentrate the search for positional candidates within regions of interest. Each

provisional site already offers several interesting possibilities, although the number of genes encoding components of the nervous, immune and signalling systems is such as to make practically any region suggestive with respect to sensible candidates. Rapid progress is being made in characterising the whole genome for the size, distribution and diversity of blocks containing a restricted number of haplotypes. If the preliminary evidence holds up, it will be possible to tag the common variants within each block in populations (such as Europeans) retaining significant linkage disequilibrium and screen individuals for the susceptibility haplotypes with relative economy.

Clinical Relevance

[▶Concordance](#) within families can be used to gauge the influence of genetic factors in determining the clinical phenotype of multiple sclerosis. Time to reach the later stages of disability does not differ between familial and sporadic cases. Conjugal pairs show no evidence for clinical concordance, clustering at year of onset or distortion of the expected pattern of age at onset in the second affected spouse. The most recent assessment of concordance in co-affected siblings and parent-child pairs supports a role for genetic factors in determining age at onset and progression either from onset or after a phase of relapsing remitting disease, but not the initial presentation or disability. Concordant parent-child pairs show no distortion in the random distribution of male-female pairings and neither sex nor line of inheritance influence disability, age at onset or course. In this situation, disability is highest in the male offspring of affected fathers, who more commonly follow a primary progressive course.

The risk of [▶autoimmunity](#) is increased in the relatives of probands with multiple sclerosis. Three surveys, together involving around 4000 relatives of 1000 probands, have shown recurrence of multiple sclerosis in 15% with another autoimmune disease (Graves' disease, rheumatoid arthritis and diabetes) in about 5% of pedigrees. Several other disorders have been considered more frequent than expected in patients with multiple sclerosis. None of these is entirely secure but there may be co-morbidity between neurofibromatosis 1 and primary progressive multiple sclerosis.

A minority of patients who meet clinical criteria for the diagnosis of multiple sclerosis and in whom there are associated magnetic resonance imaging abnormalities and cerebrospinal fluid oligoclonal bands have an illness in which there is disproportionate involvement of the anterior visual pathway. These are commonly women with male relatives already known to be affected by [▶Leber's hereditary optic neuropathy](#) and they have pathological mutations of mitochondrial

DNA. The clinical features of demyelinating disease seen in Orientals and Africans are distinct and provide another example of clinical heterogeneity. In Japan, multiple sclerosis shows either a Western phenotype, in which a number of sites are involved, or an optico-spinal pattern in which the clinical picture is dominated by involvement of visual and spinal cord pathways with a specifically different genetic background (HLA-DP*1501 rather than DRB1*1501 seen with the Western phenotype). However, recent reports of multiple sclerosis in Japanese highlight the previously under-reported extent of the so-called Western phenotype. Demyelinating disease is considered extremely rare in Africans, but a number of cases are described and the phenotype is typically a severe illness dominated by one or more episodes usually affecting the anterior visual pathway and spinal cord—again combining the anatomical features of ►Devic's disease with the clinical course of moderately severe relapsing remitting multiple sclerosis. ►Phenocopies may confuse the analysis of complex traits where diagnosis depends on pattern recognition of symptoms, signs and laboratory investigations in the absence of a test for the disease. Reassuringly, one large cohort screened for other diseases was shown not to be contaminated by cases of ►CADASIL, ►spinocerebellar degeneration, or ►adrenoleukodystrophy.

Conclusions

Six main categories of susceptibility genes can be predicted: genes which determine susceptibility to the process of inflammation across a range of disorders – the *autoimmune* genes; those which determine the specificity of that process for the development of multiple sclerosis – the *ubiquitous* genes; those which are relevant for the pathogenesis in isolated populations – the *domestic* genes; those which determine particular phenotypes – the *pleiotropic* genes; those which determine variations in the clinical course – the *modifying* genes and those which cluster to provide specifically different (heterogeneous) contributions to the pathogenesis – the *epistatic* genes. A major part of future studies will be to resolve the question of disease heterogeneity in multiple sclerosis. When eventually in place, the potential of this genetic knowledge for improved understanding of the pathogenesis of multiple sclerosis and designing novel treatments is considerable. Resolving the issues of complexity and heterogeneity in multiple sclerosis and other complex traits has practical dividends. Without knowledge linking aetiology to pathogenesis and phenotype, putative new treatments will continue to be screened in cohorts who may or may not have an appropriate pathological substrate for that particular intervention.

Genetic Redundancy

Definition

Genetic redundancy refers to the presence of genes in multiple forms in the DNA of eukaryotes. Two or more genes are capable of executing the same tasks, thus eliminating one gene's function. It does not alter the development of function.

Genetic Screen

Definition

Genetic screening is analysing a group of individuals to identify those who are at high risk of having or passing-on a specific genetic disorder. In experimental genetics, the term describes an approach to identifying genes and gene functions by random gene knock out and identifying genes causing a specific phenotype; or vice versa, identifying phenotypes caused by specific gene knock out.

Genetic Screening in Populations

VILMUNDUR GUDNASON

Icelandic Heart Association Heart Preventive Clinic
and Research Institute, Kopavogur, Iceland
v.gudnason@hjarta.is

Definition

“Genetic screening may be defined as any kind of test performed for the systematic early detection or exclusion of a genetic disease, the genetic predisposition or resistance to a disease or to determine whether a person carries a gene variant which may produce disease in offspring. Screening may be concerned with the general population or with specific sub-populations defined on some basis other than their health” (from the European Society of Human Genetics, ►<http://www.eshg.org/>).

Characteristics

Population screening has been applied in the newly born for a long time for medical conditions known to be preventable by medical intervention, such as phenylketonuria. In more recent times considerably more knowledge on underlying genetic defects for various diseases has become available. What conditions to screen for, medically, biochemically or genetically has been a matter of discussion for decades. Most common diseases have complex multifactorial and probably ►polygenic underlying causes. For that reason, genetic screening for complex diseases in populations is not really feasible for the time being. However, a number of genetic variations have been associated with the risk of developing disease and may be applied as specific tests in the evaluation of risk in groups of patients identified by a given disease. Despite that, only ►monogenic diseases or disorders fit the criteria set for appropriate population screening including genetic screening.

Wilson and Jungner (1) put forth ten criteria, which should be considered before population wide screening should be set up. These criteria are that:

1. the condition being screened for should be an important health problem.
2. the natural history should be well understood
3. there should be a detectable early stage
4. treatment at an early stage should be of more benefit than at a later stage
5. there should be a suitable test for identifying people at the early stage
6. the test should be acceptable
7. intervals for repeating the test should be determined

8. there should be adequate health service provision for the extra clinical workload resulting from the screening
9. the risk of screening, both physical and psychological should be less than the benefits
10. the costs should be balanced against the benefits

There are not many diseases or disorders that fulfil these criteria completely and far from all monogenic diseases do so. ►Familial hypercholesterolemia (FH) is one condition, which does fit exactly. FH is a monogenic disorder that is due to a defect in the low density lipoprotein (*LDL*) receptor gene with a lifelong elevation of blood cholesterol (2). It has a prevalence of 1 in 500 in most populations and a high risk of premature coronary artery disease and can be described as an important health problem. The natural history of FH is well understood and the disorder can be detected early in life. Treatment is available and there is strong evidence that early treatment is beneficial. The diagnosis of FH, whether performed by clinical or genetic testing does not require more complex intervention than venipuncture. Once the diagnosis is made, there is no need for further diagnosis. Considerable experience in screening for FH has accumulated in many populations and FH can be looked at as a paradigm for screening for other monogenic disorders or diseases.

Cellular and Molecular Regulation

Familial hypercholesterolemia is caused by a mutation in the ►*LDL receptor gene*. The ►LDL receptor takes up cholesterol from the bloodstream by binding LDL cholesterol particles, mainly in the liver and thus reduces blood levels of cholesterol. Individuals who lack LDL receptor or have a reduced number of functional receptors demonstrate considerably increased levels of blood cholesterol. FH is an autosomal dominant disorder with a gene dosage effect. This means that heterozygotes for a mutation in the *LDL receptor gene* frequently have double the amount of blood cholesterol compared to individuals from the general population and homozygotes or ►compound heterozygotes have several fold increase in blood cholesterol.

A variety of different mutations in the *LDL receptor gene* have been found to cause FH. These can be accessed on the FH web site www.ucl.ac.uk/fh/. The sheer number of mutations makes the identification of FH complicated. Most mutations are confined to a single or a few families, but others are more widespread. However, there are a number of mutations that have been found to be population specific allowing for population based screening for a given set of mutations. There are two main approaches for identifying previously unidentified individuals with FH; first, examination of first-degree relatives for a given index case and secondly, genealogical tracing in defined

populations to a common ancestor for a known mutation in the *LDL receptor gene*.

First Degree Relative Screening

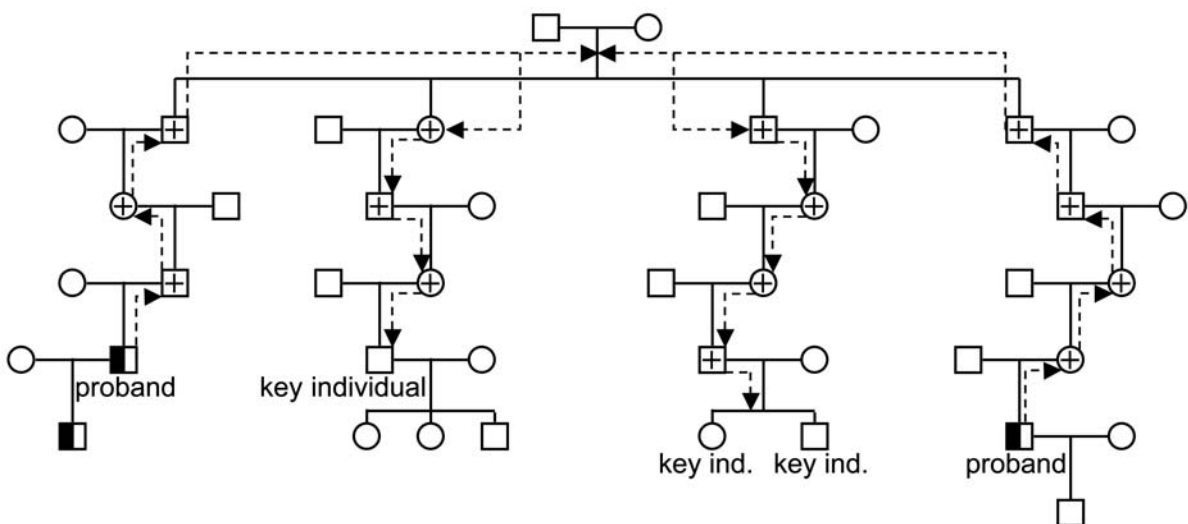

The conventional approach to identify new FH patients is to ask FH index cases for informed consent to contact their first-degree relatives. This is the method recommended by the Med Ped project (Make Early Diagnosis – Prevent Early Deaths in Medical Pedigrees) (<http://www.medped.org/>). The main advantage of such an approach is the high probability of diagnosing family members carrying the LDL-receptor mutation when contacting close relatives. The probability is 50% for first-degree relatives of the index case (parent, sibling and child) and then declines by about half for each generation. In the Netherlands, experience from FH screening using similar first degree relative approaches, revealed 2039 individuals identified as **heterozygous** FH of 5442 relatives tested (3). The main disadvantages are that the doctor needs to rely on consent from the patient to contact his/her relatives and that pedigrees based on information from the patients are seldom complete for more than one or two generations back. Therefore the search for new patients can reach a blind end.

Genealogy Tracing for Identification of Affected Individuals

The genealogy tracing approach is applicable where there is a common mutation in a specific population in an isolated area where genealogical information is available either from church records or other similar

records or genealogical information is electronically available such as in the example from Iceland described below (4).

A common mutation in the *LDL receptor gene* (14T +2C) has been identified and found to be responsible for up to 60% of FH in Iceland. For the genetic screening only probands with this mutation were included. These probands were genealogically traced to common ancestors by The Icelandic Genetic Council's family tracing office. The family tracing was performed through a partly computerized database derived from censuses (first carried out in Iceland 1703), church records and birth and marriage certificates. Once a common ancestor had been identified, a list of all descendants was produced. The oldest individual alive in each family lineage was identified as key individual and contacted for cholesterol measurements and for genetic testing (Fig. 1) after obtaining informed consent. If positive for the common mutation, his or her offspring were recruited for testing. Relatives of key individuals negative for the common mutation were not recruited. Fourteen probands positive for the common mutation were genealogically traced to four family clusters, one cluster with four probands, one with three probands and two with two probands each. The ancestors for the clusters were born in the late 18th century and early 19th century and were traced back for 3 and 4 generations. Three of the probands could not be linked to any other proband. The tracing revealed 2201 live individuals in the four family clusters and of these, 364 (17%) key individuals were identified (Fig. 1). Three

Genetic Screening in Populations. Figure 1 The pedigree shows how two individuals with FH (probands) are traced to a common ancestor (upwards tracing arrows). The oldest individual alive in each family lineage was identified as key individual and contacted for genetic testing (downward tracing arrows). Offspring of the key individuals positive for the mutation were recruited for testing. If positive, their offspring were also called in and so on. Relatives of key individuals negative for the mutation were not recruited. + means a deceased individual and black filling an affected individual.

hundred and six key individuals (84%) responded. Thirty five (11%) of the 306 key individuals who responded were positive for the common mutation or nearly one in every 9 key individuals tested. This yield is a fifty-six-fold enrichment from the 1 in 500 yield of screening the general population. No homozygotes were detected. Of the 35 positive key individuals, seven had not been diagnosed before.

This demonstrates that screening extended families is a feasible approach for achieving the goal of finding individuals with FH previously unknown to have this treatable condition. This approach may well be practical in other populations where genealogical information is available.

Clinical Relevance

Familial hypercholesterolemia is a condition with considerably elevated risk of developing coronary artery disease, which may eventually lead to a heart attack. A report from The World Health Organization (WHO) shows the mean age of onset for coronary heart disease in untreated individuals to be 45–48 years in males and 55–58 in females (5). This enormously raised risk of a heart attack that is potentially preventable calls for an active search for and identification of affected individuals at an early age and an aggressive treatment of all known risk factors for coronary heart disease. The WHO conference in Paris 1997 (5) urged an early diagnosis and treatment of individuals with FH. The main challenge is to prevent premature atherosclerosis in individuals with FH.

In recent years a new class of drugs for the treatment of hypercholesterolemia has become available. These are HMG CoA reductase inhibitors called statins, which directly affect intracellular production of cholesterol and hence lead to an increase in the number of LDL receptor molecules on the cell surface of the liver. This in turn leads to enhanced uptake of cholesterol rich particles from the circulation with a corresponding reduction in the level of blood cholesterol. It has been demonstrated that cholesterol-lowering drugs are effective in reducing coronary stenosis assessed by coronary angiography in patients with FH (6) and there is evidence for improved survival of patients with FH in recent years especially after the introduction of statin therapy (7).

The prognosis for primary prevention of coronary artery disease in heterozygous FH patients is excellent and for that reason it is a major important challenge to identify undiagnosed or inadequately treated individuals.

The above example of genetic screening fulfils all the criteria for screening in populations set by Wilson and Jungner in 1968 (1). There are a number of monogenic diseases that may benefit from the experience obtained from the effort of identifying new FH patients by systematic search.

Genomic Analysis of Single Disseminated Cancer Cells

CHRISTOPH A. KLEIN

Institute of Immunology, Ludwig Maximilian University, Munich, Germany
christoph.klein@med.uni-muenchen.de

Definition

The term “disseminated cancer cells” refers to cells that originate from a malignant primary tumour and are found at ectopic sites as single cells or small cell clusters. More than 80% of human malignant tumours stem from epithelial tissues (such as mammary glands, lung or gastro-intestinal organs). The major cause of death for patients that suffer from these types of cancer (carcinomas) is metastasis, i.e. emergence of tumour colonies that are found in organs distant from the primary site of tumour growth. Today many cancer patients are diagnosed before metastatic disease is detected by clinical imaging techniques (such as X-ray or CT scans) and will be submitted to surgery of their primary tumour. A substantial percentage of these patients, however, will eventually succumb to metastasis months, years or even decades after initial diagnosis of their primary cancer, indicating that tumour cells left the primary tumour before the surgeon removed it, and that some of these cells have the potential to found a metastasis. Therefore, great effort was undertaken to detect the precursor cells of later arising metastasis at the time of surgery in order to develop means for prevention of later arising metastasis. For cancers of epithelial origin, detection of disseminated cancer cells is often based on histogenetic markers that enable discrimination from the surrounding cells, i.e. identification of epithelial cells in purely mesenchymal organs. Clinically accessible mesenchymal organs are blood, bone marrow or lymph nodes. Thus the applied markers (e.g. epithelial cytokeratins) do not detect tumour cells directly but epithelial cells that are usually not found in mesenchymal organs of donors without epithelial malignancy. Clinical studies revealed that the finding of cytokeratin positive cells (with most studies performed on bone marrow or lymph node) at the time of surgery puts carcinoma patients at high risk for the development of metastasis later on. Depending on tumour type and clinical stage, approximately every third carcinoma patient without manifest metastases harbours disseminated cancer cells in bone marrow or macroscopically tumour-free lymph nodes. However, absolute and relative tumour cell

frequencies are extremely low, being about one or two cancer cells per two million bone marrow cells. Thus, disseminated cancer cells belong to the rarest cells in the human body and their molecular-genomic characterization requires special techniques.

Characteristics

(Whole) genome analysis of single disseminated cancer cells

The first studies that characterized cytokeratin-positive cells intended to confirm their malignant nature. It was shown by interphase fluorescence in-situ hybridisation (►FISH) that some cytokeratin-positive cells harbour chromosomal abnormalities. Then, protein expression of a variety of cancer-associated molecules was tested on cytokeratin-positive cells. Although sporadic insights into the biology of disseminated cancer cells could be obtained, double staining (or labelling in the case of FISH) was very cumbersome because of the extreme rarity of the investigated cells.

A single diploid cell contains about 6 pg genomic DNA. Multiple molecular-genetic analyses of such minute amounts therefore require amplification. To this end several methods have been developed with the most frequently used being the ►DOP-PCR (degenerate oligonucleotide-primed ►PCR) and the PEP (primer extension, preamplification) method or derivatives thereof. These methods use mixtures of degenerate or random primers to amplify the whole genome, which leads to the problem that it is impossible to control for equal binding of the primers to complex sequences for unbiased amplification. However unbiased amplification is mandatory for the application of whole genome screening techniques such as comparative genomic hybridization that measures numerical aberrations in tumour cell genomes. To circumvent this problem an adaptor-linker approach was developed. Here, the genome is cut into small fragments (about 100–2000 bp) by a frequently cutting restriction enzyme. Then, adaptors are ligated to both ends of the fragments and the fragmented genome is subsequently amplified using a single primer that binds to the adaptor and thereby amplifies all fragments alike.

The approach is increasingly applied to disseminated cancer cells of various types of tumours and the results have changed the prevailing view on metastatic progression. Of the many interesting findings perhaps the most important are that dissemination occurs often earlier than previously thought. The cancer cells often display less or different genomic aberration than their matched primary tumours. Thus metastases and primary tumours seem to develop independently to a large degree.

Gene expression analysis of single disseminated cancer cells

With the completion of the human genome project and the introduction of technologies such as DNA microarrays and laser microdissection, many fields in biology and medicine await the application of comprehensive gene expression analyses of specific cell types isolated from defined tissues. For the amplification of single cell mRNA the first protocols were introduced in the late eighties and early nineties of the last century. So far the protocols are based on either of two principal approaches, linear amplification by T7 RNA polymerase or PCR-based amplification.

As a general rule, PCR-based methods are easier to handle and less time consuming, while there are concerns about the quantitative reliability of measurements obtained after exponential amplification. The linear amplification achieved by T7 RNA polymerase, also referred to as the Eberwine protocol, has the advantage that a potentially occurring failure to amplify a given transcript will not be exponentially transmitted. Here, mRNA is transcribed by a primer containing the promoter of the T7 RNA polymerase. After **►cDNA** synthesis, in-vitro transcription is performed and the procedure is repeated once or twice. The effect of the few cycles is thought to change only marginally – if at all – the original template ratios. On the other hand, several groups have observed that the relative abundance of transcripts is also preserved by PCR-based methods – provided that the correct conditions are applied.

Our preferred method belongs to the approaches using PCR. The protocol uses a single primer that binds to two binding sites artificially introduced to all mRNA sequences. First, a poly-C flanking region is incorporated during cDNA synthesis and after reverse transcription a poly G-tail is added. Four aspects seem to be particularly important. Firstly, single cell mRNA is bound to a solid phase enabling the change of buffers and thereby always optimal conditions for each enzymatic reaction. Secondly, random primers for cDNA synthesis reduce the length of primary transcript and allow for subsequent amplification within the optimal range for PCR. Thirdly, a poly-G tail provides a much better primer binding site than a poly A or poly T tail. Fourthly, introducing a poly-C flank on one side of the template and a poly-G tail on the other makes all sequences equally G/C-rich at their primer-binding site. Adequate conditions for a single poly-C PCR primer, i.e. high annealing temperature and the addition of denaturing agents such as formamide enable highly specific and unbiased amplification of such sequences. With this amplification method in hand, gene expression profiling of single cells has become possible and first interesting results have been obtained. For example, we found that the minor histocompatibility

antigen HA-1 is aberrantly expressed on single disseminated cancer cells. This finding makes it reasonable to apply allogeneic bone marrow transplantation as immunotherapy in a HA-1 mismatch situation. We recently adopted the protocol for high-density oligonucleotide microarrays. Thus, screening of all expressed human genes may reveal new target structures on single disseminated cancer cells, the precursor cells of lethal metastasis.

Clinical Relevance

Clinically manifest metastatic disease can rarely be cured. One likely reason is that the cancer cells have genomically and phenotypically progressed so far that they are highly resistant against current ways to induce apoptosis by any type of treatment, another that the tumour burden is just too large for complete tumour cell eradication at tolerable drug doses. Therefore, systemic therapies are added to loco-regional treatment (e.g. surgery or irradiation therapy) before metastasis becomes manifest. Such therapies target the relatively few tumour cells that spread throughout the body, have therefore been called “adjuvant” and are currently in the centre of clinical efforts. The underlying rationale is to destroy the tumour seed timely when the tumour load is low and the cells still vulnerable. However, adjuvant chemotherapies, which are currently the best characterised and most effective, have not fulfilled the hopes so far. Although several therapy regimens improve significantly the overall- and the disease-free survival of the patients, the absolute benefit is rather low being in the range of few percent and improving survival time for the individual patient by few months. It is increasingly recognized that one reason for the failure of adjuvant therapies is the almost complete lack of knowledge about the target cells – the disseminated cancer cells. Disseminated cancer cells are genomically and phenotypically often very different from their matched primary tumours. Therefore, therapies that are based on mechanisms active in primary tumours do not necessarily exert an effect on disseminated cancer cells. Rather, direct analysis of single disseminated cancer cells promises to uncover novel molecular targets for effective adjuvant therapies.

Genomic Imprinting

TAKUYA IMAMURA, ANDRAS PALDI
Ecole Pratique des Hautes Etudes, Evry, France
paldi@genethon.fr

Definition

Genomic imprinting, also called parental or gametic imprinting, is a process of epigenetic marking that

allows the cells to differentiate the alleles of paternal and maternal origin of a gene without changing their DNA sequence. The phenomenon of imprinting was explicitly recognized at the beginning of the 1980s on the basis of two types of observations. First, pronuclear transplantation studies on mouse zygotes demonstrated that monoparental conceptuses were not viable, suggesting that biparental contribution is necessary for mammalian development (1, 2). Second, systematic genetic studies of mice with chromosomal translocation showed that some chromosomal regions must be inherited from both parents for normal development (3). These pioneer studies led to the construction of a low-resolution chromosomal imprinting map of the mouse genome. It was postulated that the requirement for both parental genomes to be present in the same zygote was a consequence of differential epigenetic marks on a fraction of the paternal and maternal alleles. The parental origin-specific imprints on the two alleles of the same gene lead to their differential expression. Typically, one parental allele is silenced and only the other remains functional. It is precisely this property that has been used to identify imprinted genes. A gene is considered imprinted if it is expressed monoallelically and its allelic expression depends on its parental origin. However, the real situation is more complicated. The analyses of the known imprinted genes have demonstrated that most of them are expressed biallelically in some tissues, at least at some developmental stages. As a consequence, we face a paradoxical situation. It is quite difficult to prove that a gene is not imprinted, unless its allelic expression is examined in all tissues at all stages of the life. The ambiguity of the definition might be the reason for the difficulty estimating the number of imprinted genes in the genome. On the basis of the relatively low frequency of mutations with parental origin-dependent phenotype, the number of imprinted genes was initially estimated as not more than 300. However, a systematic transcriptome analysis suggested that there might be more than 2,000 genes with differential parental origin dependent expression in the mouse.

Characteristics

Characteristics of Imprinted Genes

In order to understand the phenomenon of imprinting, current research is focused on the following major questions: 1) How are the parental alleles of a gene marked without changing the DNA sequence? The imprint has to be sufficiently stable to be inherited through mitosis, but reversible during the meiosis. 2) When do the genes acquire their parental-specific imprints? 3) What is the biological significance of this phenomenon?

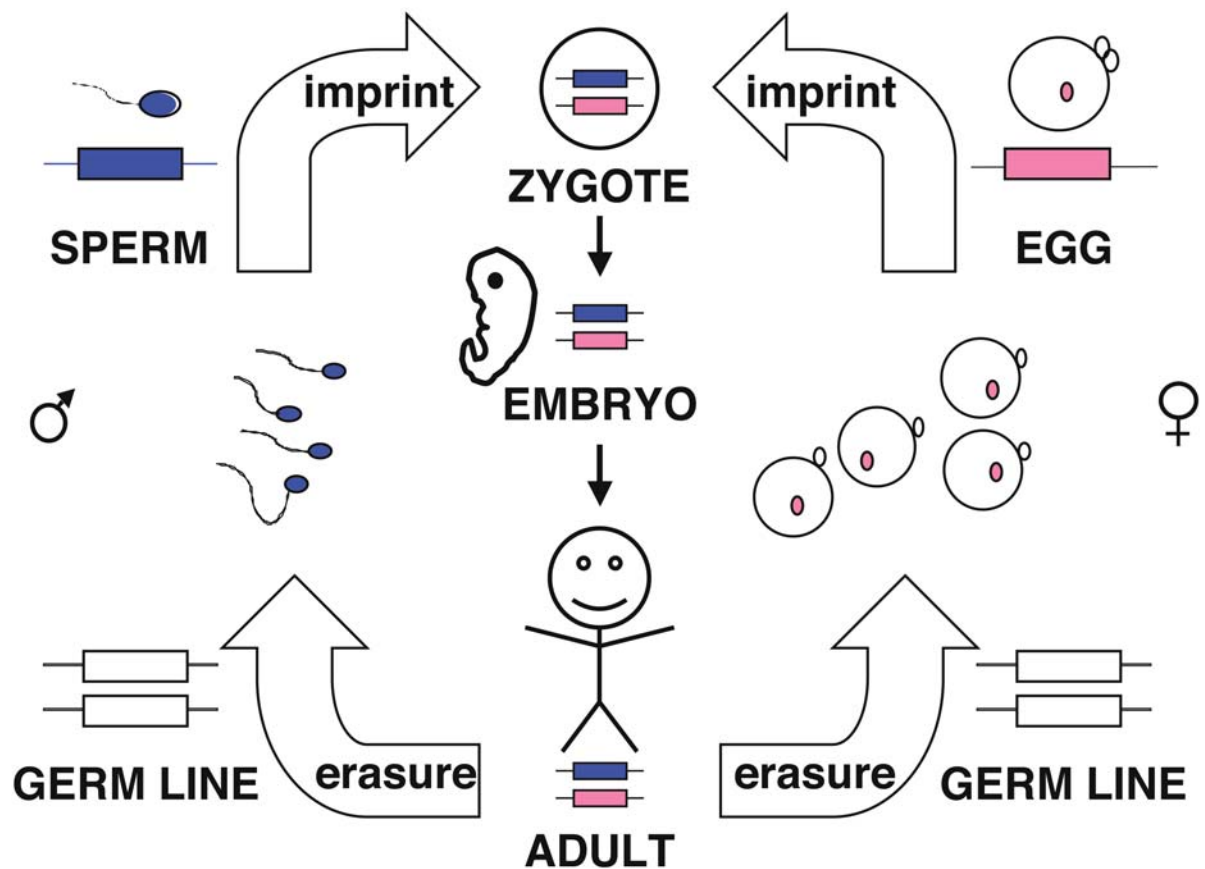

The first two imprinted genes, *Igf2r* and *Igf2*, were identified in 1991 on the basis of the parental origin-dependent phenotypes of heterozygous mutants. More than 70 genes have been identified in the mouse and human genome so far. (We quote here two comprehensive databases of imprinted genes that can be found on the web: ►<http://www.mgu.har.mrc.ac.uk/research/imprinting/imprinting2.html> and ►<http://cancer.otago.ac.nz/IGC/Web/home.html>). Detailed analyses of several of these genes made it possible to determine general characteristics of imprinted genes in addition to their monoallelic expression:

1. Imprinted genes are frequently associated with regulatory regions that carry differential ►**DNA methylation** on the two parental alleles. Several imprinted genes were identified on the basis of systematic search for ►**differentially methylated regions** (DMRs) in the genome. In general, DNA methylation upstream of genes, especially in the promoter region, is associated with attenuation of the expression.
2. It is impossible to classify the imprinted genes on the basis of the products they encode. Peptide hormones, growth factors, transcription factors, metabolic enzymes, cell surface receptors and many other proteins, but also several non-coding RNAs can be found among the products of imprinted genes.
3. Another characteristic feature of imprinted genes discovered so far is their non-random distribution in the genome. They are frequently clustered in well-defined genomic regions of up to several hundred kilobases. These clusters usually contain imprinted genes with either maternal or paternal monoallelic expression, but also genes that have been found to be biallelically expressed in all tissues analyzed so far.
4. Interestingly, many antisense transcripts are also detected in the imprinted genomic regions.
5. An important feature of the clusters is their ►**asynchronous replication**, which occurs in common as far as we know, suggesting that this phenomenon is one of the useful criteria that help determine imprinted genes (4). The paternal and maternal copies of the whole clusters replicate differentially during the mitotic cell cycle, including imprinted genes, intergenic sequences and the genes that are expressed biallelically. This characteristic is independent of the expression state of the genes in the cluster and is detected in all cell types. They all suggest that cluster level of imprinting regulation might be assigned in the context of chromatin structure as described below.
6. Imprinted chromosomal regions display strikingly different recombination frequencies during male and female meiosis. However, many non-imprinted

regions also show recombination with different frequencies during male and female meiosis.

Molecular Mechanisms

As indicated above, DNA methylation is a part of the mechanisms that differentiate the parental alleles of imprinted genes. Methylation of cytosines in CG dinucleotides (CpG methylation) is a well-known ►**epigenetic modification** of the DNA that regulates chromatin structures such as ►**heterochromatin** in concert with covalent ►**histone** modifications. The DMRs are usually relatively short, CG-rich DNA segments located at a distance from genes, but sometimes located in the promoter region or in the coding or intronic sequences. The best characterized DMRs in the human and mouse genome include those located in the regions of the *Igf2r*, *H19*, *Igf2*, *Snrpn*, *U2af1-rs1*, *Gnas* and *Gtl2* genes. The functional importance of these elements for the establishment and maintenance of the methylation imprint has been demonstrated by extensive targeted mutagenesis studies. Their deletions frequently perturb the function of the whole imprinted domain. These elements are usually called imprinting centers for their central role in the imprinting of a whole region. They most probably act as a structural organizer affecting gene expression over the whole imprinting cluster. This action is presumably mediated by recruiting various proteins, for instance the CTCF protein, that play a role in making up highly-ordered chromatin structure. Studies of chromatin structure around imprinted genes revealed differences in nucleosome positioning, histone acetylation or nuclease sensitivity between the parental alleles of imprinted genes. In general, methylated sequences are associated with hypoacetylated histones, whereas the unmethylated sequences are associated with hyperacetylated histones. The differences observed between the two alleles of an imprinted gene in the same tissue are similar to those typically observed between active and inactive copies of the same gene in different tissues. Naturally occurring, or experimentally induced mutations that alter the enzymatic mechanisms responsible for epigenetic modifications such as DNA methylation and histone modifications frequently disturb the normal imprinting process and modify the allelic expression of imprinted genes. In addition to the epigenetic modifications, the observation of several ►**antisense RNA** transcriptions in imprinted regions suggests that non-coding RNAs might be also involved in the maintenance of the characteristic chromatin structure and monoallelic expression of imprinted genes. A role of non-coding RNAs in this process has been suggested by analogy with the function of the Xist RNA in the inactivation of one of the X-chromosomes in females, although the role remains unknown.

Genomic Imprinting. Figure 1 The schematic representation of the cycle of acquisition/erasure of genomic imprinting in the germ line. Note that, in the germ cell lineage, the epigenetic marks should be erased and then re-established according to the sex of the individual.

Establishment of the Imprint

Each individual inherits a paternal and a maternal copy of every gene in the genome. However, both alleles are transmitted to the offspring either as paternal or as maternal copies depending on the individual's sex. Therefore, the parental imprint of a gene or a gene cluster has to be erased in the germ line of the individual and re-established according to its sex in mature gametes (Fig. 1). In order to follow this process, changes in CpG methylation pattern of DMRs were extensively studied at various imprinted loci. In general, the differences in CpG methylation pattern are erased from the parental alleles in early **▶primordial germ cell** (PGC) differentiation. The methylation pattern typical for the paternal or maternal alleles is established in meiotic cells. At the moment of fertilization, many DMRs are already differentially methylated and conserve their allele-specific methylation profiles at all subsequent stages of development while the bulk of the genome undergoes important methylation changes. However, some DMRs acquire their methylation profiles gradually during the somatic

cell division, suggesting that **▶CpG methylation** is not the only molecular mechanism that plays a role in marking the two parental alleles.

Other characteristics of the imprinted genomic regions follow different kinetics during development. For example, asynchronous replication of the two parental copies is maintained during the proliferation of PGC, when all methylation differences are already erased, suggesting that differences between the parental copies are still there even in the absence of methylation.

Clinical Relevance

The biological significance of the functional nonequivalence of the parental genomes is not yet known. Many hypotheses were proposed to explain why imprinting has evolved in mammals. The most popular hypothesis is the so-called parental conflict model. According to this model, imprinting has evolved in mammals because of the conflicting evolutionary interests of the paternal and maternal genomes over the allocation of parental resources. This hypothesis is based on the assumption that fetal imprinted genes

regulate resource transfer from the mother to the fetus. Therefore, parents are able to modulate the use of resources by transmitting epigenetically modified versions of imprinted genes to their offspring. Since the fetuses develop within the maternal uterus, the paternal investment in the offspring is obviously much lower than the maternal investment. This asymmetry leads to an asymmetry of the imprints on the resource usage-regulating genes.

Another possible explanation is that maintaining the differential chromosomal structure of the imprinted regions could be important for the coordinated replication of the genome and the correct segregation of the chromosomes during mitosis (5). The monoallelic expression of imprinted genes might be a byproduct of this process. Indeed, some experimental observations indicate that the parental copies of imprinted regions interact with each other during the somatic cell cycle in a way that is reminiscent of some trans-sensing phenomena observed in *Drosophila* or plants.

Whatever the biological function of parental imprinting, perturbations of the process lead to severe hereditary disorders that develop because of mutations in the active allele of imprinted genes, the normal but silenced allele being unable to compensate for the mutated copy (6). Biallelic expression of usually monoallelically expressed imprinted genes has also been implicated in various cancers. For example, Prader-Willi syndrome patients often display hypotonia, hyperphagia, obesity, hypogonadism and developmental delay. Angelman syndrome patients frequently show ataxia, tremulousness, sleep disorders, seizures and hyperactivity. Both syndromes may also show mental retardation and map to the imprinted gene cluster in human chromosome 15q11-13. Beckwith-Wiedemann syndrome maps to 11p15 and is characterized by general overgrowth with symptoms such as hemihypertrophy, macroglossia and visceromegaly.

Genomics

Definition

Genomics represents the systematic study of the entire genetic complement (DNA and RNA) of an individual or population of individuals. Since uncontrolled growth of cancerous cells results from inherited or somatically acquired mutations scattered throughout the complement of our chromosomes and often affects mRNA expression, the holistic tools of genomics are particularly relevant to understanding the molecular mechanisms underlying this set of diseases. As such, genomics has played a major role in advancing tumor subclassification, diagnosis and individualized treatment of patients.

Characteristics

Cancer results from the accumulation of genetic damage superimposed upon inherited predisposition. This damage manifests itself in the form of DNA mutations, chromosomal aberrations or epigenetic alterations in the chromatin structure. Elucidating the specific genetic events involved in the pathogenesis of different cancer types will be critical for the development of effective diagnostics and treatments. Initially, genetic studies in cancer focused primarily on heritable rare and highly penetrant alleles of cancer predisposition genes. Examples include the ►tumor suppressors *Rb1* and *p53*. However, heritable predisposition alleles account for a small percentage of cancer causing events. Multiple combinations of weak genetic variants may have a much larger impact on the development of cancer in the general population, the majority of whom do not have inherited alleles of the known highly penetrant cancer predisposing genes. Thus, cancer can be viewed as a multigenic disease. The challenge of

cancer genomics is to identify the multiple genetic variants that are involved in the development of cancer and to determine their effects on the molecular pathways of the premalignant cell type.

Identifying the genetic determinants of such a complex, multigenic disease as cancer necessitates the development and use of high throughput methods of genomic analysis. Toward that end, high throughput genomic DNA scanning technologies (sequencing, LOH, CGH and FISH) as well as microarray-based technologies have been critical. Microarray technology involves the fixation of DNA molecules to a slide or wafer. These DNA molecules can be placed on the microarray slides at very high densities, allowing for high throughput genome-wide analyses. Various microarray technologies exist, including ►[single nucleotide polymorphism](#) (SNP) arrays for linkage and LOH studies, ►[comparative genomic hybridization](#) (CGH) arrays, DNA sequencing arrays and perhaps most widely recognized, gene expression microarrays.

Single Nucleotide Polymorphism Genotyping for Linkage and LOH Studies

Traditionally, linkage analyses and ►[loss of heterozygosity](#) (LOH) have been done on a genome-wide scale using ►[microsatellite](#) markers at a density of ~10 cM (Mb) intervals. This is a tedious methodology. The resolution is appropriate for linkage studies but inadequate for LOH in the majority of cases. New information from the human genome project (HGP) has resulted in a high resolution SNP map of the human genome, as well as new technologies for rapidly genotyping these SNPs. Single nucleotide polymorphisms represent DNA base pair variations within a population of individuals. They can either have no effect on gene expression or may have subtle effects that, when combined, may lead to disease phenotypes. An SNP occurs, on average, once in every 1300 base pairs of the human genome and they account for the majority of genetic variability between individuals within a population. Although SNPs are biallelic and thus less informative, their density of ~every 30 kb (on the new Affymetrix 100k SNP array) allows larger haplotype block content to be inferred. Thus SNPs are likely to be equally informative over multiple adjacent SNPs as well as having the ability to identify smaller hemizygous deletions. SNP array technology has great potential for discovering multigenic contributions to cancer development. For example, by comparing the SNP profiles from a group of individuals that have a certain cancer type to the SNP profiles of unaffected individuals, one can identify a set of SNPs that are uniquely associated with that form of cancer (1). Since the sequence information for the SNPs is known, one can rapidly move towards identifying the relevant genes. Importantly, this technology is generally

applicable to the study of any disease with a genetic basis.

DNA Sequencing

DNA sequencing represents the ultimate in high-throughput cancer analysis. Once we fulfill the mandate of the HGP for rapid, whole-genome sequencing at minimal cost, we will revolutionize the ability to understand and diagnose cancer. Early attempts include massive parallel DNA arrays for hybridization-based sequencing. These arrays, designed by Perlegen Sciences, Inc. (CA, USA) consist of overlapping oligonucleotide probes that span the entire genome. This makes possible direct and rapid sequencing of the entire genome. This has clear advantages, particularly when an unidentified disease gene has been mapped previously using standard positional cloning strategies.

Comparative Genomic Hybridization

Comparative genomic hybridization (CGH) allows one to visualize gross chromosomal losses or gains by a modification of traditional karyotyping. The entire genomic complement of a normal individual is labeled and compared to a genomic sampling from a tumor that has been labeled with a different fluorophore. While revolutionary, the typical resolution of traditional CGH is ~10 Mb. Array CGH provides the advantage of higher resolution compared to traditional CGH methods (up to 0.5 Mb) and is generally useful for identifying large deletions, insertions, amplification events or overall changes in ploidy. Importantly, array CGH can be used as an adjunct to expression microarrays (see below) since the molecular events detected by CGH will have effects on gene expression levels.

Expression Microarrays

Gene expression microarrays are used to rapidly assess the gene expression profile of different cell types. For genetic mutations to affect cell proliferation, and hence the development of cancer, they must alter the function of at least some of the signaling pathways inside the affected cell. These effects can be seen as altered mRNA expression profiles (even members of phosphorylation cascades can be dysregulated) in malignant cell types and can be identified using expression microarrays.

There are two main variations of expression arrays currently in use, cDNA and oligonucleotide microarrays. Oligonucleotide arrays provide the benefits of greater specificity since the probes used are of shorter sequence (~25–70 nucleotides) than those used for cDNA arrays (200–2000 nucleotides). cDNA arrays have greater sensitivity but cannot, for example, discriminate between splice variants. For each type of array, sequences of DNA that are homologous to different genes of interest are attached to a glass slide at different locations. Each probe (or probe set for

oligonucleotide arrays) on a slide corresponds to a single gene and each slide can hold thousands of probes. One then hybridizes labeled cRNA from the cell type of interest to the microarray, rapidly generating an mRNA expression profile for thousands of genes.

Integration of LCM into ► Expression Profiling

One important limitation of expression profiling has been that the tissues used often contain multiple cell types in addition to the diseased or cancerous, cells. Additionally, cancers are almost always mosaic with respect to acquired somatic changes. Thus, they are heterogeneous with respect to the clinical and histopathological trait under study. This adds unwanted expression signatures to the global expression profile obtained and may generate misleading results. ► **Laser capture microdissection (LCM)** is increasingly being used to overcome this limitation. LCM uses an infrared laser to select only cell types of interest from a thin section of tissue sample. In the study of cancer, this allows the analysis of a nearly homogeneous population of malignant cells, generating a cleaner expression profile that is more indicative of the cancerous state. Because the volume of cells harvested using this technique is low, RNA amplification techniques must be used to generate enough RNA for expression profiling.

Clinical Relevance

Clearly, identification of the underlying DNA or RNA defects leading to cancer development and progression will lead to a greater understanding of tumorigenesis and will translate directly into drug design. SNP analyses provide the potential for early and reasonably noninvasive cancer diagnosis by detecting heritable cancer specific mutations in peripheral tissues, such as blood. As a result, treatments may be commenced earlier than was previously possible (2). Additionally, SNP analysis could become a routine screening procedure to identify individuals with SNP haplotypes that place them at risk for developing specific forms of cancer. This information could be used to direct at risk individuals to appropriate prevention strategies. As the technology matures, diagnosis and screening using this methodology may become economically feasible for general practice. In addition to providing a diagnosis method, SNP analyses will be useful for identifying causative mutations and affected molecular pathways in various cancers. Following validation of these pathways, new targets for therapy will emerge.

Gene expression profiling has numerous important clinical applications. First, expression profiling already has been used to predict the prognosis of disease course in ► **breast cancer** (3). In breast cancer susceptibility screening, genetic testing to identify individuals carrying known predisposition alleles has been used to indicate when more extreme prevention strategies,

such as surgical resection of at risk tissue, are needed. However, this approach suffers from the limitation that not all individuals carrying susceptibility genes will develop cancer. Further subclassifying a person's cancer risk based on additional genetic determinants will restrict such surgical prevention strategies to only a subset of individuals with the highest likelihood of developing particularly aggressive forms of disease. The above example with breast cancer illustrates the expectation that, as more tumors are profiled and subcategorized, expression profiling could become a general tool for predicting the course of cancer progression and for guiding prevention strategies in unaffected individuals. In the future, subcategorizing tumors based on their expression profiles may aid in patient-specific therapies that are designed to be most effective in the clinic on a real-time basis for the treatment of particular forms of cancer.

Microarrays are also important for identifying dysregulated genes and signaling pathways that are involved in tumor development and progression (4). Identification of these genes and pathways will have important implications for the development of novel anticancer therapies since they provide novel targets for treatment. As expression profiling in the field of cancer biology moves forward, a critical goal will be to translate the vast amounts of biological data into meaningful clinical advances. This will require large collaborative efforts pooling the combined knowledge and expertise of different institutions to accomplish successfully all of the required goals from tumor sample acquisition, to genomic analysis, to target identification and validation, to drug design and discovery.

Summary

Analysis of SNPs and gene expression profiling are valuable methods for identifying the genetic determinants of cancer. However, to realize the value of these techniques fully, it will be critical to translate the findings into practical applications that can benefit individuals who are suffering from cancer and those who are at risk of developing particular forms of cancer. Knowledge of an individual's innate susceptibility to various cancer types can be used to guide the course of prevention strategies that focus, for example, on lifestyle changes such as diet and exercise. In addition, SNP and expression profiles can be used both to diagnose cancers accurately and to subcategorize tumor types based on the severity of the malignant phenotype. This information could then be used to target the most aggressive therapies to patients with the most severe or invasive forms of disease. Ultimately, the information gleaned from these powerful genomics techniques will be used to identify novel targets for therapeutic intervention with the eventual endpoint of preventing tumor growth and metastasis.

Germline (Gonadal) Mosaicism

Definition

The term mosaicism in general refers to an organism that is composed of two or more cell lines, which originate from only one zygote and differ in their genotype or chromosomal constitution. The different

cell lines have been formed by mutations. The period of development at which this mutation is formed determines the cell type of mosaicism: somatic or germline cells. The germline of one individual consists of two or more populations of cells, due to mutation(s) in one or more clonally expanded cell(s) in the population of germline cells. Germline mosaicism may vary between only a few cells or about 50% cells, and is the reason why genetically unaffected parents may have children with more than one X-linked or dominant genetic disorder.

Glial Cells and Myelination

HAUKE WERNER, KLAUS-ARMIN NAVE

Department of Neurogenetics, Max Planck Institute of Experimental Medicine, Goettingen, Germany

hauke@em.mpg.de

nave@em.mpg.de

Definition

The large majority of non-neuronal cells in the nervous system are ►glial cells. In general, glial cells serve supportive functions for neurons, are not electrically excitable but may respond to neurotransmission. This overview focuses on two types of glial cells that myelinate axonal processes, ►oligodendrocytes in the central nervous system (CNS), and ►Schwann cells in the peripheral nervous system (PNS). ►Myelin enables ►axons to conduct action potentials much more rapidly, by insulating the axonal membrane, decreasing its capacitance and restricting ion fluxes to the ►nodes of Ranvier. Myelin is largely made during early postnatal life. Thus, developmental disorders of myelination or loss of myelin are severe neurological diseases, either inherited (►leukodystrophies, neuropathies) or acquired. One clinically important myelin disorder is multiple sclerosis, an inflammatory ►demyelination of the CNS.

Characteristics

The best understood function of oligodendrocytes and Schwann cells is to enwrap axonal processes with an insulating myelin sheath. Myelination occurs largely during early postnatal life and can be divided into several steps: (i) establishing contact between glial cell and axon (oligodendrocytes engulf multiple axons), (ii) spiral enwrapping of axonal segments with up to 50 layers of membrane, (iii) compaction of myelin by tight association of the intracellular and extracellular membrane surfaces, (iv) formation of functional nodes of Ranvier and paranodal structures. Although some of the molecules involved in myelination have been identified, the cellular mechanisms are not well understood. In humans, myelination begins around birth, with a peak in the first five years of life and is mostly completed by 11 years of age. Some active myelination has been observed until the 5th decade, possibly related to neuronal plasticity. During the peak of myelination, i.e. within a few days, oligodendrocytes produce a large amount of membrane material that exceeds their own weight several fold.

The highly periodic structure of myelin is best visualized in cross section under the electron microscope (Fig. 1). Proteins at the condensed cytoplasmic

membrane surface form the electron-dense major dense line (MDL), those at the condensed extracellular surface form the intraperiod line (IPL). The membrane itself is electron-lucent. The ultrastructure of CNS and PNS myelin is remarkably similar. Once myelinated, many axons become dependent on oligodendrocyte support. Thus, when oligodendrocytes or myelin degenerate in the course of a demyelinating disease, some axons will degenerate as well. The mechanism of this axon-glia interaction is not known.

Myelinated axons of the human PNS exhibit nerve conduction velocities (NCV) between 5 and 100 m/s, increasing with the axon diameter. In non-myelinated axons, NCV measures 0.5–5 m/s. To exhibit the same NCV, a non-myelinated axon would have to be of much larger diameter. Thus, myelin has evolved in vertebrates as means to achieve high NCV and reduced space requirements.

Molecular Interactions

Only axons with a diameter >1 µm are myelinated, smaller axons may be engulfed (i.e. in the PNS by non-myelin forming Schwann cells) but are not enwrapped. Axon diameter and myelin sheath thickness show a constant relationship (g-ratio). In the PNS, the axonal growth-factor neuregulin-I (Nrg1) plays a critical role in signaling size information to receptor tyrosine kinases erbB2/erbB3 on the Schwann cell and in regulating myelin membrane growth.

Molecularly, compact myelin is comprised of lipids and myelin proteins that differ in composition between CNS and PNS. Targeted gene inactivation in ('knock-out') mice has been used to explore the function of myelin-specific proteins systematically. Many of them are abundant integral or membrane-associated proteins with functions in membrane adhesion. Their CNS- or PNS-specific expression correlates well with the clinical picture of leukodystrophies and neuropathies respectively. Regions of non-compact myelin exist at the innermost myelin membrane, adjacent to the nodes of Ranvier and as Schmidt-Lanterman incisures in the internodal region. They provide radial connections between the periaxonal space and the glial cell soma, form a tight seal at the node of Ranvier (paranodal loops) and help organize the distribution of ion channels by interacting with proteins of the axonal membrane. Some structural proteins of non-compact myelin are quite abundant. For updated information on these genes and diseases refer to the McKusick entries of the Online Mendelian Inheritance in Man (►OMIM) database (►<http://www3.ncbi.nlm.nih.gov/Omim/>).

Myelin Lipids

Myelin has a lipid content of 70–80% (compared to less than 50% in other ►biological membranes) and lipids contribute to its insulating function. How myelin lipids

Glial Cells and Myelination. Figure 1 Cross section of a myelinated axon at the electron microscopic level (upper left), the ultrastructure of compact myelin (lower left), and schematic depictions of structural proteins in myelin. The condensed cytoplasmic membrane surfaces form the electron-dense *major dense line*, extracellular membrane adhesion forms the *intraperiod line*. The membrane itself is electron-lucent. Membrane proteins associated with human myelin diseases are depicted in red. PLP/DM20, proteolipid protein; MBP, myelin basic protein; P0, protein zero; PMP22, peripheral myelin protein of 22kD; Cx32, connexin of 32 kD; MAG, myelin-associated glycoprotein; CNP, cyclic nucleotide phosphodiesterase.

are enriched in the cell membrane is not understood. Myelin is particularly rich in cholesterol. Galactosyl-cerebroside (GalC) and its sulfated form (sulfatide) are nearly myelin-specific. Absence of GalC and sulfatide in mutant mice lacking UDP-galactose:ceramide galactosyl-transferase leads to progressive demyelination and early death. Thus, both lipids are essential for normal myelination, although glucosylcerebroside (an alternative product) may compensate for some functions of GalC. Patients with the Smith-Lemli-Opitz syndrome (McKusick #270400), a genetic disorder of cholesterol biogenesis, also have myelin abnormalities. The critical requirement for cholesterol in myelin assembly has been shown with conditional mouse mutants deficient in squalene synthase, a critical and specific enzyme of cholesterol synthesis.

Proteolipid Protein (PLP, McKusick *300401)

In the CNS, the most abundant protein of compact myelin is a hydrophobic integral membrane protein (proteolipid) with four transmembrane domains and its smaller splice isoform (DM20). PLP/DM20 may form homo-oligomers and associate with $\alpha(v)$ -integrin, but the function of these interactions is speculative. The tight association of PLP/DM20 with cholesterol may be required for membrane **raft** formation and normal membrane trafficking in oligodendrocytes. The ultrastructure of CNS myelin lacking PLP/DM20 in **knockout mice** suggests that the extracellular portion of PLP acts as a strut, organizing the extracellular apposition of myelin layers at the IPL, but myelination is possible in the absence of PLP. For comparison, point mutations in this gene (or PLP gene duplications) cause severe **dysmyelination** in Pelizaeus-Merzbacher disease (PMD) and in rodent PMD models. This is due

to ER retention of the mutant protein, unfolded protein response and oligodendroglial apoptosis

Myelin Protein Zero (MPZ, P0, McKusick *159440)

Myelin protein zero is the most abundant protein of compact PNS myelin, expressed exclusively by Schwann cells. With a single transmembrane domain and an extracellular Ig-like domain, P0 is a member of the Ig-superfamily of cell adhesion proteins. The crystal structure of the Ig-like domain, when combined with the analysis of P0-deficient mice, indicates that homo-tetrameric P0 engages in homophilic interactions with the opposing membrane layer, mediating membrane adhesion and formation of the IPL. Additionally, positive charges in the cytoplasmic domain contribute to the establishment of the MDL by direct interaction with negatively charged head groups of membrane phospholipids. Mutations of the human P0 gene cause a peripheral neuropathy (CMT1B).

Myelin Basic Protein (MBP, McKusick *159430)

Myelin basic protein refers to a group of related cellular proteins associated with both CNS and PNS myelin. The MBP gene encodes at least 5 splice isoforms, ranging from 14 to 21 kD in size. Positively charged amino acids interact with negatively charged head groups of membrane phospholipids causing MBP to mediate and stabilize myelin compaction at the MDL. The MBP gene is partially deleted in the natural mouse mutant *shiverer*, which presents with a severe demyelinated phenotype. The overall lack of myelin assembly is not yet fully explained. *Shiverer* mice provided the first opportunity to analyze the consequences of a missing myelin protein before transgenic knockout techniques became available. An involvement of the

MBP gene in a human leukodystrophy has not yet been demonstrated.

Peripheral Myelin Protein 22K (PMP22, McKusick *601097)

Peripheral myelin protein 22K is a glycosylated integral membrane protein of PNS myelin. By topology and hydrophobicity PMP22 is related to the proteolipids of CNS myelin. PMP22 interacts with myelin protein P0 in the myelin membrane and may stabilize the myelin architecture. Experiments carried out *in vitro* suggest that PMP22 also regulates Schwann cell proliferation and apoptosis, but its *in vivo* function is poorly understood. The PMP22 gene has captured interest because a gene duplication in humans underlies the most frequent peripheral neuropathy (CMT1A).

Myelin-associated Glycoprotein (MAG, McKusick *159460)

Myelin-associated glycoprotein is a member of the Ig-superfamily of cell adhesion proteins, with a single trans-membrane domain and 5 extracellular Ig-like domains. Its localization at the innermost (adaxonal) membrane of both CNS and PNS myelin suggested that MAG is engaged in adhesion and signaling events between glial cell and axon. The diameter of PNS axons is reduced in mice lacking MAG, suggesting that MAG-mediated myelin-to-axon signaling regulates the phosphorylation status of the axonal cytoskeleton. Axonal binding partners of MAG include the NoGo receptor (NoGoR / reticulon 4 receptor, McKusick *605566), and sialic acid residues of sialo-glycoproteins or sialo-glycolipids (gangliosides).

Connexin-32 (Cx32, McKusick *304040)

Connexin-32 is a member of the connexin family of gap junction proteins, permeable to molecules <1kD. The protein is expressed in many cell types, including oligodendrocytes and Schwann cells, where it is localized to Schmidt-Lanterman incisures and paranodal loops. The exact function of Cx32 in PNS myelin is not known, but its involvement in the non-classical gap junctions that form a connection between different myelin lamellae of the same Schwann cell is most likely. Radial transport may be required for second messenger molecules that are generated at the innermost myelin membrane. Mutations in the human Cx32 gene cause a peripheral neuropathy (CMT1X).

Claudin11/Oligodendrocyte-specific Protein (OSP, McKusick *601326)

Claudin11/oligodendrocyte-specific protein is a member of the claudin family of [tight junction](#)-specific integral membrane proteins with four transmembrane domains. Knockout mice revealed that OSP is an essential constituent of the radial component in CNS

myelin that stabilizes myelin through intramembranous tight junctions. The finding that OSP interacts with tetraspanin-3/OAP-1 suggests that other tight junction proteins have yet to be identified in myelin.

Nodal and Paranodal Specializations

For [saltatory nerve conduction](#), axonal voltage gated sodium (Na^+) channels must be clustered at the node of Ranvier, separated from fast potassium (K^+) channels that assemble beneath the myelin sheath at the juxtaparanode. K^+ channels are associated with Caspr2, a member of the neurexin family of [adhesion molecules](#), probably *via* a PDZ domain protein adapter. Caspr2 in turn is associated with TAG-1, a GPI-anchored cell adhesion molecule of the Ig-like superfamily on the glial adaxonal membrane. Knockout experiments in mice demonstrated that axonal Caspr2 is required to maintain K^+ channel clusters at the juxtaparanode. More devastatingly, in the absence of TAG-1, axonal Caspr2 and K^+ channels are unclustered at the juxtaparanode. Na^+ channel distribution is unaffected by deletion of juxtaparanodal proteins.

The assembly sites of axonal Na^+ and K^+ channels are divided by the paranode, a region devoid of ion channels. The paranodal axon is tightly attached to the glial paranodal loops by a septate-like junctional structure that seals against ion flux and separates Na^+ from K^+ channels. The paranodal axon is molecularly defined by a complex of the Ig-like GPI-anchored cell adhesion molecule F3/contactin associated with the neurexin Caspr1. This complex interacts with neurofascin155 on the paranodal loop. Disruption of individual components in knockout mice impedes the septate-like junction.

Global Genome Repair

Definition

Global genome repair designates the branch of nucleotide excision repair that occurs in all regions of

DNA, with the exception of actively transcribed genes, and removes damage that could block DNA replication.

► [Nucleotide Excision Repair](#)

Glomerular Filtrate

Definition

Urine formation in the kidney begins when the fluid portion of the blood leaves the glomerulus and enters the glomerular capsule as glomerular filtrate. Glomerular filtrate consists of water and small size components of blood, separated from blood cells. The glomerular filtrate flows into the tubules, where further water is extracted from the filtrate, and minerals and other body chemicals are absorbed from or secreted into the filtrate.

Glycoform

Definition

Glycoform describes various forms of a particular species of glycoproteins that differ in the structures and/or types of glycans.

►Glycosylation of Proteins

Glycated Protein

Definition

Glycated protein designates a protein containing carbohydrate that was added by a nonenzymatic, chemical modification, usually through a Schiff-base reaction with the amino group of the side chain of lysine, and subsequent Amadori rearrangement, to give a stable conjugate.

►Glycosylation of Proteins

Glycogen Synthase Kinase-3

Definition

Glycogen synthase kinase-3 (GSK3) is a constitutively active kinase that undergoes inhibition by hormones and growth factors. One of its functions is to inhibit Wnt/ β -catenin signaling by phosphorylation of β -catenin thereby targeting it for degradation. Also called zeste white 3/shaggy in *Drosophila*.

►Wnt/Beta-Catenin Signaling Pathway

Glycine

Definition

Glycine is an amino acid that is derived from dietary sources, but is also generated endogenously from glyoxylate. Glycine serves as an important inhibitory neurotransmitter, predominantly in the spinal cord, brain stem and retina.

►Peroxisomal Disorders

Glycohemoglobin

Definition

Glycohemoglobin stand for glycosylated hemoglobin. The ratio of glycohemoglobin and total hemoglobin is indicative of a person's average blood glucose level over the last months.

Definition

► [Glycoproteins](#) are proteins that contain one or more covalently attached carbohydrates, including ► [monosaccharides](#) and ► [oligosaccharides](#). The attached carbohydrates are also termed ► [glycans](#). In typical glycoproteins the glycans can contribute up to ~20% of the total weight. ► [Proteoglycans](#) are a special class of glycoproteins that contain at least one large-sized (typically >5 kD), acidic polysaccharide (► [glycosaminoglycan](#)) attached to protein. ► [Mucins](#) are another special class of glycoproteins with a repeating peptide motif that usually contains multiple Ser and Thr residues to which relatively small-sized (usually <3 kD) glycans are attached. The mucin glycans can contribute more than 25% of the total weight. The ► [storage polysaccharides](#) starch and glycogen, which contain glucose polysaccharide linked to a core protein, also represent a special class of glycoprotein. In these cases the glycan portion

contributes more than 90% of the total weight. Another type of glycoprotein is the glycosylphosphatidylinositol-anchored or ►**GPI-anchored glycoprotein**. These contain a C-terminal amino acid that is linked to ethanolamine, which is linked to the glycans of the GPI anchor. GPI-anchored glycoproteins, which may also contain covalently attached N- and/or O-glycans at other residues within the polypeptide, are usually anchored to plasma membranes of cells by insertion of the acyl chains of the GPI moiety into the membrane outer leaflet. Thus, glycoproteins are found in many different sizes, ranging from several thousand Daltons to millions of Daltons.

The presence of carbohydrate on protein is a type of ►**post-translational modification**, which along with phosphorylation constitutes one of the most common types of such modifications. The majority of the nearly 30,000 proteins expressed in human cells are glycoproteins (1). The carbohydrates of glycoproteins are added enzymatically to specific sites on a protein. This contrasts with what is seen for ►**glycated proteins** in which carbohydrate addition occurs through the chemical or non-enzymatic addition of a free monosaccharide, usually glucose or galactose, to amino groups in proteins through formation of a Schiff base and rearrangement to a stable oxoamine adduct known as an Amadori product. This process is termed glycation and is often seen in patients with diabetes and children with galactosemia. Animals, plants, fungi, Protocista, archaea and bacteria synthesize glycoproteins and many animal viruses contain glycoproteins. In animals, most of the proteins that are on cell surfaces and those that are secreted by cells are glycosylated. Glycoproteins in membranes occur as integral or intrinsic membrane glycoproteins and may contain one or more transmembrane domains. GPI-anchored glycoproteins are also considered to be integral membrane proteins. Glycoproteins can also occur as extrinsic membrane glycoproteins that associate with the membrane through other mechanisms. Many proteins within the cytosol of eukaryotes are also glycoproteins. In animal cells two of the major classes of intracellular glycoproteins are the storage polysaccharides and those that contain O-linked GlcNAc or O-GlcNAc (termed O-GlcNAcylated) modifications. The attached glycans in different glycoprotein species often exhibit tremendous diversity in size and structure. Within a single glycoprotein species these structural differences are often denoted by the term microheterogeneity and the varied forms of a single glycoprotein species are termed ►**glycoforms**. Different glycoproteins from the same cell may be glycosylated very differently, depending on the primary, secondary, tertiary and/or quaternary structure, association with other proteins and subcellular localization. However, glycosylation differences are greater among glycoproteins from different cell types within an organism; the

differences are often even greater in glycoproteins between different organisms. Identifying the structures of the glycans made by different organisms is known as the field of glycomics and identifying sites of glycan attachment in glycoproteins is known as the field of ►**glycoproteomics**.

Characteristics

Glycans on glycoproteins can vary in the types of sugars that are attached, the ►**anomeric** configuration and structure of the attached sugars, the numbers of attachments and the sites of attachments (2). The linkage of one monosaccharide to another is typically *via* a ►**glycosidic linkage**, characterized by the acetal structure. The part of the glycan linked to protein is termed the reducing end and the opposite, unattached end(s) of the glycan is termed the non-reducing end or terminal region. Although there are many types of sugar-protein linkages, which are also glycosides, most sugar-protein linkages are of two types, N-glycosides, in which the amide of Asn (and in some organisms Arg) forms the linkage group (-C-N-C-) and O-glycosides, in which the hydroxy group of hydroxyamino acids, such as Ser, Thr, Tyr, hydroxylysine (Hyl) and hydroxyproline (Hyp), forms the linkage group (-C-O-C-). C-glycosides are an exception to this generalization, here a -C-N-C- bond links the sugar to an amino acid, as seen in Man-C-Trp. Acetal or glycosidic linkages between sugars are stable to alkali. By contrast, the linkage of sugar to protein *via* Asn, Ser or Thr residues is labile to relatively mild alkali. The sugar-protein linkages *via* Tyr, Hyl and Hyp are resistant to alkali. The glycosidic linkages within a glycan and all glycosidic linkages of sugars to proteins can be hydrolyzed by treatment with strong acid. An exception to this generalization is the C-glycoside linkage, which cannot be hydrolyzed by treatment with either alkali or acid.

Table 1 lists some of the common sugar-protein linkages found in glycoproteins from animals, plants, fungi, archaea and bacteria. Many dozens of linkages are now known, but mammalian cells appear to generate about a dozen or so. In most cases the monosaccharide residues shown in Table 1 are extended by the addition of other sugar residues. For examples see the composite animal cell glycoproteins shown in Fig. 1. The typical mammalian glycoprotein may contain N- and/or O-glycans of the types shown. One exception to the generalization that glycans are extended by addition of other sugars is found in eukaryotic cytosolic proteins that contain O-linked GlcNAc (GlcNAc β -O-Ser/Thr), where this residue is not further modified. It is also one of the few examples where the sugar addition is reversible, i.e. the GlcNAc residue is removed and added back multiple times on a mature protein. This probably serves an important

Glycosylation of Proteins. Table 1 Examples of Sugar-Protein Linkages in Glycoproteins from Different Organisms

Kingdom	Sugar-Protein Linkage
Animalia	GlcNAc β -N-Asn* GalNAc α -O-Ser/Thr GlcNAc β -O-Ser/Thr Man α -O-Ser/Thr Xyl β -O-Ser Fuc α -O-Ser/Thr Glc β -O-Ser/Thr Glc α -O-Tyr (in glycogen) Gal β -Hyl Man-C-Trp

regulatory function for cytosolic glycoproteins, akin to the action of protein phosphorylation, which is also reversible. (The other example of reversible

glycosylation is found in glucosylation of N-glycans as part of the [▶quality control](#) system for glycoprotein folding, as discussed below.)

Glycosylation of Proteins. Figure 1 Examples of different types of protein glycosylation. Shown are examples of composite membrane glycoproteins in animals that may contain one or more O- or N-glycans and a GPI-anchor or a transmembrane domain. Glycoproteins in the cytosol may also contain O-GlcNAc residues. The key for the symbols and abbreviations of monosaccharides is indicated and used in other figures.

N-glycans in higher animals typically contain 7–20 monosaccharide residues, whereas O-glycans typically have 2–10 residues. However, in yeast, many N-glycans contain mannan, a polysaccharide of mannose, which can contain hundreds of mannose residues. In proteoglycans the attached glycosaminoglycans can be hundreds of residues in length. Some examples of common types of N- and O-glycans in mammals are shown in Fig. 2. Mammalian glycoproteins are largely composed of the ten sugars or building blocks shown, which are the **▶hexoses** galactose (Gal), glucose (Glc) and mannose (Man), the **▶deoxyhexose** fucose (Fuc), the **▶hexosamines** N-acetylglucosamine (GlcNAc) and N-acetylgalactosamine (GalNAc), the **▶uronic acids** glucuronic acid (GlcA) and iduronic acid (IdoA), the pentose xylose (Xyl) and the 9-carbon carboxylated amino sugar **▶sialic acid** (Sia) and its multiple derivatives. In humans Sia occurs primarily as N-acetylneuraminic acid (NeuAc). Other organisms use many of these same monosaccharide residues, but also use novel ones not found in animals. For example, both Gal and GlcNAc are commonly found in glycoproteins from all the known kingdoms. Rhamnose (Rha) and arabinose (Ara) are found in plant, but not animal, glycoproteins, whereas sialic acids are found in animal,

but not plant, glycoproteins. Some bacteria synthesize sialic acid, however it has not yet been identified on bacterial glycoproteins. Some glycoproteins from nematodes contain tyvelose (3,6-dideoxy-D-arabinohexose - Tyv), which is not found in vertebrate glycoproteins. Some of these monosaccharide residues may themselves be further modified before or after incorporation into the glycan moiety of the glycoprotein to provide even more diversity of structure, as seen for NeuAc, which may be O- and/or N-acetylated at various positions, GlcA and IdoA, which can be N-sulfated and O-sulfated at various positions, and GlcNAc and Gal, which may be O-sulfated. Thus, the number of possible glycan structures is astronomically large and the upper limit of the number of structures is not known for any organism. It is important to note that polypeptides are typified by a linear structure in which two amino acids (L-amino acids in animals) are linked by a peptide bond. By contrast, glycans in glycoproteins are usually branched structures, where the monosaccharides are linked to each in multiple ways, such as different anomeric configuration (α versus β) to various positions on a residue (position C-2, C-3, C-6, etc.). In addition, the sugars in glycoproteins can be in either pyranose (6-membered ring) or furanose

Glycosylation of Proteins. Figure 2 Examples of different types of N- and O-glycans. Animal cell N-glycans shown on the left side have a common pentasaccharide core (shown in the boxed structure), which is composed of a trimannosyl sequence linked to a chitobiosyl disaccharide, which is in turn linked to an Asn residue through N-glycosidic linkage. The N-glycans are generally classified as high mannose-, hybrid- or complex-type as shown. The complex-type N-glycans may have multiple branches or antennae, described as mono-, bi-, tri-, or tetra-antennary, etc. Animal cell mucin-type O-glycans shown on the right side have a common structure of GalNAc linked to either Ser or Thr. This GalNAc residue may be modified in various ways to generate a variety of core structures (shown in the boxed structures).

(5-membered ring) structures and the residues may be either or D- or L-enantiomers (mirror images). Considering all these possibilities, it is easy to see that two identical amino acids linked together in a protein give a single dipeptide structure, whereas two identical hexoses may be linked together to give 64 possible isomeric disaccharide structures. If two different hexoses are linked together it is possible to obtain 128 different isomers (3).

The N-glycans, also called Asn- or **N-linked oligosaccharides**, in animals, plants, fungi and protista contain the common trimannosyl core structure that is linked *via* a chitobiosyl core (-GlcNAc-GlcNAc-) to Asn, as highlighted in Fig. 2. There are various types of N-glycans in animal cells, distinguished by the outer or terminal sugar structure, as seen for **high mannose-type**, hybrid-type and **complex-type** sequences. The O-glycans in mucins of animal cells, which are also called Ser/Thr- or O-linked oligosaccharides, are characterized by the linkage to Ser/Thr residues *via* GalNAc, as shown in Fig. 2. The GalNAc residue may be modified in different ways by linkage to other sugars to give various core structures. Altogether there are at least 8 different core structures in mucin-type O-glycans of animals. Some of the more common ones are highlighted in Fig. 2 as cores 1–4.

The attachment of N-glycans to Asn residues of secreted and membrane-bound glycoproteins occurs within a **consensus sequence** or sequon –Asn-X-Ser/Thr- (or Cys) (Table 2), although not all Asn residues within the sequon of such glycoproteins are always used. Asn residues outside this sequon are not N-glycosylated. In addition, cytoplasmic proteins with the N-glycosylation sequon are not N-glycosylated, because the pathway of N-glycosylation occurs within the lumen of the **endoplasmic reticulum** (ER), as discussed below. Although the N-glycosylation sequon is the most well known glycosylation sequon, a few other sugar-amino acid linkages also occur in definable sequences of proteins, as seen for addition of O-Glc, O-Fuc, C-Man and O-Gal (collagen) (Table 2). For most other attachments of sugars to proteins however, there are no clearly predictable consensus sequences, although the probability of attachment of some sugars to protein, such as GalNAc or GlcNAc to Ser/Thr residues in mucins and in cytosolic glycoproteins, appears to be enhanced by clusters of Ser and/or Thr residues and nearby amino acids (e.g. Pro) (Table 2). Some mathematical algorithms have been developed based on this information to predict sites of addition of GalNAc to Ser/Thr residues in animal mucins.

Glycosylation of Proteins. Table 2 Some Protein Consensus Sequences for Sugar Addition

Glycoprotein Biosynthesis

N-Glycan Biosynthesis

In animal cells glycoprotein biosynthesis occurs in several cellular compartments. The primary sites for N-glycan biosynthesis are the ER and **Golgi apparatus**. N-glycans are generated by a unique pathway, involving the addition of a preformed glycan to Asn residues in the consensus sequence –Asn-X-Ser/Thr- in nascent or forming polypeptides during their translation (**co-translational modification**) through the translocon Sec61p, the pore-forming protein in the ER associated with ribosomes on the cytoplasmic face of the ER. The preformed glycan added to newly synthesized glycoproteins occurs as a lipid-linked donor **dolichol**-pyrophospho-oligosaccharide (dol-P-P-oligosaccharide), which in vertebrates contains 14 monosaccharide residues in the formula Glc₃Man₉GlcNAc₂-dolichol (Fig. 3). This large oligosaccharide can be eventually converted, as described below, to the high-mannose-, hybrid- and complex-type N-glycans discussed above. The enzyme that transfers this preformed glycan is called the **oligosaccharyltransferase** (OST) and occurs in all eukaryotes as a complex, hetero-oligomeric enzyme associated with the ER membrane. Dolichol (dol) is a polyisoprenoid alcohol (prenol) whose general formula can be seen from the structure of dolichol-phosphate (P-dol) (Fig. 3). Dolichol contains 75–95 carbons and is one of the largest, and most unusual lipids found in animals. It is synthesized from the same initial precursors and using the same early enzymatic steps that are used to generate sterols, such as cholesterol.

The synthesis of the dol-P-P-oligosaccharide also occurs in the ER and is initiated by the addition of N-acetylglucosamine from the sugar nucleotide donor

UDPGlcNAc to generate GlcNAc-P-P-dol (4). This step in the biosynthesis of N-glycans is blocked by the naturally occurring inhibitor **tunicamycin**, a transition state analog of UDP-GlcNAc, which was originally identified in the fungus-like soil bacterium *Streptomyces lysosuperificus*. (The name tunicamycin derives from its discovery as an antiviral agent that blocked viral coat (tunica) formation.) Treatment of animal cells with tunicamycin blocks N-glycosylation of proteins by blocking formation of the precursor dol-P-P-oligosaccharide) and results in cell death, due to the inability to synthesize and correctly fold glycoproteins, as discussed below. Interestingly, the synthesis of GlcNAc-P-P-dol and several other steps beyond this occurs on the cytoplasmic side of the ER. Following this first step to synthesize GlcNAc-P-P-dol, additional GlcNAc and mannose (Man) residues are added stepwise from their respective sugar nucleotide donors (Fig. 3). After the formation of Man₅GlcNAc₂-P-P-dol, which faces the cytoplasm, the Man₅GlcNAc₂-P-P-dol is “flipped” across the membrane of the ER by an unknown mechanism so that it now faces the lumen or inner region of the organelle. This Man₅GlcNAc₂-P-P-dol is then further elongated in the lumen of the ER by donation of Man residues from the dolichol intermediate dol-P-Man (Fig. 3). In vertebrate cells, following completion of the mannose addition to give Man₉GlcNAc₂-P-P-dol, 3 glucose residues are added by the intermediate donor dol-P-Glc, to generate the final product Glc₃Man₉GlcNAc₂-dol. Each step from the formation of GlcNAc-P-P-dol to the formation of Glc₃Man₉GlcNAc₂-P-P-dol is catalyzed by a distinct enzyme. Mutations in any steps in the pathway usually result in an inability to add other sugars, thus truncated dol-P-P-oligosaccharides are generated, which are often

Glycosylation of Proteins. Figure 3 Biosynthesis of dolichol-P-P-oligosaccharide in higher animals. The pathway shown occurs in the cytosolic and luminal regions of the endoplasmic reticulum (ER). A separate enzyme catalyzes each step in the pathway shown. The mechanism by which the intermediate dolichol-P-P-oligosaccharide is reoriented in the ER membrane by “flip-flop” is not yet understood.

not efficiently utilized by the OST. The blockage in the addition of Dol-P-man, because of an inability to synthesize it, was first identified in a cultured mammalian cell line and resulted in the accumulation of $\text{Man}_5\text{GlcNAc}_2\text{-P-P-dol}$, leading to the addition of

$\text{Glc}_3\text{Man}_5\text{GlcNAc}_2$ instead of $\text{Glc}_3\text{Man}_9\text{GlcNAc}_2$ to proteins. Such mutant cell lines, which are viable *in vitro*, helped to elucidate one of the key intermediate steps in this complex pathway of N-glycan biosynthesis. The addition of $\text{Glc}_3\text{Man}_9\text{GlcNAc}_2$ to proteins occurs on the nascent polypeptides and multiple $\text{Glc}_3\text{Man}_9\text{GlcNAc}_2$ residues can be added to Asn residues within the N-glycosylation sequon as they emerge translationally into the ER through the translocon Sec61p (Fig. 4). But protein folding can also begin with polypeptide intermediates and such folding may interfere with glycan addition to Asn residues. Thus, while Asn residues in some N-glycosylation sequons are quantitatively and efficiently N-glycosylated, Asn residues within other sequons may be only partly or inefficiently N-glycosylated. This partial glycosylation at some Asn residues may not be accidental however, and may be under metabolic control and help to regulate glycoprotein function. Following the addition of $\text{Glc}_3\text{Man}_9\text{GlcNAc}_2$ to protein, the glucose residues are removed sequentially from nascent polypeptides and completely translated glycoproteins by two different α -glucosidases (I and II) in the ER to generate $\text{Man}_9\text{GlcNAc}_2\text{-Asn}$ (Fig. 4). Glucosidases are examples of enzymes termed glycosidases, which are able to cleave glycosidic linkages. The actions of the α -glucosidases are the first steps in glycoprotein biosynthesis termed processing, where specific sugars are removed from a newly synthesized glycoprotein in an orderly fashion. These α -glucosidases are inhibited by some sugar analogs, such as australine, which inhibits α -glucosidase I and castanospermine and 1-deoxynorijirimycin, which inhibit both α -glucosidases I and II.

Following removal of the three Glc residues, a single glucose residue can be added back to $\text{Man}_9\text{GlcNAc}_2\text{-Asn}$ to generate $\text{Glc}_1\text{Man}_9\text{GlcNAc}_2\text{-Asn}$ (Fig. 4). This re-glycosylation is catalyzed by the enzyme UDPGlc: glycoprotein glucosyltransferase (UGGT), a protein found in the ER (5). UGGT adds Glc from the sugar nucleotide donor UDPGlc, and generates a UDP byproduct. The action of UGGT is part of a quality control process in which glycoprotein folding in the ER is regulated. Improperly folded proteins either fail to leave the ER and are degraded there or leave to be degraded by the **proteasome** machinery located in the cytoplasm. Mature proteins have a specific shape that results from folding the polypeptide backbone and chemical cross-linking between Cys residues to form disulfide bonds. While protein folding is spontaneous, it is relatively slow and inefficient. Protein folding during biosynthesis is rapid and this is usually achieved through the assistance of **molecular chaperones**. Chaperones are proteins that assist other proteins in acquiring their mature and active forms. This is often associated with proper protein folding and prevention of

generally defined as non-immune proteins that recognize and bind to specific glycan structures without catalyzing a chemical modification. Calnexin/calreticulin bind in a reversible manner and their binding is probably associated with binding of other chaperones that recognize specific peptide features of the protein. Once released from calnexin/calreticulin, the Glc₁Man₉GlcNAc₂-Asn is subject to action of α -glucosidase II, resulting in reformation of Man₉GlcNAc₂-Asn. If a glycoprotein is still not properly folded, the UGGT adds back Glc to regenerate Glc₁Man₉GlcNAc₂-Asn. UGGT participates in quality control of N-glycan biosynthesis and protein folding through this cycle of

glucosylation/deglucosylation, which is repeated until a glycoprotein assumes a conformation that blocks its interaction with UGGT. Blocking the action of α -glucosidase with castanospermine or other glucosidase inhibitors can result in glycoprotein accumulation in the ER, due to inefficient protein folding. This single Glc residue serves as a type of ER-retention signal, preventing glycoprotein exit from the ER.

Following the formation of $\text{Man}_9\text{GlcNAc}_2\text{-Asn}$ on a folded glycoprotein, the ER α -mannosidase removes one of the mannose residues of $\text{Man}_9\text{GlcNAc}_2\text{-Asn}$ to form $\text{Man}_8\text{GlcNAc}_2\text{-Asn}$ (Fig. 4). Interestingly, some cells contain an endomannosidase that can remove Glc-Man disaccharide from $\text{Glc}_1\text{Man}_9\text{GlcNAc}_2\text{-Asn}$ in an α -glucosidase II-independent pathway to form an alternative $\text{Man}_8\text{GlcNAc}_2\text{-Asn}$. The endomannosidase can also act on $\text{Glc}_{1-3}\text{Man}_9\text{GlcNAc}_2\text{-Asn}$ derivatives. Following formation of $\text{Man}_8\text{GlcNAc}_2\text{-Asn}$ on ER glycoproteins, they usually exit to the Golgi apparatus by vesicular transport involving COP-coated vesicles. The Golgi apparatus is recognized as a multi-compartment organelle, with cis, medial and trans compartments and a terminal compartment called the transGolgi network (TGN). The Golgi apparatus is usually positioned in the cell so that the cis-Golgi is nearest or proximal to the ER and the trans-Golgi is away from or distal to the ER.

Upon reaching the cis-Golgi the $\text{Man}_8\text{GlcNAc}_2\text{-Asn}$ in glycoproteins is subjected to further processing by α -mannosidase I (Fig. 4). This enzyme removes 3 additional α -linked mannose residues from $\text{Man}_8\text{GlcNAc}_2\text{-Asn}$ to generate $\text{Man}_5\text{GlcNAc}_2\text{-Asn}$. Not all the high-mannose N-glycans, however, are susceptible to α -mannosidase I. The $\text{Man}_8\text{GlcNAc}_2\text{-Asn}$ in some glycoproteins are not very accessible to α -mannosidase I, leading to formation of mature glycoproteins having $\text{Man}_8\text{GlcNAc}_2\text{-Asn}$ or partly processed forms such as $\text{Man}_7\text{-}$, $\text{Man}_6\text{-}$, or $\text{Man}_5\text{GlcNAc}_2\text{-Asn}$. The action of α -mannosidase-I can be inhibited by several drugs, including the plant alkaloid kifunensine and the mannose derivative 1-deoxymannojirimycin.

Acid hydrolases that are destined to enter lysosomes are subject to the action of an alternative pathway in which they acquire phosphorylated mannose residues (Man-6-P) that are recognized by the mannose-6-phosphate (Man-6-P) receptors (Fig. 4). These receptors help to deliver lysosomal enzymes to endosomes, from which the **lysosomal acid hydrolases** can enter mature lysosomes and the Man-6-P receptors recycle to the Golgi for additional rounds of delivery (6). The high mannose-type N-glycans of lysosomal acid hydrolases in the early Golgi apparatus are recognized by the UDPGlcNAc:lysosomal enzyme phosphotransferase. Many of the lysosomal acid hydrolases have unique 3-dimensional structures that generate a surface patch, which is a basic region that includes

Lys residues. The phosphotransferase recognizes the signal patch and adds GlcNAc-1-P from the donor UDPGlcNAc to nearby Man residues on the high mannose-type N-glycans to generate the phosphodiester $\text{GlcNAc-1-P-6-Man}_{5-8}\text{GlcNAc}_2\text{-Asn}$. Following formation of $\text{GlcNAc-1-P-6-Man}_{5-8}\text{GlcNAc}_2\text{-Asn}$ on lysosomal enzymes, they are subjected to the action of the α -N-acetylglucosamine-1-P phosphodiesterase ("uncovering" enzyme or UCE), which removes the α -linked GlcNAc residue, resulting in formation of the phosphomonoester structure $\text{P-6-Man}_{5-8}\text{GlcNAc}_2\text{-Asn}$. Thus, lysosomal enzymes acquire one or more Man-6-phosphate- (Man-6-P) phosphomonoester residues on high mannose-type N-glycans. The presence of Man-6-P blocks action of α -mannosidases on the specifically phosphorylated Man residues. Thus, as described below, phosphorylated glycans cannot be converted to complex-type N-glycans, although they can be converted to Man-6-P-containing hybrid-type N-glycans.

It is important to note that sugar nucleotides, which are important donors for glycosyltransferases in the lumen of the ER and Golgi apparatus, are synthesized in the cytosol. The sugar nucleotides are imported into the lumen of the ER and Golgi apparatus by specific transporters. Most of these transporters function as antiporters; they move a sugar nucleotide into the lumen and the cognate nucleoside monophosphate into the cytosol for reutilization. Defects in transporter function are associated with human genetic diseases, as discussed below.

The recognition of lysosomal hydrolases by the phosphotransferase is dependent on the folded structure of lysosomal enzymes and unfolded proteins are not recognized by the phosphotransferase (6). As discussed below, mutations in the phosphotransferase can result in lack of addition of GlcNAc-1-P to the more than 50 lysosomal enzymes. Alternatively, the phosphotransferase can stochastically fail to add the GlcNAc-1-P to a fraction of the lysosomal acid hydrolases. Such non-phosphorylated glycans of lysosomal acid hydrolases are subject to further processing and modification in the Golgi apparatus and can acquire complex-type N-glycan structures that contain sialic acid and other terminal sugars.

The $\text{Man}_5\text{GlcNAc}_2\text{-Asn}$ structures are potential acceptors for the enzyme N-acetylglucosaminyltransferase I (GNT-I), which adds GlcNAc from the donor UDPGlcNAc to form $\text{GlcNAcMan}_5\text{GlcNAc}_2\text{-Asn}$ (Fig. 4). This is a hybrid-type N-glycan, that contains non-reducing terminal Man residues and other terminal sugars, such as GlcNAc. In vertebrate cells the product $\text{GlcNAcMan}_5\text{GlcNAc}_2\text{-Asn}$ is usually acted upon by α -mannosidase II, which specifically recognizes $\text{GlcNAcMan}_5\text{GlcNAc}_2\text{-Asn}$ and removes two mannose residues to form $\text{GlcNAcMan}_3\text{GlcNAc}_2\text{-Asn}$. The

concerted action of α -mannosidases and GNT-I, which appears to occur largely in the cis-Golgi region, generates the trimannosyl structure common to all complex-type N-glycans (7). This GlcNAcMan₃-GlcNAc₂-Asn is usually acted upon by N-acetylglucosaminyltransferase II, which adds GlcNAc from UDPGlcNAc to form the product GlcNAc₂Man₃-GlcNAc₂-Asn. This is an example of a biantennary complex-type N-glycan, which is characterized by the lack of non-reducing terminal Man residues and the presence of other terminal sugars. The biantennary nature refers to the presence of two branches of the complex-type N-glycan. But within the cis-Golgi additional N-acetylglucosaminyltransferases (GNT-III through VI) can add additional GlcNAc residues to the Man residues to form bisected N-glycans, or multi-antennary N-glycans, such as tri-, tetra-, penta- and hexa-antennary structures. Within the more distal trans-Golgi apparatus, the GlcNAc₂Man₃GlcNAc₂-Asn is subjected to modification by galactosyltransferases, causing addition of Gal residues to GlcNAc residues from the donor UDPGal to form Gal β 4GlcNAc-R sequences. This disaccharide terminal sequence is termed N-acetylglucosamine (LN). In vertebrates the pituitary glycoprotein hormones, such as lactating hormone and follicle stimulating hormone, acquire biantennary N-glycans but are subject to addition of GalNAc residues from the donor UDPGalNAc to form the sequence GalNAc β 4GlcNAc-R; this terminal disaccharide is termed lactosamine-di-N-acetyl (LacdiNAc or LDN). This formation of LDN sequences on pituitary glycoprotein hormones requires the action of a specific N-acetylgalactosaminyltransferase that appears to recognize primary sequences within the hormones, and does not generally act on other glycoproteins within the pituitary (8). But less specific N-acetylgalactosaminyltransferases are also expressed in other cells to generate the LDN structure on non-pituitary glycoprotein hormones. The LDN termini of pituitary glycoprotein hormones are sulfated at the C-3 position of the terminal GalNAc residues by a PAPS:GalNAc 3-O-sulfotransferase to form S-3-GalNAc moieties. The resultant formation of (S-3-GalNAc)₂ GlcNAc₂Man₃GlcNAc₂-Asn on pituitary glycoprotein hormones promotes their recognition and clearance from the blood circulation by a liver receptor for S-3-GalNAc.

In most glycoproteins following the addition of Gal residues to GlcNAc residues, the complex-type N-glycans can acquire other modifications in the trans-Golgi and TGN. These include addition of sialic acid from CMPNeuAc, fucose from GDPFuc, and other residues. Each addition or modification is catalyzed by a separate enzyme. A tremendous variety of modifications are possible depending on a wide variety of factors, such as expression of the modifying enzymes

and the availability of the glycoprotein glycans to the enzymes. Following these modifications of the N-glycans in the Golgi apparatus, secretory glycoproteins are released into the extracellular space by secretory vesicles, while membrane-bound glycoproteins may be targeted to the plasma membrane or lysosomes.

GPI-Anchor Biosynthesis

Many glycoproteins in eukaryotes contain a novel C-terminal modification of a glycosylphosphatidylinositol lipid anchor, the GPI anchor (9). The addition of the GPI-anchor to proteins occurs in the ER and involves recognition of a C-terminal domain of newly synthesized protein (Fig. 5). A preformed lipid-linked precursor is generated from phosphatidylinositol by initial reactions in the cytosolic face of the ER. An intermediate containing glucosamine is then reoriented (“flip-flop”) by translocation across the ER membrane to allow further elongation of the precursor by addition of Man residues from dol-P-Man. Ethanamine phosphate is added to Man residues by donation from phosphatidylethanolamine to generate a GPI precursor. In all organisms this GPI precursor is characterized by having glucosamine linked to inositol and the trimannosyl sequence linked to ethanolamine in a “core” structure. But this core structure may be differentially modified in a tremendous variety of ways, depending on the organism, by addition of other sugars, e.g. Man and Gal residues, additional ethanolamine residues, addition of phosphate, fatty acylation of the sugars and further acylation of inositol.

The GPI precursor is the substrate for a transamidation reaction by the GPI transamidase complex. This enzyme complex recognizes the C-terminal lipophilic portion of some proteins with a GPI anchor sequence, causing the cleavage of the polypeptide bond and transfer of the GPI precursor to the new C-terminal amino acid. The GPI transamidase forms a carbonyl intermediate with the substrate protein. The signal sequence for GPI anchor addition is a C-terminal region with an amino acid to which the anchor is eventually attached that is termed the ω site. The amino acids that are two residues to the carboxyl side of ω residue (the $\omega + 2$ site) have small side chains, whereas the residues at the $\omega + 1$ site can have large side chains. In all cases the $\omega + 2$ site is followed by a stretch of 5–10 hydrophilic amino acids and then 15–20 hydrophobic residues at or very near the carboxyl or C-terminus of the protein. Following the addition of the GPI anchor, the GPI-anchored glycoproteins move to the plasma membrane. These glycoproteins usually have other sugar residues attached to other amino acids, such as N-glycans, that may or may not be processed within the ER and Golgi apparatus. It is interesting that the formation of N-glycans and GPI-anchored glycoproteins uses a common intermediate, i.e. dol-P-Man.

Glycosylation of Proteins. Figure 5 Biosynthesis of GPI-anchored glycoproteins. The pathway shown is for human GPI anchor biosynthesis from phosphatidylinositol, which occurs in the cytosolic and luminal regions of the ER. Following generating of the GPI anchor precursor, the GPI anchor is added *en bloc* to the C-terminal region of an ER protein by the transamidase complex, resulting in the cleavage and release of a C-terminal peptide.

Some individuals have a mutation in the gene (termed *PIG A*) encoding the first enzyme of the pathway for GPI anchor biosynthesis that normally adds GlcNAc from UDPGlcNAc to phosphatidylinositol. Thus, these individuals are defective in generating the mature GPI anchor precursor and are deficient in generating GPI-anchored glycoproteins. Such individuals are often clinically recognized as having paroxysmal nocturnal hemoglobinuria (PNH), a form of hemolytic anemia. GPI-anchored glycoproteins also occur in many protozoans, and have been especially well characterized in African trypanosomes, where the GPI-anchored glycoprotein is recognized as a highly antigenic variant surface glycoprotein (VSG).

Mucin-Type O-glycan Biosynthesis

Many glycoproteins within the Golgi apparatus are modified to contain GalNAc α 1-Ser/Thr residues, typically found in animal mucins, by the action of a family of UDPGalNAc:polypeptide α -N-acetylgalactosaminyltransferases (ppGalNAcTs). While mucins may contain hundreds of such linkages, some glycoproteins, such as the transferrin receptor, contain only a single O-glycan. Yet, all such linkages are categorized as mucin-type. The ppGalNAcTs recognize Ser and Thr residues in glycoproteins and add GalNAc in O-glycosidic linkage from the donor UDPGalNAc to these amino acid side chains to form GalNAc α 1-Ser/Thr, which is also called the Tn antigen (10). Well over a dozen different ppGalNAcTs are known and many of these are expressed simultaneously within cells. Some of these enzymes may have unique, but partly overlapping, recognition of Ser/Thr residues within the polypeptide sequence. Interestingly, many ppGalNAcTs are dual function enzymes containing a catalytic domain that transfers GalNAc and a lectin domain (ricin- or R-type) that binds to GalNAc residues. Thus, addition of GalNAc to some Ser/Thr sites may promote further modification by attracting more ppGalNAcTs. Such concerted actions of ppGalNAcTs in the Golgi apparatus may promote the relatively efficient modifications of hundreds of Ser/Thr residues within some very large mucin polypeptides, some of which have over 10,000 amino acids.

Following the formation of GalNAc α 1-Ser/Thr residues, glycoproteins are subjected to the action of a β -3-galactosyltransferase, also called the T-synthase, to form the disaccharide Gal β 3GalNAc α 1-Ser/Thr, which is called the Thomsen-Friedenrich, TF or simply T antigen, using the donor UDPGal. The T antigen disaccharide is also the simplest core 1 O-glycan structure (Fig. 2). However, occasionally the GalNAc α 1-Ser/Thr residues may be sialylated to generate the disaccharide NeuA α 6GalNAc α 1-Ser/Thr (sialyl Tn antigen), which cannot be further modified. Upon formation of Gal β 3GalNAc α 1-Ser/Thr, the core 1 structure may be modified by an

N-acetylglucosaminyltransferase (the core 2 GlcNAcT) to generate the trisaccharide Gal β 3(GlcNAc β 6)GalNAc α 1-Ser/Thr (core 2 O-glycan) from the donor UDPGlcNAc. This core 2 O-glycan can be subsequently modified by addition of other sugars, such as galactose, fucose and N-acetylneuraminic acid, and/or sulfate residues on selected sugars to generate a wide variety of O-glycan structures.

Biosynthesis of Other O-Glycans

The biosynthesis of non-mucin type O-glycans is incredibly varied depending on the cellular compartment. O-GlcNAc residues are added to proteins in the cytoplasm, as discussed below. Glycosaminoglycan addition is initiated by UDPXyl:core protein β -D-xylosyltransferases I and II, which transfer Xyl from UDPXyl to specific Ser residues in proteoglycan core proteins in the ER. The Xyl residue is subsequently modified by addition of Gal and GlcA residues by galactosyltransferases and glucuronyltransferases respectively, to form the core linkage tetrasaccharide of glycosaminoglycans, GlcA β 1-3Gal β 1-3Gal β 1-4Xyl β 1-Ser, which occurs in all proteoglycans. This synthesis of the glycosaminoglycan core region may be completed in the ER, while the subsequent elongation of the glycans and sulfation and epimerization, which is an orchestrated and incredibly complex series of reactions, appear to occur primarily in the Golgi apparatus. The elongation of glycosaminoglycans on proteoglycans can be partly averted by feeding cells β -xylosides, that act as acceptors for addition of Gal, thus effectively decreasing elongation of glycosaminoglycan within the proteoglycan acceptors. Remarkably, β -xylosides appear capable of penetrating the ER and possibly the Golgi apparatus of cells. This inhibition by competition can result in synthesis of free glycosaminoglycans on the β -xyloside and reduced addition of glycosaminoglycan to proteoglycans. O-Mannosylation of proteins in yeast is initiated in the ER by transfer of Man from the donor dol-P-Man using a specific O-mannosyltransferase. Further elongation to generate mannose-containing polysaccharides in yeast occurs by Man donation from GDPMan in the Golgi apparatus by additional mannosyltransferases. An equivalent enzyme in animals, termed POMT1, may initiate O-Man formation on selective Ser/Thr residues in glycoproteins in the ER using dol-P-Man as the donor, while further elongation and addition of other sugars may occur in the Golgi apparatus. O-fucosylation and O-glucosylation of EGF-like domains on glycoproteins are catalyzed by specific enzymes that transfer Fuc or Glc from GDPFuc or UDPGlc, respectively, in the Golgi apparatus. Collagen is glycosylated in the ER following hydroxylation of Lys residues to generate hydroxylysine (Hyl). The addition of Gal to Hyl is catalyzed by a collagen-specific enzyme UDPGal:

procollagen-5-hydroxy-L-lysine D-galactosyltransferase, which adds Gal to Hyl residues on procollagen in the ER during procollagen biosynthesis and concomitantly with Hyl formation on nascent polypeptides catalyzed by lysyl hydroxylase activity.

Glycosylation in the Cytosol

Many cytosolic proteins in animals (and probably plants) contain one or more residues of β -linked GlcNAc in O-glycosidic linkage to Ser/Thr residues (11). These O-GlcNAcylated proteins (O-GlcNAc-containing glycoproteins) are generated by the action of the UDPGlcNAc:polypeptide O-acetylglucosaminyltransferase (O-GlcNAc transferase), which transfers GlcNAc from UDPGlcNAc to selected Ser/Thr residues of cytosolic proteins. Some of the more prominent O-GlcNAcylated glycoproteins include RNA polymerase II, c-myc and the estrogen receptor. O-GlcNAcylation is one of the only types of glycosylation that is reversible. The O-GlcNAc may be selectively removed by the action of an O-GlcNAc specific acetylglucosaminidase (O-GlcNAcase) in the cytosol. This alternating addition and removal of O-GlcNAc by these two enzymes is akin to reversible phosphorylation and dephosphorylation of cytosolic proteins. O-GlcNAcylation may serve to regulate many metabolic pathways and is required for animal and plant cell growth.

The storage polysaccharide glycogen, which is a glycoprotein in animals, is generated on the core protein glycogenin within the cytosol of animals, by its autocatalytic “self-glucosylation” of a Tyr residue at position 194 using UDPGlc as a donor. The Glc-O-Tyr is then elongated by addition of other Glc residues (up to ~ 10) from UDPGlc by glycogenin activity. The Glc-containing oligosaccharide on glycogenin is then elongated by glycogen synthase. A similar type of activity may occur on the starch protein amylogenin.

Plant Glycoproteins

Many plant glycoproteins contain N-glycans, which are also synthesized *via* the dolichol pathway in the ER. They can also be subsequently modified by processing reactions and addition of other sugars to generate high mannose-, hybrid- and complex-type N-glycans. Many plant wall proteins are typically glycoproteins rich in the amino acids hydroxyproline (**►hydroxyproline-rich glycoprotein**, HRGP), proline (proline-rich protein, PRP), and glycine (glycine-rich protein, GRP). The O-glycans in HRGPs may account for up to 95% of the glycoprotein weight and the glycans can range in size from a single attached Ara residue to large **►arabino-galactans** containing nearly 100 residues of Ara and Gal. Many of these glycoproteins form rods (HRGP, PRP) or β -pleated sheets (GRP). Extensin is one of the best-studied HRGPs. HRGP expression is increased by

plant wounding and pathogen attack. The pistil and pollen tube extracellular matrix are enriched in these highly glycosylated proteins.

Bacterial Glycoproteins

Glycoproteins are also found in prokaryotes and in archaeobacteria, although the general structures of the attached glycans and sugar residues are very different from those found in animals and plants. Among the best studied prokaryotic glycoproteins are the cell surface or S-layer glycoproteins (12). Such S-layer glycoproteins can assemble into ordered lattice-like structures on the cell surface. Each S-layer glycoprotein may contain more than one attached glycan, which can be linked *via* Asn or other amino acid residues (Table 1). In many cases the bacterial S-layer glycan chains are linear or branched homo- or hetero-saccharides having 20–50 identical repeating units. By contrast, archaeal S-layer glycoproteins have shorter glycans, generally lacking repeating units. Although the exact mechanisms of S-layer glycoprotein biosynthesis are not yet defined, it appears that most sugar residue addition occurs in the outer membrane following protein translocation.

Many Factors Regulate Protein Glycosylation

As discussed above, two of the major factors regulating protein glycosylation are the sequence motifs within the primary structure of glycoproteins and the site of biosynthesis. But many other factors also contribute to regulation of protein glycosylation. These include the expression of glycosyltransferases, expression of glycosidases, secondary, tertiary and/or quaternary structures of proteins, availability of donor substrates, e.g. sugar nucleotides and dolichol, cations, e.g. magnesium and manganese, temperature and membrane lipid composition and structure. Many of these factors, especially expression of glycosyltransferases, vary tremendously between cell types. Dozens of different glycosyltransferase genes encoding enzymes that act on glycoproteins exist in the genomes of most multicellular organisms. Together, these many factors help to explain the huge differences in glycosylation observed between different cells and tissues.

Glycoproteins Have Many Biological Functions

Because glycoproteins are so common in all cells, it is not surprising that the glycan moieties have many different functions. Although many of the specific functions of glycoproteins are being defined, it is likely that the complete picture of glycoprotein functions will take many years to complete. Some of the known functions of glycoproteins and their attached glycans include cell-cell adhesion, cell-matrix interactions, glycoprotein targeting to organelles and cell signaling. For example, glycoproteins regulate many different

types of cell adhesion, including sperm-egg adhesion, leukocyte-platelet-endothelial cells adhesion, recognition and phagocytosis and neuronal cell-matrix adhesion. Some of the non-specific functions of glycoprotein glycans include protein folding and assembly, protein protection and stability against proteases, control of the circulatory half-life of glycoproteins, regulation of protein conformation and thermal stability and control of enzyme kinetics. Many glycoprotein glycan functions are generated by glycan recognition through carbohydrate-binding proteins or lectins. Lectins are made by all organisms, including animal, plants, bacteria and viruses.

Human Disorders Associated with Defective Protein Glycosylation

There are many human disorders associated with an altered ability to add carbohydrate residues to glycoproteins. One of the first defined examples of this was [►I-cell disease](#), where patients were found to have a recessive genetic mutation of the gene encoding the phosphotransferase activity that helps to generate Man-6-P residues on lysosomal acid hydrolases. Consequently, their cells are unable to synthesize lysosomal acid hydrolases with Man-6-P residues efficiently (13). Most of the non-phosphorylated lysosomal acid hydrolases from these patients become processed within the Golgi apparatus, acquire sialic acid and other sugar residues on hybrid- and complex-type N-glycans and are secreted into body fluids. The patients accumulate undegraded macromolecules in lysosomes due to lack of acid hydrolases and these accumulations are recognized microscopically as inclusion or I-cells, hence the name I-cell disease. Another historically important defect in glycoprotein glycosylation associated with human disease is PNH. Patients with PNH have reduced ability to generate the GPI anchor, due to mutation in the X-linked *PIG A* gene. Hemolytic anemia results due to deficiencies in the normally GPI-anchored glycoproteins termed decay accelerating factor (DAF or CD55) and membrane inhibitor of reactive lysis (MIRL or CD59), which function to decrease autolysis of erythrocytes by activated complement.

Many of the genetic defects in the ability to glycosylate proteins are now recognized within the broad category of [►congenital disorders in glycosylation](#) (CDGs) (14). The CDGs are highly varied depending on the glycan structures made and are recognized as different types, such as Type 1a, 1b, 1c, 1d, 1e, and IIa. Each type of CDG results from mutations in one of the many genes encoding proteins involved in N-glycosylation *via* the dolichol pathway or subsequent processing and glycosylation reactions, or in genes regulating organelle trafficking and biosynthesis. CDGs are often diagnosed by examining the N-glycosylation pattern of serum glycoproteins, such as transferrin, where altered

N-glycosylation can affect mobility upon isoelectric focusing chromatography. CDG patients, depending on the altered gene, exhibit a variety of changes in physiognomy and suffer from neurological, liver and/or intestinal problems. Children with CDG, depending on the type of genetic mutation, exhibit impairments in cognitive ability, speech and balance and motor skills. Other disorders where altered protein glycosylation is observed include several forms of congenital muscular dystrophy, such as Fukuyama congenital muscular dystrophy, [►limb-girdle muscular dystrophy](#), muscle-eye-brain disease and Walker-Warburg syndrome (15). Many of these diseases are associated with mutations in genes encoding glycosyltransferases that add GlcNAc or Man residues to generate O-linked Man-containing glycans on α -dystroglycan, which is a membrane-associated glycoprotein that helps to link neuronal cells and their cytosolic signaling machinery to extracellular matrix molecules such as laminin. Patients with progeroid-type Ehlers-Danlos (E-D) syndrome have defects in a galactosyltransferase that is required to synthesize the common linkage region of glycosaminoglycans. Another disorder where altered protein glycosylation is observed is leukocyte adhesion deficiency type II (LAD II), where patients lack the ability to add fucose to glycoproteins. This deficiency in fucosylation results in a lack of leukocyte adhesion to selectins, a group of carbohydrate-binding proteins that recognize fucose-containing O-glycans and serve to regulate leukocyte trafficking from the bloodstream. Some LAD II patients have mutations in the gene encoding the Golgi transporter for GDPFuc, thus preventing normal movement of GDPFuc from its site of synthesis in the cytosol into the Golgi apparatus for utilization by fucosyltransferases. Finally, defects in glycoprotein glycosylation are also seen in patients with some autoimmune diseases, such as may occur in congenital dyserythropoietic anemia type II, where a defect in N-glycosylation may occur due to deficiency of α -mannosidase II activity and in IgA nephropathy, where a subset of IgA molecules lack appropriate O-glycan structures within the hinge region. These are just a few of the many examples where protein glycosylation is essential to biological processes.

Glycosylphosphatidylinositol (GPI) Anchors

Definition

In the lumen of the endoplasmic reticulum, the GPI anchor is covalently attached to the C terminus of proteins destined for the plasma membrane, and the transmembrane segment of the protein is cleaved off. As proteins are only attached to the exofacial leaflet of the plasma membrane by the GPI anchor, they can be

released in soluble form from the cell surface by the action of specific phospholipases.

Glycosyltransferase

Definition

Glycosyltransferase is a member of a large family of enzymes expressed in the endoplasmic reticulum and Golgi apparatus, which catalyze the transfer of a monosaccharide unit from a sugar-nucleotide donor, typically to the non-reducing terminus of an oligosaccharide chain in glycoproteins and glycolipids.

Glypidation

Definition

Glypidation describes the attachment of a glycosylphosphatidylinositol-(GPI)-anchor to certain integral membrane proteins. The anchor is composed of the lipid phosphatidylinositol to which a carbohydrate and an ethanol and phosphate moiety is linked. The GPI-anchor is attached post-translationally in the lumen of the endoplasmic reticulum, thereby replacing a transient transmembrane region of the modified protein. The ▶ [GPI-anchor](#) attaches proteins to the exoplasmic leaflet of membranes, possibly to certain subdomains such as caveolae and lipid-rafts.

Golgi Apparatus (Golgi Complex)

Definition

Golgi apparatus (Golgi complex) refers to a cytoplasmic organelle in eukaryotes consisting of stacked, flattened membrane cisternae, surrounded by vesicles, which is involved in transport and post-translational modification (especially glycosylation) of proteins on their journey through the secretory pathway. The Golgi complex is also a central sorting station in the secretory pathway; on the trans- or exit-side of the Golgi complex, proteins get sorted into several distinct vesicle types for transport to different final destinations.

Gorlin's Syndrome

Definition

Gorlin's syndrome (also known as naevoid basal cell carcinoma syndrome (NBCCS)) is a rare autosomal dominant cancer disorder characterised primarily by a predisposition to several tumours, most commonly basal cell carcinoma (BCC). In addition to cancer susceptibility, this syndrome is also associated with a range of defects resulting from abnormal embryonic development. Gorlin's syndrome results from mutation of the *patched* gene which functions in the hedgehog signalling pathway. The developmental defects are believed to result from ▶ haploinsufficiency, with subsequent mutation of the remaining allele resulting in tumour formation.

GPI (-Anchored) Protein

Definition

A GPI-anchored protein is a protein that is anchored in the membrane by glycosylated derivatives of phosphatidylinositol (GPI). The carboxyl group of the C-terminal amino acid is connected through an amide link to phosphoethanolamine, which is attached to a core tetrasaccharide composed of three mannose sugars and a single glucosamine sugar. The tetrasaccharide is in turn attached to phosphatidylinositol embedded in the membrane. Proteins with this type of lipid anchor are only found on the extracellular face (outer leaflet) of the membrane, and can be released in soluble form on the cell's surface by the action of specific phospholipases.

G-Protein Coupled Receptors

Definition

G-protein coupled receptors (GPCRs) comprise of the largest family of cell surface receptors, which communicate their signal through G-proteins. A common structural feature of GPCRs is the presence of seven hydrophobic transmembrane helices. Several hundred subtypes exist, which bind a huge variety of ligands, such as hormones and neurotransmitters. About 50% of the currently used drugs are directed at GPCR's.

Synonyms

Heterotrimeric guanine nucleotide-binding proteins

Definition

A plethora of extracellular signaling molecules like hormones, neurotransmitters, autacoids and growth factors convey information between cells of a living organism. The majority of these extracellular signaling molecules transmit their signal by interacting with a three-protein transmembrane signal transduction system composed of receptors, G-proteins and cellular effectors. All mammalian cells are endowed with a complement of G-protein-coupled receptors and several types of heterotrimeric G-proteins. Over the last few years systematic biochemical, cell biological and structural studies have laid a solid foundation for our understanding of G-protein dependent signal transduction processes. The characterization of genetically engineered mice carrying mutations in different G-protein genes as well as the clinical phenotype of patients affected by mutated G-proteins have greatly furthered our understanding of the biological functions of heterotrimeric G-proteins as central processors of information.

Characteristics

Basic Structures, Mechanisms and Classifications

The vast majority of extracellular signals interact with transmembrane receptors which couple to heterotrimeric guanine nucleotide-binding proteins (G-proteins) acting as transducers and signal amplifiers (1). Activated G-proteins then modulate the activity of cellular effectors. A comprehensive analysis of the human and mouse genomes defined a repertoire of G-protein-coupled receptors (GPCRs) for endogenous ligands comprising close to 400 genes (2, 3). GPCRs form a large and functionally diverse superfamily, participate in a variety of physiological processes and are prime targets for pharmaceutical drugs. They are integral membrane proteins, characterized by 7 α -helical transmembrane domains arranged in an anti-clockwise bundle (as viewed from the extracellular side) and connected by alternating extracellular and intracellular loops of variable lengths. The crystal structure of the prototypical GPCR **►rhodopsin** in the

inactive ground state has been resolved, by and large confirming the overall architecture deduced from analogy-based biomodelling and various mutagenesis approaches (4). As yet, it is only rudimentarily understood how ligand-induced conformational change of a GPCR is translated into G-protein activation.

G-Protein Composition and Structural Aspects

G-proteins are heterotrimers composed of α , β , and γ subunits. The α subunit is responsible for guanine nucleotide binding and GTP hydrolysis; the β and γ subunits are associated in a tenaciously linked $\beta\gamma$ complex and can be regarded as one functional unit. To date 16 distinct genes for α , 5 for β and 12 for γ subunits have been identified and characterized functionally (Table 1). Access to a deeper understanding of G-protein structure and function at the atomic level has been granted by solving crystal structures of G-protein α subunits in the GDP- and GTP-bound forms as well as in the transition state (5). In addition, atomic structures of G-protein $\beta\gamma$ dimers and of $\alpha\beta\gamma$ heterotrimers are also available. $G\alpha$ proteins are principally composed of a **►Ras-like GTPase** and an α -helical domain, both forming a deep cleft harboring the guanine nucleotide. $G\beta$ subunits fold into a highly symmetrical β propeller with an approximate 7-fold symmetry. $G\gamma$ binds to $G\beta$ in an extended conformation devoid of intrachain tertiary interactions. Those segments in the $G\alpha$ protein that undergo structural changes upon GTP hydrolysis are named switch I, II, and III regions. The most obvious changes occur in the switch II region. A mechanistic explanation for subunit dissociation and reassociation contingent upon the guanine nucleotide bound to the α subunit can be derived from the observation that the most extensive contact area between $G\alpha$ and $\beta\gamma$ comprises the protein surface around the switch II region of $G\alpha$. So far, structural information does not provide an obvious cue as to the specificity in the pairing of a particular α subunit with a defined $\beta\gamma$ dimer.

Because effector contact sites of $G\alpha$ have also been mapped to areas around the switch II region, $G\beta\gamma$ - and effector-interacting surfaces of $G\alpha$ overlap significantly. Thus, $G\alpha$ cannot interact with cellular effectors unless it dissociates from $G\beta\gamma$. Conversely, activation of $G\beta\gamma$ is a consequence of its release from $G\alpha$, which functions as a negative regulator of free $\beta\gamma$ subunits within the cell. The regions of $G\beta\gamma$ that interact with downstream effectors map to an N-terminal $G\beta$ fragment of approximately 100 amino acids. As yet, it is not understood how an activated receptor catalyses the dissociation of GDP from a G-protein heterotrimer. The most clearly defined $G\alpha$ contact sites with heptahelical receptors are located in the C-terminal region of the α subunit. However, compelling evidence

G-Proteins and G-Protein Mutations in Human Diseases. Table 1 G-protein α subunits

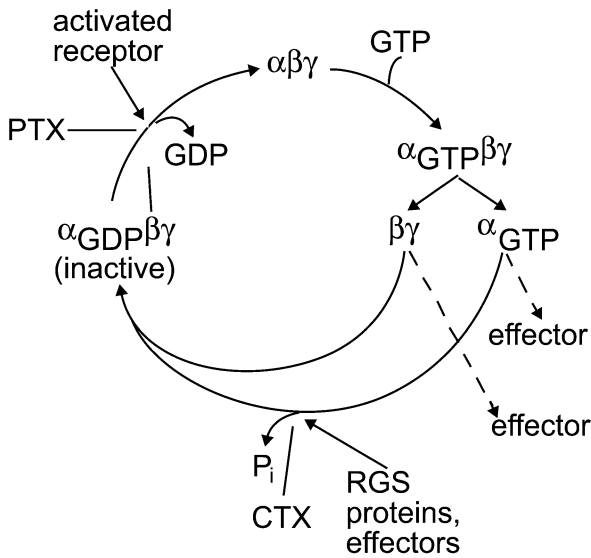

Name	Expression	Examples of effectors	Bacterial Toxins

has also been presented for participation of the $G\alpha$ N-terminus as well as the $\beta\gamma$ dimer in receptor interaction. Considering the proximity of the $G\alpha$ N-terminus and $G\gamma$ C-terminus on a common face of the G-protein heterotrimer anchored to the plasma membrane *via* lipid modifications, cytoplasmic receptor domains have access to large surface areas of α , β and γ subunits. However, according to the crystal structures available, the distance between the posttranslationally modified $G\alpha$ N-terminus and $G\gamma$ C-terminus (estimated minimum of 40 Å) appears to be too large to interact with rhodopsin's cytoplasmic surface area (maximal distance between interacting loop sites approximately 35 Å) at the same time, thus implying a two-step sequential interaction mechanism. The structural basis underlying the selectivity of receptor-G-protein interaction still remains only partially defined.

G-Protein Cycle

Binding of an agonist to a heptahelical receptor entails the formation of a ternary complex consisting of agonist, receptor and heterotrimeric G-protein in its GDP-liganded form. The binding of $\beta\gamma$ subunits to $G\alpha$ stabilizes the flexible switch regions and hence the GDP-dependent inactive $G\alpha$ conformation. The activated receptor fulfills the role of a catalytically acting **▶guanine nucleotide exchange factor** that facilitates the release of GDP (Fig. 1). The short-lived guanine nucleotide-free G-protein heterotrimer stabilizes the receptor in its high-affinity conformation. Due to its high intracellular concentration, GTP is rapidly incorporated into the guanine nucleotide-binding pocket in $G\alpha$, resulting in a conformational change in the α subunit and a dissociation of GTP-bound $G\alpha$ and $G\beta\gamma$. Both reaction products are intracellular signaling

G-Proteins and G-Protein Mutations in Human Diseases. Figure 1 The G-protein cycle. The activated receptor functions as a guanine nucleotide exchange factor to release bound GDP. G-protein $\beta\gamma$ subunits stabilize the inactive, GDP-bound $G\alpha$ conformation. Pertussis toxin (PTX) modifies the C-terminus of some G-protein α subunits and uncouples these G-proteins from the receptor. Both GTP-bound α subunits and $\beta\gamma$ dimers are signaling proteins in their own right and interact with effector proteins. $G\alpha$ activation is terminated by hydrolysis of GTP. The endogenous GTPase activity is accelerated by effectors such as phospholipase C- β or RGS (for “regulator of G-protein signaling”) proteins. Cholera toxin (CTX) modifies a highly conserved arginine residue in some α subunits, thereby abolishing GTPase activity and rendering the G-protein α subunit constitutively active. For further details see text.

proteins in their own right, activating distinct and overlapping portfolios of cellular effectors. In contrast to the situation with monomeric GTPases of the Ras family, G-protein α subunits are endowed with an endogenous GTPase activity. A highly conserved arginine residue in the helical domain, Arg²⁰¹ in $G\alpha_s$, directly participates in GTP hydrolysis by stabilizing the negative charge on γ -phosphoryl oxygen atoms in the transition state. Ras proteins lack such a residue and are essentially inactive as GTPases. The conformation of GDP-bound $G\alpha$ allows for the reassociation with the $\beta\gamma$ dimer and the inactive $G\alpha_{GDP}\beta\gamma$ complex is now prone to another round of activation and deactivation. Two bacterial toxins interfere with the GTPase cycle by covalently modifying G-protein α subunits. ▶**Cholera toxin** (CTX) ADP-ribosylates the aforementioned conserved arginine residue in the GTPase domain of some G-protein α subunits (Table 1), thus blocking

GTP hydrolysis and rendering the α subunit constitutively active. ▶**Pertussis toxin** (PTX) adds the ADP-ribosyl moiety to a cysteine residue in the C-terminus of most G_i proteins, thereby effectively uncoupling modified G-proteins from the receptor. Both toxins have been extensively used to dissect G-protein-mediated signaling pathways.

In a physiological setting, the GTPase activity of α subunits is controlled by a diverse family of multifunctional signaling proteins, ▶**regulators of G-protein signaling** (RGS), which bind directly to activated $G\alpha$ subunits in order to accelerate the rate of GTP hydrolysis by several orders of magnitude. In addition, G-protein effectors such as phospholipase C- β can also potentiate GTPase activity of α subunits (Fig. 1). Apart from deactivation of G-protein α subunits and termination of downstream signals, RGS proteins may also be viewed as *bona fide* effectors setting in motion various intracellular signaling cascades by means of protein-protein interactions mediated by a host of defined structural signaling motifs. Furthermore, they may profoundly shape the dynamics and determine the efficacy of G-protein cycling. An approximately 120-amino acid region that directly interacts with GTP-bound α subunits, called the RGS domain, is the structural hallmark of more than 30 RGS family members. The majority of RGS proteins appear to target G_i and G_q family members, whereas some (p115-RhoGEF, PDZ-RhoGEF, LARG-RhoGEF) specifically interact either with $G\alpha_{12/13}$ proteins or with $G\alpha_s$ (RGS-PX1). The exact physiological functions of RGS proteins are still poorly understood.

Within the past few years alternative modes of signal input into G-protein cascades have been discovered which are independent of heptahelical receptors. Four proteins, called AGS1-4 (for ▶**activators of G-protein signaling**), have been identified that engage G-protein-dependent signaling pathways in the absence of a classical receptor. AGS1 is a distinct member of the large superfamily of Ras-related proteins and targets α subunits. AGS2 represents a $G\beta\gamma$ -binding component of the cytoplasmic motor protein dynein and has undefined roles in cellular signaling. The third protein, AGS3, possesses seven tetratricopeptide (TRP) repeats and four amino acid repeats termed GoLoco motifs (meaning $G\alpha_{i/o}$ -Loco interaction motif) also described as G-protein regulatory (GPR) motifs. The GoLoco motif, which can also be found in other signaling proteins like RGS12 and 14 functions as a selective $G\alpha$ binding partner. The GoLoco/ $G\alpha$ interaction releases $\beta\gamma$ subunits and at the same time inhibits guanine nucleotide exchange in the bound α subunit, thus “freezing” monomeric $G\alpha$ in the inactive, GDP-bound state. Recently, an additional AGS protein, AGS4, was identified which contains three GPR motifs and regulates the activation state of $G\alpha_i$. At present, the

cell physiological role of AGS proteins is still fairly obscure. Possibly, these proteins are involved in the regulation of basic cellular processes like the maintenance of cell polarity and cell division. By acting in concert with GPCRs they may provide for a signal amplification mechanism and at the same time allow signal transmission *via* G-proteins independent of heptahelical membrane receptors.

G-Protein Families and Effectors

Based on the primary amino acid sequence of their α subunits, G-proteins are subdivided into four distinct families: G_s , G_i , G_q , and G_{12} (Table 1) (6, 7). Concentrations of G_i proteins in the cell considerably exceed those of other families, and in brain G_o may amount to 1–2% of total membrane protein. Some G-protein α subunits are characterized by a very restricted expression pattern (Table 1), while others like G_s , G_{i2} , G_q , G_{12} , and G_{13} are ubiquitously expressed. G-proteins can also be classified on the basis of the cellular effectors to which they couple. G_s proteins classically stimulate adenylyl cyclase activity, while G_i proteins inhibit adenylyl cyclase *via* their α subunits, but activate inwardly rectifying potassium channels and inhibit P/Q-, N- and R-type voltage-gated calcium channels *via* $\beta\gamma$ subunits released upon GTP binding to $G\alpha_i$ proteins. G_q proteins activate phospholipase C- β isoforms, and G_{12} proteins couple to Rho guanine nucleotide exchange factors resulting in Rho activation and stress fiber formation (Table 1). Both GTP-loaded α subunits and $\beta\gamma$ dimers are *eo ipso* signaling proteins exerting their action through activation or inhibition of an ever expanding list of cellular effector proteins (for $G\alpha$ effectors see: Table 1). Effectors for G-protein $\beta\gamma$ subunits include inwardly rectifying potassium channels (Kir3.1–3.4), G-protein-coupled receptor kinases (GRKs), adenylyl cyclases (adenylyl cyclases II and IV), phospholipases C (PLC)- β_1 , β_2 and β_3 and phosphatidylinositol 3-kinases (PI3K) β and γ .

Considering that hundreds of GPCRs transduce signals by interacting with a limited number of G-proteins, the question of coupling specificity is worth considering. The concept of linear G-protein-mediated signal transduction pathways, i.e. one receptor coupling to one distinct G-protein activating one receptor, appears to be inadequate to describe physiology. G-protein-mediated signal transduction is a complex signaling network with diverging and converging transduction steps at each coupling interface. Deciphering the mechanism of signal specificity in living cells still remains a scientific challenge of paramount importance.

G-Protein Mutations as the Molecular Basis of Human Diseases

Because of their central role in controlling many physiological functions, naturally occurring activating

and inactivating mutations in GPCRs and G-proteins are responsible for an increasing number of human diseases. Functional variability resulting from polymorphisms may underlie interindividual differences in response to endogenous ligands as well as drugs. At present, the $G\alpha_s$ gene (*GNAS1*) is the only G-protein gene that has been unequivocally shown to be afflicted with activating or inactivating mutations that cause human diseases (8–10).

Activating Mutations in $G\alpha_i$

Mutations in the $G\alpha_{i2}$ gene were diagnosed in fixed sections of human ovarian sex chord stromal tumors and adrenal cortical tumors. In a few affected specimens, the highly conserved Arg¹⁷⁹ corresponding to the aforementioned Arg²⁰¹ in $G\alpha_s$ in the helical domain was found to be exchanged for a histidine (Arg¹⁷⁹H) giving rise to a $G\alpha_{i2}$ protein devoid of any GTPase-activity. Constitutively active $G\alpha_{i2}$ was subsequently referred to as the *gip2* oncogene. Most notably, this finding could not be confirmed by subsequent studies on fresh surgically resected tumors, and transgenic animals expressing the *gip2* oncogene in selected tissues have not been reported yet. Therefore, one has to conclude at this point that the oncogenic potential as well as the frequency of activating mutations of $G\alpha_{i2}$ appear to be rather low.

Activating Mutations in $G\alpha_s$

In many endocrine glands, cAMP stimulates proliferation, differentiation and hormone secretion. A first hint to the possible causative contribution of activating mutations in *GNAS1* arose from the identification of a subset of growth hormone (GH)-secreting pituitary tumors characterized by high intracellular cAMP concentrations and increased adenylyl cyclase activity. These adenomas accounting for approximately 40% of GH-secreting tumors were shown to harbor heterozygous missense mutations in *GNAS1* exons 8 or 9 giving rise to Arg²⁰¹Cys/His and Gln²²⁷Arg/Lys missense mutations, respectively. Both the highly conserved Arg and Gln residues are essential for GTP hydrolysis to occur in the α subunit with the requirement of Gln²²⁷ to orient and polarize the catalytic water in the transition state. Therefore, these missense mutations ablate the endogenous GTPase activity of $G\alpha_s$ and render the α subunit constitutively active, leading to uncontrolled, excessive cAMP production in somatotrophs. As cAMP stimulates proliferation and differentiation in these cells, the GTPase-deficient $G\alpha_s$ mutants have been designated *gsp* oncogenes.

Gsp mutations are also rarely observed in other pituitary tumors like corticotrophs, resulting in increased ACTH release (Table 2). Besides, approximately 10% of non-functional pituitary adenomas carry

G-Proteins and G-Protein Mutations in Human Diseases. Table 2 Diseases associated with *GNAS1* mutations

Type of mutation	Disease	Mode of inheritance

GH, growth hormone; PHP, pseudohypoparathyroidism; PPHP, pseudopseudohypoparathyroidism

gsp mutations. Several studies have confirmed the presence of activating mutations in $G\alpha_s$ in up to 30% of toxic thyroid adenomas and in less than 10% of thyroid carcinomas. Sporadically, *gsp* mutations are found in parathyroid and adrenocortical tumors as well as in ►[pheochromocytomas](#).

The ►[McCune-Albright syndrome](#) (MAS) is classically defined by the clinical triad of *café-au-lait* hyperpigmented skin lesions, precocious puberty and polyostotic fibrous dysplasia of the bone. Apart from the gonads, other endocrine glands such as the pituitary, adrenal cortex and thyroid that are sensitive to trophic cAMP-dependent stimuli were also found to be hyperfunctional in MAS. Nodular and diffuse goiters as well as benign thyroid nodules are associated with MAS. The sporadic occurrence of thyroid cancer (papillary and clear cell thyroid carcinoma) in MAS patients suggests that additional mutational or epigenetic events in addition to gain-of-function $G\alpha_s$ mutations are mandatory for thyroid carcinogenesis in these patients. In 1986 the dermatologist Happle suggested MAS to be caused by a dominant somatic mutation as an early postzygotic event resulting the mosaic pattern of clinical stigmata. Mutations in *GNAS1* have been confirmed in affected endocrine tissues and in hyperpigmented skin lesions of all MAS patients. Interestingly, missense mutations were detected at only one position, i.e. Arg²⁰¹His/Cys. The overall clinical picture of an individual MAS patient is determined by the distribution of cells bearing the somatic *gsp* mutation. It is tempting to speculate that germline *gsp* mutations are incompatible with life. In contrast to the latter concept, one patient with severe

developmental, skeletal and endocrine abnormalities was described to harbor a germline Arg²⁰¹Leu mutation in *GNAS1*.

$G\alpha_s$ mutations have also been found in all cases of fibrous dysplasia (FD) of the bone. The majority of FD patients has only a single bone defect, a small group suffers from multiple bone lesions or has other features of MAS. Missense mutations in *GNAS1* identical to those in MAS patients, i.e. Arg²⁰¹His/Cys, were diagnosed in nearly all forms of FD. A possible explanation for the clinical phenotype relates to the general concept that elevated intracellular cAMP levels in osteogenic precursors entail increased proliferation and decreased differentiation of these cells resulting in benign fibrous bone lesions. Activating $G\alpha_s$ mutations have also been reported to occur in isolated intramuscular myxomas and those that present in conjunction with FD (Mazabraud syndrome)

Loss-of-Function Mutations in $G\alpha_s$

More than 60 years ago, Fuller Albright and his colleagues described several patients presenting with short stature, obesity, skeletal abnormalities, mental retardation and often subcutaneous ossification. This syndrome, now collectively called ►[Albright's hereditary osteodystrophy](#) (AHO) frequently concurs with resistance to parathyroid hormone (PTH) and other hormones like GH-releasing hormone, thyrotropin and gonadotropins acting *via* G_s -coupled receptors. AHO in conjunction with this kind of hormone resistance gives rise to the complex syndrome of ►[pseudohypoparathyroidism](#) (PHP) type Ia (Table 2). Patients with pseudopseudohypoparathyroidism (PPHP) show the

typical features of AHO, yet do not suffer from any kind of hormone resistance. On the contrary, PHP Ib patients present with symptoms of isolated PTH resistance, but lack the typical AHO phenotype. A mild form of thyrotropin resistance has recently been observed in PHP Ib patients raising the possibility that other endocrine systems may also be affected. Subsequent systematic studies were able to allocate the molecular defect in these three main forms of PHP to *GNAS1*.

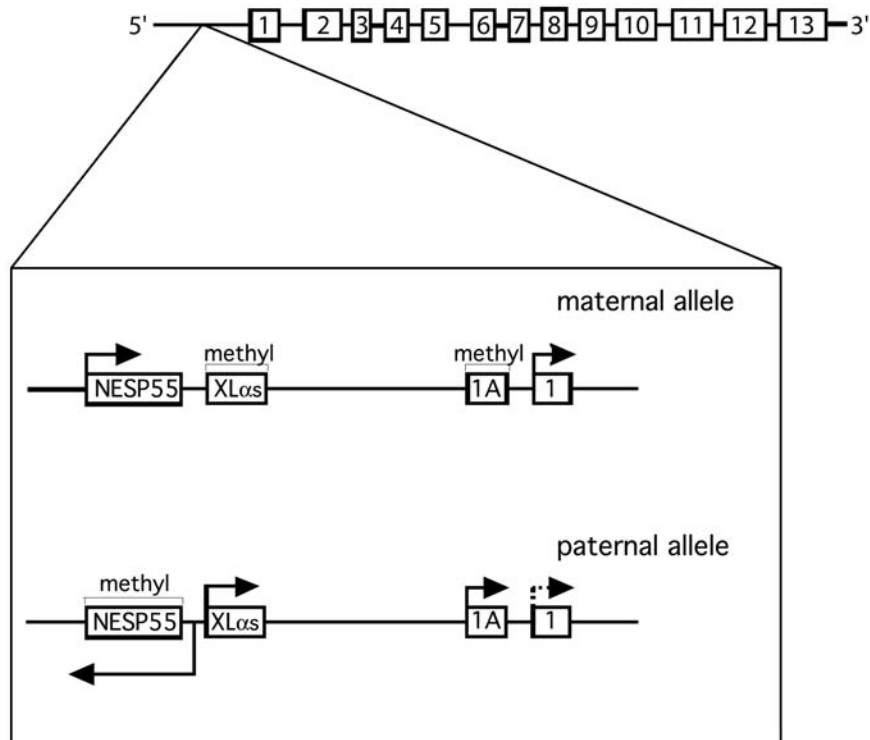

Heterozygous inactivating mutations affecting one of the $G\alpha_s$ -specific exons are the molecular cause of PHP Ia, PPHP and of progressive osseous heteroplasia (POH). POH patients suffer from severe heterotopic ossification involving skeletal muscle and deep connective tissue. They frequently lack hormone resistance and typical AHO features. Many of the *GNAS1* mutations are deletions or insertions that give rise to frameshifts and premature stop codons, nonsense mutations or splice junction mutations. In addition, a number of missense mutations adversely affect protein stability. The latter scenario is exemplified by a missense mutation, A³⁶⁶S, in the critical guanine nucleotide binding motif of the GTPase domain, leading to an accelerated release of GDP from the α subunit and marked instability of the guanine nucleotide-free protein at the body core temperature of 37 °C. At lower ambient temperatures, for instance in the testis, protein stability is not impaired and the accelerated nucleotide exchange manifests as constitutive $G\alpha_s$ activity. Therefore, the clinical phenotype of PHP Ia and excessive testicular testosterone production (testotoxicosis) arise from the intriguing A³⁶⁶S mutation (Table 2). In most tissues, an approximately 50% reduction of functional $G\alpha_s$ activity significantly reduces cAMP formation in the case of inactivating $G\alpha_s$ mutations. However, the cAMP levels that can still be generated are sufficient to maintain physiological functions. Thus, there is no evidence for haploinsufficiency to explain the hormone resistance observed in patients.

Retrospective analyses of PHP patients revealed that the clinical phenotype was strongly influenced by the parent transmitting the mutated allele. Any inactivating $G\alpha_s$ mutation leads to AHO irrespective of the parent transmitting the defective gene. Hormone resistance characteristic of PHP Ia occurs only if the genetic defect is inherited from a mother suffering from either PHP Ia or PPHP. Conversely, there is mounting evidence that POH is inherited from the father. This conspicuous parent-of-origin-specific inheritance pattern suggests that *GNAS1* is imprinted.

The human gene for $G\alpha_s$ is a single-copy gene located at 20q13.2-13.3. $G\alpha_s$ is encoded by exons 1–13 (Fig. 2). Alternative splicing of exon 3 produces two

long and two short forms of $G\alpha_s$. There is little evidence to suggest that these splice variants have distinct signaling properties. During the past few years it has become obvious that *GNAS1* not only codes for $G\alpha_s$, but also for several other transcripts by using 4 alternative promoters and first exons which splice onto a common exon 2 (Fig. 2). The most upstream alternative promoter gives rise to transcripts coding for the chromogranin-like neuroendocrine secretory protein 55 (NESP55) whose entire coding sequence resides in the upstream exon, thus leaving $G\alpha_s$ exons 2–13 within the 3' untranslated region of the NESP55 transcript. The NESP55 promoter is methylated on the paternal allele, so that the NESP55 gene is exclusively transcribed maternally. The XLa_s transcript encodes a protein with an extended N-terminus when compared to $G\alpha_s$ and is transcribed from the paternal allele only (Fig. 2). The C-terminal 348 amino acid residues are identical to $G\alpha_s$. XLa_s is highly expressed in the pituitary, is targeted to the plasma membrane, interacts with $\beta\gamma$ subunits and can be activated by non-hydrolysable GTP analogs. However, there is no evidence that XLa_s is regulated by GPCRs. An additional transcript derived from the sense strand of the paternal allele uses exon 1A (exon A/B) as the first exon and also splices onto exons 2–13 (Fig. 2). However, exon 1A generates transcripts that are presumably untranslated. Upstream of the XLa_s exon, a promoter for antisense transcripts traversing the NESP55 exon has been identified. These NESP55 antisense transcripts are only expressed from the paternal allele and may contribute to the imprinting of NESP55 by silencing the NESP55 promoter on the paternal allele.

Around 100 autosomal genes are subject to [genomic imprinting](#). One genomic region controlled by this epigenetic phenomenon is located in the distal portion of chromosome 2 and encompasses *GNAS1*. All imprinted genes have one or more regions in which the cytosines within CpG dinucleotide stretches are methylated on one parental allele only. Very often these methylated regions coincide with gene promoters. As described above and illustrated in Fig. 2, the promoter regions of *GNAS1* display a complex imprinting pattern. To complicate the scenario even further, the promoter region giving rise to $G\alpha_s$ transcripts does not exhibit allele-selective methylation and in most tissues expression occurs biallelically. This situation notwithstanding, paternal $G\alpha_s$ expression is silenced in a few tissues by a mechanism that is presently unknown. In proximal renal tubular cells, adipocytes, pituitary gland, thyroid and gonads, $G\alpha_s$ expression is largely driven by the maternal allele. In PHP Ia patients, renal proximal tubule cells are resistant to PTH action, because $G\alpha_s$ expression is restricted

G-Proteins and G-Protein Mutations in Human Diseases. Figure 2 Organization and imprinting of the *GNAS1* locus. *GNAS1* is characterized by 4 alternative first exons which splice onto exon 2. Methylation patterns (*methyl*) and transcriptional activation (*arrows*) of the maternal and paternal allele are indicated. The *hatched arrow* for exon 1 of the paternal allele indicates that it does not contribute to Gα_s expression in all cells. An antisense mRNA is transcribed across the NESP55 exon on the paternal allele.

to the maternal allele that carries an inactivating mutation. Yet PHP Ia patients are not prone to hypercalciuria, suggesting that the anticalciuric PTH action in the thick ascending limb is fully operative because of biallelic Gα_s expression in this part of the nephron. Thus, tissue- and cell-specific imprinting represents the molecular mechanism underlying the clinical features of PHP Ia, while haploinsufficiency alone may lead to AHO.

A first glance at the mechanism of tissue-specific Gα_s imprinting was granted by studies on patients with PHP Ib. The vast majority of these patients who present with renal PTH resistance, sometimes accompanied by partial TSH resistance, exhibit a loss of methylation at the *GNAS1* exon 1A, while lacking mutations in the exons coding for Gα_s. This loss of the maternal allele-specific methylation pattern, linked to an upstream 3 kb deletion, makes the maternal allele look like the paternal one, resulting in silencing of maternal Gα_s expression in renal proximal tubules. One possible explanation is based on the hypothesis that the non-methylated exon 1A region allows for the binding of a

tissue-specific repressor protein that hampers Gα_s expression. Alternatively, the deletion may disrupt a cis-acting imprinting control element necessary for the methylation imprint at exon 1A (exon A/B). As the described deletions disrupt another gene, *STX16* coding for Syntaxin 16, one may speculate that the *STX16* region comprises such an imprinting control element. The relevance of these epigenetic changes, i.e. the loss of maternal-specific methylation of *GNAS1*, for the clinical PHP Ib phenotype is emphasized by a patient with paternal uniparental disomy of chromosome 20q. In this situation both long arms of chromosome 20q are of paternal origin resulting in PTH resistance, but not in AHO.

A unique heterozygous 3 bp deletion causing loss of Ile³⁸² in the C-terminus of Gα_s was detected in 3 affected boys with PHP Ib. When heterologously expressed, the mutant Gα_s was found to be unable to couple to the PTH receptor, while interaction with the G_s-coupled thyrotropin and luteinizing hormone receptors was unaffected. These results explain PTH-specific hormone resistance in the affected patients.

The absence of any phenotype in the mother and maternal grandfather carrying the same mutation is commensurate with our current understanding of paternal imprinting of the *GNAS1* gene.

The $G\beta_3$ -C825T Polymorphism in Multigenic Disorders

A single base substitution (C825T) in the $G\beta_3$ subunit leading to a truncated protein has originally been reported in association with primary hypertension. More recently, genetic associations with a number of other disorders such as obesity and insulin resistance have been suggested. So far, the underlying mechanism by which the $G\beta_3$ variant causes the different phenotypes remains elusive.

Conclusions

In the past few years significant progress has been made towards a truly molecular understanding of receptor/G-protein-mediated signal transduction. One crystal structure of a heptahelical receptor, rhodopsin, and several of G-proteins provide a solid foundation for future work on the mechanisms of receptor and G-protein activation. An important goal will be to determine the structural differences between the inactive and active receptor conformations as well as the structure of receptors in complex with heterotrimeric G-proteins. Studies on engineered gene-deficient mice as well as the thorough *in vivo* and *in vitro* characterization of naturally occurring G-protein mutations detected in patients have taught us invaluable lessons on the physiology of these cardinal signaling proteins. Studying clinical and molecular aspects of the different forms of PHP has highlighted the complex regulation of $G\alpha_s$ expression and provided remarkable insights into the basic mechanisms of genomic imprinting. Our understanding of receptor and G-protein-mediated signaling processes has shifted from studying linear signaling cascades towards the consideration of complex signaling networks which will require novel collaborative research initiatives to integrate bits and pieces of knowledge into a coherent instructive model.

G-Quartet DNA

Definition

G-quartet DNA (also know as G4 DNA) defines a four-stranded DNA structure formed by nucleic acid rich guanine/cytosine regions. This structure is highly stabilized by a planar array of four hydrogen-bonded guanine bases.

►DNA Helicases

Graafian Follicles

Definition

Graafian follicles designate cellular components of the ovary, each consisting of a germ cell (oocyte), surrounded by somatic cells (follicle cells), and a large

fluid-filled cavity from which the unfertilized egg emerges.

► [Mammalian Fertilization](#)

Grade of Malignancy

Definition

Grade of malignancy designates the histomorphological assessment of the malignant behavior of a tumor, as estimated by cytological criteria such as nuclear pleomorphism and number of mitoses, and histological criteria such as the formation of differentiated structures. Usually, three grades (G1, well differentiated; G2, moderately differentiated; and G3, poorly differentiated; with increasing aggressiveness in this order) are distinguished.

► [Breast Cancer](#)

Granulation Tissue

Definition

Granulation tissue defines a new connective tissue that is formed during the wound repair process and temporarily replaces the lost dermal part of the skin. The name derives from the granular appearance of numerous new capillaries.

► [Wound Healing](#)

Granuloma

Definition

Granuloma represents a chronic inflammatory lesion initiated by various infectious and non-infectious agents. Granuloma consists of either small, nodular aggregations of mononuclear inflammatory cells or of aggregations of different cells, usually modified macrophages surrounded by lymphocytes and multinucleated giant cells. Sometimes granuloma may also contain eosinophils and B cells, and are surrounded by fibrotic tissue.

► [Morbus Wegener](#)

Granulomatosis

Definition

Granulomatosis refers to a multisystem disease that is characterized by an inflammation of the blood vessels (► [vasculitis](#)) involving the upper and lower respiratory tracts and variable degrees of systemic, small vessel vasculitis, which is generally considered to represent a hypersensitivity reaction to an unknown antigen.

Green Fluorescent Protein

Definition

GFP stands for Green Fluorescent Protein. It is a natural, 27 kDa fluorescent protein, originally produced by the marine jellyfish *Aequorea victoria*, and fluoresces or

glows green visible light when excited by UV light (395 nm). GFP is commonly used in the laboratory for labeling, detecting and tracking proteins and biological processes. It can be cloned without co-factors in most organisms, and is used as a reporter molecule in light microscopic imaging in co-expression assays to visualize cellular structures and molecules. The protein has been mutated to generate blue, cyan, yellow, photo-activatable, and monomeric variants.

Definition

Polypeptide growth factors are proteins with a fundamental role during embryogenesis and regeneration of tissues. In contrast to some hormones, which regulate growth of entire organisms, growth factors are essential for replication of individual cells and to the maintenance of normal cell function. Some growth factors stimulate cell division in numerous different cell types, while others are specific for particular cells. Growth factors mediate their effects on cells by binding to specific surface receptors. Binding of growth factors to their corresponding receptors activates signaling systems inside cells, which regulate transcription of genes involved in cellular processes such as differentiation, proliferation, migration, protein synthesis and metabolism. In adult organisms, certain growth factors are essential for the regeneration of cells in the bone marrow and for tissue repair, whereas other factors regulate the development and growth of tissues in the embryo (see ►Limb Development). In human disease, growth factors contribute to the abnormal regulation of cell proliferation found in cancer but also regulate cellular processes in cardiovascular and inflammatory diseases. The progressive accumulation of new information regarding the function of growth factors in human health and disease is providing new alternatives for future treatment strategies.

Characteristics

In 1986, Rita Levi-Montalcini and Stanley Cohen were awarded the Nobel Prize in Physiology or Medicine for their discoveries of the first identified growth factors, nerve growth factor (►NGF) and epidermal growth factor (►EGF). NGF regulates the development and survival of neurons whereas EGF stimulates cell proliferation in a number of different cell types. Ever since, numerous other growth factors have been identified and their functions in human development, homeostasis and disease explored. These discoveries have to a large extent been promoted by cancer research, especially investigations into how viruses cause tumors. Some viruses that infect cells cause permanent mutations in the host cell DNA, which lead to the expression of genes that disturb the internal control of the cell's ability to proliferate. These so

called ►**oncogenes** can promote abnormal cell proliferation, a hallmark of cancer cells, by changing the function of any protein involved in the normal control of cell replication. Thus oncogenes can lead to abnormal expression of a particular growth factor, altered expression of growth factor receptors, increased growth factor receptor activity or any other disruption of the intracellular machinery that regulates cell division. These insights have led to the discovery of individual growth factors, growth factor receptors and intracellular signaling pathways that transmit growth stimuli to the cell nucleus. These naturally expressed growth regulatory proteins are called proto-oncogenes and historically, they have been named after the virus that gave rise to the growth disturbing mutation. For example, the proto-oncogene that encodes for platelet-derived growth factor (►**PDGF**) was named *sis* after the virus simian sarcoma virus, which induces proliferation in infected cells through over-expression of a PDGF-like protein.

The polypeptide growth factors include a wide variety of signaling molecules that can be categorized into several groups or families. They can be produced and secreted by cells in order to act locally on neighboring cells (►**paracrine** function) or actually even on the same cells that produced them (►**autocrine** function). Some growth factors are also produced in organs but exert their action on target cells after being transported in the blood to a distance from the source (►**endocrine** function).

One of the first growth factors characterized, EGF, is found in salivary glands in the gastrointestinal tract and promotes proliferation of a large variety of cells, epithelial cells and mesenchymal cells included. ►**Erythropoietin** is a growth factor produced in the kidney, which stimulates proliferation of immature red blood cells in the bone marrow. Some growth factors are stored extracellularly in tissues or in cells and can be released to stimulate cells in the immediate vicinity. For example, fibroblast growth factor (►**FGF**), a member of a large family of growth factors, has the capacity to be stored in tissues by binding to sugar residues on proteins in the extracellular matrix, the so-called proteoglycans, and can be released after injury to participate in tissue repair by stimulating cell proliferation. Several members of the FGF family stimulate proliferation of endothelial cells and participate in the formation of new vessels, angiogenesis. FGF is also an important growth factor in the developing embryo and mutations in receptors for these growth factors have been associated with several different bone disorders, for example achondroplasia (dwarfism). There are numerous other growth factors that are involved in angiogenesis. Vascular endothelial cell growth factor (►**VEGF**) can be produced in tissues with a deficient blood supply, for example after myocardial infarction,

and selectively stimulate proliferation of endothelial cells to recruit new vessels into the anoxic tissue. VEGF can also be released from cancer cells and stimulate growth of vessels from the surrounding tissues, which ensures a blood supply in the growing tumor. PDGF is stored in blood platelets and can act on cells after platelet degranulation in association with tissue injury, bleeding and blood clotting. Together with other growth factors such as EGF, which is also stored in platelets, PDGF acts locally on cells in the injured tissue and promotes cell proliferation in the healing process (Fig. 1). Insulin-like growth factor-1 (►**IGF I**) chemically resembles the hormone insulin and is mainly produced in the liver under the control of growth hormone. During development, this growth factor participates in the regulation of skeletal growth and maturation after birth, but it is also involved in tissue repair and may be important for abnormal proliferation of cancer cells. The transforming growth factor family (►**TGF**) is a large family of different growth factors that were initially characterized by their ability to transform normal cells into tumor cells in culture. They have profound effects on cell metabolism and cellular synthesis of extracellular matrix proteins, and in some cell types they rather prevent than stimulate cell proliferation. ►**Cytokines** are a unique family of growth factors, which primarily act on cells in the immune system and stimulate proliferation of lymphoid cells. Cytokines such as the interleukins (►**IL**), a large family with more than 20 members, regulate proliferation on a variety of lymphocytes but also affect differentiation and growth of cells in the bone marrow.

The identification and characterization of growth factors have yielded potential therapeutic tools for the management of a large variety of human diseases. In patients with chronic kidney failure, the metabolic dysfunction of the organ will lead to anemia due to insufficient production of erythropoietin. Today, patients suffering from this condition receive injections of recombinant erythropoietin that stimulate production of red blood cells in the bone marrow. A number of other conditions where the bone marrow does not produce enough blood cells can also be corrected through the addition of specific growth factors. For example, deficient production of white blood cells in the bone marrow, a side effect of cancer treatment with chemotherapy, can now be corrected through injections of growth factors that specifically stimulate proliferation of leukocytes. In some disorders, especially in cancer, pharmacological approaches are taken to develop drugs that prevent the effects of growth factors, for example drugs that interfere with the binding between specific growth factors and their corresponding receptors on the surface of cells.

Growth Factors. Figure 1 Growth factors regulate healing responses. After tissue injury, bleeding and formation of a blood clot, growth factors can be released from degranulating platelets (1) and stimulate fibroblast proliferation or growth of new blood vessels in the injured tissue. In addition, inflammatory cells recruited from the blood stream can produce growth factors (2); they may be released from storage pools in the tissue (3) or they may be released from proliferating cells (4).

Regulatory Mechanisms

Growth factors are secreted into the extracellular environment of cells where they may come in contact with specific receptors on the same cell that secreted them, on nearby cells or on distant cells after transportation through the blood stream. Polypeptide growth factors usually bind with high affinity to their corresponding receptors. The receptors are transmembrane proteins with an extracellular domain that has a specific binding site for the growth factor. Upon binding of the ligand, a signal is sent to the intracellular domain, which initiates an intracellular signal transmitted from the receptor to the cell nucleus through specific signaling pathways. Once the signal has reached the nucleus, a specific response is elicited in the regulation of gene transcription and the cell will express specific genes, for example genes involved in the control of proliferation.

Growth factor receptors can be classified into three different groups, receptor tyrosine kinases (▶RTK), ▶tyrosine-kinase-associated receptors, and G-protein coupled receptors (▶GPCR). Most growth factor receptors are RTKs. These growth factor receptors have a

single transmembrane domain, an extracellular domain that binds to the ligand and a cytosolic domain, which harbors an enzymatic activity that catalyzes addition of phosphate residues to the amino acid tyrosine, ▶tyrosine kinase activity. Many growth factors, such as PDGF, are dimers, two separate polypeptides linked to each other, which bind to two separate receptor subunits at the cell surface. This dimerization of the receptor subunits facilitates tyrosine kinase activity in the cytosolic domains whereby tyrosine residues are phosphorylated, a phenomenon termed ▶autophosphorylation. Other monomeric growth factors, such as FGF, may instead form pairs by binding to sugar structures at the cell surface and thereby achieve simultaneous binding of two corresponding cell surface receptors and receptor dimerization. Autophosphorylation of tyrosine residues in the cytosolic domains of RTKs allows binding and initiation of catalytic activity in intracellular proteins that transmit signals to the nucleus through different pathways. These signaling pathways generally function by a series of kinases that step by step are phosphorylated and activated one after the other so that the signal is propagated to the final activation of gene expression in the nucleus (Fig. 2).

Growth Factors. Figure 2 Growth factors regulate gene transcription in cells. 1) Binding of a growth factor to a corresponding receptor (receptor tyrosine kinase; RTK) on the cell surface induces dimerization of two receptor subunits, which elicits phosphorylation (P) of tyrosine residues on the cytosolic domains of the receptor. 2) Specific intracellular adaptor proteins (AP) bind to the receptor and facilitate activation of catalytic proteins, such as Ras, which thereafter activate intracellular signaling through the mitogen activated protein kinase (MAPK) pathway. 3) In this pathway, phosphorylation of amino acid residues activates a series of kinases and the last activated protein in the pathway enters the cell nucleus (4) where it induces activation of transcription factors (tf), which promote expression of specific genes, for example genes coding for proteins necessary for cell proliferation.

Cytokines bind to tyrosine-kinase-associated receptors that are structurally similar to RTKs but lack intrinsic tyrosine kinase activity in their cytosolic domains. Instead, these growth factor receptors are associated with molecules that have tyrosine kinase activity. Receptor binding of cytokines also facilitates dimerization of receptor subunits, which then mediate phosphorylation of associated tyrosine kinases. Activation of these tyrosine kinases leads to phosphorylation of

tyrosine residues on the receptor, which provides binding sites for downstream signaling molecules and initiation of signaling cascades. The receptors of the GPCR family are traditionally regarded as mediators of signaling for substances that regulate specific physiological responses in differentiated cells, for example contraction and relaxation in muscle cells. Lately, it has been understood that these receptors may also transmit growth signals in less differentiated and proliferative

cells after stimulation by factors not normally perceived as growth factors, for example angiotensin II which stimulates contraction of smooth muscle cells in the vessel wall but also initiates proliferation in de-differentiated smooth muscle cells in diseased vessels. GPCRs have an extracellular domain that binds the ligand, seven transmembrane segments and an intracellular domain that associates with a guanine nucleotide-binding protein (hence the name G-protein). Ligand binding, for example of thrombin or angiotensin, to its specific GPCR extracellular domain, leads to a conformational change in the cytosolic domain of the receptor. The altered receptor structure facilitates binding of G-proteins to the intracellular domain, which in turn activates an enzyme attached to the plasma membrane. This enzyme catalyzes a reaction leading to the release of a second messenger, which can then activate intracellular signaling molecules that reach the nucleus and affects gene transcription.

Cascades of intracellular signaling molecules constitute links between growth factor binding to a growth factor receptor and expression of genes in the nucleus that control cell proliferation. The ►**mitogen activated protein kinase** (MAPK) pathways are the most well studied and understood intracellular signaling pathways, which are activated after binding of growth factors to their corresponding cell surface receptors. For example, binding of PDGF to the PDGF receptor leads directly to receptor dimerization and autophosphorylation of tyrosine residues on the cytosolic domains of the receptor. Tyrosine autophosphorylation provides binding sites for an adaptor protein called Grb2. Grb2 in turn binds to another adaptor protein SoS (son of sevenless) that can activate the small GTP binding proto-oncogene protein Ras. Ras then phosphorylates a Map-kinase-kinase-kinase, which in turn phosphorylates a MAP-kinase-kinase and then finally, the last signaling molecule of the pathway, a MAP-kinase (MAPK) is activated. After phosphorylation, MAPK translocates into the nucleus and activates a set of ►**transcription factors**, which promote expression of growth-related genes (Fig. 2).

The ►**cell cycle** is divided into four phases, G0, G1, S, G2 and M. Non-malignant eukaryotic cells are normally resting in the G0 phase. In cells that harbor the capacity to proliferate, such as fibroblasts, growth factors stimulate the cells to leave the G0 phase and enter the G1 phase. When cells have been stimulated with growth factors for a specific time period in the G1 phase, further progression in the cell-cycle and cell division will inevitably follow, even if the growth factor is removed. This so called ►**restriction point** is followed by the S-phase where DNA replication takes place, the G2 phase when factors necessary for the physical division of the cell are produced and finally the M phase when mitosis occurs. Passage through the cell-cycle is controlled by periodic

changes in the expression and activity of families of cell-cycle regulatory proteins termed ►**cyclins** and cyclin dependent kinases (►**cdk**). The expression of some cyclins is largely dependent on growth factors and activation of growth factor receptors. After growth factor stimulation, cyclins are synthesized, which form complexes with cdks. These complexes catalyze massive phosphorylation of the retinoblastoma protein, ►**Rb**. In resting cells, Rb is bound to the transcription factor E2F but upon hyperphosphorylation, E2F is released and can activate transcription of a number of genes necessary for S-phase initiation and further cell-cycle progression.

GTPase-Activating Proteins

Definition

GTPase-activating proteins (GAPs) comprise of proteins that bind to a GTP-binding protein and inactivate it by stimulating its GTPase activity so that it hydrolyzes its bound GTP to GDP.

► [Rho, Rac, Cdc42](#)

GTPases

Definition

GTPases comprise of a large group of intracellular signaling proteins characterized by an active state when GTP-bound, and an inactive state when GDP-bound. Their enzymatic activity hydrolyzes GTP.

► [Cardiac Signaling: Cellular, Molecular and Clinical Aspects](#)

► [Rho, Rac, Cdc42](#)

Guanine Nucleotide Dissociation Inhibitors

Definition

Guanine nucleotide dissociation inhibitors (GDIs) are protein factors that inhibit the dissociation of guanine nucleotides (GDP/GTP) from GTPbinding proteins.

► [Rho, Rac, Cdc42](#)

Guanine Nucleotide Exchange Factors

Definition

Guanine nucleotide exchange factors (GEFs) are proteins that catalyze the release of guanine nucleotides (mostly GDP) from monomeric or heterotrimeric GTPases, thereby allowing them to bind GTP in its place. In the latter case, heptahelical receptors serve as GEFs.

Gut Epithelium

MICHÈLE KEDINGER, JEAN-NOËL FREUND
INSERM U682, Strasbourg, France
michele.kedinger@inserm.u-strasbg.fr

Definition

The intestinal epithelium lines the gut lumen, dividing the outside from the interior of the body. It is implicated in most digestive and absorptive functions of the gut, but also in the immunological and non-immunological protection against nutritional, bacterial, viral and parasite aggressions. Its importance in terms of evolution is demonstrated by its presence early in the animal kingdom long before the spinal cord or neuronal cells. The intestinal epithelium forms invaginations into the stroma, the crypts, and outwardly projecting villi in the small intestine or flat cuffs in the colon. Taking into account the length of the gut (5–6 m in humans), these structures, and additional microscopic foldings at the apical membrane of epithelial cells, the microvilli, provide an overall absorptive surface of about 300 m². The gut epithelium exhibits a morphological and functional regionalization along the proximo-distal axis, mainly obvious between the small intestine and colon.

Characteristics

1. The gut epithelium develops in interaction with multiple partners.
The intestinal epithelium derives from the mid and posterior parts of the definitive endoderm (midgut and hindgut), which itself originates from the ingression of primitive streak cells at gastrulation. Specification of the presumptive intestinal endoderm is driven by interactions with lateral mesoderm. Morphogenesis of the gut generates the single layer columnar epithelium laid on and separated from lamina propria myofibroblasts by a ►**basement membrane**, which is a specialization of the ►**extracellular matrix**. Intestinal epithelial cells also interact with lymphocytes (either intra-epithelial lymphocytes or organized into sub-jacent nodules), and with neuronal cell processes. On the luminal side, nutrients and the intestinal microflora are able to signal and modulate the epithelial cell behavior.
2. The gut epithelium is highly polarized.
Intestinal epithelial cells exhibit an asymmetrical morphology shaped by a highly organized network of microtubules, intermediate filaments and actin filaments connected to the plasma membrane. Apical-lateral ►**junctional complexes** (tight and

adherent junctions) link the cells together, regulate the barrier function, and delineate two compartments of the plasma membrane, the apical and the basolateral membranes. These complexes are composed of at least 40 different proteins, among which are transmembrane proteins such as occludin, claudins and cadherins, and cytoplasmic proteins, among which are some which can shuttle to the nucleus like the transcription factor ZONAB associated to ZO-1 and β -catenin which connects E-cadherin to actin filaments. The apical membrane, called the brush border, is formed by microvilli sustained by an actin core associated to a number of cytoskeletal proteins among which is villin, which regulates the plasticity of the brush border. The functional proteins (digestive enzymes, outside-in transporters) are anchored into the brush border membrane. The basolateral membrane carries inside-out transporters and ion channels involved in the processing of nutritional metabolites, but also receptors to basement membrane molecules. These receptors, including ►**integrins** and ►**dystroglycan**, ensure the link with the basement membrane and also act synergistically with growth factor receptors to initiate intracellular signaling and to participate in the regulation of cell functions.

3. The gut epithelium is composed of several functionally different cell types.
The main cell type in the small intestine (about 90%) is a columnar absorptive cell responsible for the digestive functions, the enterocytes. Additional cytotypes belong to the secretory cell lineages and comprise (i) mucus-producing goblet cells, which produce the protective mucus layer on top of the epithelium, (ii) entero-endocrine cells composed of at least 15 different cell subtypes classified on the basis of their hormonal content, which control important physiological functions such as glycemia, exocrine pancreatic secretion and growth/repair of the gut epithelium and (iii) Paneth cells, which are involved in the mucosal defense function and produce a variety of antibiotic and antimicrobial factors. The last cytotype is composed of M cells, which correspond to a specialization of absorptive cells facing lymphoid nodules and participate in the control of intestinal immunity and tolerance. Mucous cells represent the major cell type in the colon.
4. The gut epithelium is continually and rapidly renewed throughout life.
The adult intestinal epithelium is compartmentalized. Stem cells confined near the crypt bottom generate proliferative transit amplifying cells, which cycle every 12 h, and migrate vertically towards the crypt mouth. When leaving the crypts, epithelial cells abruptly stop proliferating and become differentiated. All the differentiated cell types – except the

Paneth cells, which migrate downwards to the crypt bottom – migrate to the villus tip in the small intestine or to the surface of the colon cuffs, and subsequently undergo apoptosis and exfoliation into the gut lumen. The overall life cycle of the gut epithelial cells is around 5 days in humans.

5. Multipotent stem cells are maintained in the adult gut epithelium.

The continuous renewal of the gut epithelium implies the presence of stem cells located in a specific niche near the crypt bottom surrounded by sub-epithelial myofibroblasts and specific extracellular molecules. Although intestinal stem cells have still not been isolated, several experimental approaches – transgenesis, mouse embryo aggregation chimeras, mutagenesis, regeneration after X-ray irradiation – have provided evidence that all the differentiated cell types of the gut epithelium derive from ►multipotent stem cells (1, 2). Stem cells undergo asymmetrical division to stochastically produce one new self-maintaining stem cell and one daughter cell that cycles and fuels a population of potential clonogenic stem cells. These cells are further displaced into the compartment of transit amplifying cells that eventually go into the differentiation process. Potential clonogenic stem cells, unlike transit amplifying cells, can replace true stem cells if this population is altered. The process towards differentiation uses two minor pathways consisting of long-lived progenitors of absorptive and of mucous cells respectively and one major pathway in which short-lived progenitors can produce both absorptive and mucous short-lived progenitors. Interestingly, glucagon-like peptide-2 produced by one of the enteroendocrine cell types – known to prevent intestinal damage and to facilitate repair – signals through enteric neurons to produce a mediator that stimulates the production of long-lived progenitors of the absorptive lineage (2).

6. Malignant epithelial tumors develop in the colon and rectum.

Colorectal cancer is a major disease in terms of incidence and malignancy. It results from imbalanced cell proliferation, differentiation, migration and apoptosis in colonic crypts. The vast majority of tumors are of sporadic origin while a small proportion is familial. The major familial form, ►Hereditary Non-Polyposis Colon Cancer (HNPCC), is characterized by microsatellite DNA instability resulting from germ line mutations in the MLH1 or MSH6 genes, which cause defects in the DNA mismatch repair system. The second familial form, ►Familial Adenomatous Polyposis (FAP), is characterized by chromosomal instability and is linked to germ line mutations in the tumor suppressor gene ►APC. Loss of function of

APC leads to inappropriate activation of the Wnt/ β -catenin signaling pathway (3) and to chromosomal instability linked to altered kinetochores. Rare cases of FAP without germ line mutation of APC are associated to biallelic germ line mutations in the base excision repair gene MYH. The sporadic form of colorectal cancer is mainly related to chromosomal instability and to gradual histological changes, the adenoma-carcinoma sequence, associated to the accumulation of somatic alterations in a number of tumor suppressor genes (APC, p53) and oncogenes (K-ras, Bcl2). Malignant tumors occur almost exclusively in the colon and rectum, while atypical tumors develop in the small intestine in the context of chronic inflammatory bowel disease. The primary incidence of tumors in the colon correlates with the colon specific expression of the anti-apoptotic gene Bcl2 at the stem cell positions in the crypt base.

Regulatory Mechanisms

1. Intestinal epithelial identity and homeostasis: involvement of the ►Cdx genes.

►Homeobox genes belong to a large family of transcription factors acting at multiple levels during embryonic development. *Cdx1* and *Cdx2* are two paralogue homeobox genes, which are expressed in the presumptive gut endoderm and in posterior organs in the embryos, and specifically in the gut epithelium throughout adult life. *Cdx2* displays the homeotic function devoted to defining the intestinal identity (4). Indeed, ectopic expression of *Cdx2* in the stomach epithelium – normally devoid of *Cdx* gene expression – converts gastric mucosa to an intestinal phenotype, whereas loss of expression in the gut endoderm leads to a gastric transdifferentiation. *Cdx1* and *Cdx2* are also modulators of cell renewal *via* distinct and complementary functions; *Cdx1* stimulates cell proliferation, resistance to apoptosis and eventually cell differentiation, whereas *Cdx2* reduces cell proliferation and stimulates differentiation. The *Cdx1* and/or *Cdx2* proteins act directly on a panel of target genes and cellular functions including regulators of cell cycle and apoptosis (p21WAF, Bcl2), transcription factors (KLF4), proteins involved in cell interactions (L1-cadherin), in calcium metabolism (vitamin D receptor, calbindin-D9k) and in glucose metabolism (glucagon, glucose-6-phosphatase), digestive enzymes (sucrase, lactase) and mucus production (Muc2). Interestingly, the expression profiles of *Cdx1* and *Cdx2* are altered in colorectal cancers and pro-oncogenic pathways have opposite effects on the two homeobox genes. For instance *Cdx1* is upregulated by the Wnt/ β -catenin pathway,

whereas *Cdx2* is down-regulated by the ►PI3K/Akt pathway. These observations suggest that *Cdx1* and *Cdx2* dysfunctions contribute to cancer progression. In accordance with this, the alteration of the *Cdx2* status sensitizes the colon epithelium to carcinogenesis, linked to a lower capacity to switch on apoptosis. Thus, in addition to its homeotic function during embryonic development of the digestive tract, the *Cdx2* homeobox gene is a gut-specific tumor suppressor gene in the adult colon.

2. The Wnt/ β -catenin signaling pathway.

Cell growth and polarity are major attributes of the gut epithelium, and the Wnt/ β -catenin pathway plays a pivotal role in this balance. β -catenin contributes to cell polarity by cross-linking the membrane E-cadherin to the actin cytoskeleton. In differentiated epithelial cells, an excess of β -catenin molecules not coupled to E-cadherin are loaded on a complex comprising APC, Axin and the CKI and GSK3 β kinases that phosphorylate β -catenin and target it to the proteasome degradation system. During intestinal development as well as in the crypts, the Wnt/ β -catenin signaling pathway is activated by secreted morphogens of the Wnt family that bind to Frizzled receptors and activate several downstream pathways, one of which leads to the inhibition of GSK3 β activity. In this context, β -catenin escapes degradation and translocates into the nucleus to bind HMG-box transcription factors of the Tcf/Lef family. These factors play a major role in the maintenance and self-renewal of the stem cell stock, since Tcf4-deficient mice lack proliferative cells in the prospective intervillous regions; in contrast over-expression of Lef1 causes increased stem cell apoptosis. Major targets of the activated Wnt/ β -catenin pathway are the proto-oncogene *c-myc* and cyclin D₁, which subsequently down-regulates the cell cycle inhibitor p21WAF (5). Interestingly, a transcriptomic approach has identified a set of genes of the *c-myc* cascade in the stem cells/progenitors compartment, including regulators of *c-myc* gene transcription and protein stability and *c-myc* downstream targets (6). As mentioned above, a direct Wnt/ β -catenin tissue-specific target is *Cdx1*, and an indirect target is *Cdx2*, through another HMG-box factor, SOX9. Finally, the Wnt/ β -catenin pathway also controls crypt cell sorting *via* the regulation of combinations of ephrin receptors EphB2/EphB3 and their ligands EphrinB1/EphrinB2 (5). Thus, crypt formation, cell sorting and the mechanism of stem cell selection appear to depend on an adequate threshold of β -catenin-mediated signaling during normal intestinal homeostasis, whereas inappropriate activation of this pathway contributes to colorectal tumorigenesis. Cooperating with the WNT/ β -catenin pathway,

BMP (Bone Morphogenetic Protein) signaling and Hh (Hedgehog) signaling also control the proliferation/differentiation equilibrium of the gut epithelium (7, 8, 9).

3. Molecular determinants of gut stem cells and progenitors. Although gut stem cells and progenitors have been described near the crypt base, molecular markers remain elusive. Yet, a gene product, *Msi1*, has been reported in intestinal crypts, specifically in individual cells that display the theoretical location attributed to stem cells (1). *Msi1* is an RNA-binding protein associated with asymmetrical division of neural progenitors. *Msi1* controls the translation of several RNAs; in particular, it acts as a translational repressor of *numb*, an antagonist of Notch signal activation. The Notch pathway is involved in the maintenance of an undifferentiated state by a lateral inhibition mechanism by which a cell differentiating along a given pathway produces a signal that prevents neighboring cells from differentiation along the same pathway. Upon activation by their ligands, the intracellular domains of Notch receptors are released and translocated into the nucleus where they bind to CSL (CBF1/Suppressor of hairless/Lag1) DNA binding proteins. This results in the transcriptional activation of downstream targets encoding ►bHLH transcription factors of the Hes family, among which is *Hes1*. These are negative regulators of differentiation, by repressing other bHLH genes that promote differentiation. Indeed, a series of gene invalidations led to the conclusion that cell fate commitment in the intestine depends essentially on a genetic cascade controlled by bHLH transcription factors. Firstly, *Hes1*, which is expressed in crypt cells like *Math1* and *Ngn3*, maintains the precursor pool expansion and prevents premature endocrine and mucous cell differentiation. Secondly, *Hes1* antagonizes *Math1*, which is required for the commitment of the three secretory cell lineages of the gut epithelium (goblet, endocrine and Paneth cells). This suggests that the choice between absorptive and secretory cell lineages is balanced by *Hes1* and *Math1* (2). Thirdly, within the population of *Math1* expressing-cells, *Ngn3* specifies the endocrine progenitors (10), whereas *NeuroD*, which is expressed in the villus cells, is required for the differentiation of a subset of endocrine cells. Genetic modulations of the Notch pathway have confirmed its influence on the maintenance of undifferentiated, proliferative cells in the crypts and on intestinal cell lineage specification by acting on the balance between bHLH factors (11).

In conclusion, the renewal of the gut epithelium has long been recognized as a paradigm in cell biology as

regards well-ordered cell proliferation followed by differentiation from self-renewing stem cells. Recent investigations have provided new insights into the molecular mechanisms implicated in multiple aspects of this process, such as the determination of intestinal identity, the cell commitment into differentiated lineages. Emerging concepts propose integrative models involving the interplay of local and reciprocal stimulatory and inhibitory signals between epithelial cells and the underlying myofibroblasts, to fine-tune the homeostatic balance between stemness, commitment, proliferation and differentiation (7, 9). Furthermore, these results enlarge our knowledge of the molecular alterations at the basis of malignant transformation in ►colorectal cancers. However, the exact nature of the gut stem cells and their relationship and regulation by neighboring elements of the stem cell niche remain to be elucidated. Understanding the biology of the gut stem/progenitor cells is a challenge for the future that should open new avenues in the field of cancer therapy, intestine regeneration and cellular therapy of type-1 diabetes.

Hair

► Skin and Hair

Hair Bulge

Definition

Hair bulge is that part of the outer root sheet of the hair follicle that is located above the insertion of the arrector pili muscle. It corresponds to the lowest non-cycling part of the hair follicle and contains multipotent skin stem cells.

► Skin and Hair

Hair Matrix

Definition

Hair matrix consists of transit-amplifying, epithelial cells that are located at the base of the hair follicle, the hair bulb. The progeny of hair matrix cells withdraw from the cell cycle and move upwards in cellular cohorts while undergoing terminal differentiation.

► Skin and Hair

Hairpin End

Definition

Hairpin end refers to the end of a DNA double strand that is sealed in the form of a hairpin by the covalent linkage of the 5' strand to the 3' strand.

► DNA Recombination

Hairpin Ribozyme

Definition

A hairpin ribozyme can cleave oligoribonucleotides at specific sites, GUC.

► Catalytic RNA

Half-Life

Definition

Half-life defines the time required to decrease the concentration of a substance/drug to the half of its original value.

► Biochemical Engineering of Glycoproteins

Hamartoma

Definition

Hamartoma is a benign outgrowth of tissue composed of normally differentiated cells and matrix components typical for that site without signs of dysplasia.

► Peutz-Jeghers Syndrome

► Tuberous Sclerosis

Hammerhead Ribozyme

Definition

Hammerhead ribozymes can cleave oligoribonucleotides at specific sites, e.g. NUX, where N and X are A, G, C, U and A, C, U, respectively, with most efficient cleavage at GUC triplets.

► Catalytic RNA

Haploid

Definition

The term haploid describes a cell that has only a single copy of each chromosome (e.g. post-meiotic germ cells).

► [Mutagenesis Approaches in the Zebrafish](#)

Haploid Analysis

Definition

Haploid analysis refers to an analysis technique aimed at separating two paternal and maternal chromosome pairs into two different cell lines. Haploid analysis makes it possible to separately detect a mutation in each chromosome.

► [Spinal Muscular Atrophy](#)

Haploinsufficiency

Definition

Haploinsufficiency describes the situation in which an individual, who is heterozygous for a certain gene ► [mutation](#) or ► [hemizygous](#) at a particular ► [locus](#), is clinically affected because the protein produced by a single copy of an otherwise normal gene is not sufficient to assure normal function.

Heart

INGO MORANO

Max-Delbrück-Center for Molecular Medicine,
Berlin, Germany
imorano@mdc-berlin.de

Definition

The heart is a four-chamber pump, the size of a fist, mainly made of muscle tissue (the ►myocardium), located between the lungs behind the breastbone. It is separated into a right heart, which pumps blood through the lungs, and a left heart, which pumps blood through the peripheral organs, roughly 70 times per min during the whole of life.

Characteristics

The heart is embedded into a fibrous pericardium, which secretes lubricating liquid. It consists of left and right atria and ventricles, which are separated by the interventricular septum. Desoxygenated blood from the superior and inferior vena cavae of the body enters through the right atrium into the right ventricle, which ejects it through the pulmonary artery into the lungs. Oxygenated blood coming from the lungs enters through the pulmonary vein into the left atrium and then into the left ventricle, which pumps it through the aorta into the body circulation. Atria, ventricles and the outflow tracts are separated by valves, called atrioventricular valves (tricuspid valve right, mitral valve left) and semilunar valves that separate the outflow tracts (pulmonary valve between right ventricle and pulmonary artery, aortic valve between left ventricle and aorta) (Fig. 1). The heart consists of the epicardium, that covers the outer surface and the endocardium, which covers the inner surfaces. The ventricular myocardium, the largest mass, lies between epi- and endo-cardia and consists of overlapping sheets of muscle bundles which follow spiral paths from the base to the apex of the heart.

► **Cardiomyocytes** of the working myocardium are cross-striated, longitudinally arranged cells (around 50 µm in length and 20 µm in width) with one or two nuclei and a well-developed ► **sarcoplasmic reticulum** (SR). The SR communicates with invaginations of the plasmalemma, the T-tubuli. Cardiomyocytes are inter-connected by electron-dense structures, the ► **intercalated discs**, consisting of specialized cell-cell junctions, which provide mechanical and electrical communication between cells (Fig. 2).

Cardiomyocytes represent just about 1/3 of the total cells of the heart and remain terminally differentiated. However, multipotent cardiac stem cells able to regenerate the myocardium during life may exist. This process may also be relevant for myocardial repair after heart infarction (1).

The right and left coronary arteries, which arise at the root of the aorta, run as epicardial blood vessels and provide the blood supply of the right and left atria and ventricles, respectively. The left main ► **coronary artery** divides into the left anterior descending and the circumflex branches. The venous effluent is collected in veins that parallel the epicardial coronary arteries. The main venous drainage of the left ventricle enters the coronary sinus, emptying into the right atrium. The main venous drainage of the right (and some of the left) ventricle reaches the right atrium by the anterior coronary veins. A small fraction drains through the thebesian veins directly into the cavities of the right and left ventricle.

Activation of the heart by depolarization and generation of ► **action potentials** normally starts in pacemaker

Heart. Figure 1 Scheme of the structure of the heart and blood flow. Desoxygenated blood (dark red) from the superior and inferior vena cava of the body enters through the right atrium into the right ventricle, which ejects it through the pulmonary artery into the lungs. Oxygenated blood (light red) coming from the lungs enters through the pulmonary vein into the left atrium and then into the left ventricle, which pumps it through the aorta into the body circulation.

Heart. Figure 2 Scheme of myocardial cells of the ventricle. The mono- or binucleated cross-striated cardiomyocytes are connected by intercalated discs.

cells of the sinoatrial (SA) node, specialized cells on the junction between the superior vena cava and the right

atrium. Action potentials cross the atrioventricular (AV) node and reach the left and right ventricles through AV bundles (or His bundles), which divide into left and right branches. Ramifications of the bundle branches continue as a subendocardial network of Purkinje fibers. Electrical impulses then propagate between cardiomyocytes by a special class of ion channels, each made up of 6 connexin molecules, found in the gap junctions (or nexus) of the intercalated discs. The heart therefore represents a functional syncytium.

Regulatory Mechanisms

The Heartbeat

A heartbeat, or cardiac cycle, consists of a contraction (systole) and a relaxation (diastole) generating blood ejection (normal stroke volume around 70 ml) and blood filling (normal filling volume around 130 ml), respectively. Cardiac output is the product of beating frequency (normal 60–80× per min) and stroke volume, representing an important factor of arterial blood pressure determination and organ perfusion. The heart is innervated by both sympathetic nerve fibers (which originate from the stellate ganglia and cardiac plexus, innervated mainly from the 4th and 5th thoracic segments of the spinal cord) and parasympathetic vagal nerve fibers, (which originate in the dorsal efferent nuclei of the medulla oblongata). Whereas postganglionic sympathetic fibers innervate all heart regions (with a bilateral functional asymmetry), parasympathetic innervation supplies mainly the SA and AV nodes. Vagal stimulation decreased, sympathetic stimulation increased the beating frequency. Beating frequency of the completely denervated heart is considerably above normal, which demonstrates the predominance of parasympathetic tone during rest.

Compared to nerve fibers or skeletal muscle fibers, the action potential of a heart cell is very long, roughly 200–300 ms, almost the duration of a contraction-relaxation cycle. Autonomous activation by SA node cells relies on an unstable resting potential (Fig. 3). A continuous decline in the conductance of K^+ channels and an inward Na^+/Ca^{2+} current depolarize the membrane potential of SA node cells to the threshold potential, around -40 mV, where voltage-operated Na^+ and Ca^{2+} channels open to elicit an action potential which is then propagated through the whole heart (see above). Repolarization is associated with the inactivation of Na^+ and Ca^{2+} channels as well as K^+ outward currents. Action potentials of cardiomyocytes of the ventricular myocardium start with a rapid depolarization caused by gating of the voltage-operated Na^+ channels and a subsequent characteristic long-lasting plateau phase due to a Ca^{2+} current through voltage-operated L-type Ca^{2+} channels (Fig. 3). Inactivation of the Na^+ and Ca^{2+} channels as well as

Heart. Figure 3 Action potentials of sinus nodal cells (top) and ventricular cardiomyocyte (bottom).

outward K^+ currents through various types of K^+ channels are involved in the repolarization mechanism. Acetylcholine (ACh), the parasympathetic transmitter, binds to muscarinic ACh receptors, 7 membrane-spanning receptors that are associated with small regulatory heterotrimeric inhibitory G-proteins. The activated inhibitory G_i -protein dissociates into its $G_{i\alpha}$ and $G_{i\beta\gamma}$ subunits. The latter directly increased the conductance of K^+ channels, thus stabilizing the resting potential of SA node cells. This causes a prolongation of the time-to-threshold potential, thus decreasing frequency of pacemaker action potentials and therefore heartbeats. G_{α} inhibits adenylyl cyclase (AC), thus reducing the intracellular cAMP levels, antagonizing the influence of sympathetic activation. Norepinephrine, the major sympathetic transmitter, binds to its β -receptor, a representative of the 7 membrane-spanning receptors associated with stimulating Gs-proteins. Upon binding of NE to its β -receptor and subsequent activation of Gs, AC is activated by the G_{α} subunit, thus increasing cAMP levels. The second messenger cAMP activates protein kinase A (PKA) which phosphorylates K^+ channels and Ca^{2+} channels, thus decreasing the outward K^+ current and increasing the inward Ca^{2+} current and thereby rendering the resting potential of pacemaker cells even more unstable. Time-to-threshold potential becomes lessened, pacemaker frequency and therefore beating frequency increase.

The ► Electrocardiogram (ECG)

Electrical changes in the beating myocardium can be recorded using electrodes placed on the skin on opposite sides of the heart. A normal ECG is composed of a P-wave, a QRS-complex and a T-wave, which can be recorded during atrial depolarization, ventricular depolarization and ventricular repolarization, respectively (Fig. 4). ECG recordings allow insights into the anatomical orientation of the heart, relative sizes of the chambers, disturbances of rhythm and conduction, extent, location and progress of ischemic damage, effects of altered electrolyte concentrations and the influences of certain drugs.

Excitation-Contraction Coupling of the Ventricular Cardiomyocyte

The small Ca^{2+} inward current during the action potential triggers the release of large amounts of Ca^{2+} from the sarcoplasmic reticulum (SR) through Ca^{2+} release channels (ryanodine receptors; RyR), which are inserted into the SR membrane (Ca^{2+} -induced Ca^{2+} release). Free cytosolic Ca^{2+} rises to about 600 nm, which roughly half-maximally activates the ►myofilaments of the cardiomyocytes, generating force (for ventricular pressure) and shortening (for blood ejection). Activation of the myofilaments of the heart by Ca^{2+} via binding to troponin C, conformational changes in the regulatory troponin-tropomyosin system and chemo-mechanical energy transformation by the ATP-driven interaction between actin filaments and myosin cross-bridges are very similar to those of skeletal muscle (c.f. chapter "Muscle Contraction"). Hence, force generation in the heart can be regulated by alteration of both the free systolic Ca^{2+} -concentration and the sensitivity of the myofilaments to Ca^{2+} . During diastole, systolic intracellular Ca^{2+} is reduced to resting levels mainly by an ATP-driven Ca^{2+} pump located in

Heart. Figure 4 A normal electrocardiogram. P wave (atrial depolarization), QRS complex (ventricular depolarization prior contraction) and T wave (ventricular repolarization).

the SR membrane (SERCA) and a $\text{Na}^+/\text{Ca}^{2+}$ exchange (NCX) (2). Decreased free cytoplasmic Ca^{2+} inactivates the myofilaments; the heart relaxes (Fig. 5).

Modulation of Cardiac Contraction by Sympathetic Innervation

Since a normal systole caused just around half-maximal activation of the myofilaments, there is a large contractile reserve, which can be recruited by sympathetic stimulation. As mentioned above, β -adrenergic stimulation causes an increased beating frequency (positive chronotropy), which itself increases free cytoplasmic Ca^{2+} -activation. Furthermore, activated PKA upon β -adrenergic stimulation phosphorylates L-type Ca^{2+} channels and ryanodine receptors. These interventions cause an increased Ca^{2+} current through the L-type Ca^{2+} channels and Ca^{2+} release from the SR, respectively, which caused an increased contraction (positive inotropy). In addition, PKA phosphorylates the small SERCA inhibitory protein phospholamban, which thereby loses its inhibitory effect. Hence, SERCA activity rises, causing an accelerated Ca^{2+} sequestration into the SR and therefore accelerated relaxation (positive lusitropic effect). PKA-dependent phosphorylation of troponin I reduces Ca^{2+} sensitivity of the myofilaments, supporting the relaxation process. In addition, the connexin molecules of the gap junctions are phosphorylated by PKA which is believed to increase the ion conduction between the cardiomyocytes, thus accelerating the wave of electrical current through the heart (positive dromotropy) (4).

Heart. Figure 5 Scheme of excitation-contraction coupling in cardiomyocytes. DHP = dihydropyridine receptors or L-Type Ca^{2+} channels; RyR = ryanodine receptors or Ca^{2+} release channels; NCX = $\text{Na}^+/\text{Ca}^{2+}$ exchanger; PMCA = plasmalemmal Ca^{2+} ATPase; SERCA = sarcoplasmic-endoplasmic Ca^{2+} ATPase; PLB = phospholamban.

Cardiac Mechanics

The structure of the cardiac **myofibrils** with its organization of contractile proteins into **sarcomeres** as well as the regulation of activation of the myofibrils are very similar to those of skeletal muscle (cf. Chapter on “Muscle Contraction”). There are actin and myosin filaments anchored into the Z-line and M-line, respectively as well as titin filaments that connect the Z-line with the M-line. A troponin-tropomyosin regulatory system located at the actin filament confers Ca^{2+} regulation of actin-myosin interaction. However, structural and functional features of the sarcomeric proteins differ between cardiac and skeletal muscles due to the expression of different genes and/or alternative splicing of genes. Thus, mechanical features of the two muscle types vary and there are specific regulatory systems that are unique to cardiomyocytes. The resting cardiomyocyte is much stiffer than the skeletal muscle fiber, possibly due to the presence of titin isoforms with different elastic properties. In addition, the presence of the incompressible pericardium restricts extensibility of the whole heart *in situ*. The systolic pressure developed by the heart decreases as its diastolic volume is altered in either direction from an optimum value (law of Frank-Starling) (Fig. 6). In accordance with the sliding filament theory (c.f. Chapter “Muscle Contraction”), developed force rises with increasing sarcomere length to an optimum length of $2.2\ \mu\text{m}$ and declines beyond $2.3\ \mu\text{m}$ (2). In addition, length-dependent differences of Ca^{2+} release from the SR and changes in the Ca^{2+} sensitivity of myofilaments may also contribute to the Frank-Starling law of the heart.

Functional Adaptations of the Heart

Increased work demands on the heart cause a panel of acute and chronic functional adaptations. Thus, increased filling pressure could be acutely compensated by an increased stroke volume (cf. Frank-Starling law, cf. above). Furthermore, sympathetic stimulation increases beating frequency and the ability of the heart to generate tension, thus increasing stroke volume and cardiac output. Chronic overload induces hypertrophy of the myocardium, elicited by quantitative and qualitative changes of gene expression. Chronically enhanced sympathetic drive and increased free Ca^{2+} concentrations upon cardiac overload are translated into hypertrophic gene expression patterns, associated with the activation of numerous signaling pathways in the cardiomyocyte. In particular the calcineurin-NFAT pathway, stimulated by Ca^{2+} -calmodulin, activates the hypertrophic reprogramming of cardiac gene expression (6).

Clinical Relevance

Disorders of the heart can be acquired (e.g. chronic hypertension, viral or bacterial infections, coronary

Heart. Figure 6 Scheme of pressure-volume relationship of the heart. Left ventricular filling increases ventricular pressure during diastole. Upon stimulation, systole starts and the heart contracts, thus increasing left ventricular pressure until the aortic valve opens. Blood is ejected into the aorta. During diastole, aortic valves close and the heart relaxes.

artery disease, valve diseases etc) or inherited. Mutations affecting genes coding for myofibrillar, plasmalemmal, cytoplasmic or Ca^{2+} handling proteins are associated with different types of cardiomyopathies that cause congestive heart failure (3). Mutations that disrupt sarcolemmal-myofibrillar functions are more involved in dilated cardiomyopathy, while mutations causing myofibrillar disruption may lead to hypertrophic cardiomyopathy (7). Mutations in ion channels cause arrhythmic disorders of the heart. Thus, loss of function of K^{+} channels has been implicated in heritable long-QT syndrome. Mutations of Na^{+} channels were associated with idiopathic ventricular fibrillation (8).

Definition

The hedgehog signalling pathway is central to the embryonic development of a vast array of vertebrate organ structures (reviewed in 1). Aberrant functioning of this pathway results not only in a range of dysmorphology syndromes, but also contributes to a number of common cancers in both their familial and sporadic forms (reviewed in 2, 3, 4). This highlights the importance of hedgehog signalling in embryonic development as well as in further growth and differentiation in the adult.

Hedgehog signalling is highly conserved from *Drosophila* through to humans, with much of what we know about this pathway gleaned from classic studies in the fly. As is the case with many processes, hedgehog signalling is complicated in the vertebrate by the presence of families of homologous molecules, which in *Drosophila* are represented by a single protein. In some cases the role of these family members can be inferred to some extent from their expression patterns, as is the case with the three vertebrate hedgehog molecules, Sonic hedgehog (Shh), Indian hedgehog (Ihh) and Desert hedgehog (Dhh). In other cases such as the three Gli molecules, which mediate the transcriptional output of hedgehog signalling, their role is regulated not only by site of expression but also by post-translational modification in a context-dependent manner.

Characteristics

Hedgehog Signalling and Developmental Disease

Mutation of key members of the hedgehog signalling pathway has been implicated in a range of human disease states (reviewed in 2, 3). The array of phenotypes highlights the importance of hedgehog signalling in regulating a large number of diverse processes in the developing embryo. *SHH* itself has been shown to be mutated in a subset of familial ►holoprosencephaly (HPE), a midline defect of the forebrain and face. The gene encoding the hedgehog receptor patched (*PTCH*) is mutated in ►Gorlin's syndrome, which is characterised by tumour susceptibility

as well as associated developmental defects. The gene encoding the downstream transcription factor *GLI3* has also been implicated in developmental anomalies, with mutations identified in ►Greig's cephalopolysyndactyly (GCPS) and a number of other syndromes primarily characterised by limb defects.

Hedgehog Signalling and Tumorigenesis

In terms of tumorigenesis, up-regulation of hedgehog signalling has been associated with a number of common cancers (reviewed in 3, 4). The *PTCH* gene acts as a ►tumour suppressor gene and has been implicated as a key factor in the development of a range of tumour types including the common skin tumour ►basal cell carcinoma (BCC) and ►medulloblastoma, a paediatric brain tumour. While to date no mutations have been detected in human ►rhabdomyosarcoma, heterozygous *PTCH* knockout mice develop these muscle-related tumours, suggesting a role for hedgehog signalling in their genesis. Mutations in the suppressor-of-fused (*SUFU*) gene, which encodes a downstream negative effector of hedgehog signalling, have also been identified in medulloblastoma.

In keeping with an up-regulation of hedgehog signalling leading to cancer formation, activating oncogenic mutations in BCCs and brain tumours have been identified in genes encoding positive regulators of the hedgehog pathway, including smoothened (SMO), also a component of the hedgehog receptor complex. In addition, several mouse models of BCC result from activation of the pathway by over-expression of either *Gli1*, *Gli2*, *Shh* or an activated *Smo* allele in the skin. Until recently, dysregulation of hedgehog signalling was associated primarily with cancers that occur with increased incidence in Gorlin's syndrome, such as skin and brain tumours. However, several reports now implicate up-regulation of this pathway in small cell lung carcinoma (SCLC), pancreatic adenocarcinoma, prostate cancer and digestive tract tumours (reviewed in 4), thus suggesting a more widespread role for hedgehog signalling in tumour formation.

It is clear that a range of tumours result from constitutive activation of hedgehog signalling, and for a long time it was believed that this was due to the nature of the downstream target genes regulated by this pathway. While this is likely to be a contributing factor, the demonstration that hedgehog signalling is directly involved in regulation of a number of cyclin genes suggests that some of the tumorigenic effects of this pathway may result from a more direct effect on cell-cycle progression.

Molecular Interactions

Reception and Transduction of the Hedgehog Signal

The prevailing model of hedgehog signalling predicts that reception of the hedgehog ligand at the cell surface

is mediated by a multimeric complex involving two transmembrane molecules, patched and smoothened (Fig. 1). In the absence of a hedgehog ligand, patched, a twelve-pass transmembrane protein, is thought to inhibit the activity of smoothened, a protein with homology to a G-protein coupled receptor. On binding of hedgehog to patched this inhibition is relieved and smoothened transduces the hedgehog signal into the receiving cell.

A number of other molecules have more recently been implicated at this stage of hedgehog signalling but to date their role is less clearly defined. These include dispatched, gas1 and hedgehog interacting protein (Hip).

Transcriptional Mediation

Within the cell the hedgehog signal is mediated primarily by the zinc finger ►transcription factor cubitus interruptus (ci) in *Drosophila*. In vertebrates there are three members of the Gli family, which together have evolved to perform the function of ci. In flies the single hedgehog molecule regulates whether the bipartite factor ci acts as an activator or a repressor through proteolytic cleavage of the full-length protein, which is capable of acting as an activator, into an N-terminal repressor form. A major question in understanding vertebrate hedgehog signalling is how the role of ci has been partitioned between the three Gli molecules in a context-dependent manner. This has

Hedgehog Signalling. Figure 1 Model for hedgehog (hh) signal transduction in *Drosophila*. In the absence of hh (-hh) patched inhibits the activity of smoothened. The cytoplasmic hedgehog signalling complex (HSC) which includes costal2 (cos2), fused (fu), suppressor of fused (su(fu)) and ci is bound to microtubules. PKA phosphorylates ci-155, which triggers processing and cleavage by the proteasome to generate ci-75 which enters the nucleus and represses target gene expression. Upon hh stimulation (+hh), hh binds ptc at the plasma membrane and together they are internalised and degraded. The HSC complex is translocated to the plasma membrane and components are phosphorylated. Cleavage of ci is inhibited and the full-length form (ci-155) enters the nucleus to activate target gene transcription.

been the subject of intense debate for some years and only now is starting to be unravelled (reviewed in 5). It now appears that Gli1 and 2 act primarily in gene activation, while Gli3 is predominantly a transcriptional repressor. Gli1 contains only an activator domain and is not proteolytically cleaved. Interestingly Gli1 is also a universal transcriptional target of hedgehog signalling. Gli2 contains both activator and repressor domains and can undergo cleavage under certain conditions, but its major role *in vivo* is thought to be as an activator. In contrast Gli3 contains activator and repressor domains and undergoes proteolytic cleavage in an analogous manner to ci to generate a transcriptional repressor. While the major role of Gli3 is to repress target genes, recent studies have shown that, at least in the spinal cord, the full-length form is also capable of activation (6).

A number of the known downstream target genes regulated by Gli molecules have been extrapolated from studies in *Drosophila*. However, with the advent of transcriptional profiling approaches such as microarray analysis, we now have the opportunity to identify novel downstream targets of hedgehog signalling on a genomic scale and thus potentially link the hedgehog pathway to a host of other signalling networks within the cell.

The Hedgehog Signalling Complex (HSC) – Linking the Cell Membrane to the Nucleus

One of the remaining questions in understanding the molecular basis of hedgehog signalling is the nature of the Smo signal and how this is transmitted to the ci/Gli molecules in the nucleus. This has at least in part been solved by a number of recent studies showing a direct interaction between Smo and the kinesin-like protein Costal-2 (Cos2) (reviewed in 7). Previous studies in *Drosophila* have shown that in the absence of hedgehog, ci is bound to microtubules in a complex involving cos2, the serine-threonine kinase fused (fu) and the novel protein suppressor of fused (su(fu)). In this state, phosphorylation of full-length ci (ci-55) by protein kinase A (PKA) triggers proteolytic cleavage to a 75 kD N-terminal repressor fragment (ci-75) which enters the nucleus and inhibits transcription of target genes. Stimulation by hedgehog results in translocation of this complex to the cell membrane and phosphorylation of component molecules. At the same time cleavage of ci is inhibited and under certain conditions, the full-length molecule enters the nucleus and activates transcription. As discussed above a similar process in vertebrates is thought to be mediated by the three Gli molecules. These studies provide a direct link between the hedgehog receptor complex and transcriptional outputs in the nucleus and take us a step forward in understanding the events involved in transmission of the hedgehog signal.

In addition to the key components of hedgehog signalling discussed above there exist a number of accessory proteins that have been implicated in hedgehog signalling. In addition, there will undoubtedly be a host of yet to be discovered molecules that interact with the core signalling components to modulate the final output of the hedgehog pathway.

Regulatory Mechanisms

The mechanisms regulating hedgehog signalling at each step from reception and transduction of the signal through to transcriptional mediation of downstream target genes are extremely complex and still poorly defined. At the level of signal reception and transduction there is mounting evidence to suggest that both intracellular sterol levels and trafficking events play key regulatory roles. A role for sterols in hedgehog signalling is supported by a number of independent observations. Firstly, Shh is autoproteolytically cleaved into an active 19 kD molecule which is modified by addition of a cholesterol moiety to its C-terminus and is also N-terminally palmitoylated. Second, mutations in Shh have been implicated in holoprosencephaly, which is also seen in a subset of individuals with ►Smith-Lemli-Opitz syndrome, (SLOS), which results from a defect in cholesterol biosynthesis. In addition, the offspring of animals fed with the steroidal alkaloid ►cyclopamine, which also directly inhibits Shh signalling, develop HPE. The final link between hedgehog signalling and cholesterol came with the discovery that patched contains a putative sterol-sensing domain (SSD). While the role of the SSD in patched is yet to be fully elucidated, a similar domain in a number of other proteins, mostly involved in cholesterol homeostasis, has been shown to be responsive to sterol levels. A role for trafficking events in regulating hedgehog signalling is supported by the finding that the Rab23 vesicular transport protein acts as a negative regulator of hedgehog signalling (8). Rab23 is a member of the Rab GTPase family of proteins, and was shown to be mutated in the open-brain mouse whose phenotype resembles a partial loss of patched function (8). While the exact function of Rab23 is yet to be determined, recent studies suggest that it is localised to both the plasma membrane and the endocytic pathway, and that it is likely to act downstream of patched and smoothed in hedgehog regulation (9).

Since the first discovery of the *Drosophila* hedgehog mutant over twenty years ago genetic, biochemical and cell biological approaches have combined to unravel the central role of the vertebrate hedgehog pathway in embryonic development and disease. This highlights the value of comparative analysis across species in the elucidation of developmental signalling pathways, although it should be noted that a number of hedgehog pathway components are thought to be mammalian

specific. With the advent of large scale functional genomics and proteomics type approaches, it is likely that the coming years will see an expansion of our knowledge of the intricacies of hedgehog regulation and of how links with other signalling networks combine to orchestrate complex developmental processes.

Helix Boundary Motif

Definition

At either end of the α -helical rod domain, forming the main structural feature of all intermediate filament proteins, is a recognizable and well conserved stretch of amino acid sequence known as a helix boundary motif. The helix initiation motif (HIM) is located at the amino terminal end of the rod domain, and the helix termination motif (HTM) is located at the carboxyl end is. The HTM is recognizable in all intermediate filament sequences from different organisms. The HIM is more specific to each type of intermediate filaments. These helix boundary motifs are involved in end-to-end overlaps of the subunits in the assembled filament, and mutation in these regions can severely compromise the function of intermediate filaments, leading to cell fragility.

Hemidesmosomes

SANDY H.M. LITJENS, ARNOUD SONNENBERG

Division of Cell Biology, The Netherlands Cancer Institute, Amsterdam, The Netherlands

s.litjens@nki.nl

a.sonnenberg@nki.nl

Definition

Hemidesmosomes are multi-protein complexes that provide firm adhesion of basal epithelial cells to the underlying ► [basement membrane](#) in (pseudo-) stratified and some complex epithelia. Hemidesmosomes were initially defined as distinctive electron-dense structures, composed of an inner plaque connected to the intermediate filament system, an outer plaque, which is linked to the extracellular basement membrane and a sub-basal dense plate located beneath the outer plaque in the lamina lucida of the basement membrane (Fig. 1).

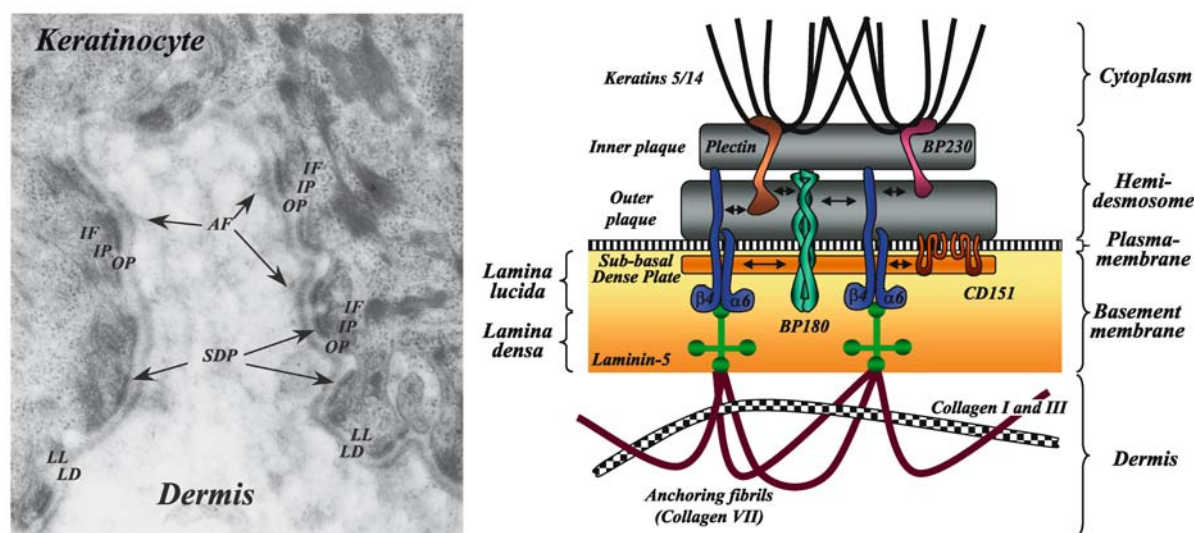

Characteristics

Anchoring of basal cells to the basement membrane is of fundamental importance for maintaining the integrity of epithelial tissues. For instance in the skin,

hemidesmosomes are crucial for the stable adhesion of the epidermis to the underlying dermis and mutations in components of these adhesion-complexes result in tissue fragility and blistering of the skin. In order to form a stable adhesion structure, six hemidesmosomal proteins are assembled into large clusters at the basal side of cells (1, 2) (Fig. 1). The ► [integrin](#) $\alpha 6 \beta 4$ is the central component of hemidesmosomes and is essential for their efficient assembly. Compared to other integrin β subunits, the β subunit of $\alpha 6 \beta 4$ has an unusually large cytoplasmic domain, containing two pairs of fibronectin type III (FNIII) repeats, which are separated by a connecting segment (Fig. 2). The integrin forms a link between its extracellular ligand ► [laminin-5](#) and the inner plaque proteins plectin and BP230 (Fig. 1). Plectin and BP230 are members of the ► [plakin](#) family of ► [cytoskeletal linker](#) proteins. In hemidesmosomes, plectin and BP230 serve as a bridge between the outer plaque and the ► [intermediate filament](#) system, to which the hemidesmosome is connected. The other two hemidesmosomal components are the collagenous transmembrane protein BP180, also referred to as type XVII collagen and the ► [tetraspanin](#) CD151, which like $\alpha 6 \beta 4$, reside in the outer plaque of the hemidesmosome (Fig. 1). BP180 occurs as a homotrimeric complex and is thought to contribute to the stable attachment by linking the hemidesmosome to the extracellular matrix. The role of CD151 in hemidesmosomes is largely unknown.

Molecular Interactions

Some simple epithelia (e.g. the epithelium of the gut) do not contain the complex ultra structure of the epidermal hemidesmosome. However, these epithelia do contain clusters of $\alpha 6 \beta 4$ bound to laminin-5, in which plectin and possibly CD151 are also localized. These complexes are called type II hemidesmosomes, as opposed to type I hemidesmosomes, which also contain BP180 and BP230. The presence of type II hemidesmosomes, which can be regarded as rudimentary hemidesmosomes, suggests that the interaction of the integrin $\alpha 6 \beta 4$ with plectin is the first step in hemidesmosome assembly (3). Indeed, single amino acid substitutions in the $\beta 4$ subunit that abrogate its interaction with plectin result in a complete loss of hemidesmosome formation *in vitro* and a reduced number of rudimentary hemidesmosomes *in vivo*. The main interaction between $\beta 4$ and plectin occurs *via* the first pair of FNIII repeats and the N-terminal part of the connecting segment of $\beta 4$ (PBS-1) and the actin binding domain (ABD) of plectin. However, secondary binding sites have been determined in the connecting segment (PBS-2) and the C-terminal tail of $\beta 4$ (PBS-3) by which this subunit interacts with the plakin domain of plectin (Fig. 2). These additional binding sites may

Hemidesmosomes. Figure 1 Structure of the hemidesmosome. (left) Electron micrograph of a skin sample containing hemidesmosomes. AF, anchoring fibrils; LL, lamina lucida; LD, lamina densa; SDP, sub-basal dense plate; OP, outer plaque; IP, inner plaque; IF, intermediate filaments. (right) Schematic representation of a hemidesmosome illustrating the molecular interactions involved in its assembly.

stabilize the original interaction between $\beta 4$ and the ABD of plectin. However, they are not capable of generating a primary interaction between these two proteins, e.g. when the binding site for the plectin-ABD is destroyed.

All the other hemidesmosomal components also bind to the $\alpha 6 \beta 4$ integrin (Fig. 1). The tetraspanin CD151 interacts with the $\alpha 6$ subunit of the integrin. Tetraspanins contain short cytoplasmic carboxy and amino terminal domains, a small cytoplasmic loop, and one small and one large extracellular loop (4). They typically contain conserved polar residues in their transmembrane domains and 4–6 conserved extracellular cysteine residues linked into 2–3 disulfide bonds in their large extracellular loop. Four of these cysteine residues are absolutely conserved, and two of these appear in a CCG (cysteine-cysteine-glycine) motif. These features distinguish tetraspanins from other proteins containing four transmembrane domains. In the large extracellular loop of CD151, the residues QRD^{194–196} are involved in binding to the integrin $\alpha 6$ subunit. The binding of $\alpha 6$ to CD151 and the binding of $\beta 4$ to plectin are early steps in hemidesmosome assembly. Once plectin is recruited by $\alpha 6 \beta 4$, BP180 can bind to both the α - and the β -subunit of the integrin as well as to plectin, thereby stabilizing the ternary complex (3). The extracellular domains of BP180 and $\alpha 6$ interact, whereas the cytoplasmic domain of BP180 binds to the third FNIII repeat of the $\beta 4$ cytoplasmic domain and the plakun domain of plectin (Fig. 2). Although BP230 can directly bind to the second pair of FNIII repeats of $\beta 4$ (Fig. 2), this interaction is not

sufficient for its recruitment into hemidesmosomes. The presence and interaction with BP180 is also necessary for the incorporation of BP230 into hemidesmosomes (3). Both plectin and BP230 contain an intermediate filament-binding domain in their C-terminus, and link the hemidesmosome to intermediate filaments (keratin 5/14 in the basal keratinocytes of the epidermis). Plectin has been shown to interact with various types of intermediate filaments, including several keratins, vimentin and desmin. BP230, however, only binds to keratin 5/14, and not to keratin 8/18 or vimentin. Finally, to link the hemidesmosomal complex to the basement membrane, both the integrin $\alpha 6 \beta 4$ and BP180 bind to ligands in the extracellular matrix. The main ligand for $\alpha 6 \beta 4$ in the skin is laminin-5, but other laminins (1, 2/4, 10/11) can also bind to this integrin. The ligand for BP180 is unknown, although there is data suggesting that BP180 might bind to laminin-5, albeit with low affinity.

Acquired and Genetic Skin Diseases Involving Hemidesmosomes

The degree and complexity of the interactions between the components of the hemidesmosome indicate that the integrity of the complex is crucial for its role in anchoring cells to the basement membrane. Indeed, down-regulation or deletion of any of the hemidesmosomal components can result in severe and sometimes fatal blistering diseases of the skin, both in human patients and in mouse models. Diseases affecting hemidesmosomes can be roughly classified into two

Hemidesmosomes. Figure 2 Domain structure of two major hemidesmosomal components, the integrin $\alpha 6 \beta 4$ and plectin. The binding sites for plectin (PBS-1 to 3), BP180 and BP230 on the $\beta 4$ cytoplasmic domain and the binding sites for $\beta 4$, F-actin, BP180 and intermediate filaments on plectin are indicated. groups, acquired and hereditary skin diseases. Acquired skin diseases are characterized by the presence of autoantibodies against one or more of the hemidesmosomal components (5). Autoantibodies against the $\beta 4$ subunit of the $\alpha 6 \beta 4$ integrin, plectin, BP180, BP230 and laminin-5 have all been identified in patients with different kinds of pemphigoid diseases (Table 1). The main characteristic of these diseases is blistering of the skin and sometimes of other epithelia, e.g. the oral mucosa. Hereditary skin diseases are caused by mutations in the genes coding for hemidesmosomal components, leading to a reduced expression, absence or dysfunction of the protein. Genetic diseases are also characterized by severe and often fatal blistering of the skin. Mutations have been identified in all the genes encoding hemidesmosomal components, except BP230 (*BPAG1*) (6) (Table 1). *BPAG1* encodes multiple neuronal isoforms. Consequently, *BPAG1* knockout mice not only suffer from blistering of their skin, but also develop a neurological disease characterized by severe neuro-degeneration with dystonia and ataxia. Similarly, if mutations in *BPAG1* occur in humans, they might lead to such severe neurological diseases that they are lethal in the embryonic stage, or before skin disorders can manifest themselves.

The loss of any of the hemidesmosomal components causes fragility of the skin and blistering upon application of mechanical stress. Nonetheless, the loss

of each of them produces a characteristic cleavage pattern of the epidermis, often reflecting the position and function of the protein involved. For example, defects in plectin cause rupture of cells at the level of the hemidesmosomes, leading to epidermolysis bullosa simplex (EBS). When $\alpha 6 \beta 4$ is absent, the split occurs either within the cell at the location of the hemidesmosome and/or through the extracellular basement membrane, producing a combined cellular (EBS) and junctional (JEB) phenotype. Additional complications that characterize defects of plectin and $\alpha 6 \beta 4$ are **muscular dystrophy** (MD) and pyloric atresia (PA), respectively. Loss of BP180 has been mainly associated with cleavage of the skin at the basement membrane zone as is the case when laminin-5 is absent. Notably, while loss of BP180 only causes a mild form of **epidermolysis bullosa** (simplex) (GABEB), the absence of laminin-5 results in a severe and fatal skin disorder (JEB). Absence of CD151 also leads to a relatively mild form of EB. However, patients without CD151 suffer from fatal renal failure. In contrast to the other available knock-out mice (see Table 1), *CD151* knock-out mice do not have the same phenotype as human patients; i.e. they do not have epidermal blistering or renal failure. These mice only show minor abnormalities in tissue homeostasis. Probably, compensatory mechanisms are responsible for this much milder phenotype. Cleavage above the hemidesmosome, leading to EBS are due to mutations in either

keratin 5 or 14, whereas that beneath the basement membrane in the sub-basal lamina lead to dystrophic epidermolysis bullosa (DEB). The latter defect is caused by mutations in type VII collagen, which forms the anchoring fibrils of the hemidesmosomal adhesion complex (Fig. 1). Thus, the clinical features associated with the loss of these hemidesmosomal components may vary from a relatively benign form of epidermolysis bullosa (in the case of loss of BP180) to very severe forms of junctional epidermolysis bullosa (when $\alpha 6\beta 4$ or laminin-5 is absent) (6) (Table 1).

Regulatory Mechanisms

The skin is a dynamic tissue that is constantly renewed and therefore the assembly and disassembly of hemidesmosomes needs to be tightly regulated. When the basal cells of the epidermis differentiate and move upwards, the expression of $\alpha 6\beta 4$ integrin is down regulated and hemidesmosomes are disassembled. Furthermore, during healing of cutaneous wounds, the stable hemidesmosomal adhesions must be weakened to allow basal keratinocytes to migrate into the

wound site and to re-establish the epidermis. Not only is regulation of hemidesmosome assembly and disassembly important for the proper functioning of normal cells. Also in cancer cells, hemidesmosomes are disassembled to enable invasion into the surrounding tissues (7). In many carcinomas, $\alpha 6\beta 4$ expression is increased; however, the integrin is not clustered in hemidesmosomes but evenly distributed over the membrane. Furthermore, abnormal expression of $\alpha 6\beta 4$ in carcinoma cells is correlated with an invasive phenotype, both in humans and in mouse models. How these processes are regulated is not well understood. It is clear that the phosphorylation state of the $\beta 4$ integrin is crucial for the nucleation of hemidesmosome assembly, and therefore also for their disassembly (1, 2, 3). Phosphorylation of the $\alpha 6$ subunit appears to be less crucial. In fact, there are two cytoplasmic variants of the $\alpha 6$ subunit, A and B, of which only $\alpha 6A$ is a target for phosphorylation by protein kinase C. In the adult skin, $\alpha 6A$, but not the $\alpha 6B$ subunit is expressed. However, replacement of $\alpha 6A$ by $\alpha 6B$ in mice had no effect on the ability of this integrin to induce the

Hemidesmosomes. Table 1 Involvement of hemidesmosomal components in acquired and genetic skin diseases. formation of hemidesmosomes, suggesting that phosphorylation of the $\alpha 6$ subunit is not involved. Ligation of the integrin to laminin-5 also triggers specific phosphorylation and dephosphorylation events downstream of the receptor, which may have an impact on its ability to initiate hemidesmosome assembly (8). Furthermore, there is evidence suggesting that the composition of the substrate is of key importance in the assembly of hemidesmosomes. Both the $\alpha 3$ and the $\gamma 2$ chains of laminin-5 can be cleaved and, depending on whether laminin-5 in the basement membrane is in its cleaved or non-cleaved form, it either enhances cell motility or induces stable adhesion. A further factor found to play a role in the assembly of hemidesmosomes is the distribution and density of laminin-5. If laminin-5 is deposited into dense clusters, it efficiently induces hemidesmosome assembly. Conversely, if it is evenly distributed, the assembly is less efficient.

The kinases found to regulate hemidesmosome assembly through phosphorylation of the integrin $\beta 4$ subunit include members of the protein kinase C family, which are ser/thr kinases, and the tyrosine kinase Fyn. However, there is some contradiction in the results. For example, in some studies PKC α has been implicated in the assembly of hemidesmosomes, whereas in others PKC α was involved in the disassembly and PKC δ in the assembly of the hemidesmosomal complex. Furthermore, it has been reported that a wide range of [▶receptor tyrosine kinases](#), e.g. the EGF-receptor (erbB-1), erbB-2, Met (receptor for hepatocyte growth factor) and Ron (receptor for macrophage stimulating protein), can associate directly or indirectly with the $\alpha 6\beta 4$ integrin and influence hemidesmosome assembly and disassembly (8). Some of these associations may be cell type specific. For instance, in carcinoma cells $\alpha 6\beta 4$ was found to be associated with Met, whereas in many kinds of normal cells Met and $\beta 4$ are independently expressed. Thus, the association of $\alpha 6\beta 4$ with Met might be more general in transformed cells, for which it is essential to mediate their invasion into surrounding tissues. Nevertheless, extracellular factors, such as the matrix to which the cells are attached and growth factors present in the matrix, are important regulators of hemidesmosome formation and their breakdown. Clearly, further studies need to be carried out to unravel the precise role of signaling via $\alpha 6\beta 4$ in the assembly and disassembly of hemidesmosomes.

Hemizygous

Definition

Hemizygous describes an individual who has only one member of a chromosome pair or chromosome segment rather than the usual two. It refers in particular to X linked genes in males who under usual circumstances have only one X chromosome.

Hemochromatosis

ERNEST BEUTLER

The Scripps Research Institute, Department of Molecular and Experimental Medicine, La Jolla, CA, USA

beutler@scripps.edu

Synonyms

Bronzed diabetes; iron storage disease

Definition

Hemochromatosis is a metabolic disorder in which excessive amounts of iron accumulate in the body, leading to tissue damage. It is to be distinguished from hemosiderosis in which excess iron may be present in

tissues, but without tissue damage. Hemochromatosis occurs in hereditary (or primary) and in secondary forms. The most common primary form of the disease is designated hereditary hemochromatosis, once termed idiopathic hemochromatosis. It is the adult onset form of the disease, usually diagnosed after the age of forty. Although it can be a serious disorder characterized by cirrhosis, diabetes, and cardiac disease, in most cases there are no clinical manifestations. Juvenile hemochromatosis is an early onset form of the disease with a different genetic basis and usually severe clinical manifestations. Neonatal hemochromatosis occurs at birth, but it is not clear that the iron deposition that occurs in this poorly defined disorder plays a primary role in pathogenesis. It is probably a heterogeneous disorder, not actually a form of hemochromatosis, and will not be discussed further here.

Excess iron accumulation may be secondary to a variety of disorders of ▶[hematopoiesis](#). This type of hemochromatosis is usually designated secondary hemochromatosis. The most common cause is β -thalassemia major. It also occurs in ▶[congenital dyserythropoietic anemias](#), ▶[hereditary sideroblastic anemia](#), hemolytic anemia due to ▶[pyruvate kinase deficiency](#) and other erythroenzymopathies and in patients with myelodysplastic syndromes such as acquired sideroblastic anemia. It is particularly likely to occur in patients who have ▶[ineffective erythropoiesis](#) and who receive many blood transfusions.

Characteristics

Fully developed hemochromatosis is characterized by the accumulation of large amounts of iron in the form of ▶[ferritin](#) and hemosiderin in many organs. Iron storage is particularly prominent in the liver, where the parenchymal cells become heavily iron loaded, but the macrophages (▶[Kupffer cells](#)) are actually iron-poor. In the liver the reaction to excess iron is fibrosis, occasionally with progression to frank cirrhosis. Liver damage can be very severe and is a common cause of death in the disease. But tissue damage is not limited to the liver alone. Compromise of pancreatic function leads to diabetes mellitus. Deposition of iron in joints is thought to result in arthritis and in the heart in cardiomyopathies. Darkening of the skin is the consequence of both the presence of hemosiderin in the skin, and interference by iron with melanin metabolism.

The characteristics of milder forms of hemochromatosis are by no means so clear, however. It has been suggested that symptoms such as fatigue, impotence and heart disease may occur in such patients. However, controlled studies have shown no increase in such putative manifestations in persons with the biochemical phenotype (1). It has even been proposed that the

heterozygous state is associated with an increased incidence of cancer and/or heart disease, but evidence for this concept has been, at best, contradictory.

Cellular and Molecular Regulation

Iron enters most cells through what has been termed the ▶[transferrin](#) cycle. Transferrin is a plasma protein that binds iron with high affinity at neutral or alkaline pH levels, but readily releases it when the pH is lowered. Iron-containing transferrin binds to a ▶[transferrin receptor](#) on the plasma membrane. The transferrin receptor and transferrin are internalized and transported to the interior of the cell as a vacuole in which the pH is lowered to a point at which the iron dissociates from transferrin and can be transported through the vesicle wall into the cytoplasm. The iron-free transferrin (apotransferrin) is then carried back to the membrane, where it is ready to bind another molecule of transferrin. Although most iron is delivered to cells in this manner, iron enters macrophages in the form of phagocytosed erythrocytes.

Iron regulates the expression of several proteins involved in its metabolism, and the best understood mechanism is a post-transcriptional one (2). Either the 5' or the 3' untranslated portion of the mRNA contains a loop structure that is known as an iron responsive element (IRE). This structure can bind an iron regulatory protein (IRP). There are two types of IRPs, IRP-1 and IRP-2. IRP-1 has been found to be cytoplasmic aconitase. It has an iron-sulfur cluster, and the saturation of this cluster with iron affects binding to the IRE. IRP-2 is regulated by iron-induced ▶[ubiquitination](#) and degradation, and its availability as a ligand for the IRE is therefore a function of iron concentration. The binding of an IRP to a 5' IRE serves to inhibit translation; binding of an IRP to a 3' IRE stabilizes the mRNA.

Although there is considerable understanding of intracellular trafficking and regulation of iron, the regulation of the total iron content is less well understood. Since there is very little loss of iron from the body, regulation of body iron content depends upon increasing or decreasing the amount of iron absorbed from the gastrointestinal tract. Much of what we know about this process is derived from mutations that cause hemochromatosis in humans and genes, targeted disruption of which causes excess iron storage in mice. The most powerful regulator of iron absorption seems to be a small peptide that has been designated hepcidin. It is up-regulated when iron stores are increased and down-regulated in iron deficiency. A lack of hepcidin, both in humans and in mice, causes rapid accumulation of iron (3). The receptor for hepcidin is the transport protein ferroportin. Another protein that influences body iron content is Hfe. It is the product of a gene

designated ►*HFE* that resides on chromosome 6 of man. While it is known that Hfe interacts with the transferrin receptor, it is not clear how this causes increased iron absorption from the intestine. However, in the absence of Hfe, increased body iron fails to stimulate production of hepcidin. This could indicate that Hfe is involved, directly or indirectly, in the regulation of hepcidin levels, and that its effect on iron homeostasis is the result of its regulation of hepcidin.

Clinical Relevance

General Considerations

Under normal circumstances most iron in the body is firmly bound to proteins, particularly transferrin in the plasma and ferritin within cells. However, as the iron burden increases it is likely that the amount of free iron also increases, and this is generally believed to result in tissue damage, particularly to the liver, heart, and endocrine organs through the Haber-Weiss reaction:

Hereditary Hemochromatosis

The most common mutation of the *HFE* gene is 187 G→C predicting a H63D substitution. This mutation is relatively mild with respect to its effect on indicators of iron homeostasis. Its distribution is worldwide, with the highest gene frequencies of approximately 0.16 found in European populations. A second mutation, 845 G→A resulting in the C282Y substitution is confined almost entirely to the European population and generally has a gene frequency of approximately 0.07 in northern Europe (4). This mutation has a stronger phenotypic effect than does the H63D mutation. Most homozygotes for the C282Y mutation and compound heterozygotes for the C282Y and H63D mutation manifest increased saturation of transferrin with iron and usually also have increased ferritin levels during adult life. Although the penetrance of these genotypes is quite high with respect to biochemical parameters, it is very low with respect to clinical manifestations. Indeed, in large controlled population studies it has been impossible to show an effect on either general health or on longevity. There is, however, an increased frequency of abnormal liver function tests in homozygotes for the C282Y mutation. Nonetheless, there is a small subset of patients who develop severe liver disease. The other factors that cause these patients to develop disease remain undefined, although environmental factors such as alcohol intake and hepatitis infections, and probably some genetic factors presumably play a role.

Mutations of transferrin receptor-2 are rare causes of the same clinical syndrome that is caused by *HFE* mutations (5).

Juvenile Hemochromatosis

Juvenile hemochromatosis is a much more severe form of iron storage disease, with an earlier onset than the type of hereditary hemochromatosis that is a result of the *HFE* mutations. Cardiomyopathies and endocrine disturbances are the most prominent clinical features, although cirrhosis of the liver also occurs. The disease locus has been mapped, in most patients, to 1q. The gene that causes the disease has been cloned and is designated *HJV*. In a few families in which the mutation does not map to 1q it has been identified as being a mutation in the hepcidin gene (6).

Iron Overload in Patients with Ferroportin Mutations

Excess iron storage in macrophages has been encountered in a number of families with mutations of ferroportin, an iron transport protein. Unlike the other inherited forms of iron storage disease, transmission is as an autosomal dominant disorder. Several different mutations have been observed, but a recurrent mutation appears to be the deletion of one of a series of 3 sequential valines at amino acid positions 160-162 (7). Mild anemia has been reported in some patients with this form of iron storage disease.

African Iron Overload

This disorder is much less well defined than are hereditary hemochromatosis and juvenile hemochromatosis. Among Africans in South Africa iron overload is extremely common. It has been associated with the ingestion of a large amount of a local beer that has a very high iron content because it is brewed in iron pots. However, familial aggregation of elevated ferritin levels has been documented, affecting even family members who do not ingest the beer. Moreover, African-Americans also have increased serum ferritin levels when compared with whites.

Secondary Hemochromatosis

Accumulation of iron in children with β -thalassemia major is the result of transfusions and of the increased iron absorption that is characteristic of patients with ineffective erythropoiesis. It is the most common cause of death in this disorder, the increased iron burden causing severe cardiomyopathies and cirrhosis of the liver. The same syndrome occurs when excessive iron accumulates in patients with other disorders characterized by anemia, transfusion, and ineffective erythropoiesis (see Definition).

Treatment

Treatment of iron overload is directed at mobilizing the stored iron and removing it from the body. This is best accomplished in patients who have intact erythropoiesis by multiple phlebotomies. As iron-containing blood is removed, the body mobilizes stored iron, which is then incorporated into newly formed erythrocytes in the marrow. This approach cannot be used in patients who have abnormal erythropoiesis, and in such patients the stored iron must be removed by the use of chelating agents, such as ►desferrioxamine.

Heparin Sulfate Proteoglycans

Definition

Heparin sulfate proteoglycans (HSPGs) belong to the family of proteoglycans. They are cell surface molecules that are part of the extracellular matrix. HSPGs consist of a protein core, such as syndecan and glypican, to which long unbranched chains of sulphated repeating disaccharides are attached. Dally is the *Drosophila* proteoglycan while in vertebrates Knypek and Syndecan-1 typify this family. HSPGs have been implicated in regulating the signaling activities and distribution of both Wnt and Hedgehog.

Hepatitis B Virus

Definition

Hepatitis B virus belongs to the hepadna virus family. The virus infects and replicates in liver, where it can induce chronic disease. Hepatocellular carcinoma is the frequent consequence of chronic hepatitis B virus infection. The enveloped virus particles contain small circular DNA genomes with four major genes. At least one of its proteins, the X protein, has transforming features. Broad vaccination against Hepatitis B virus has significantly lowered the prevalence of Hepatitis B. This provides the first example of a highly efficient prophylaxis against virus associated tumour forms in the general population.

►Viral Oncogenesis

Hepatocellular Carcinoma

Hepatocellular carcinoma (HCC) refers to liver cancer as a frequent consequence of chronic hepatitis B virus infection.

►Wnt/Beta-Catenin Signaling Pathway

Hepatocyte Nuclear Factor 4a

Definition

Hepatocyte nuclear factor 4a is a member of the hormone receptor superfamily of transcription factors. Mutations in the HNF4A gene cause the MODY1 form of diabetes.

Hereditary Disease, Genetic Basis

JÖRG SCHMIDTKE

Institute of Human Genetics, Hannover Medical School, Hannover, Germany

Schmidtke.Joerg@mh-hannover.de

Definition

Hereditary disease is due to mutations of the genetic material of germ cells. Such mutations can occur at the level of a chromosome (chromosomal mutations), the genome (genome mutation), or a gene (gene mutations). Mutations alter either the structure or the dosage of one or several genes, the functional units of inheritance. Most, but not all, hereditary diseases are individually rare (1), but taken together they comprise about 5% of the disease load in developed countries.

Characteristics

Chromosomal Disorders

The normal human chromosome complement of somatic cells consists of 46 chromosomes. Every individual inherits one half set of 23 chromosomes from each parent, and thus carries two functional homologues of each gene, with the exception of those genes that are located on the sex chromosomes, X and Y. Males inherit a 23,Y complement from their fathers and a 23,X complement from their mothers (male karyotype: 46,XY), while females receive 23,X complements from both parents (female karyotype 46,XX). The 22 chromosomes shared by male and female germ cells are called autosomes. Most, but not all genes of one of the two X chromosomes are functionally silenced (inactivated) in a random fashion in female somatic cells.

Chromosomes can be mutated either with respect to their number [numerical aberrations (“aneuploidies”)] or their structure (structural aberrations). Numerical aberrations are the result of misdivision of the chromosome complement during parental meiosis. Numerical aberrations that can be found in live-born individuals comprise trisomies 13, 18, and 21, as well as sex chromosome aneuploidies including 45,X (Turner syndrome), 47,XXX (Triple-X syndrome), XXY (► [Klinefelter syndrome](#)), and 47,XYY. Occasionally, numerical aberrations occur in a mosaic fashion, i.e. only a proportion of tissues or cells within a tissue carry the abnormal chromosome complement; such changes are due to postzygotic (somatic) mutations within the affected individual. Chromosomal ► [mosaicism](#) is usually associated with milder disease manifestation than non-mosaic cases. Autosomal and

X-chromosomal ►aneuploidies with added chromosomes in newborns are associated with increased maternal age. Numerical chromosomal aberrations are a frequent cause of spontaneous abortions (trisomy 16, 45,X-karyotype). The same is true for genome mutations (triploidy, tetraploidy), which are extremely rare among new-borns.

Structural ►chromosomal aberrations are due to rearrangement of chromosomal material. Inversions are the result of chromosomal breakage at two locations and re-insertion of the central fragment in the opposite orientation; translocations are the result of interchange of fragments between non-homologous chromosomes; loss of fragments of chromosomes results in ►deletions; extra fragments are called duplications (sometimes called partial trisomy). Apart from cases where one of the chromosomal breakpoints is intragenic, structural aberrations are associated with a pathological state only if they are unbalanced with regard to the amount of genetic material. Infertility with recurrent abortions is sometimes due to a balanced parental translocation that has segregated into an unbalanced state in the fetus. Male sterility is sometimes caused by deletions of Y-chromosomal material, involving genes required for normal spermatogenesis.

Single-Gene Disorders

About 4000 different disorders without visible chromosomal alterations have been shown to follow Mendelian rules (at least in some families) and are thus assumed to be caused by mutations of single genes. The great majority of single-gene disorders is encoded by nuclear genes. A small number of heritable diseases is due to mutations in the mitochondrial genome. The on-line catalogue of Mendelian inheritance in man (2) contains comprehensive clinical and genetic information, as well as useful links to other resources regarding these disorders. In mid-2003, disease-causing mutations were known for 1446 nuclear genes, and 1933 clinical phenotypes were associated with a mutation in a nuclear gene (3). However, because of locus and allelic heterogeneity, molecular diagnosis is usually not possible in all patients affected by a given disease.

At the gene level, structural alterations comprise nucleotide exchanges, deletions or insertions of single or multiple nucleotides, and more complex rearrangements. A mutation can be pathogenic if it results in a structurally and hence functionally altered protein product, or if it leads to altered, usually reduced dosage of gene products (►haploinsufficiency).

The inheritance pattern of genetic disease depends on the chromosomal location (autosomal or sex-chromosome linked) and on the phenotypic result of the mutation. If a disease fully manifests itself in the

►heterozygous carrier of the disease-causing mutation, the inheritance pattern of the disease is called dominant. If a disease manifests itself only in the homozygous or ►compound heterozygous carriers of the disease-causing mutation, the inheritance pattern of the disease is called recessive. If the phenotype of the heterozygote is intermediate between the homozygous affected and non-affected individuals, the pattern of inheritance is called codominant (or intermediary). If the disease-causing mutation is in an autosomal gene, individuals are affected independent of gender. If a disease causing mutation is on the X-chromosome and the mode of inheritance is recessive, only males will be affected. If a disease-causing mutation is on the Y chromosome, the mode of inheritance is dominant and the disease restricted to males. The only known disease that is Y-linked is male sub- or infertility, the latter being heritable only through assisted reproduction.

In practical clinical genetics, the terms dominant and recessive are used in a pragmatic fashion and are associated with both the mode of inheritance and the disease itself. The vast majority of dominant disorders are strictly speaking co-dominant in that homozygosity for the underlying mutations would result in a much severer phenotype including early lethality. Heterozygous mutation carriers for a recessive mutation often show mild phenotypic expression (heterozygote manifestation); in the special case of X-linked recessive disease, the phenomenon can be ascribed to deviation from randomness regarding X-chromosome inactivation.

It should also be noted that some disorders following a dominant pattern of inheritance in pedigrees, require ►homozygosity (or usually compound-heterozygosity) at the cellular level. Thus, most familial cancer syndromes follow an autosomal-dominant pattern, because a mutation in a tumor-suppressor gene is transmitted through generations. In order for the disorder to become manifest, a second mutation must occur in one or more somatic cells of the germ-line mutation carrier.

Contiguous Gene Syndromes

Disorders that are caused by a mutation affecting a contiguous set of genes, usually a deletion, are referred to as contiguous gene syndromes. These mutations are not normally visible using classical cytogenetic methods, and their detection requires a combination of cytogenetic and molecular methodology, ►FISH (fluorescence-in situ-hybridization). They usually arise *de novo* and act through haploinsufficiency.

Genetic Risk

In disorders following a Mendelian mode of inheritance, the expected genetic risk to members of affected

families can easily be calculated. In autosomal-recessive disorders, the disease risk is 1 in 4 for sibs of affected individuals; 2 out of 3 healthy sibs will be heterozygous carriers. In autosomal-dominant disorders, the risk is 1 in 2 for offspring of affected individuals. In X-linked recessive disorders, the disease risk is 1 in 2 for male offspring of heterozygous female carriers. All daughters of affected males and 1 in 2 daughters of female heterozygous carriers will be heterozygous carriers; sons of affected males will not be affected. It should be noted that absence of a family history in the case of a hereditary disease can either reflect recessivity or can be ascribed to a *de novo* mutation with a dominant effect.

However, a number of factors lead to deviations from calculated risk figures regarding disease manifestation.

- **germ line mosaicism**
Occasionally, a person who does not carry a disease-causing mutation in his or her somatic cells has multiple affected offspring. Given that repeated *de novo* mutations in the same gene are extremely unlikely, the phenomenon is ascribable to some or all germ-line cells of this person carrying the mutation.
- **late or sex-skewed disease manifestation**
A number of single-gene disorders become manifest in middle or late adult life, and the time of onset may vary greatly even within families. Thus a disease may be inherited from an ancestor who did not reach the age of disease manifestation him- or herself (phenotypic “skipping” of generations). Some mutations, such as those within genes predisposing to familial breast cancer, rarely manifest themselves in males but frequently in daughters of male carriers.
- **reduced genetic penetrance**
Genetic penetrance is the proportion of persons manifesting a disease among those that carry the responsible genotype. In single-gene disorders, full penetrance is indeed the exception rather than the rule, whereas chromosomal disorders and contiguous gene syndromes are usually fully penetrant. Which factors cause reduced penetrance is usually not known. Both other genetic (presence or absence of mutations in other genes contributing to the pathogenesis or of protective variants) and environmental factors (presence or absence of precipitating or protective agents) could be involved. Thus, the notion of penetrance mediates a transition to the concept of polygenic and multifactorial inheritance typical for “complex” diseases. Late and sex-skewed

disease manifestation can also be regarded as the result of age- or sex-dependent penetrance.

- **variable expressivity**
Variable expressivity is the term used to describe the situation when a disease, even within a family, differs greatly with respect to severity. The contribution of other genes or environmental factors, as well as allelic heterogeneity may be responsible for this common phenomenon.
- **locus heterogeneity**
This term is used when a disease may be caused by mutations in different genes. In the case of autosomal-recessive disorders, this could lead to none of the offspring of affected parents developing the disease.
- **genomic imprinting**
If the phenotype depends on the gender of the transmitting parent, genomic imprinting may be invoked. Here, ►**epigenetic** chemical change (methylation) of genomic DNA during the paternal or maternal gametogenesis leads to inactivation of specific parental alleles.
- **uniparental disomy**
Rarely, both members of a chromosome pair are of identical parental origin. This can be the result of the attempt of the zygote to repair a trisomy that was caused by non-disjunction during gametogenesis. Deleterious effects may arise in conjunction with genomic imprinting or recessivity.
- **anticipation**
Some diseases occur at progressively earlier age and/or with pronounced severity in successive generations. Unless due to ascertainment bias, the phenomenon can be ascribed to dynamic repeat expansion mutations.
- **mitochondrial inheritance**
A small number of diseases are caused by mutations in one of the 37 genes of the mitochondrial genome. Due to the fact that the mitochondrial material of the zygote is (almost) entirely derived from the egg, mitochondrial disorders are inherited in a strictly maternal fashion. Variable expressivity of mitochondrial disease can be ascribed to ►**heteroplasmy**.

Hereditary Hemostatic Defects and Recombinant Proteins for Treatment

ELISABETH ERHARDTSEN

Novo Nordisk A/S, Bagsværd, Denmark
eer@novonordisk.com

Definition

Hereditary hemostatic defects caused by human gene mutations can be divided into the more commonly occurring coagulation factors defects (e.g. ►[hemophilia A](#) and [B](#)), the rare defects responsible for platelet adhesion and aggregation defects (e.g. ►[Glanzmann's thrombasthenia](#) and ►[Bernard-Soulier syndrome](#)) and defects within ►[fibrinolysis](#). This essay will cover the most frequently reported coagulation factor defects and the recombinant proteins for their treatment.

Hemophilia A and B, caused by deficiencies of coagulation factors VIII (FVIII) or IX (FIX), are the best described hemostatic defects of high prevalence, causing lifelong bleeding disorder in mild, moderate or severe forms. Von Willebrand factor deficiency leads to ►[von Willebrand's disease](#) with an estimated prevalence of 1% of the general population. A range of more rare inherited coagulation factor deficiencies are reported, such as deficiency of coagulation factors V, VII, X, XI, or XIII.

The hereditary coagulation factor deficiencies are either ►[X-linked](#) ►[recessively](#) or ►[autosomal](#) recessively transmitted gene defects.

Characteristics

X-linked Gene Mutations

Coagulation FVIII Deficiency (Hemophilia A)

Hemophilia A caused by the deficiency of coagulation FVIII has a prevalence of 1:5,000 males. The bleeding symptoms depend upon the FVIII concentration in the patient's blood, and may be characterized by spontaneous joint and muscle bleeds in severe hemophilia (FVIII<1%) and excessive bleeding after surgery or trauma in mild, moderate and severe hemophilia.

Coagulation FIX Deficiency (►Hemophilia B)

Hemophilia B is caused by coagulation FIX deficiency, with a prevalence of 1:30,000 males. The bleeding symptoms depend upon the FIX concentration in the patient's blood with a pattern similar to that affecting hemophilia A patients.

Table 1 shows the laboratory and clinical manifestations of hemophilias A and B.

Bleeding Pattern in Hemophilia

A characteristic of hemophilia is the frequent and painful joint bleedings. Persistent or recurrent joint bleeding may result in the development of chronic arthropathy and incapacity with fixed flexion and other deformities particularly of the knees, ankles and elbows. Associated muscle wasting can be profound and in the worst scenario the patient becomes confined to a wheelchair.

Muscle bleeds may be life- or limb-threatening due to compression of blood vessels and nerves. Before effective therapy became available, a cut in the finger could result in death. Today, any bleeding episode in a severe hemophilia patient is treated promptly.

Autosomal Recessive Gene Mutations

Von Willebrand's Disease (vWD)

vWD is caused by a deficiency or abnormality of ►[von Willebrand Factor](#) (vWF) which is a multimeric adhesive protein playing an important role partly in the initial hemostasis by promoting platelet adhesion at site of vascular injury and partly as the carrier of coagulation FVIII to which it is associated in plasma as a tight complex. A clear distinction between FVIII and vWF deficiencies was not made until 1957.

vWD has a prevalence of up to 1% in the general population; however, only about 1/10,000 inhabitants receive treatment for the disorder. More than 20 subtypes of vWD are described with a broad division into two types, i.e. associated with quantitative deficiency (types 1 and 3) and qualitative deficiency (type 2). Diagnosis of vWD, especially type 1 accounting for ~70% of all vWD cases, may be difficult because the laboratory phenotype is highly ►[heterogeneous](#) and factors such as e.g. blood group influence the vWF level. It has been established that type 1 vWD represents the ►[heterozygous](#) or carrier state for type 3 vWD.

Bleeding Pattern

Mucosal bleeding is predominant in vWD, whereas hematomas and muscle bleeds are seen only in type 3 vWD.

Coagulation Factor VII Deficiency

Factor VII (FVII) deficiency is a common autosomal recessive coagulation disorder with a prevalence of 1:500,000 in the general population; a severe bleeding phenotype is only seen in patients with FVII activities <2% of the normal level but the severity of symptoms is reported to be poorly correlated with plasma levels. The majority of FVII-deficient patients are either asymptomatic or the clinical phenotype is unknown and the mutations are often identified through pre-operative screening.

Hereditary Hemostatic Defects and Recombinant Proteins for Treatment. Table 1 Laboratory and clinical manifestations of hemophilia A and B

Factor VIII/IX Activity Level			
Normal	Severe	Moderate	Mild
(0.5 – 1.5 U/mL)	(<0.01 U/mL)	(0.01 – 0.05 U/mL)	(>0.05 U/mL)
% of all hemophilia A	70%	15%	15%
% of all hemophilia B	50%	30%	20%
Bleeding Manifestations			
Age of onset	≤1 year	1-2 years	2 years – adult
Neonatal symptoms	PCB: common ICH: occasionally	PCB: occasionally ICH: uncommon	None Rare
Muscle/joint hemorrhage	"Spontaneous"; requires no trauma	Requires minor trauma	Requires major trauma
CNS hemorrhage	High risk (2-5%)	Moderate risk	Rare
Post surgical hemorrhage (without prophylaxis)	Frank bleeding, severe	Wound bleeding common	Wound bleeding with factor <0.3 U/ml
Oral hemorrhage following trauma, tooth extraction	Common	Common	Often

PCB: postcircumcisional bleeding; ICH, intracranial hemorrhage

Bleeding Pattern

Epistaxis and mucocutaneous bleedings are the most frequently observed bleedings in FVII-deficiency.

Coagulation Factor XI Deficiency

Factor XI (FXI) deficiency is an injury-related autosomal bleeding disorder with a frequency of up to 8% of Ashkenazi Jews. It is characterized by a decrease in FXI activity usually accompanied by correspondingly low levels of FXI antigen; however, a clear relationship between FXI plasma level and bleeding tendency has not been demonstrated.

Bleeding Pattern

Patients who are mildly affected with FXI deficiency may have oral and postoperative bleeding, while severe FXI deficiency (<1%) is characterized by bleeding symptoms after trauma or surgery.

Inhibitory Antibodies

Spontaneous inhibitors may develop in patients lacking various coagulation proteins as a response to treatment with blood components containing the missing factor. Such inhibitors are most often directed against FVIII; however, any coagulation protein may be affected. So far, no clinical consequences of inhibitory antibodies have been reported in FVII-deficient patients, whereas inhibitors to FXI and von Willebrand patients have been reported to have clinical consequences.

Development of inhibitory antibodies to treatment occurs mainly in severe hemophilia, with a rate of 30–50% in hemophilia A and 1.5–3% in hemophilia B patients. The risk is associated with the type of mutation: mutations that severely truncate or prevent production of FVIII lead to a frequency of 35% of inhibitor development, while a missense mutation or small deletions lead to about 5% inhibitor development in hemophilia A patients. Hemophilia B patients with large gene deletions (1–3% of patients) or rearrangements have a risk of about 50% and are at particular risk of developing anaphylaxis when given therapy with the missing factor. Frameshift, premature stop, or splice-site mutations lead to a risk of about 20% of inhibitor development.

Cellular and Molecular Regulation Factor VIII

The mutation usually occurs in males in whom the mutant gene (X_H) is inherited from the carrier mother (X_H/X). However, in approximately 30% of cases the mutation occurs spontaneously. The gene measures 186 kb and contains 26 exons, with a large inversion and translocation of exons 1–22 as the most common genetic defect.

Further information on mutations, phenotype data etc. is available on the Internet ► <http://europium.csc.mrc.ac.uk>.

Factor IX

The FIX gene is located at band Xq27 on the X-chromosome, contains eight exons and measures 33.5 kb. More than 2100 mutations are assembled in a worldwide database of mutations for FIX gene causing hemophilia B that is accessible through the Internet ►<http://www.kcl.ac.uk/ip/petergreen/haemB-database.html>).

von Willebrand Factor

The vWF cDNA was cloned in 1985; the gene spans 178 kb on the short arm of chromosome 12 and contains 52 exons. Different mutations, missense, nonsense or frameshift, will result in loss of or unstable expression of vWF with missense mutations being the basis for most qualitative vWD variants.

Factor VII

The FVII gene is small (12 kb, nine exons) and found on chromosome 13 adjacent to the FX gene. A mutation database can be found on the Internet at ►<http://europium.csc.mrc.ac.uk> with data from 238 individuals described in the world literature.

Factor XI

The gene is found on chromosome 4 and is 23 kb in length. Two mutations in the gene encoding FXI are responsible for most cases of FXI deficiency, a nonsense mutation Glu117Stop and a missense mutation Phe283Leu.

Clinical Relevance

The progress made in understanding the mechanisms of coagulation defects over the past three decades has provided a basis for development of recombinant products in the treatment of patients suffering from the coagulation deficiencies with a great impact on their quality of life.

Recombinant Proteins for Treatment

The genes for FIX and FVIII were cloned in 1982 and 1984 resulting in molecular characterization of the defects. The development of recombinant DNA technologies soon led to the production of recombinant proteins for treatment of hemophilia. The alternatives to plasma-derived products have reduced the risk of transmission of blood-borne pathogens; some countries prioritize treatment with recombinant products to patients with newly diagnosed hemophilia.

Factor VIII

The first rFVIII preparations were introduced in the early 1990s with an excellent efficacy and high correlation between the dose given and the FVIII plasma level. Recently, a new rFVIII preparation has been licensed, which is a sucrose-formulated,

full-length rFVIII produced by baby hamster kidney cells into which the human FVIII gene has been introduced. Compared to its predecessor product, it incorporates a revised purification and formulation process that eliminates the addition of human albumin. Future strategies are aimed at producing FVIII molecules with an enhanced expression, stability, prolonged half-life and reduced antigenicity and immunogenicity.

Factor IX

Only one rFIX product is licensed for treatment of patients with hemophilia B. This rFIX product is expressed in Chinese hamster ovary cells cultured in a medium without any blood or plasma products. It has shown satisfactory results although the plasma level obtained is lower than that found after treatment with conventional plasma-derived FIX concentrates. A wide patient-related variability in the recovery rate is found which seems to impede the development of next generation rFIX products.

Treatment

The aim of the treatment is to raise the plasma level of FVIII or FIX to levels that cause arrest of bleeding and prevent rebleeding. Treatment is done on demand as bleeding occurs or as ►[prophylaxis](#). The aim of prophylaxis is to abolish spontaneous joint bleeding and the long-term consequences such as wheel-chair confinement; it is now the recommended strategy for children with severe hemophilia in many countries even though it may be demanding for the families and many questions remain to be answered, e.g. at what age should prophylaxis begin.

Patients with a moderate bleeding pattern are either treated before major physical activities or when a bleeding starts.

Immune Tolerance

Inhibitory antibodies in hemophilia patients are a frequent and significant complication and management is difficult. High-responding inhibitors to FVIII or FIX may be eradicated by immune tolerance regimens, i.e. regular infusions with either plasma factor concentrates or recombinant factor products. Several protocols have been established for immune tolerance regimens, mainly with the use of very high daily doses of factor VIII or FIX in combination with immunosuppressive therapy.

Recombinant Activated Coagulation Factor VII (rFVIIa)

Recombinant activated factor VII is a bypassing product licensed in 1996. It has been shown to induce hemostasis in hemophilia patients with inhibitors against FVIII or FIX independent of FVIII/FIX. FVIIa binds to tissue factor (TF) exposed at the site of injury

and generates through FX activation of the TF-bearing cells a limited amount of thrombin, enough to activate FVIII, FV and FXI as well as platelets. The local thrombin activated platelets provide a perfect template for binding of activated FVIII, FIX, FV, further activation of FX and thrombin generation. rFVIIa in high concentrations binds to thrombin activated platelets and is capable of activating FX, thereby generating thrombin independently of the presence of FVIII or FIX.

Treatment

rFVIIa has been shown to have a 90% efficacy in severe hemophilia patients with inhibitors subjected to major surgery and suffering from serious limb- or life-threatening bleedings. Since rFVIIa enhances thrombin generation thereby providing the formation of tight, stable fibrin hemostatic plugs resistant to premature lysis, it should be hemostatic also in other situations characterized by an impaired thrombin generation. A hemostatic effect has accordingly been reported in patients suffering from various platelet disorders, as well as FVII- and FXI-deficiencies. Fig. 1 shows the mechanism of action of rFVIIa.

Recombinant von Willebrand Factor

A recombinant vWF preparation was developed in the mid 1990s; however, due to inconsistent pre-clinical results this program was discontinued. A combined rFVIII/vWF product is now under development.

Treatment

At present, most cases of type 1 vWD are treated with desmopressin (DDAVP) to correct the FVIII/vWF levels; for severe forms of vWD a plasma FVIII/vWF concentrate is needed.

Hereditary Hemostatic Defects and Recombinant Proteins for Treatment. Figure 1 Mechanism of Action of rFVIIa (adapted from Hoffman and Munroe). rFVIIa directly activates Fx on the surface of the locally activated platelets.

Carrier or Fetus Screening

Screening of FVIII and FIX genes for point mutations has been introduced. It is more feasible for the FIX gene than for the FVIII gene due to the difference in length of the genes (33.5 vs 186 kb).

A substantial proportion of female carriers have low concentrations of FVIII or FIX, which may equal a mild hemophilia. Factor concentrations should therefore be measured in girls and women who are definite or possible carriers; however, a reproducibly normal concentration does not exclude carrier status, which can then be identified only by mutation detection.

Gene Therapy

Hemophilia is a prime target for gene therapy for several reasons. The patient lacks only a single gene product and a small rise in coagulation factor concentration is considered to be sufficient to obtain the desired effect. Based on promising animal results, different gene therapy systems have been or are being tested in both hemophilia A and B patients and more than 25 hemophiliacs have by now been treated in phase I clinical trials. However, reliable therapeutic concentrations of FVIII or FIX have not yet been obtained. Further, the safety profile has not yet been established and concern is expressed as to the possible risk of developing inhibitory antibodies along with possible hepatotoxicity and germline gene transfer.

Definition

► **Charcot-Marie-Tooth disease (CMT)** is the most common inherited peripheral neuropathy. Since the first description in 1886, it has become apparent that CMT is not one single disease entity, but is clinically and genetically heterogeneous. Dyck et al. (1) introduced a classification of peripheral neuropathies that distinguished hereditary motor and sensory neuropathies (HMSN), hereditary motor neuropathies (HMN), hereditary sensory neuropathies (HSN) and hereditary recurrent focal neuropathies. Each of these entities is further subdivided on the basis of genetic, electrophysiological and neuropathological criteria.

Characteristics

The prevalence of CMT is 1:2500. CMT is symmetrically slowly progressive affecting at first the distal limbs. Most patients suffer from demyelinating neuropathies (CMT type 1). This group is characterized by reduced nerve conduction velocities (► **NCV**, motor median NCV ≤ 38 m/s) due to a partial or complete loss of the myelin sheath. Patients suffering from a primary axonal neuropathy (CMT type 2) are characterized by a reduced compound muscle action potential (► **CMAP**), while NCV is normal or slightly reduced. A morphological examination of sural nerve biopsies is, due to the rapid progress and implementation of molecular genetics in the diagnosis of this group of disorders, not

usually performed on a routine basis. However, it is still an important diagnostic tool in some cases with an equivocal diagnosis. Morphological analysis of sural nerve biopsies reveals typical signs of de- and remyelination with “onion bulb formation” in CMT type 1 and axonal regeneration in CMT type 2. HNPP, a related peripheral neuropathy, is characterized by temporary recurrent nerve palsies. Histopathological analysis of sural nerves reveals focal hypermyelination manifested in structures called “tomacula”(lat.= “sausage”) and segmental demyelination. With emerging genetic knowledge some overlap of demyelinating and axonal forms is apparent in that specific mutations in a given disease gene manifest themselves either as CMT 1 or CMT 2. The mixed phenotype is most likely due to different mutation-dependent disease mechanisms; alterations in the myelin sheath will almost invariably also affect the axonal partner cell and *vice versa* reflecting the intimate interactions between supporting Schwann cells and the axon of the nerves (2, 3).

Distal HMN, also called spinal CMT or distal spinal muscular atrophy (distal SMA), primarily presents with a classical CMT phenotype, since it also produces the clinical picture of peroneal muscular atrophy, although in the absence of sensory losses.

HSN presents with sensory abnormalities, sometimes leading to poorly healing ulcers and eventually amputation of distal parts of the limbs. Varying degrees of autonomic disturbances may be present; therefore HSN is also called hereditary sensory and autonomic neuropathy (HSAN).

Genetics

Autosomal dominant (AD), autosomal recessive (AR) and X-linked patterns of Mendelian inheritance are observed for inherited peripheral neuropathies (Table 1), with AD-CMT1 being the most common pattern. During the last 20 years, efforts have been made to determine the chromosomal loci, to clone genes and to identify mutations for CMT and related peripheral neuropathies. To date, 32 genes and 14 additional genetic loci have been associated with inherited peripheral neuropathies (Table 1). Over 500 distinct mutations involving these genes have been reported (4). Interestingly, distinct mutations in the same gene can result in different phenotypes (e.g. CMT1, CMT2, DSS and CHN caused by *MPZ* mutations, Fig. 1), while mutations in distinct genes can result in the same phenotype (e.g. CMT1 caused by mutations in *PMP22*, *MPZ*, *GJB1*, *EGR2* and *SIMPLE*). The genes involved in peripheral neuropathies code for proteins with very diverse function: structural myelin component (*PMP22*, *MPZ*), transport through myelin sheath (*GJB1*), axonal transport (*NEFL*, *KIF1B*, *GAN*), transcription factor (*EGR2*, *IGHMBP2*), signaling

(*PRX*, *MTMR2*, *SBF2/MTMR13*, *NDRG1*, *GDAP1*) and endosome function (*RAB7*, *SIMPLE*). A summary of some of these genes and the associated phenotypes is presented.

Genes Associated with HMSN

Peripheral Myelin Protein 22 Gene (*PMP22*; ►OMIM *601097)

Seventy percent of AD-CMT1 patients carry a 1.4 Mb tandem duplication in chromosome 17p12. The

reciprocal deletion of the 1.4 Mb region leads to HNPP (5, 6). The CMT1A duplication/HNPP deletion region contains the *PMP22* gene, which was shown to be the dosage-sensitive gene. *PMP22*, a 4-transmembrane domain protein, plays a structural role in myelin formation and maintenance.

Point mutations in *PMP22* are associated with a wide variety of clinical phenotypes, such as CMT1, DSN (DSN is traditionally viewed as a recessive disease but has recently been used to describe severe cases of CMT 1 regardless of the mode of inheritance), CHN or

HNPP. Most *PMP22* mutations are located in the transmembrane domain of the protein (3, 4, 7).

Myelin Protein Zero Gene (*MPZ*; OMIM *159440)

In 1993, the first mutations in *MPZ* that were associated with demyelinating peripheral neuropathies (classified as CMT1B) were identified. Most mutations are associated with the demyelinating forms CMT1B, DSN or CHN, but in some cases signs of primary axonal involvement similar to CMT2 have been described. *MPZ* is highly expressed by myelinating Schwann cells of the PNS, where it accounts for more than half of the protein in the peripheral myelin sheath. The protein consists of a single extracellular immunoglobulin-related domain that mediates homophilic adhesion, a transmembrane domain and a short basic intracellular domain. Most *MPZ* mutations are located in the extracellular domain (3, 4, 7).

Gap Junction Protein β 1 (*GJB1*; OMIM *304040)

GJB1, a four transmembrane domain protein, is localized to the paranodes and the Schmidt-Lanterman incisures of myelinating Schwann cells and enables a shortened lateral diffusion pathway for ions and low-molecular-weight compounds between the adaxonal and abaxonal Schwann cell cytoplasm. The first mutations in *GJB1* associated with the X-linked form of CMT (CMTX) were identified in 1993 and alterations in *GJB1* have turned out to be the second most common mutations in CMT, after the CMT1A duplication. Over 250 different mutations in *GJB2* have been described. The mutations are scattered over the entire protein and are not concentrated in a specific domain. Electrophysiological findings in patients suggest a significant contribution by an axonal component associated with specific *GJB1* mutations (3, 4, 7).

Early Growth Response 2 Gene (*EGR2*; OMIM *129010)

Expression of *EGR2* starts before the onset of myelination, when Schwann cells are formed from their precursors, persists throughout life and, as a **zinc finger** transcription factor, plays a major role in the development of the peripheral nervous system. *EGR2* regulates the expression of myelin proteins (including *PMP22*, *MPZ*, *GJB1* and *PRX*) and enzymes required for the synthesis of lipids. *EGR2* mutations are found in severe CMT1, DSN and CHN. Mutations in the DNA-binding domain of *EGR2* lead to dominantly inherited CMT1. In contrast, mutations in the inhibitory R1 domain appear to be recessive. The spectrum of disease severity associated with *EGR2* mutations is broad and can vary considerably, even in patients with the same mutation (3, 4, 7).

Periaxin (*PRX*; OMIM *605725)

Mutations in *PRX* have been identified in CMT type 4F, a recessively inherited severe form of demyelinating peripheral neuropathy and autosomal recessive DSN. CMT4F patients suffer from severe neuropathic pain in addition to the common features of a pronounced neuropathy. *PRX* is specifically expressed by myelinating Schwann cells. Alternative splicing leads to two different proteins, S-periaxin and L-periaxin. L-periaxin is targeted to the nucleus in embryonic Schwann cells, in myelinating Schwann cells it redistributes to the plasma membrane. S-periaxin is restricted to the cytoplasm. L-periaxin forms a complex with dystrophin-related protein-2 (DRP2) and with dystroglycan linking the cytoskeleton of the Schwann cell with the extracellular matrix in the abaxonal Schwann cell membrane (3, 4).

Myotubularin-related-protein-2 Gene (*MTMR2*; OMIM *603557)

Mutations in *MTMR2* have been shown to be responsible for the rare form of CMT4B1. CMT4B1 is a demyelinating motor and sensory neuropathy characterized by focally folded myelin sheets on sural nerve biopsy. The onset of the disease is very early in life, adult patients are severely handicapped and usually wheelchair bound. *MTMR2* is a member of the myotubularin family, which contains a domain with similarity to dual-specificity phosphatases in which diverse associated mutations have been found to affect protein function (3, 4).

N-myc Downstream-regulated Gene 1 (*NDRG1*; OMIM *605262)

A nonsense mutation in *NDRG1* is associated with hereditary motor and sensory neuropathy-Lom (HMSN-L; CMT4D). HMSN-L is a severe autosomal recessively inherited neuropathy with deafness and unusual neuropathological findings. Individuals with HMSN-L carry a stop codon within the *NDRG1* gene resulting in a truncated *NDRG1* protein. Transcription of *NDRG1*, a phosphatase, is up-regulated by various chemical agents and the *NDRG1* protein contains several phosphorylation sites susceptible to substances that induce stress in the endoplasmic reticulum (3, 4).

Kinesin Family Member 1B Gene (*KIF1B*; OMIM *605995)

A missense mutation in *KIF1B*, was identified in a single family with axonal CMT type 2A. *KIF1B* is a member of the kinesin superfamily. This superfamily represents a group of proteins that are essential for the transport of organelles and materials along microtubules within cells. *KIF1B α* and *KIF1B β* , the two isoforms, result from alternative splicing. *KIF1B α* is responsible for the transport of mitochondria and shows a widespread expression pattern, whereas

Hereditary Neuropathies, Motor and/or Sensory. Figure 1 Structure of MPZ, illustrating that mutations can cause distinct clinical phenotypes.

KIF1B β is specifically expressed in neurons where it is essential for the transport of synaptic vesicles (3, 4).

Mitofusin 2 (MFN2; OMIM *608507)

In seven families linked to the CMT2A locus, mutations in *KIF1B* were excluded. Mutation analysis of other genes in the linked region revealed missense mutations in *MFN2*. Therefore, mutations in *MFN2* are the primary cause underlying CMT2A. *MFN2* is ubiquitously expressed and mRNA transcripts were detected in spinal cord and peripheral nerve. *MFN2* is localized to the outer mitochondrial membrane and regulates the mitochondrial network architecture by fusion of mitochondria.

Gigaxonin (GAN; OMIM *605379)

Mutations in the gigaxonin (*GAN*) gene lead to the rare and severe autosomal recessive giant axonal neuropathy. This neuropathy affects the peripheral and central nervous system. *GAN* is involved in the dynamic organization of the actin network. Defects in *GAN* cause the main stigmata of the disease, severe neuropathy, ataxia and curled, kinky hair (3, 4).

Neurofilament, Light Polypeptide Gene (NEFL; OMIM *162280)

Mutations in *NEFL* are found in patients with CMT2, CMT1 and DSN. Most patients have an early onset, severe phenotype with moderate to severely reduced

NCVs. NEFL codes for a subunit of neurofilaments, the major type of intermediate filaments in neurons. Most mutations are clustered in the head domain of the protein (3, 4).

Ganglioside-induced Differentiation-associated Protein 1 Gene (*GDAP1*; OMIM *606598)

Mutations in *GDAP1* were found to be associated with demyelinating CMT4A, axonal AR-CMT2 with vocal cord paresis and AR-CMT with both demyelinating and axonal features. *GDAP1* might have a function in a signal transduction pathway in neuronal development (3, 4).

Lamin A/C Gene (*LMNA*; OMIM *150330)

A specific missense mutation in *LMNA* has been linked to autosomal recessive axonal CMT (CMT2B1). Different mutations in *LMNA* cause several other disorders, including Emery-Dreyfuss muscular dystrophy and Hutchinson-Gilford progeria. *LMNA* is a nuclear membrane structural protein that can be classified with the intermediate filament polypeptides (3, 4).

SET Binding Factor 2 Gene (*SBF2*) / Myotubularin Related Protein 13 (*MTMR13*; OMIM *607697)

Mutations in *SBF2*/*MTMR13* have been associated with CMT4B2, a recessive demyelinating peripheral neuropathy with focally folded myelin associated with early-onset glaucoma. *SBF2*/*MTMR13* is a member of the pseudo-phosphatase branch of myotubularins, since it contains inactivating substitutions at the catalytic cysteine (4).

Small Integral Membrane Protein of Lysosome/Late Endosome (*SIMPLE*) (OMIM *603795)

CMT type 1C is associated with missense mutations in *SIMPLE*. The protein may play a role in protein degradation pathways (4).

Small GTP-ase Late Endosomal Protein (*RAB7*; OMIM *602298)

Mutations in *RAB7* are associated with CMT type 2B, an ulcero-mutilating neuropathy. *RAB* proteins are important regulators of vesicular transport and are located in specific intracellular compartments. *RAB7* has been localized to late endosomes and shown to be important in the late endocytic pathway (4).

Solute Carrier 12 (Potassium/Chloride Transporter), Member 6 (*SLC12A6*; OMIM *604878)

Mutations in *SLC12A6* are associated with peripheral neuropathy with agenesis of the corpus callosum, also known as Andermann syndrome. The protein, a K^+ - Cl^- cotransporter, is involved in the electroneutral movement of ions across the plasma membrane (4).

Glycyl t-RNA Transferase (*GARS*; OMIM *600287)

Missense mutations in *GARS* were found in families with CMT2D and distal HMN V (distal SMA V). Aminoacyl-tRNA synthetases perform an essential function in protein synthesis by catalyzing the esterification of an amino acid to its cognate tRNA (4).

Genes Associated with HMN

Immunoglobulin mu Binding Protein 2 Gene (*IGHMBP2*; OMIM *600502)

Distal HMN type VI, also called spinal muscle atrophy with respiratory distress type 1 (*SMARD1*), results from mutations in the *IGHMBP2* gene. *IGHMBP2* is a transcription factor with a function important to motor neuron maintenance and integrity (4).

Glycyl t-RNA Transferase (*GARS*)

See above.

Dynactin 1 (*DCTN1*; OMIM *601143)

A missense mutation in *DCTN1* was identified in patients with distal HMN with vocal fold paralysis. *DCTN1* encodes the largest subunit of the axonal transport protein dynactin. The mutation is predicted to distort the folding of dynactin's microtubule-binding domain (4).

Genes Associated with HSN

Neurotrophic Tyrosine Kinase Receptor Type 1 Gene (*NTRK1*; OMIM *191315)

HSN type IV or congenital insensitivity to pain and anhidrosis (*CIPA*), is associated with mutations in *NTRK1*. Neurotrophins and their receptors play an important role in regulating development of the nervous systems (4).

Serine Palmitoyl transferase, Long Chain Base Subunit 1 Gene (*SPTLC1*; OMIM *605712)

HSN type I is caused by missense mutations in *SPTLC1*. Serine palmitoyl transferase is the key enzyme in sphingolipid biosynthesis. The mutations in *SPTLC1* are associated with increased *de novo* glucosyl ceramide synthesis in lymphoblast cell lines in affected individuals. Increased *de novo* ceramide synthesis triggers apoptosis and is associated with massive cell death during neural tube closure, raising the possibility that neural degeneration in HSN I is due to ceramide-induced apoptotic cell death (4).

Inhibitor of Kappa Light Polypeptide Gene Enhancer in B-cells, Kinase Complex-associated Protein Gene (*IKBKAP*; OMIM *603722)

HSN type III, also known as familial dysautonomia or Riley-Day syndrome, is observed predominantly in the Ashkenazi Jewish population. The condition is characterized by widespread sensory and variable autonomic

dysfunction. HSN III is caused by mutations in IKBKAP, a scaffold protein and a regulator for 3 different kinases involved in proinflammatory signaling (4).

Molecular Diagnostics

The analysis of the CMT1A duplication is the initial step in a diagnostic evaluation of a suspected hereditary neuropathy patient. The reciprocal HNPP deletion is usually detected in this test. It is important to include the deletion analysis in the first test since HNPP patients sometimes present with symptoms similar or identical to CMT type 1. Two groups of methods are used, binary methods resulting in a “yes” or “no” answer and dosage sensitive or other methods.

Binary Methods

These methods include the detection of junction fragments by restricted genomic DNA and pulsed field gel electrophoresis (►PFGE) as well as fluorescence *in situ* hybridization (►FISH).

PCR Methods Based on Simple Tandem Repeat (STR) Markers

For STR based methods several protocols for multiplex ►PCRs are available. At least two of the markers should be positive for three alleles to be indicative of the CMT1A duplication. The HNPP deletion may be suspected when several polymorphic markers reveal only one allele (hemizygosity or homozygosity). Quantitative methods are now available using real-time quantitative PCR that allow direct quantification of the product during the amplification. These methods are highly sensitive for dosage differences but need a very careful calibration with a large number of controls.

Mutation Screening in Candidate Genes

If the CMT1A duplication/HNPP deletion is excluded, screening for mutations in candidate genes may follow. Due to the large number of mutations in different genes, a detailed clinical, genetic, electrophysiological and neuropathological record of the patient should be available to orient the genetic testing.

In order to identify mutations within coding regions of candidate genes several screening methods have been applied. The most common ones are single strand conformation polymorphism analysis (►SSCP), heteroduplex analysis and denaturing high-performance liquid chromatography (►dHPLC). Screening large numbers of patient samples is often performed by these screening methods and is useful for validation of known mutations. To overcome the difficulties with sensitivity, DNA sequence analysis is the state of the art technique for diagnostic purposes.

Hereditary Nonpolyposis Colorectal Cancer

PÄIVI PELTOMÄKI

Department of Medical Genetics, University of Helsinki, Helsinki, Finland
paivi.peltomaki@helsinki.fi

Synonym

Lynch syndrome

Definition

Based on clinical features and family history, hereditary nonpolyposis colorectal cancer (►HNPPCC) (MIM No.

120435-6) is an autosomal dominant disorder, characterized by the development of cancers of the colon and rectum, endometrium, and to lesser extent other organs, at an early age (1). Molecular definition of the syndrome additionally requires that there is evidence of a DNA mismatch repair (►MMR) defect.

Characteristics

Historical Perspectives

HNPCC was first described by Dr. Aldred Warthin in 1913. Dr. Henry Lynch, working with A. Krush, updated the original family ("Family G") in 1971. In 1990, the newly established International Collaborative Group on HNPCC (►ICG-HNPCC) agreed on operational diagnostic criteria for HNPCC, referred to as Amsterdam criteria I, to provide uniformity in collaborative studies. In 1993, a Finnish-American collaborative group localized the first HNPCC susceptibility gene on chromosome 2, establishing that HNPCC is a single-gene Mendelian disorder and providing a reliable molecular marker for HNPCC susceptibility. To date, nine human DNA mismatch repair genes have been isolated, including three major genes, *MSH2*, ►*MLH1*, and *MSH6*, associated with HNPCC predisposition.

Prevalence

HNPCC is among the most common hereditary diseases in man and the most common hereditary disorder predisposing to colorectal cancer. Based on clinical criteria, it is estimated to account for up to 13% of all colorectal cancers. Molecular estimates based on germline mutation carriers among consecutive patients with colorectal cancer have arrived at somewhat lower figures (0.3–3% of the total colorectal cancer burden).

Clinical Features

The most stringent diagnostic criteria for HNPCC (Amsterdam criteria I) require that at least three close relatives (one of which is a first-degree relative - parent, sibling, child - of the other two) are affected with colon cancer in two successive generations and the age at diagnosis is below 50 years in at least one. In addition to colon cancer, HNPCC patients often have an excess of extracolonic cancers. Of these, endometrial cancer, and cancer of the small intestine, ureter, or renal pelvis are considered to be highly specific for HNPCC and are recognized in the revised, less stringent diagnostic criteria for HNPCC (Amsterdam criteria II), besides colon cancer. Other cancers that are common in HNPCC include cancers of the stomach, ovary, and hepatobiliary tract.

Hereditary Nonpolyposis Colorectal Cancer.

Table 1 Clinical syndromes associated with germline mutations in DNA mismatch repair genes

Syndrome	Tumor site	Predisposing gene
HNPCC	Colon, endometrium, small bowel, ureter/renal pelvis, stomach, ovary, hepatobiliary tract	<i>MLH1</i> , <i>MSH2</i> , <i>MSH6</i> (<i>PMS2</i> , <i>MLH3</i>)
Muir-Torre	Sebaceous glands and sites typical of HNPCC	<i>MSH2</i> (<i>MLH1</i>)
Turcot	Brain and colorectum	<i>MLH1</i> , <i>PMS2</i>

Hereditary Nonpolyposis Colorectal Cancer.

Table 2 HNPCC-associated human MMR genes and their contribution to HNPCC predisposition

Gene	Chromosome	No. of mutations (%)
<i>MLH1</i>	3p21-23	225 (50%)
<i>MSH2</i>	2p21	175 (39%)
<i>MSH6</i>	2p21	32 (8%)
<i>PMS2</i>	7p22	5 (1%)
<i>MLH3</i>	14q24.3	16 (2%)

Two variant forms of HNPCC are known, Muir-Torre syndrome and Turcot syndrome, which, like classical HNPCC, are associated with germline mutations in MMR genes (Table 1). Muir-Torre syndrome is characterized by the occurrence of sebaceous gland tumors together with HNPCC type internal malignancy. In Turcot syndrome, primary brain tumors (usually glioblastomas) are associated with multiple colorectal adenomas or carcinomas. On the molecular level, Turcot syndrome overlaps with both HNPCC (the subset with MMR gene mutations) and ►*FAP* (the subset with ►*APC* mutations).

Cellular and Molecular Regulation

Susceptibility Genes

At present, four (*MSH2*, *MLH1*, *MSH6*, ►*PMS2*), possibly five (*MLH3*) human MMR genes are known, whose germline mutations cause predisposition to HNPCC (Table 2). The international collaborative group on HNPCC, currently known as InSiGHT (International Society for Gastrointestinal Hereditary

Tumors), maintains a database of mutations associated with susceptibility to this disorder (2; ►<http://www.insight-group.org>). To date, more than 450 different predisposing mutations are known that occur in over 700 families from all over the world. Of all HNPCC-associated mutations, 50% affect *MLH1*, 39% *MSH2*, and 9% affect *MSH6*, whereas the share of *PMS2* and *MLH3* is only a few percent.

Generally, *MSH2* and *MLH1* mutations give rise to typical HNPCC. The overall lifetime cancer risk associated with germline mutations of these genes is around 90%. *MSH6* mutations are found in both typical and atypical HNPCC families with a frequent occurrence of endometrial cancer. *PMS2* mutations are mainly associated with the Turcot variant and their penetrance may vary. More data are necessary to evaluate the role of *MLH3* in HNPCC predisposition; according to preliminary experience, *MLH3* mutations mostly occur in atypical HNPCC families.

DNA Mismatch Repair Defect in HNPCC

The primary function of the protein products of the MMR genes is to correct ►single nucleotide mismatches and ►insertion/deletion loops that may arise during DNA replication. Failure to accomplish this function results in elevated (~100-fold) rates of point mutations as well as instability at repetitive tracts

(►microsatellites), termed as microsatellite instability (►MSI) (3). Increased mutational load and microsatellite instability (appearing as extra alleles as compared to paired normal tissue) are typical features of tumors from HNPCC patients.

Human MMR requires at least six different MMR proteins (4; Fig. 1, left panel). For mismatch recognition, the *MSH2* protein forms a heterodimer with either *MSH6* or ►*MSH3* depending on the type of lesion to be repaired: *MSH6* is required for the correction of single-base mispairs while both *MSH3* and *MSH6* may contribute to the correction of insertion-deletion loops. A heterodimer of *MLH1* and *PMS2* coordinates the interplay between the mismatch recognition complex and other proteins necessary for MMR. Besides *PMS2*, *MLH1* may interact with *MLH3* and *PMS1*. Recent observations suggest that *PMS2* is required for the correction of single base mispairs while both *MLH3* and *PMS2* contribute to the correction of insertion-deletion loops. The role of the *MLH1*-*PMS1* complex in MMR needs to be clarified.

A majority of HNPCC-associated MMR gene alterations are ►frameshift or ►nonsense mutations that lead to truncated proteins, although for *MLH1* and *MSH6* in particular, ►missense mutations are also common. Such mutations typically result in the loss of important interaction domains (truncating mutations) or changes

Hereditary Nonpolyposis Colorectal Cancer. Figure 1 Normal and defective DNA mismatch repair.

in the local structure or conformation (missense mutations) that impair the ability of the proteins to interact with their partners or other components of the MMR pathway, or otherwise properly accomplish the MMR function (Fig. 1, right panel).

Tumorigenesis and Pathology

HNPCC tumors, as well as sporadic colorectal carcinomas with high-degree of MSI (~15% of all colorectal cancers), show common clinicopathological features, whose molecular or cellular mechanisms are only partly understood. These characteristics include predilection for the proximal colon, diploid DNA content, high histological grade, high mucin content, marked host-lymphocytic infiltration, association with female sex and better survival.

Adenomas, the precursor lesions of colon cancers, are not more frequent in HNPCC patients than in the general population, but they are more likely to undergo malignant transformation due to the accumulation of mutations as a result of MMR deficiency. Hence, HNPCC is viewed as a disease of progression. Non-neoplastic cells (such as those from blood) that carry one normal and one defective copy of a given MMR gene are still MMR-proficient, but when the wild-type copy is lost or acquires somatic mutations, as occurs in tumor precursor cells, the cells become MMR-deficient. Apart from anonymous microsatellites, hypermutability in HNPCC affects important growth-regulatory genes, especially those containing repeat sequences as mutation targets (e.g. *TGF β RII*, *BAX*, *MSH3* and *MSH6*), thus providing a driving force for cancer development and progression ("mutator pathway") (5).

Clinical Relevance

Cancer Surveillance

Colonoscopy screening every 1–2 years, beginning at age 20–25, is recommended for mutation carriers or at-risk individuals from HNPCC families. It has been demonstrated that colonoscopy screening and removal of precursor lesions, adenomas, significantly reduces morbidity and mortality in such families. Surveillance for extracolonic cancers is also indicated, notably for endometrial cancer (through regular pelvic examination and transvaginal ultrasound or endometrial aspirate).

Diagnostics

The detection of a predisposing mutation in an HNPCC family is important since it makes it possible to focus cancer screening and surveillance on those members truly at increased risk, namely mutation carriers. MSI analysis and/or immunohistochemical staining for MMR protein expression offer useful preliminary tests

for MMR gene involvement. Loss of a specific MMR protein by immunohistochemical analysis of tumor tissue can pinpoint the defective gene and provide a basis for screening that gene for possible mutations in blood DNA (or RNA). For most cases, exon-by-exon sequencing is the method of choice for detecting mutations in *MSH2*, *MLH1*, and *MSH6*, and results in the identification of predisposing changes in up to two-thirds of families. As many as one-fifth of HNPCC families may have large genomic deletions or duplications in MMR genes, and the identification of such alterations requires more complex technology (e.g. multiplex ligation-dependent probe amplification or ▶ [Conversion technology](#)).

There is increasing evidence that a proportion of families clinically presenting with HNPCC are not associated with MMR defects and have an as yet unknown molecular etiology. The absence of MSI, combined with normal MMR protein staining, is a strong indication against MMR gene involvement.

Drug Sensitivity or Resistance

Detection of a MMR defect may provide an important piece of information to guide clinical management of the patients. For example, malfunction of the MMR system may modify the response to cytotoxic drugs; cancers with MSI may be particularly sensitive to 5-fluorouracil and other antimetabolites, whereas the same tumors show increased resistance to alkylating agents. It is speculated that 5-fluorouracil, which acts as a competitive inhibitor for substrates critical for DNA synthesis, may work in concert with MMR deficiency and enhance apoptosis in these cells. The resistance of MMR-deficient cells to alkylating agents may result from the fact that defective MMR proteins are unable to detect alkylation adducts and consequently, fail to induce apoptosis.

Hereditary Spastic Paraplegia

EVAN REID

Department of Medical Genetics, University of Cambridge, Cambridge, UK
ereid@hgmp.mrc.ac.uk

Synonyms

Familial spastic paraplegia; Strümpell disease

Definition

The principal neurological pathway over which signals pass to drive a deliberate movement can be divided into 2 stages. In the first stage, a descending connection is made from neurons in the motor cortex of the brain (often referred to clinically as “►upper motor neurons”) to cells in the anterior and posterior horns of the spinal cord, while in the second stage “►lower motor neurons” in the anterior horn of the spinal cord connect to the skeletal muscles at the neuromuscular junction. The axons that project from the upper motor neuron cell bodies to the spinal cord constitute the corticospinal tract and this tract is “crossed”, so that upper motor neurons in the motor cortex of one side innervate lower motor neurons on the opposite side of the spinal cord. A wide variety of insults to the corticospinal tract result in ►spastic paralysis. The ►hereditary spastic paraplegias (HSPs) are ►single gene disorders in which the axons of the corticospinal tract either fail to develop

normally, or show progressive degeneration after initial normal development.

Characteristics

All HSPs share the principal clinical feature of progressive lower limb spastic paralysis. They are conventionally subdivided into pure and complicated forms, depending on the absence or presence of additional neurological or non-neurological features (1).

Pure HSPs

Pure hereditary spastic paraplegia is probably the single largest subgroup of HSP conditions. A majority of pure HSP (PHSP) families show autosomal dominant inheritance, with autosomal recessive inheritance accounting for most of the remainder. X-linked recessive inheritance is very rare. Histopathological studies of pure HSP show a length dependent “dying back” of the terminal ends of the corticospinal tract axons, with longest axons involved first, suggesting that these conditions might provide useful models for understanding the molecular factors involved in normal maintenance of the corticospinal tracts.

Complicated HSPs

The complicated HSPs comprise a large number of conditions in which spasticity is accompanied by other features such as muscle wasting, mental retardation, epilepsy, cerebellar signs, extrapyramidal movement disorder, optic atrophy, pigmentary retinopathy or ichthyosis. Unlike PHSP, they are most commonly inherited in an autosomal recessive pattern, although autosomal dominant and X-linked inheritance can occur.

Cellular and Molecular Regulation

The hereditary spastic paraplegias show extreme genetic heterogeneity. The 20 HSP genes that have been mapped to date are shown in Table 1. Eight of these genes have now been identified and their pathological mechanisms can tentatively be divided into 4 groups.

Cell Recognition and Signalling: L1-CAM

The cell adhesion molecule L1 (L1-CAM) is a cell-surface membrane-associated glycoprotein that is a member of an immunoglobulin superfamily. Mutations in L1-CAM are found in a form of X-linked complicated (by mental retardation and absence of the extensor pollicis longus muscle) spastic paraplegia termed SPG1, in MASA (mental retardation, aphasia, shuffling gait, adducted thumbs) syndrome and in X-linked hydrocephalus (2). Over 90 different mutations, of varying forms, in the L1-CAM gene can cause these conditions.

Many of the mutations are predicted to eliminate expression of L1-CAM, although some ►**missense mutations** affect particular functions of the protein. L1-CAM is expressed throughout the nervous system on populations of developing and differentiated neurons, as well as in Schwann cells in the peripheral nervous system. *In vitro* studies have suggested that, along with several other functions, L1 interactions may mediate axon bundling and may be involved in the processes of neurite extension and axonal guidance. L1-CAM knockout mice show phenotypes similar to the human L1-CAM associated conditions, including disruption of the normal anatomy of the corticospinal tracts, where impaired axonal pathfinding results in failure of the normal crossing over of the tracts in the medulla.

L1 CAM sits at the centre of a complex set of extracellular and intracellular interactions and it binds to a wide variety of extracellular ligands (2). Binding of L1-CAM to other L1-CAM molecules (i.e. ►**homophilic binding**) promotes cell adhesion and neurite outgrowth. This may be influenced (positively or negatively) by interaction with other potential ligands. The molecule is linked to a number of intracellular signalling pathways. Key amongst these is its interaction with fibroblast growth factor receptors (FGFRs), membrane associated molecules that have intracellular tyrosine kinase signalling domains. Homophilic binding of L1-CAM stimulates FGFR tyrosine kinase activity, which in turn stimulates Ca^{2+} influx, resulting in modification of the axonal growth cone by a mechanism that is not yet entirely clear. L1-CAM also has important interactions *via* its cytoplasmic domain, notably with ankyrin, a linker protein of the spectrin-based cytoskeleton, so that homophilic binding may cause re-organisation of the cytoskeleton.

Abnormalities of Myelination: Proteolipid Protein

Mutations in the *proteolipid protein gene* (PLP1) can cause pure or complicated HSP (SPG2), or the much more severe Pelizaeus-Merzbacher disease (PMD) (3). Several missense mutations in the gene are associated with HSP, whereas PMD is associated with other missense mutations or, more commonly, with duplications of the entire gene. The PLP1 gene codes for 2 myelin proteins, PLP and DM20. There is a correlation between PLP1 gene mutation and phenotype, with point mutations that affect highly conserved DM20 amino acid residues being associated with the most severe PMD phenotypes. The PLP and DM20 proteins are thought to play a major role in oligodendrocyte maturation and also form structural components of the myelin sheath. The precise mechanism by which certain missense mutations in the PLP1 gene cause spastic paraplegia is not clear. MRI studies in human

SPG2 families demonstrate central nervous system white matter abnormalities reminiscent of the pathological changes found in the rumpshaker natural mouse mutant model of SPG2, which shows hypomyelination with reduced levels of PLP, but not DM20. It seems likely that perturbations of corticospinal tract myelination, perhaps accompanied or caused by abnormal trafficking-induced toxic effects on oligodendrocytes, may contribute to spasticity in SPG2.

Abnormalities of Mitochondrial Molecular Chaperones: Paraplegin and HSP60

Mutations in the *paraplegin* gene (SPG7), at chromosome 16q24, are associated with pure or complicated (by optic, cortical or cerebellar atrophy) autosomal recessive HSP (4). *Paraplegin* is a mitochondrial metalloprotease and a member of the AAA (ATPases associated with diverse cellular activities) protein family. Members of this large family of proteins are characterised by the presence of one or two copies of a 220–250 amino acid long sequence motif, the AAA cassette. Members of the AAA family of proteins are proven or putative ATPases that take part in many cellular functions, including cell-cycle regulation, protein degradation in the 26S proteasome, organelle biosynthesis, membrane fusion and intracellular membrane trafficking events. HSP patients with *paraplegin* mutations have defects in mitochondrial oxidative phosphorylation. The precise mechanism of action of paraplegin has not been characterised. However, it has a high degree of homology to a mitochondrial subclass of yeast and fungal ATPases that have proteolytic and ►**chaperone**-like activities at the inner mitochondrial membrane. These proteins may participate in protein “quality control”, degrading misfolded proteins in the mitochondrial intermembrane space. Yeast and fungi lacking the respective paraplegin homologues Yme1 or *iap-1* have defective respiration under certain conditions, with yeast accumulating abnormally formed mitochondria. By analogy, it has been suggested that defects in paraplegin may cause an accumulation of abnormally synthesised mitochondrial proteins, leading to mitochondrial respiratory dysfunction and eventual axonal degeneration.

A missense mutation in the mitochondrial chaperone heat shock protein HSP60 has been found in the original family used to map the chromosome 2q autosomal dominant pure HSP (SPG13) locus. Elegant complementation studies demonstrated that the mutant has a functional effect and so it is highly likely that abnormalities of this gene can cause HSP. The pathological mechanism of the mutation is not yet clear and may involve loss of function or a dominant negative effect on the multimeric chaperone complex in which HSP60 participates.

Defects of Intracellular Molecular Trafficking: KIF5A, Spartin, Spastin and Atlastin

The most direct evidence for the pathological involvement of HSP proteins in intracellular membrane traffic events comes from the identification of a mutation in the kinesin heavy chain gene KIF5A in a family with autosomal dominant pure HSP (SPG10). Deletion of the [orthologous](#) kinesin heavy chain genes of several

species causes movement defects reminiscent of human spastic paraplegia. KIF5A is a member of the kinesin superfamily and forms part of a conventional kinesin-1 motor, a molecular complex that transports membrane-bound cargoes on microtubules in an ATP dependent fashion. Kinesins have been implicated in multiple membrane traffic events, including transport from the Golgi to endoplasmic reticulum, from the trans-Golgi

network to the plasma membrane or endosomes and, in neurons, in fast anterograde axonal transport (5). KIF5A is a neuronal specific kinesin and is localised diffusely in mouse motor and sensory neuronal bodies. Its precise cellular function and sites of action are not known.

Mutations in the chromosome 2p24 HSP gene *spastin* (SPG4) are responsible for approximately 40% of autosomal dominant pure HSP. More than 100 spastin mutations have been described, including numerous missense, ►nonsense, ►frameshift, and ►splice site mutations, as well as less frequent large-scale deletions. Although not entirely certain, the broad mutational spectrum observed in spastin-associated HSP suggests that the molecular pathological mechanism in most cases is likely to be loss-of-function, with disease occurring once functioning spastin levels fall below a critical threshold level. Tolerance for reduced dosage of functioning spastin may be very low, since some “leaky” (i.e. creating both wild type and aberrant splice variants) splice site mutations result in only slight reductions in wild type mRNA expression. Initial sequence analysis was not helpful in identifying a functional role for the spastin protein, since it placed it in a subgroup of the AAA family, members of which participate in many different cellular processes (see above). It has been suggested that spastin might have a microtubule severing effect, similar to related AAA proteins such as katanin. On the other hand, evidence based on recent sequence analysis has suggested that spastin may have a role in intracellular membrane traffic events (6). The identification of the *spartin* gene as the cause of Troyer syndrome, an autosomal recessive HSP complicated by dysarthria, distal amyotrophy, mild developmental delay and short stature, led to the delineation of a novel protein domain termed MIT (microtubule interacting and trafficking), present in spartin and spastin. This domain is also present in several proteins involved in membrane traffic events, including the yeast vacuolar sorting protein (VPS) VPS4 and its mammalian homologue SKD1, sorting nexin 15 (SNX15) and RPK118. Interestingly, VPS4/SKD1 is also an AAA protein, belonging to the same AAA family subgroup as spastin.

The chromosome 14q autosomal dominant pure HSP gene, *atlastin* (SPG3A) codes for a novel GTPase that has sequence homology to members of the dynamin family of large GTPases, particularly guanylate binding protein-1 (7). The dynamins are non-conventional motor molecules that take part in vesicle trafficking events, including recycling of synaptic vesicles and in the dispersion of mitochondria. *Atlastin* is widely expressed, most abundantly in brain and spinal cord, and codes for a protein of 558 amino acids. Mutations

in atlastin are responsible for approximately 10% of autosomal dominant pure HSP, and are particularly associated with childhood onset disease.

Clinical Relevance

Identification of the genes and corresponding proteins involved in HSP has significant implications for families affected by these conditions, where in some cases ►diagnostic gene testing and ►predictive gene testing can now be offered. In the long term and more widely, a full understanding of the function of molecular factors involved in corticospinal tract maintenance may eventually have implications for the treatment of more common diseases of the corticospinal tracts that cause spastic paralysis.

Definition

Keratin Disorders

Keratin disorders are a clinically and genetically heterogeneous group of ►Mendelian disorders with abnormal differentiation and desquamation of stratifying epithelia resulting from pathogenic mutations in more than 19 different ►keratin genes (1) (Fig. 1). Keratin defects may affect ►epidermis, hair, nails, sebaceous glands and mucous membranes. The nature and distribution of clinical features generally correspond to the function and expression pattern of the faulty keratin proteins. Because keratins are expressed in pairs that form obligate ►heterodimers, mutations in either gene generally produce a comparable ►phenotype resulting in ►genetic heterogeneity. Mutations are usually ►autosomal dominant and exert a deleterious, dominant-negative effect on the assembly of ►keratin intermediate filaments (KIF), causing weakening of the ►cytoskeleton and cell fragility, the hallmarks of keratin disorders (Fig. 2). At least 7 distinct clusters of mutations have been recognized, of which mutational ►‘hot spots’ at the beginning and end of the central rod domain are most common and consistently produce a severe phenotype (1). In addition, a few ►autosomal recessive mutations leading to the ‘►knock-out’ of a keratin in the basal epidermis have been described in ►epidermolysis bullosa simplex.

Characteristics

Introduction

Heritable skin disorders comprise a group of phenotypically diverse conditions with variable degrees of skin involvement. In some diseases, there is only a minor, occasionally cosmetic, involvement of the skin, hair and/or nails, whereas in other conditions, skin manifestations can be part of severe multi-system disorders with significant morbidity or even premature demise of the affected individuals. Over the past decade or so, with the advent of molecular genetics in general, spectacular progress has been made in understanding the genetic basis of many heritable skin diseases, and in

fact, mutations have now been identified in some 200 genes in these diseases (2).

Examination of the mutation database in genodermatoses has revealed a number of both predictable and surprising genes. In several conditions, the mutated genes could have been predicted, on the basis of clinical, histopathological, immunohistochemical and/or ultrastructural analysis, to serve as the candidate gene/protein systems. For example, certain genes encoding structural proteins, such as basal cell keratins 5 and 14, were predicted to serve as candidate gene/protein systems in skin fragility syndromes and this prediction is now shown to be true in case of epidermolysis bullosa simplex (EBS). At the same time, a number of mutated genes have turned out to be rather surprising and the exact relationship of the mutations in the affected genes and their consequences at the clinical and morphological level are not well understood. An example of such conditions is ►steatocystoma multiplex characterized by dermal cysts of the pilosebaceous origin, which is known to result from mutations in the keratin 17 gene.

As an example of the progress in understanding the molecular basis of heritable skin disorders, we will highlight keratin disorders as a paradigm for cell fragility and perturbed differentiation.

Epidermolysis Bullosa Simplex (EBS)

EBS was the first human keratin disorder to be discovered in 1991. It is a clinically heterogeneous, ►congenital blistering skin disorder due to fragility of basal cells of the epidermis. Three major subtypes have been recognized and share a common disease pathology with an abnormal KIF network, i.e. ►cytolysis of basal cells leading to intraepidermal blister formation and skin fragility, while the differentiation of keratinocytes in the upper layers of the epidermis remains largely undisturbed (1). The structural abnormalities result from faulty keratin-5/keratin-14 heterodimers due to mutations in their corresponding genes, *KRT5* and *KRT14*. These are the primary keratins synthesized by undifferentiated keratinocytes in the basal layer of the epidermis, corresponding with the sites of disease pathology in EBS. Clinical features and severity of EBS subtypes are determined by the nature and location of the underlying mutations in the basal keratin genes *KTR5* and *KRT14* (3).

EBS Dowling-Meara (EBS-DM) is a common and the most severe subtype manifesting at birth with erythema, widespread blistering, erosions and areas of denuded skin. Later in life, spontaneous development of grouped blisters and severe thickening of palms and soles (►palmoplantar keratoderma) prevail. Typically, pathogenic defects are ►heterozygous ►missense

Heritable Skin Disorders. Figure 1 Schematic diagram of keratin protein depicting the structural domains and common mutation sites. The non-helical head domain consists of E1, V1 and H1 (only in type II keratins). The α -helical rod domain is composed of 4 segments, 1A, 1B, 2A and 2B (with stutter-s), which are interrupted by non-helical linker domains L1, L12 and L2. H2 (only in type II keratins), V2 and E2 form the non-helical tail domain. The highly conserved helix initiation and termination motifs, which are mutational hot spot regions, are shown in pink. Common sites of dominant mutations are depicted above the diagram. The height of bars reflects the relative frequency of mutations.

mutations clustering at 2 regions that encode the highly conserved boundaries of the alpha-helical rod domain of keratin 5 or keratin 14 (Fig. 1). An arginine codon of the ►helix initiation peptide in keratin 5 (R125) is most commonly mutated, probably because it contains a hypermutable ►CpG dinucleotide (4). While most keratin gene mutations in EBS are dominant, recessive *KRT14* mutations have been identified in 6 families, encompassing predominantly nonsense and splice site mutations leading to premature termination of protein translation and ablation of the affected keratin. While the 'knock-out' of *KRT14* usually results in severe EBS-DM, 2 mutations were noted to have a milder phenotype with minimal extracutaneous involvement. The Köbner variant of EBS (EBS-K) is characterized by milder blistering of the skin without apparent clustering, predominantly involving hands, feet and extremities. *KRT5* or *KRT14* mutations appear more widely distributed across the keratin polypeptides and may lie within and outside the highly conserved helix boundaries as well as in non-helical linker segments (1, 4) (Fig. 1).

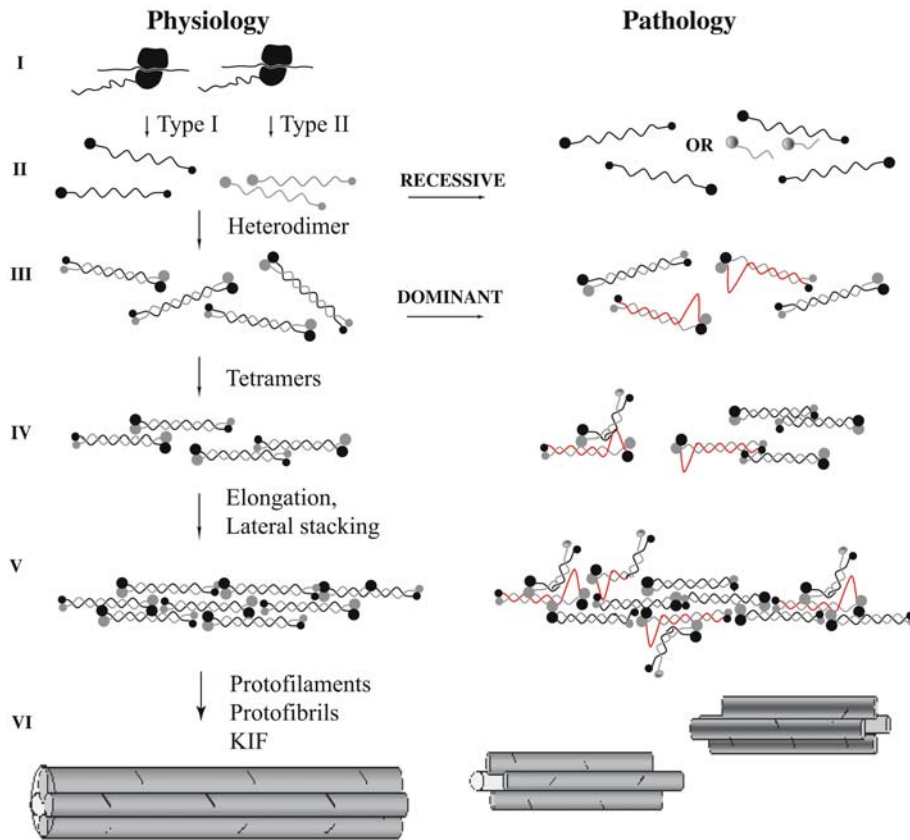

The most common Weber-Cockayne subtype (EBS-WC) is a mild, localized variant, in which serous blisters are confined to the hands, feet and areas of friction or trauma. In contrast to the other EBS subtypes, blisters are usually not present at birth but develop later

in response to mechanical irritation of the skin. In this mild form of EBS, pathogenic mutations lie in principle outside the helix boundaries in the rod domain of K5 or K14 or in the amino-terminal homologous domain of K5. Dominant point mutations usually result in amino acid substitutions, but small ►in-frame deletions in *KRT14* have also been described (1, 4).

A rare form of EBS with generalized or acral blistering and small, hyper- and hypo-pigmented spots that form a reticulate pattern has been reported as EBS with mottled pigmentation (EBS-MP). This variant is also associated with thickened, dystrophic nails and punctate PPK. The molecular basis of EBS-MP is a heterozygous missense mutation in exon 1 of *KRT5* that results in substitution of proline 25 with leucine (P25L) in the non-helical head domain of K5. This mutations was consistently detected in each of 7 unrelated families tested to date (4).

Epidermolytic Hyperkeratosis (EHK; Bullous Congenital Ichthyosiform Erythroderma of Brocq; Bullous Ichthyosis)

This autosomal dominant congenital ►ichthyosis manifests with erythroderma and widespread areas of erosions and denuded skin. While skin fragility decreases with age, patients develop progressively

Heritable Skin Disorders. Figure 2 Physiology and pathophysiology of keratin intermediate filaments (KIF). The syntheses of type I and type II keratin polypeptides and their assembly into keratin intermediate filaments are depicted on the left side of the figure. The keratin mRNAs are translated on the ribosomes of epithelial cells, which synthesize these keratins (I). In the cytoplasm, a type I and a type II keratin polypeptide align in parallel and register (II) and oligomerize to obligate heterodimers (III). Pairs of heterodimers align in an antiparallel, mostly overlapping fashion to tetramers (IV), which subsequently polymerize to elongated chains packed into keratin intermediate filaments (V). The presence of a mutation in a keratin gene can lead to different pathological processes depicted on the right side of the figure. For example, mutations that introduce a premature termination codon or affect mRNA splicing may result in the synthesis of truncated polypeptides. Subsequent nonsense-mediated mRNA decay or enhanced degradation of the truncated polypeptide results in absence of the mutant protein and lack of formation of corresponding heterodimers and KIF, usually associated with severe disease (EBS-DM) (I). Alternatively, the truncated or altered keratin polypeptides can prevent the heterodimer formation and KIF assembly (II). In autosomal dominant keratin disorders, the majority of mutations result in non-conservative amino acid replacements at sites of high sequence conservation (helix boundaries). The mutant keratin polypeptides interfere in a dominant negative manner with head-to-tail interactions and proper alignment of heterodimers (IV) as well as elongation and lateral packing during KIF assembly (V), thus producing a severe phenotype. Mutations with a less severe phenotype reside outside the helix boundaries and may have a more subtle effect on KIF assembly or affect keratin phosphorylation or interaction with other proteins.

severe hyperkeratosis with a verrucous, ridged or cobblestone surface. However, there is considerable phenotypic variability giving rise to at least six clinical subtypes. Structural and ultrastructural abnormalities of keratinocytes are distinct and described as ‘▶**epidermolytic hyperkeratosis**’. The KIF are fragmented and clumped leading to cytolysis of the upper epidermis and small intraepidermal blisters, combined with massive thickening of the stratum corneum

(hyperkeratosis) and epidermis. Epidermolytic hyperkeratosis is caused by heterozygous mutations in the genes encoding keratin 1 and keratin 10 (*KRT1*, *KRT10*). These keratins are expressed in the differentiated suprabasal and granular layers of the epidermis, which are the sites of disease pathology in this disorder. Mutations in the keratin 1 gene are usually associated with severe palmoplantar keratoderma, whereas mutations in the keratin 10 gene spare palms

and soles because the gene is not expressed at these locations. About 50% of all cases harbor ►**sporadic mutations**. As with EBS, mutations cluster at the boundaries of the α -helical keratin rod (mutational ‘hot spots’) and represent predominantly missense mutations that alter conserved amino acid residues. Mutations in the remainder of the rod are rare and generally associated with a milder and often unusual phenotype, such as ‘cyclic ichthyosis with epidermolytic hyperkeratosis’ and ‘annular epidermolytic ichthyosis’. A third category of mutations is known to affect the variable head and tail domains of keratin 1 resulting in severe palmoplantar keratoderma and ►**ichthyosis hystrix Curth-Macklin** (5). Finally, postzygotic ►**somatic mutations** in *KRT1* or *KRT10* have been detected in patients with a mosaic variant of epidermolytic hyperkeratosis, which is characterized by typical skin lesions following the lines of Blaschko. Because mutations may also involve gonadal cells (►**germline mosaicism**), they can be transmitted from the germline to the offspring resulting in full-blown, generalized disease.

► **Ichthyosis Bullosa of Siemens (IBS; Ichthyosis Exfoliativa)**

This congenital ichthyosis overlaps with mild epidermolytic hyperkeratosis. Characteristics are superficially denuded areas described as ‘molting’ or ‘Mäuserung’, which develop due to superficial blistering and shedding of the stratum corneum. Histopathological abnormalities are similar to EHK but are limited to the granular cell layers, which express keratin 2e. The disorder is due to heterozygous missense mutations in the *KRT2e* gene clustered at sites corresponding to the boundaries of the rod domain of keratin 2e, which preferentially alter a glutamic acid codon (E493K) in the helix termination peptide (1, 4).

► **Epidermolytic Palmoplantar Keratoderma (EPPK)**

In this keratinopathy, epidermolytic hyperkeratosis and occasional blistering are mostly confined to palmar and plantar skin. Typically, a sharp, erythematous border surrounds the waxy-appearing thickened skin of palms and soles. The sites of skin pathology correspond with the expression pattern of keratin 9 and disease-causing missense mutations have been identified in the *KRT9* gene, all of which cluster at the helix initiation motif (1, 4).

► **Pachyonychia Congenita (PC), Focal Non-epidermolytic Palmoplantar Keratoderma and Steatocystoma Multiplex**

PC is characterized by thickened, hard, convex nails, variably associated with follicular hyperkeratosis and plaque-like hyperkeratosis of palms and soles (focal

palmoplantar keratoderma). In PC type I, focal PPK is severe and oral leukokeratosis is common. This variant is caused by germline mutations in the genes encoding the keratin pair K6a and K16. In PC type II, patients often have natal teeth, hoarseness and pili torti as well as multiple steatocysts (dermal cysts arising from the pilosebaceous unit), which appear after puberty. Molecular changes are consistently detected in the co-expressed K6b and K17 genes. Interestingly, *KRT16* mutation may also result in isolated focal PPK and *KRT17* mutations may lead to steatocystoma multiplex, an autosomal dominant disorder with pilosebaceous cysts without other associated features, underscoring the phenotypic variability of the disease phenotype (4).

► **Monilethrix**

This congenital hair disorder manifests with fragile, easily breakable hair resulting in alopecia and short stubble of hair. On microscopic examination, hair shafts appear beaded (moniliform) due to alternating constrictions and elliptical nodes. Other features include follicular hyperkeratosis, especially on the nape of the neck, scalp, and sometimes the extremities, and nail dystrophy. Monilethrix results from missense mutations in the keratin genes *hHb1* and *hHb6*, which encode basic ‘hard’ or ‘trichocyte’ keratins specifically expressed in the hair cortex (4).

Other Keratinopathies

Following the paradigm of keratin disorders of the skin and its adnexae, mutations in other tissue-specific keratin genes have been detected. An example is ►**Meesmann corneal dystrophy**, a congenital, superficial keratitis with formation of corneal epithelial microcysts that may lead to photophobia, contact lens intolerance and recurrent decline of visual acuity. Keratin gene mutations affecting the helix boundary motifs were detected in *KRT3* and *KRT12*, both of which are co-expressed in the stratifying corneal epithelium. Another example is mutations in the mucosal keratin genes *KRT4* and *KRT13* resulting in ►**white sponge nevus**, a congenital disorder with benign, ‘spongy’ hyperkeratosis (leukokeratosis) of the mucous membranes of mouth, tongue, esophagus, nasopharynx, urogenital and anal regions (4).

Cellular and Molecular Regulation

Keratin proteins are the major constituents of epithelial cells, representing up to 85% of the cellular protein. They represent a large family of over 49 proteins that form intermediate filaments and are expressed in tissue and differentiation specific patterns (5). Keratins are expressed in pairs of acidic (type I) and basic (type II)

proteins, the genes of which cluster on chromosomes 17q12-q21 and 12q11-q13. Keratin monomers are organized as a central, alpha-helical rod domain flanked by variable, non-helical head and tail domains (Fig. 1). They form obligate heterodimers, which polymerize and assemble into intermediate filaments. The discovery of keratin gene mutations in numerous cell fragility disorders has fostered our understanding that keratins are important cytoskeletal proteins providing the structural stability and flexibility of epithelial cells. To date, over 80 distinct mutations have been identified in *KRT5* and *KRT14* in EBS, and over 36 distinct pathogenic mutations in *KRT1* and *KRT10* in EHK. This wealth of data has been instrumental in recognizing the specific functions of keratins and individual protein domains as well as for [▶genotype-phenotype correlations](#). For example, we have learned that the site and pathology of human keratin disorders are primarily determined by the tissue and differentiation-specific expression profile of the faulty keratin as illustrated above. Disease severity, however, predominantly depends on the position of the altered amino acid residue (Fig. 1). Between 60% and 80% of all mutations in EBS and EHK, respectively, alter the conserved boundaries of the rod segment, known as helix initiation peptides and helix termination peptides, with half of them involving a conserved arginine codon in the helix initiation motif of type I keratins. Functional [▶in vivo](#) and [▶in vitro](#) studies demonstrated that the helix boundaries are zones of overlap between keratin heterodimers during filament assembly and that mutant keratin molecules perturb proper keratin alignment and thereby oligomerization, filament assembly and integrity (Fig. 2). Consequently, the KIF network is fragile, disrupted and less resistant to stress, thus compromising mechanical strength and cell integrity of the epidermis, leading to cytolysis, blistering and generally a severe phenotype. The age-dependent improvement of skin fragility observed in EBS might be attributable to the compensatory overexpression of the alternate (hyperproliferative) keratins 6 and 16 in affected skin. On the other hand, blistering and cell fragility in EHK and other suprabasal keratin disorders are in general less severe than in EBS because basal keratin proteins, which may persist throughout the differentiated cell layers, provide a KIF scaffold and reinforce the cytoskeleton. Other mutation sites, such as the homologous domain in the head of type II keratins or non-helical linker and stutter motifs are associated with a milder phenotype as mentioned earlier.

In contrast, keratin mutations outside the central rod segment, in the variable head and tail domains, often differ considerably in pathological features and pathogenesis. KIF appear normal and cell fragility or

cytolysis are not observed, confirming experimental *in vitro* observations that non-helical keratin tail domains are not necessary for KIF oligomerization, alignment and assembly. Since the keratin ends vary greatly in sequence and length between different members of the keratin family, they are thought to confer unique and perhaps tissue-specific properties. The tail domain of type II keratins, for example, might be instrumental in bundling of KIF, anchorage of the cytoskeleton to the nucleus and interactions with loricrin, a major component of the cornified cell envelope (5). Certain areas of the keratin head have been shown to engage in interactions with loricrin and involucrin as well as desmosomal proteins. In addition, investigations of the proline 25 residue in K5 implicated in EBS with mottled pigmentation suggest that the keratin head domain binds directly to a cytoplasmic dynein cargo complex that transports melanosomes, thus unraveling the basis for abnormal pigment distribution in this rare disorder.

While the major molecular and cellular mechanisms leading to cell fragility and blistering in keratin disorders have been recognized, those responsible for hyperkeratosis remain to be elucidated. The mechanisms for inducing hyperproliferation and decreased desquamation of the epidermis are not well understood. Recent studies in patients and mouse models of EHK demonstrated a dramatic loss of [▶skin barrier](#) function with increased [▶transepidermal water loss](#) despite a normal-appearing stratum corneum. It is possible that the massive hyperkeratosis seen in many keratin disorders is a physical compensation to overcome this permeability barrier defect but the exact pathophysiological processes are still unknown.

Clinical Relevance

Advances in molecular genetics and biology of inherited skin disorders have impacted and benefit patient care already in different ways. Identification of specific mutations and genotype-phenotype correlations advance our ability to diagnose these rare disorders with certainty, allow accurate family counseling, offer the opportunity for reliable and early [▶prenatal testing](#) and will potentially lead to the development of targeted therapies for these disorders. DNA based mutation testing is available for numerous heritable skin disorders and has already provided means for recognizing and delineating the phenotypic spectrum of disorders, such as clinical subtypes of epidermolysis bullosa and EHK or in connexin disorders and establishing genotype-phenotype correlations (1, 2, 4). Molecular testing increasingly becomes a valuable tool to assist in early and reliable diagnosis in heritable disorders that are difficult to

distinguish solely on clinical grounds. This has important prognostic implications regarding the severity and natural course of the disease as well as preventive or therapeutic interventions where possible. Another direct benefit of molecular genetics relates to improved genetic counseling in families with increased ►[recurrence risk](#) for a disorder in the same or subsequent generations, especially when it is not possible to distinguish between autosomal dominant and recessive form of inheritance. Molecular testing in patients with sporadic, severe EBS-DM, for example, allows distinction of *de novo* occurring keratin mutations on one allele (autosomal dominant inheritance) from recessive keratin mutations on both alleles (autosomal recessive inheritance). In the first scenario, the risk of the parents having another affected child is very low whereas in the latter scenario the risk is one in four. At the same time, patients with a dominant, *de novo*, keratin gene mutation face a risk of 50% of having an affected child. Due to the low carrier frequency of EBS in the general population, the risk of having an affected child for a patient with recessive EBS is very small, barring consanguineous unions. Recognizing the specific molecular abnormalities underlying inherited skin disorders has tremendously advanced the development of DNA-based prenatal testing in families with severe forms of disease. Such testing is readily available for EBS, EHK and a wide range of other genodermatoses and can be performed in the first trimester of pregnancy, either from ►[chorionic villi samples](#) as early as the 10th week of gestation or from amniotic fluid from the 15th week on. Another newly developed method to determine the genotype of a fetus even before the pregnancy is established is ►[preimplantation genetic diagnosis](#), which is performed in conjunction with ►[in vitro fertilization](#). Together, these methods have replaced troublesome mid-trimester fetal skin biopsies and present for many disorders the only means of recognizing an affected fetus.

Finally, the elucidation of the molecular basis of inherited skin disorders provides essential information for understanding of the complex cellular mechanisms leading to disease with the ultimate goal of developing new and efficient therapeutic interventions. An important step in this process is the successful generation of animal models for these disorders. They may emulate the human disease phenotype and permit elucidation of the specific functions and contributions of individual proteins during embryological development and for physiological processes in a given tissue. In addition, animal models, such as those for EBS and EHK with targeted expression of mutant keratin chains in the epidermis, will be needed to evaluate various new therapeutic strategies. ►[Ex vivo](#) or *in vivo* gene

correction and gene and protein replacement approaches are currently under intense scrutiny for various genodermatoses, including keratin disorders, epidermolysis bullosa and recessive ichthyoses. Although much more time, effort and technological breakthrough will be needed to overcome the current problems with stem cell targeting, efficacy, long-term application, safety and other difficulties, durable gene therapy will undoubtedly become feasible for severe and debilitating genodermatoses in the future.

Heroin

Definition

Heroin (“smack,” “H,” “skag,” and “junk”) is a highly addictive drug. Street heroin is associated with serious health conditions. Heroin is processed from morphine, a naturally occurring substance extracted from the seedpod of the Asian poppy plant. Heroin usually appears as a white or brown powder. Heroin is injected, smoked or snorted. It is a misconception that the latter form of administration will not lead to addiction.

Heterochromatin

Definition

The eukaryotic genome is divided into euchromatin and heterochromatin, the latter representing a relatively

inaccessible form of chromatin that is structurally condensed and generally transcriptionally silent. Facultative heterochromatin defines chromatin that is capable of undergoing a transition between heterochromatic and euchromatic. According to the classical definition, it is a fraction of the chromatin that can be positively stained with Gimsa. From a cytogenetic point of view, heterochromatin is found around the centromeres and/or in the G-bands of metaphase chromosomes. It is rich in highly repetitive sequences, such as satellite DNA. More recently, the term heterochromatin has been used to indicate the transcriptionally inactive and highly compacted chromatin states.

Heterodimer/Heterodimeric protein

Definition

Heterodimer defines a protein consisting of two different polypeptide chains, which are encoded by two different genes.

- ▶ Heritable Skin Disorders
- ▶ Nucleotide Excision Repair

Heterogeneous, Genetically/ Heterogeneity, Genetic

Definition

The terms describe a single phenotype or disease with different genotypes that may originate from different mutations in one particular disease gene, or mutations in different genes.

- ▶ Atopy Genetics
- ▶ Heritable Skin Disorders
- ▶ Hereditary Hemostatic Defects and Recombinant Proteins for Treatment

Heterologous Inducers

Definition

During kidney development, unknown signals derived from the ureteric bud induce metanephric mesenchymal cells to differentiate into kidney tubules. In addition to the ureteric bud, a number of other tissues, so called heterologous inducers (for example embryonic spinal cord), can induce this process *in vitro*.

- ▶ Kidney

Heterologous Promoter Control

Definition

Heterologous promoter control refers to antigen-encoding sequences in genetic immunization, which are cloned into expression plasmids in which antigen expression is driven by strong viral promoter/enhancer sequences.

- ▶ DNA-based Vaccination

Heteronuclear NMR Experiments

Definition

Heteronuclear NMR experiments describe nuclear magnetic resonance (NMR) experiments in which the frequencies, and thus chemical shifts, of two or more different types of nuclei are recorded in the several dimensions of a multidimensional experiment.

- ▶ Multidimensional NMR Spectroscopy

Heteronuclear RNP Proteins

Definition

Heteronuclear RNPs (ribonucleoproteins) comprise of a large set of proteins that assemble on newly synthesized RNA and form an RNA-protein complex.

- ▶ Splicing

Heteronuclear Single Quantum Coherence

►HSQC

parent. A heterozygous individual with a mutated allele is also called a carrier.

Heteroplasmy

Definition

Heteroplasmy is a mixture within a cell of mutant and wild-type mitochondria.

- Hereditary Diseases Genetic Basis

Heterotrimeric Guanine Nucleotide-Binding Protein

Definition

A heterotrimeric guanine nucleotide-binding protein (G protein) is a complex of three proteins involved in signal transduction arising from activation of classical seven transmembrane-type receptors. Ligand binding to the G protein coupled receptor induces dissociation of the α and β - γ subunits, which then activate downstream pathways, e.g. adenylate cyclase and phospholipase C, respectively.

Heterozygote (Heterozygous)

Definition

A heterozygote (or heterozygous organism) is a diploid organism possessing two different alleles at a given gene locus under analysis, one inherited from each

Hexosamine

Definition

Hexosamine defines a six-carbon monosaccharide, where at least one of the OH groups is replaced by an NH_2 group, such as glucosamine and galactosamine.

- Glycosylation of Proteins

Hexose

Definition

Hexose is a six-carbon monosaccharide, such as glucose, galactose, and mannose.

- Glycosylation of Proteins

HFE

Definition

HFE is a gene located on human chromosome 6. The gene product of the HFE gene is homologous to major histocompatibility complex (MHC) class I proteins, but unlike MHC class I molecules, HFE lacks the usual peptide binding cleft of HLA molecules and does not present peptides to T cells. Mutations of this gene are present in homozygous form in most white patients with hemochromatosis. However, most persons who are homozygous for such mutations do not develop clinical hemochromatosis. Thus, the mutations may be thought of as risk factors, rather than the sole cause of the disease.

HIF-Prolyl-Hydroxylase

Definition

HIF-prolyl-hydroxylase is a member of the 2-oxoglutarate dependent hydroxylase family, which hydroxylates prolyl residues within the oxygen-dependent degradation domain of HIF- α , allowing binding of the von Hippel-Lindau (VHL) tumour suppressor protein (pVHL), which induces subsequent ubiquitination by an E3 ubiquitin-ligase and proteosomal degradation.

Hierarchical Clustering

Definition

Hierarchical clustering is a particular type of clustering, which results in a hierarchy of clusters, typically presented as a dendrogram of clustered objects.

► Microarray Data Analysis

High Content Screening

Definition

High content screening comprises cell based assays that collect multiple kinds of information from each well of microplates. This data can be any combination of multiple targets, phenotypes, and cell subpopulation activities or different cell types. In contrast to HCS, enabling single cell evaluations, High Throughput Screening (HTS) typically makes only one measurement per well as a cell population average.

High Mannose-Type

Definition

High mannose-Type is an N-glycan containing primarily mannose, which usually has multiple non-reducing terminal mannose residues.

► Glycosylation of Proteins

High Performance Liquid Chromatography

Definition

High performance liquid chromatography refers to various forms of chromatography, where sample compounds are separated at high pressure, resulting in mobile phase velocities that are 10–60 times greater than conventional chromatographic techniques. Components of a mixture are resolved according to their physical properties such as their size, shape, charge, hydrophobicity, and affinity. The compounds are partitioned between a liquid mobile phase and a stationary phase, packed within a column. The stronger a compound interacts with the stationary phase, the longer the retention time on the column.

High-Density Lipoprotein

Definition

High-density lipoprotein (HDL) is operationally defined as the class of lipoproteins from the serum isolated between 1.063–1.21 g/ml in ultracentrifugation. Large size of HDL is called HDL2 corresponding to 1.063–1.125 g/ml. Small size of HDL is called HDL3 corresponding to 1.125–1.21 g/ml. About 50% of HDL consists of apoA-I apoA-II and apoC. Several enzymes and transfer proteins are also located on HDL. Low HDL levels may indicate an increased risk of atherosclerotic heart disease.

inazua@mhs.mp.kanazawa-u.ac.jp

Synonyms

► **High-density lipoprotein (HDL)** is an established negative coronary risk factor, in contrast with low-density lipoprotein (LDL) as a positive risk factor. On a quantitative basis, there are two syndromes of hyperalphalipoproteinemia (HALP) and hypoalphalipoproteinemia; the former indicates excess HDL in plasma, the latter insufficient amounts of HDL. Alpha-lipoprotein is named after the alpha-migration characteristics of HDL in agarose gel electrophoresis. Cholesteryl ester transfer protein (CETP) is also named lipid transfer protein-I. Hepatic triglyceride lipase (HTGL) is a tri-acyl glycerol lipase located in the liver and is also named hepatic lipase. ► **Scavenger receptor class B type I**, SR-BI is also named CD36 and LIMPII analogous-1 (CLA-1).

Definition

The recent cholesterol guidelines propose that low HDL-cholesterol is <40 mg/dl. The frequency of the low HDL state is 18% in men and 12% in women in Japan. Low HDL-cholesterol is usually associated with ► **hypertriglyceridemia**, ► **insulin resistance**, and

obesity. Severely low HDL-cholesterol is associated with genetic disorders such as Tangier disease, lecithin: cholesterol acyl transferase (LCAT) deficiency and apoA-I deficiency. In Japan, high HDL-cholesterol >100 mg/dl is considered to be hyperalphalipoproteinemia (HALP). The frequency of this condition is 0.8% in men and 0.5% in women. In a hospital-based study, the frequency of HALP values >100 mg/dl is 0.2%, 43 out of 46 subjects were women from the US.

Characteristics

HDL levels depend on the synthetic rate of apoA-I from liver and intestine, ►cholesterol efflux activity mediated by ►ATP-binding cassette transporter A1 from liver and peripheral tissues, and the efficacy of lipolysis during which free cholesterol (FC) and phospholipid (PL) are generated as surface remnants of chylomicrons and VLDL (see Fig. 1). The catabolic rate of HDL also affects HDL levels in plasma. The catabolic rate depends on receptor-mediated uptake of HDL through the LDL-receptor or the ►LDL-receptor related protein (LRP). These receptors can bind apoE-containing HDL as well as intermediate density lipoprotein (IDL) and ►chylomicron remnants. Both LDL-receptor and LRP actively take up chylomicron remnants by 55–75% and 20–25%, respectively.

SR-BI is a hepatic HDL-receptor, which mediates selective CE uptake from HDL, without endocytosis of HDL particles. The rate of neutral lipid transfer / exchange from HDL to other lipoproteins through cholesteryl ester transfer protein (CETP) determines the efficacy of remodeling of HDL lipids, thereby modifying the catabolic rate of HDL. Phospholipid transfer protein (PLTP) is another plasma lipid transfer protein, which mediates PL transfer from very low-density lipoprotein (VLDL) to HDL. ApoA-I is catabolized in kidney probably *via* megalin and cubilin; both are members of the LDL receptor superfamily (1). Megalin is also known as Heymann nephritis antigen or glycoprotein 330. HTGL activity hydrolyzes TG in IDL and HDL. High HDL-TG levels are accompanied by increased HDL size (HDL2) and a decreased catabolic rate of HDL.

In hyperalphalipoproteinemia (HALP), there are two genetic syndromes combined. One is CETP deficiency, and the other is HTGL deficiency. CETP deficiency is characterized by increased HDL-cholesterol > 100 mg/dl with low CETP activity. The normal level of plasma CETP is about 2 mg/l. HTGL activity or amount determined in a plasma sample after heparin injection is known as post-heparin lipolytic activity (PHLA). The differentiating features between CETP and HTGL deficiencies are HDL-TG and IDL-LDL levels; HDL-TG is low in CETP deficiency because of less TG transfer from VLDL to HDL, but it is high in HTGL

High-HDL Syndrome. Figure 1 Synthesis and catabolism of HDL including the reverse cholesterol transport pathway. The ApoE-dependent pathway, shown in yellow, involves receptor-mediated uptake of large HDL with apoE, IDL, and chylomicron remnant. CE is shown in black, and TG is shown in white in lipoproteins. CM, chylomicron; CM-R, chylomicron remnant.

deficiency. Cholesterol levels in VLDL-IDL-LDL are decreased in CETP deficiency, but increased in HTGL deficiency. HTGL deficiency is not always associated with increased levels of HDL-cholesterol, but some mutations are associated with increased TG levels in IDL-LDL and HDL and also with combined hypertriglyceridemia/ HALP and familial combined hyperlipidemia (2) or type III hyperlipoproteinemia (dysbetalipoproteinemia). Also, some cases of familial hypobetalipoproteinemia caused by truncated apoB, have HALP in addition. This condition results from a decrease in net CE transport from HDL to VLDL-IDL-LDL because of fewer CE acceptors, in contrast to normal acceptors but less carrier protein in CETP deficiency.

Secondary causes of HALP are chronic obstructive pulmonary disease, alcohol and drug-related effects of estrogen, insulin, steroids and some H₂ blockers (ranitidine). The mechanisms of secondary HALP are not yet understood.

Rare genetic causes of HALP are less characterized. Cases with excess lipoprotein lipase (LPL) activity associated multiple symmetric lipomatosis, or increased production of apoA-I, have been described. However, the molecular bases have yet to be determined. The oculocerebrorenal syndrome of Lowe is a X-linked recessive disorder, which is characterized by congenital cataracts, cognitive impairment and renal tubular dysfunction and frequently manifests HALP (3). The genetic cause of Lowe syndrome is a

deficiency of phosphatidylinositol 4,5-bisphosphate 5-phosphatase.

Another candidate gene for HALP is endothelial lipase (EL), also named endothelial-derived lipase (EDL). EL is synthesized by endothelial cells and primarily acts as a phospholipase. Increased EL activity reduces HDL levels, and its inhibition causes high HDL (large HDL) through decreased clearance of HDL-PL *in vivo*.

High HDL syndrome is generally associated with low coronary artery disease (CAD) risk, but some cases have evidence for CAD. The genotype/CAD relationship is less well-established in HALP. Premature CAD and xanthoma are not observed in homozygous CETP deficiency (4). Cross-sectional surveys of the TaqIB polymorphism frequently demonstrated that low CAD prevalence is associated with the 'low CETP genotype'. However, a protective effect of HDL, induced by CETP lowering, on CAD is not yet established in a prospective study or an intervention study in humans. HTGL deficiency produces VLDL remnant (i.e. IDL) accumulation as well as increased HDL levels, thereby making it somehow pro-atherogenic. Gene/environmental interaction between low HTGL activity and intake of saturated fat was demonstrated (5). Plasma HDL-cholesterol levels are high in low *HTGL* genotypes when saturated fat intake amounts to >30% of energy, but conversely it is low when fat intake exceeds 30%. Therefore, coronary risk may depend on fat intake.

Clinical Relevance

Genetics

Variation of plasma HDL-C levels has been shown to be heritable to ~50%. Yet it appears that haplotype blocks associated with activity changes in several genes as described below, represent multifactorial causes of HALP. In familial HALP, 2 persons with increased HDL-C >100 mg/dL within a nuclear family are not commonly found.

Autosomal recessive inheritance is usually seen in HALP caused by CETP deficiency except for a dominantly expressed mutation (e.g. D442G) (4). Half of HALP cases were diagnosed by *CETP* gene mutations. Genetic cause(s) of the remainder are not known except for HTGL deficiency, which is reported in <10 families in the world. Frequency of CETP deficiency is high in Japanese as compared to Caucasians.

Human and murine genome-wide scans suggested that quantitative traits for regulating HDL-C levels are rather overlapped between species (6).

There is no report indicating association between HALP and HDL receptors such as SR-BI and the

ectopic beta-chain of ATP synthase, except Imerslund-Grasbeck syndrome, autosomal recessive malabsorption of vitamin B12 due to cubilin deficiency (7).

Molecular Diagnostics

CETP (chromosome 16q13) consists of 16 exons, encoding 476 amino acids in the mature protein. CETP deficiency is caused by missense and nonsense mutations in addition to mutations affecting splicing. Intron 14 (+1) G→A and D442G are prevalent mutations in Japan. The allele frequency of the former mutation is 0.006 and the latter is also common in Asian populations with allele frequency 0.02–0.06 (4). Homozygosity of intron 14(+1) G→A mutation is caused by ▶[consanguinity](#) or mating between unrelated mutant carriers, resulting in severe HALP (CETP <0.1 mg/l, HDL-cholesterol 167 mg/dl). Frequency of ▶[compound heterozygotes](#) of intron 14(+1) G→A and D442G is also high (CETP 0.6 mg/l, HDL-cholesterol 134 mg/dl). Rare mutations are also reported in Caucasians.

HTGL (LIPC) (chromosome 15q21) consists of 9 exons, encoding 476 amino acids in the mature protein. V73M and L334F are susceptibility alleles for combined hypertriglyceridemia/HALP (2). A useful haplotype block involving –514 in the promoter could explain up to 30% of variability of HTGL activity in the general populations of various ethnic groups, thereby modify CAD risk (8).

EL (LIPG) (chromosome 18q21) consists of 10 exons, encoding 482 amino acids in the mature protein. Complete deficiency has not been documented. However, several polymorphisms are associated with HDL levels.

LPL (chromosome 8p22) consists of 10 exons, encoding 448 amino acids in the mature protein. S447X polymorphism lacks the last 2 amino acids (S-G), resulting in increased LPL activity by 4% and reduced CAD risk in the meta-analysis.

SR-BI (chromosome 12q24) consists of 13 exons, encoding two transmembrane regions and a large extracellular loop. A few polymorphisms are associated with both LDL and HDL levels (8).

In summary high-HDL syndrome is predominantly caused by CETP deficiency. Other genetic causes are rare or not well defined yet. Atherogenicity may depend on genetic causes; however, molecular diagnosis could be performed in only half of the HALP subjects with HDL-cholesterol >100 mg/dl.

High-Mobility-Group Transcription Factor

Definition

High-mobility-group (HMG) proteins constitute a family of transcription factors that contain a structurally defined HMG domain, which binds DNA in a sequence specific manner and affects the chromatin structure. The name “high-mobility” refers to the unusual physico-chemical behaviour of these proteins.

Definition

►DNA microarrays have revolutionized molecular biology and have greatly increased the rate at which genes are discovered. The functional analysis required for determining the putative causal role of newly discovered candidate genes and proteins in cellular processes however, and their potential clinical impact or suitability as drug targets, is slow and rate limiting. Functional validation is usually accomplished in molecular- and cell-based assays on a gene-by-gene basis, creating a bottleneck effect for the characterization of the plethora of targets arising from ►genomics and ►proteomics surveys. A recently described, novel cell-based microarray system, called the ►transfected cell array (TCA) (1) paved a way for high throughput gene analysis in the field of ►functional genomics. The principle of the TCA technique is based on the ►transfection of DNA or RNA molecules immobilized on a solid surface into mammalian cells with subsequent detection of the physiological effects caused by the introduction of the foreign nucleic acid on these cells. Briefly, full-length ►open reading frames of genes inserted in ►expression vectors are printed at a high density on a glass slide along with a lipid transfection reagent, using a robotic arrayer. Densities of up to 10,000 cell clusters per standard slide can be achieved. When the microarray of DNA constructs is covered with a ►monolayer of adherent cells only the cells growing on top of the DNA spots become transfected, resulting in the expression of specific proteins in spatially distinctive groups of cells. The phenotypic effects of this ►reverse transfection of hundreds or thousands of genes can be detected using specific cell-based bioassays, such as autofluorescence or immunofluorescence (Fig. 1).

Characteristics

The transfected cell array (in short the cell array) combines microarray technology with cellular biology methods such as transfection and cell culture. The process of assay preparation and performance can be divided into three distinct steps namely (i) microarray preparation, (ii) reverse transfection and (iii) detection assay.

Microarray Preparation

In contrast to microarrays that are used for gene expression profiling studies, the DNA that has to be transfected in the cell arrays cannot be immobilized permanently on the glass surface. The reason is that in the following steps of the procedure, DNA should enter the cells growing on top of the DNA spot. Therefore the DNA to be arrayed is first dissolved in a gelatin solution, which facilitates transfer of the DNA from a solid support into the cells. The generation of arrays of DNA/gelatin solutions is performed using either stealth

Transfected Cell Array

High-Throughput Analysis of Gene Function in Mammalian Cells Using Transfected Cell Arrays.
Figure 1 Schematic presentation of the principles of the transfected cell array technique.

pins (e.g. SMP4 from TeleChem) and any standard robotic arrayer or using a non-contact piezoelectric dispensing printer. The diameter of the single DNA spot can range from 100–300 μm whereas spots are separated from each other by 400–1000 μm , depending on the detection assay used. Design of the cell array, in terms of spot arrangement throughout the slide, does not differ from the classical array and is determined by the number of pins attached to the printing head of the roboter and individual settings of the robotic arrayer software. For example, in our laboratory we routinely prepare blocks of 8×8 spots that are separated by 1.5–2.0 mm (Fig. 2). 10 such blocks are prepared on a single slide, resulting in a total of 640 spots, though the density can be increased up to 10,000 spots per slide if required. Microarrays can be stored in a desiccator at room temperature for up to six months without any negative effect on reverse transfection efficiency.

Reverse Transfection

Before covering the array with a monolayer of cells the spots have to be incubated with transfection reagent so that the DNA becomes complexed with liposome-like structures and consequently can be taken up by the overlying cells. The time of incubation with the transfection reagent is crucial for successful transfection and has to be optimized for each cell line. Subsequently, the prepared array is placed in a culture

High-Throughput Analysis of Gene Function in Mammalian Cells Using Transfected Cell Arrays.
Figure 2 An example of signals detected from a transfected cell array. (a) Expression plasmid containing green fluorescence protein (GFP) has been spotted in 8×8 spot blocks and subsequently reverse transfected in an array format into the human epithelial kidney derived HEK293-T cell line. Green fluorescence signal indicates cells expressing GFP. Cells covering the area outside of the spots remain negative for GFP. (b) The same plasmid also contains the beta galactosidase (lacZ) gene, which can be detected with specific antibody labeled with Cy3 dye giving a red fluorescence. In this case lacZ detection serves as a control of reverse transfection efficiency. Detection of fluorescence signals was performed with a microarray scanner.

dish and covered with cells. The cells are allowed to grow on the slide surface for up to 3 days. Longer incubation times lead to a decline in the signals detected following transfection, because the viability of cells cultured at such a high density decreases gradually with time. Therefore, the transfected cell array is limited to those cellular events that are induced up to 72 h after reverse transfection.

Detection Assay

Depending on the nature of the molecular event to be monitored, signal detection can be performed either on living (e.g. calcium influx detection) or fixed cells (e.g. immunohistochemical protein detection). A common detection method uses signals emitted by fluorescent dyes (e.g. Cy3 or Cy5) coupled to primary or secondary [monoclonal antibodies](#). Alternatively autofluorescent reporter proteins such as [green fluorescence protein](#)

(GFP) can be readily detected. Preference in fluorescence detection is defined by the possibility of collecting signal intensities from the whole slide using standard microarray scanners. Alternatively, fluorescence microscopy allows for the detection of single or several cell clusters by collecting the signal intensities from single cells and application of statistical analysis of signal to background ratios.

In the case of studies where ►apoptosis or cell adhesion are of interest, abnormal morphology of the transfected cells can be observed as a functional read out. For example, particular cell clusters on the array can be examined for induction of cell fragmentation or expression of proteins serving as early markers of apoptosis such as annexin V.

Transfected Cell Array as a Functional Genomics Tool

Transfected cell arrays offer a number of advantages when used to study gene function. One of the most important features is that this assay provides a unique opportunity to study protein function in the context of the living cell. For obvious reasons studying mammalian cells using TCA gives several advantages over analyzing gene expression in yeast and *Drosophila melanogaster*. Not the least important is that proteins expressed in the cell array can undergo post-translational processing such as glycosylation and folding, which can be very distinct in different organisms and different cell types. Secondly, functional analysis of proteins in their natural environment guarantees that additional molecules involved in the functional process are present during the assay (e.g. cofactors, proteins involved in large complex formation etc). In fact the transfected cell arrays allow for the generation of protein arrays without the need for tedious purification of the individual proteins. Since the DNA arrays can be stored for months before subjecting them to reverse transfection, they can be converted into the ►protein arrays when needed.

There are a number of advantages in using TCA as compared to functional assays performed in microwell plate format. The array approach requires fewer cells per number of genes tested. This is especially relevant for human primary cells since only small numbers of these can be isolated out of a tissue and the *in vitro* expansion of these cells is rather limited. Although primary cells are notorious for their lack of capacity to be transfected, reverse transfection of these cells is possible but requires careful optimization of the experimental conditions for each cell type tested (Vanhecke et al., unpublished data) (Fig. 3). Transfected cell arrays also require far less DNA/RNA as well as transfection and signal development reagents as compared to assays performed in microwell plate

High-Throughput Analysis of Gene Function in Mammalian Cells Using Transfected Cell Arrays.

Figure 3 Comparison of spots of transfected cells obtained after reverse transfection of a GFP coding plasmid into three different cell types. Highest transfection efficiency (number of green cells and fluorescence intensity per cell) is obtained in the common cell line HEK293-T (a) and WI-38 human fibroblasts immortalized following transformation with SV40 virus (b). Hard-to-transfect primary human skin fibroblasts from adult healthy individuals (c) are less efficiently reverse transfected. Detection of fluorescence signals was performed with a fluorescence microscope with 10x objective.

format. Since in the case of high throughput technologies the cost of the single sample analysis must be reduced to an absolute minimum, cell arrays are at the moment the most cost-effective functional genomic tool available.

Cell arrays have already been used in a number of assays designed for high throughput gene and protein characterization, as for example in ►loss-of-function studies (2, 3) and protein-protein interactions screening (4).

Gene Silencing Studies

In the case of loss-of-function studies the cell array is combined with the technique of ►RNA interference

(RNAi) (5). ► **Small interfering RNAs (siRNAs)** are spotted in gelatin solution onto a modified glass surface using a standard robotic arrayer. The RNA array is subsequently treated with transfection reagent and covered with a monolayer of recipient cells. The decrease in expression of targeted genes is monitored using, for example, fluorescent-labeled monoclonal antibodies or autofluorescent reporter proteins. In order to control transfection efficiency, the siRNA can be labeled with rhodamine. Alternatively, the siRNA can be cotransfected with a reporter plasmid, which can be detected in parallel to the detection of the target protein. The transfection of siRNA can be performed in different experimental configurations. In one application, siRNA is co-transfected together with a plasmid that will express a ► **target gene**. This approach allows for the evaluation of the silencing capacity of different siRNAs specific for the same target gene (2). A more challenging application is the targeting of endogenous genes by reverse transfection of a genome wide collection of siRNA molecules. The cellular processes that are affected by silencing endogenous genes can be monitored by specific antibodies that can, for example, detect changes in the phosphorylation state of cell membrane bound receptors or transcription factors or that can be used to monitor changes in cellular localization of genes of interest. Alternatively, the effects of silencing genes can result in cellular processes such as apoptosis or changes in intercellular adhesion, which can be monitored by specific reagents (e.g. annexin V) or by simply analyzing morphological changes in the transfected cells.

Protein-Protein Interactions Studies

The cell array can also be used as a platform for high throughput analysis of protein-protein interactions. For example, in our laboratory we have developed the so-called THETA (two-hybrid-edition of transfected array) system, where the transfected cell array is combined with a mammalian ► **two-hybrid system** to identify proteins that interact with a protein of interest (4). The advantage of the mammalian 2-hybrid is that proteins interact in their natural environment, which is advantageous when posttranslational modifications or interactions with third party proteins are required. In the case of the THETA assay, bait and prey plasmid constructs were created whereby the bait is a known signal transduction molecule that is tested for its interaction with unknown proteins by coexpressing it with a huge number of single clones (preys) from a unigene cDNA library. Thus, thousands of human or rodent cDNAs (preys) can be screened with particular target proteins (baits) representing metabolic or signal transduction pathways.

Cellular Localization Studies

Because transfected proteins are expressed in their natural environment in the cell array, the synthesized proteins will also localize to their natural cellular compartments such as nucleus or cell membrane. Accomplishment of the human and mouse genome projects resulted in accumulation of extensive gene sequence information. However, information about the biological function of the identified genes remains a bottleneck of the post-genomic era. Thus assays providing simple functional information such as localization of the protein within the cell can be very helpful in elucidation of its function. For example, detection of protein expression on the surface of the cell will strongly suggest receptor function whereas location in the nucleus will indicate a role as transcription factor. Transfected cell array offers a robust platform for protein localization studies. Open reading frames of unknown genes can be linked to a ► **His tag** or GFP reporter protein in suitable expression vectors and are then subsequently transfected in the cell array. Cellular localization of the transfected proteins is detected either by specific anti-His antibody or directly by fluorescence of the GFP fusion protein and by counterstaining with dyes that target particular ► **organelles**. In this application the fluorescent signal is detected using a microscope equipped with a scanning platform and appropriate software for the automatic analysis of a large number of transfected spots. Although, the degree of automation of the whole procedure is limited in this application, we have been able to investigate several hundred cDNA clones derived from a human chromosome 21 library, out of which the localization of approximately 30% of expressed proteins could be unambiguously determined (Hu et al. submitted). This relatively low percentage is due to the fact that some proteins will be expressed below the detection level or will not be expressed at all as a result of improper out of frame cloning. However the high throughput of the method in terms of information provided per single experiment makes this approach still superior to the classical immunohistology methods for protein localization.

Clinical Relevance

Since the transfected cell arrays allow the analysis of many genes in parallel and furthermore can be adopted to many existing cell based assays it promises to become a robust and high-throughput means to profile disease related proteins or to study protein-protein and protein-drug interactions. The transfected cell array can be regarded as a sophisticated protein expression system where location of particular proteins on the slide can be identified by the coordinates of the arrayed cDNA. It can be used, for example, to identify

disease related proteins by analyzing the binding of sera of patients on arrays of expressed cDNA libraries, leading to identification of molecular diagnostic markers. The TCA is also well suited for screening of small molecules for their ability to specifically interact with protein targets such as G-protein-coupled receptors (GPCRs). In this case, the cell microarrays present a more advance alternative to standard protein arrays, since in TCA the proteins are *in situ* synthesized in the physiological environment of the cells, thus enabling proper post-translational protein folding and glycosylation. Furthermore, cell arrays represent a powerful functional genomics tool for target gene identification. Through the accurate selection of cell line characteristics (e.g. tumor-derived cell lines) and detection assays (e.g. induction of apoptosis) usage of cell arrays on a genome-wide scale can rapidly lead to identification of target genes related to particular diseases.

Hippocampus

Definition

The hippocampus is a part of the brain located inside the temporal lobe. It plays a central role in memory storage and also forms part of the limbic system. The name derives from its curved shape, which supposedly resembles that of a seahorse (greek: hippocampus). The hippocampus is the first region of the brain that suffers attack from Alzheimer's disease; memory problems and disorientation appear amongst the first symptoms.

- Brain
- Neutrophilic Factors

His-Tag/6xHis

Definition

His-Tag refers to a polyhistidine sequence that is used to tag recombinant proteins. The recombinant protein can then be purified using immobilized metal ions, traditionally nickel or cobalt, in a procedure termed immobilised metal chelate affinity chromatography (IMAC). Further analysis of the protein can be achieved by using an antibody that recognises a 6xHis (or 5xHis) sequence in proteins.

Histocompatibility

Definition

Histocompatibility is the state in which a donor and recipient share antigens so that a graft is accepted and remains functional. It also refers to the study of factors that determine the acceptance or rejection of grafted tissues or organs. Histocompatibility testing is the performance of assays to determine whether recipient and donor are histocompatible.

Histone

Definition

Histone refers to a group of highly conserved proteins in eukaryotes with a very high proportion of positively-charged amino acids (lysine and arginine), which is involved in the packaging of the DNA into tightly packed chromosomes. The positive charge helps to tightly bind to DNA, regardless of its nucleotide sequence. There are five major types of histones in the somatic cell. H2A, H2B, H3, and H4 compose the nucleosome, the structural unit of the chromatin. H1 functions as a linker between nucleosomes. The N-terminal regions of the core histones are targets for epigenetic modifications such as acetylation, methylation, phosphorylation, poly(ADP-ribosylation), or ubiquitination that can influence the stability of the chromatin.

Histone Code

Definition

The pattern of different posttranslational modifications that occur on the N-terminal tails of histones is referred to as the histone code. It is hypothesized that this code is “read” or bound by different proteins.

- ▶ [Methylation of Protein](#)

Histone Deacetylase

Definition

Histone deacetylases comprise of a class of enzymes that catalyze the deacetylation of histones. Acetylation of the ϵ -amino group of lysine residues of histones reduces the net positive charges of the core histones, leading to a decrease in their binding affinity for DNA. The termini are subsequently displaced from the nucleosome, the nucleosome unfolds and provides access for transcription factors. Deacetylation of histones by histone deacetylases removes the acetyl group, allowing ionic interactions between the negatively charged DNA phosphate backbone and the positively charged amino termini of the core histones. This results in a more compact chromatin structure, which is not as accessible to the transcriptional machinery. While histone acetylation and hyperacetylation has been correlated with transcriptionally active chromatin, histone deacetylation is thought to be involved in repression of transcription.

Histone Methylation

Definition

Histone methylation is a covalent attachment of methyl groups to lysine or arginine side chains in histone amino-termini by histone methyltransferases. H3 lysine 4 methylation correlates with gene activation, whereas

methylation of lysine residue 9 of histone H4 (H3–mLys9) generates a high affinity binding site for the silencing protein heterochromatin protein 1 (HP1), which is essential for the establishment and maintenance of heterochromatin.

Definition

The human ►major histocompatibility complex (MHC), located on the short arm of human chromosome 6, consists of three regions, i.e. classes II, III and I from the centromeric side toward the telomeric side. The nucleotide sequences of the entire human MHC regions over 3.6 megabases long were determined in 1999, and numerous known and unknown genes were localized (1). MHC is one of the most gene-rich regions in the human genome and contains more than 130 expressed genes. The human leukocyte antigen (HLA) gene family contains several genes including HLA-A, -B and -C belonging to class I and HLA-DRB1, -DRA, -DQB1, -DQA1, -DPB1 and -DPA1 belonging to class II. It is well known that these genes are involved in immune response control by presenting antigen peptides to T cells and in NK cell activity control by functioning as NK receptor ligands. However, a majority of the expressed genes located in MHC are non-HLA genes and include not only the genes of TAP1, TAP2, PSMB9(LMP2), PSMB8(LMP7) and tapasin (TAP-binding protein) involved in the antigen peptide presentation, a gene cluster of C4A, C4B, C2 and BF belonging to the complement system and others belonging to the immune system, but also many genes unrelated to the immune system.

Characteristics

Variations Within the MHC and Their Associations with Diseases

It has been demonstrated that the HLA gene family shows the highest degree of polymorphism in functional genes, and approximately 350 alleles for the HLA-DRB1 gene and over 500 alleles for the HLA-B gene have been identified. Many of the polymorphic sites in HLA genes are of functional significance, altering the pocket structures and affinities in which antigen peptides are sandwiched, thus associations with a number of diseases have actually been reported (Table 1). A majority of these MHC-associated diseases are autoimmune or infectious diseases, and are genetically classified as multifactorial diseases in which various genetic and environmental factors are involved. The associations between MHC and some of the diseases were commonly observed in different populations, as reported in the association of HLA-B27 with ankylosing spondylitis, HLA-DRB1*1501 and HLA-DQB1*0602 with narcolepsy and HLA-DR4 shared epitope with rheumatoid arthritis. Associations with other diseases vary in different populations. These findings may be interpreted in several ways. First, there may be variations in the repertoire of HLA alleles and/or environmental factors between populations. Secondly, HLA genes themselves might not be disease susceptibility factors. Rather, polymorphisms

of non-HLA genes adjacent to HLA genes in the MHC region might be primary factors. Furthermore, it is also possible that not a single gene but multiple susceptibility genes are situated in MHC. In addition to the determination of the nucleotide sequences of the entire human MHC, two kinds of most useful polymorphic markers, microsatellites and ►single nucleotide polymorphisms (SNPs), have recently been extensively screened in MHC (2, 3). This led to the establishment of the strategy of identifying the primary susceptibility genes, on the basis of detailed linkage disequilibrium analyses and inter-population comparative analyses. The present status of MHC-disease association studies is described in the following by discussing four diseases: type 1 diabetes, ►rheumatoid arthritis, ►systemic lupus erythematosus, and ►narcolepsy.

Type 1 Diabetes

MHC is a region showing the most prominent susceptibility in type I diabetes, detected by genome-wide linkage analyses with affected sib pairs (IDDM1). The strong associations with type I diabetes of HLA-DRB1 and HLA-DQB1 genes in the class II region in particular, have been established. The association of HLA-DRB1*0301 and HLA-DRB1*0401 with type I diabetes in European populations have been reported. It was proposed that the primary factor is attributable to the 57th amino acid of DQB1 gene product being non-Asp. However, this view cannot explain the

associations of DRB1*0405 and DRB1*0901 with type 1 diabetes in the Asian populations. Thus, the current view is that the degrees of susceptibility or resistance shown by various alleles of DQB1 and DRB1 genes are hierarchical. Furthermore, the potential existence of a second susceptibility gene in the class I or class III region has been reported in many publications recently. The HLA-B and TNF genes and the genes adjacent to them, in particular, were considered to be the candidates for the second susceptibility gene (4). The basis of onset of type I diabetes could be hypothesized as follows; class II genes may determine the immune response to diabetogenic peptides, while class I genes may determine the degree of target cell destruction.

Rheumatoid Arthritis

Several genome-wide linkage analyses with affected sib pairs demonstrated that MHC is a major susceptibility region for rheumatoid arthritis, and the association of HLA-DR4 with the disease has been established in most populations. When these reports were examined in detail, a strong association of HLA-DRB1*0401 and DRB1*0404 with rheumatoid arthritis was observed in the European populations, whereas there was a strong association of HLA-DRB1*0405, a different allele, with the disease in the East Asian populations and of HLA-DRB1*0101 in the Jews, who rarely have these DR4 genes. From these findings, it was

HLA and Disease. Figure 1 Chromosome-wide association analysis of human narcolepsy with 1,265 microsatellite markers on human chromosome 6.

established that the sequence around the 70th amino acid of the HLA-DRB molecule being dominated by basic amino acids (QRRAA or RRRRAA: shared epitope) is a shared susceptibility factor. In addition, the existence of a second weak susceptibility locus has been suggested recently. The probable region was narrowed down by a high-density microsatellite marker analysis, and an association analysis was then carried out using SNPs. Thus, it was reported that the *IkBL* gene in the class III region might be the second susceptibility gene (3).

Systemic Lupus Erythematosus

Non-parametric linkage studies with affected sib pairs have identified the MHC region as a candidate susceptibility region for systemic lupus erythematosus. In the European populations, both HLA-DRB1*0301 and HLA-DRB1*1501 were reported to be associated with the disease. The association of HLA-DRB1*1501 with the disease was also observed in the Japanese, whereas HLA-DRB1*0301 was very rare. In the Thai population, in contrast, another allele of the HLA-DRB1*15 group, HLA-DRB1*1502, was associated with the disease (5). Accordingly, HLA-DRB1 polymorphisms may predispose to systemic lupus erythematosus in different populations.

Narcolepsy

The association of the HLA-DRB1*1501-HLA-DQB1*0602 haplotype with narcolepsy is one of the

strongest MHC-disease associations, comparable to the association of HLA-B27 with ankylosing spondylitis. The elucidation of causative genes in dog and mouse models for narcolepsy contributed to the findings that a reduced cerebrospinal fluid level of orexin (hypocretin) leads to the onset of narcolepsy. The proposed basis of onset of narcolepsy is that an autoimmunity, in which the HLA class II haplotype is involved, destroys cells containing orexin (hypocretin). We recently performed an extensive association analysis on the entire chromosome 6 using 1,265 microsatellite polymorphic markers (6). A very strong association of the markers around the HLA class II region with narcolepsy ($P < 10^{-34}$) was noted, as had been predicted (Fig. 1). In contrast, the orexin (hypocretin) receptor 2 gene (*HCRT2*), which is also located on the chromosome 6, was not associated with human narcolepsy. We already reported that the polymorphism in the *TNFA* gene promoter region might be a weak genetic factor in the Japanese population (7). The same association was also observed in the German population, recently.

Clinical Relevance

Associations of MHC with a large number of multifactorial diseases have been reported, but the exact mechanisms of onset of the diseases have not been elucidated. Hence, few of these reports have led to the development of new therapies for the diseases until now.

However, associations between different clinical characteristics of various diseases and particular HLA alleles have been reported. Therefore, the typing of HLA gene polymorphisms is diagnostically significant and is expected to become essential to achieve personalized medicine for immune disorders in the future.

►DNA Recombination

Holoprosencephaly

Definition

Holoprosencephaly is a heterogeneous disorder (1:20,000 newborns), which is frequently caused by functional loss of sonic hedgehog (SHH) at human chromosome 7q36.3, and characterized by highly variable expressivity. It results from a failure of the foetal prosencephalon (the embryonic forebrain) to divide normally into hemispheres. It is often associated with other midline defects particularly of the skull and face. These range in severity from close set eyes (hypotelorism) and a single maxillary incisor, to a single eye (cyclopia) and a missing nose or a proboscis (a tubular-shaped nose). Mildly affected individuals may only show microsigns, such as ►ptosis or single maxillary incisor, and low normal intelligence.

►Microdeletion Syndromes
►Hedgehog Signalling

HOM-C

Definition

HOM-C refers to a cluster of evolutionarily conserved homeobox genes found in insects and nematodes.

►Homeodomain Transcription Factors

Homeobox

Definition

Homeobox describes a conserved DNA sequence of 180 nucleotides that codes for the homeodomain, a

protein domain of 60 amino acids. This homeodomain is a DNA-binding domain that occurs in proteins that are usually transcription factors. The sequence of the homeobox is similar enough, even across species, to identify homeotic genes.

- [Axis Formation – Formation and Function of the Dorsal Organizer](#)
- [Drosophila Model of Cardiac Disease](#)
- [Homeobox Transcription Factors](#)
- [HOX Genes](#)

Homeobox Genes

Definition

Homeobox genes comprise of a family of genes encoding transcription factors that bind DNA via a conserved 60 amino acids domain, the homeodomain. Homeobox genes play crucial functions during embryonic development including antero-posterior axis formation, segmentation and cell identity. Some of them are required for cell specific expression in adult organs. In blood cell progenitors, the expression of individual HOX genes follows tightly regulated programs, which are specific for the stage and lineage of progenitor-cell development, with universal down-regulation of HOX gene expression as the progenitors differentiate into mature blood cells.

- [Leukemia](#)
- [Gut Epithelium](#)

Homeobox Transcription Factor

Definition

Homeobox genes encode transcription factors that are characterized by the presence of a homeobox. This domain forms three α -helical regions, one of which is involved in sequence specific DNA binding. The name “homeobox” derives from findings that mutations in some of these genes lead to homeotic transformations: one body structure develops in place of another.

- [Neural Development](#)

Homeodomains

MARY TRUSCOTT¹, ALAIN NEPVEU^{1,2,3}

Departments of Biochemistry¹, Medicine², and Oncology³, McGill University, Montreal QC, Canada
alain.nepveu@mcgill.ca

Definition

The [homeodomain](#) is a highly conserved 60-amino-acid protein domain that is encoded by the [homeobox](#) and is found in organisms as diverse as mammals, insects, plants and yeast. Homeodomains function as DNA binding domains and are found in many transcription factors that control development and cell fate decisions. Structurally, homeodomains are related to helix-turn-helix proteins of bacteria and consist of three α helices folded around a hydrophobic core and a flexible N-terminal arm. Homeodomain-containing proteins are often referred to as homeoproteins.

► [Homeotic](#) transformations cause one body segment to adopt the identity of another segment. Homeotic transformations were later found to result from mutations affecting the expression of genes that share a 180-nucleotide sequence, the homeobox. Some homeobox genes are found in clusters, termed [HOM-C](#) in insects and nematodes and [HOX](#) in mammals. Clustered homeobox genes specify body segment identity and positional information along the antero-posterior axis. Other homeobox genes are dispersed throughout the genome and play a role at another level in development.

Characteristics

Historical Background

Homeotic transformations, whereby a body segment exhibits the features of another body segment, were first reported over a century ago. As they were segregated in a Mendelian fashion, homeotic transformations were assumed to be caused by genetic variations, termed [homeotic mutations](#), and the affected genes were called [homeotic genes](#). Sequence analysis revealed that the coding sequence of all homeotic genes share a conserved sequence of 180 nucleotides, the homeobox. The homeobox codes for the homeodomain, a protein domain that is capable of DNA binding and can also be involved in protein-protein interactions. Although not all homeobox-containing genes are homeotic genes (i.e. control segment identity), most if not all homeobox-containing genes play a role in development at one level or another.

Classification

Homeodomain proteins can be subdivided into many classes on the basis of several criteria including organization into a gene complex, sequence identity within the homeodomain itself or in the flanking region, association with other DNA binding or protein-interaction domains and the position of introns (Table 1) (1).

The Complex Superclass

Phylogenetic analysis suggests the existence of a primordial gene cluster, which was duplicated once, or more in the various evolutionary branches. Thus, in all metazoans there are one or more clusters of homeobox genes known as HOM-C in insects and nematodes and HOX in mammals. However, the term Hox is often used loosely to describe clustered and non-clustered homeobox genes in invertebrates as well as in vertebrates. In *Drosophila*, there are two gene clusters, the ►Bithorax complex (BX-C) and the ►Antennapedia complex (ANT-C). In mammals, there are four Hox clusters, called *HOXA*, *HOXB*, *HOXC*, and *HOXD*. The corresponding genes in the four mammalian clusters are said to be paralogous. Thus, ►paralogs belong to the same species. In contrast, the term ►orthologs describes homologous genes of different species. ►Orthologous genes and ►paralogous genes not only exhibit sequence conservation within the homeobox and its flanking sequences but are also positioned similarly within the gene cluster, are expressed in an analogous manner and fulfill a similar function.

The Dispersed Superclass

A large number of homeobox genes are also found dispersed throughout the genome. Recent advances in phylogenetic analysis have revealed that some of these genes also reside within clusters, extended HOX, NKL, paraHOX, metaHOX and EHGBbox. In many cases, homeodomain-encoding exons are found associated with exons coding for a second DNA binding domain (like Paired, Pou, Cut repeat, MADS box or a zinc-finger domain) or a protein-protein interaction domain (like LIM). Homeoproteins encoded by such genes are thus classified on the basis of this additional domain.

Biological Functions

Homeoproteins are transcription factors that play regulatory roles at all stages of development (2). In yeast, the homeoproteins MAT alpha 2 and MATA1 control the switch between the two different haplotypes, a and alpha. In metazoans, homeoproteins are involved early on in the formation of the overall body plan and then later in virtually every developmental decision including the determination of cell

Homeodomains. Table 1 Classification of Homeodomain Proteins

fate, the specification of segment identity and cell-type identity and the regulation of cell differentiation and tissue patterning. In the adult, homeoproteins continue to control cell-type specificity and participate in the establishment and maintenance of overall homeostasis.

Much of our knowledge of the role of homeoproteins in development derives from studies performed in genetically tractable organisms like the fruit fly, *Drosophila melanogaster*, or the worm, *Caenorhabditis elegans*. Conclusions drawn from these genetic studies were generalized during the last decade using the laboratory mouse as a system. In some of the most spectacular experiments, it was shown that a human or murine ortholog was able to complement the corresponding mutant in *Drosophila*, thus demonstrating the evolutionary conservation in function. Moreover, the human diseases that are caused by mutations in homeobox genes conform exactly with the function of these genes in mouse and *Drosophila*.

In *Drosophila*, earlier studies focused on the role of Hox genes in the determination of segment identity

along the antero-posterior (A-P) axis (1, 2). A number of rules regarding the expression and function of homeotic genes were found to be conserved between vertebrates and invertebrates. The order of HOM and Hox gene expression along the A-P axis reflects the order of the genes along the chromosome, a phenomenon referred to as the ►colinearity rule. The spatial distribution and differing concentrations and combinations of homeotic transcription factors control the expression of segment-specifying factors according to a ►Hox code. A larger number of genes are usually expressed in more posterior regions. The effects of the deletion or aberrant expression of Hox genes revealed ►posterior prevalence – a hierarchy of regulatory effects whereby more posteriorly expressed Hox genes ultimately determine the specification of the segment in which the Hox genes are expressed. For example, loss-of-function mutations cause loss of structures and development of anterior structures where more posterior structures should have formed. However, the homeotic transformation occurs only in the anterior-most regions where that Hox gene is normally expressed and not within regions where a more posterior Hox gene is expressed. Thus, the more posterior Hox genes are able to promote the appropriate morphological structures without the contribution of more anterior genes. In contrast, gain-of-function mutations cause the development of posterior structures where more anterior structures should be found; however, ectopic expression of most homeotic genes does not lead to the transformation of segments posterior to their normal domains of expression.

In higher organisms, paralogs in the different Hox clusters are often expressed in similar patterns, suggesting some redundancy in function of the genes. However, there are some differences in expression patterns and there is a growing amount of evidence for the existence of functions specific to individual or pairs of paralogs.

Many conserved, non-clustered *Hox* genes exist in various chromosomal locations throughout the genome and also regulate cell fate specification in many tissues and organs. Furthermore, subsets of Hox genes display patterning functions in structures that are more phylogenetically recent than those along the main A-P axis, such as limbs and epithelial appendages. Many such functions are mediated along dorso-ventral, left-right and proximo-distal axes and involve the formation and maintenance of asymmetry in all tissues and organs including the regulation of cell-type specificity and determination of cell fate. In addition, the same homeobox genes that are expressed in different cells of a developing region in early stages of development can be expressed differently at a later stage, in specific cells in a given tissue, and can control gene expression in a cell-type-specific manner.

In addition to their role in development, homeodomain proteins have also been implicated in the regulation of cell proliferation, signaling, migration and adhesion.

Biochemical Activities and Regulation

The homeodomain functions as a DNA binding domain that exhibits preference for sequences containing a TAAT core. Homeoproteins have been characterized as transcription factors that can either activate or repress transcription. Whether a homeoprotein acts as a repressor or activator is determined by the presence within the protein of a repression or activation domain, but the directionality of the regulatory effect can also be influenced by promoter context, cooperation with other transcription factors, association with co-factors and various post-translational modifications.

There is an apparent discrepancy between the highly selective biological functions of homeoproteins and their relative lack of DNA binding specificity (3). Indeed, homeoproteins exhibit promiscuous DNA binding specificities *in vitro* and it is not clear whether a given homeoprotein regulates a limited or a large number of target genes. A partial solution to the specificity problem was provided by the findings that homeoproteins encoded by HOX genes bind to DNA in cooperation with homeoproteins of the three-amino-acid-loop-extension (TALE) family. These include PBX, MEIS and PREP1/KNOX1. Interaction requires the presence within the Hox protein of a conserved sequence N-terminal to the homeodomain. The consensus sequence of this PBX-interaction motif (PIM) is IYPWMK. Cooperative DNA binding also occurs in the case of homeoproteins that contain one or more DNA binding domain(s) in addition to the homeodomain. In cells, factors that may also contribute to increased specificity include the state of the chromatin, cooperation with proteins that are bound to other regulatory elements and interaction with co-activators, co-repressors and general transcription factors. Finally, like other transcription factors, the activity and intracellular localization of homeoproteins is regulated by a whole array of post-translational modifications.

Clinical Relevance

Mutations Associated with Diseases and Syndromes

A large number of clinical conditions were found to be caused by mutations within a homeobox-containing gene (Table 2). Point mutations (missense and nonsense) within the coding sequences of a homeobox gene have been documented in several congenital diseases (4). In addition, short deletions outside of coding regions have been noted in certain cases and were assumed to affect gene expression; however, this remains to be formally demonstrated. Most diseases due to point mutations within a homeobox-gene show a

dominant inheritance. In several cases, the dominant effect of HD mutations was demonstrated to result from [▶haploinsufficiency](#), but in a few instances a dominant negative effect of the mutated protein was suggested

from the more severe phenotype observed when the mutated protein was partially active instead of completely inactive. In several cases, mutation of a single homeobox gene causes malformation of multiple

Homeodomains. Table 3 Homeobox Genes At Sites Genomic Rearrangement

Gene (OMIM no.)	Cancer	Genomic Rearrangement
HOX11 186770	T-cell acute leukemia	t(10;14) or t(7;10) The HOX11 gene adjacent to the 10q24 region is transcriptionally activated after translocation to the proximity of either the T cell receptor D at 14q11, or B at 7q35.
PBX1 176310	Pre-B-cell acute lymphoblastic leukemias	t(1;19)(q23;p13.3) The translocation juxtaposes the 5' portion of the E2A transcription factor gene (147141) on 19p13.3 with the 3' portion of the PBX1 TALE homeobox gene on 1q23 resulting in the synthesis of a chimeric protein E2A-PBX11.
TLX3 (HOX11L2) 604640	T-cell acute lymphoblastic leukemia	t(5;14)(q35;q32) The translocation brings the TLX3 gene on 5q35 under the control of transcriptional regulation elements on 14q32 that drive expression of the CTIP2 gene during normal T-cell differentiation.
HOXA9 142956 HOXD11 142986 HOXC13 (142976) PMX1 (PRRX1)	Acute myeloid leukemia	t(7;11)(p15;p15); t(2;11)(q31;p15) t(11;12)(p15;q13) t(1;11)(q24;p15) The translocation juxtaposes the 5' portion of the NUP98 gene (601021) on 11p15 with the 3' portion of the HOXA9, HOXD11, or HOXD13 gene thereby generating a chimeric protein.
HOXA9 142956	Chronic myeloid leukemia	t(7;17)(p15;q23) The translocation juxtaposes the 5' portion of the MSI2 gene (607897) on 17q23 with the 3' portion of the HOXA9 gene on 7p15 thereby generating a chimeric protein.
PAX3 (193500)	Rabdomyosarcomas	t(2;13)(q35;q14) The translocation juxtaposes the 5' portion of the PAX3 gene on 2q35 with the 3' portion of the FKHR gene (136533) on 13q14 thereby generating a chimeric protein.
LHX4 (602146)	Pre-B-cell acute lymphoblastic leukemia	t(1;14)(q25;q32) The translocation resulted in the 5'prime regulatory region of LHX4 on 1q25 being replaced by the enhancer region of the IgH gene on 14q32.
NKX3.1	Prostate cancer	Loss-of-heterozygosity on 8p21
CDX2	Colorectal carcinoma	Loss-of-heterozygosity on 13q12.3 and mutations within coding sequences

body structures. This is probably due to the fact that a single homeobox gene can be expressed in several different cell types and control multiple developmental decisions.

There are over 200 homeobox genes in the human genome, of which 39 are members of one of the four HOX clusters. Mutations in only two HOX genes have been identified so far. Considering the importance of these genes in development, the identification of such a relatively small number of mutations in HOX genes may suggest the existence of functional redundancy among paralogs of the *HOX* clusters. Alternatively, it has been suggested that severe mutations in these genes might lead to defects early in embryonic development,

which therefore would not be found in the living population.

Homeobox Genes Implicated in Cancer

A number of homeobox genes have been implicated in various cancers. In human cancers, both gain- and loss-of-function of homeobox genes have been reported to occur. The general trend is that those homeobox genes that are over-expressed in tumors are normally expressed in proliferating cells, whereas those homeobox genes that are down-modulated are normally expressed in the terminally differentiated cells of that tissue-type (5). It is not always clear whether mis-expression of a homeobox gene is a direct cause of

cancer or is merely a consequence of the cancer phenotype. However, there is abundant experimental evidence in cell-culture models and in the laboratory mouse to support a direct role of homeobox genes in cancer. In particular, ectopic expression of some homeodomain proteins and gene inactivation of two homeobox genes were found to cause various types of neoplasias in the mouse. Moreover, for some homeobox genes that are implicated in human cancers, the homologous murine gene was found to be activated following the integration of a retrovirus in murine cancer models.

In human cancers a number of homeobox genes have been found at the site of genomic rearrangements including chromosomal translocation and allelic loss (Table 3) (6). Allelic loss has been reported for two homeobox genes, CDX2 and NKX3.1, which exhibited properties of tumor suppressor genes in mouse models. Chromosomal translocations can result in the generation of fusion proteins that acquire novel biochemical properties or the juxtaposition of tightly regulated homeobox genes next to highly active promoter regions. Deregulated expression may also be caused by more subtle regulatory events not involving changes in DNA (5). In most of these cases, however, expression studies were limited to mRNA analysis and it remains to be verified whether protein expression or function always reflects the level of mRNA expression.

Homeotic Genes

Definition

Homeotic genes were originally identified because of the fact that mutations in these genes can cause extraordinary phenotypes (▶ homeotic mutations) in *Drosophila*. Homeotic genes regulate, for example, whether the segment develops a halter or a wing, by regulating a large number of downstream genes required for the development of segment specific structures. Accordingly, different homeotic genes are active in different segments. Thus, “homeotic” is a functional description for genes that cause homeotic transformations (see also ▶ HOX genes). Homeotic genes include a conserved DNA sequence called the ▶ homeobox.

Homologous Recombination

Definition

Homologous recombination describes the recombination of DNA sequences bearing significant homology on the same chromosome, on homologous chromosomes or on non-homologous chromosomes. This term was previously restricted to the exchange of DNA sequences between homologous chromosomes, and accompanied by a crossover event, as during meiosis. It occurs widely in bacteria and viruses. The recombination reaction is equivalent to highly specific cutting and ligation reactions. Homologous recombination is distinguished from other types of recombination (site-specific recombination). Homologous recombination in mouse ► [ES-cells](#) is a commonly used method to introduce targeted mutations into a host genome (► [gene targeting](#)).

Comparative modeling

Definition

Homology modeling or comparative modeling is the prediction of the tertiary structure of an unknown protein using a known three-dimensional (3D) structure of a homologous protein. This is based on the observation that protein 3D structure is better conserved than the amino acid sequence and that therefore similar sequence implies similar 3D structure. The homology modeling method is based on sequence alignment and molecular modeling techniques (such as Monte Carlo or molecular dynamics simulations). Homology modeling has important applications in structural biology (for solving experimental X-ray crystal or ► [NMR](#) structures) and for the prediction and characterization of functional aspects of proteins of unknown structure.

Description

Our knowledge about the primary sequences of proteins grows much faster than that of their 3D structures. There are approximately 20,000,000 protein sequences known (1), but only around 20,000 3D structures (2). As a complement to the experimental structure determination methods, homology modeling plays an indispensable role in obtaining structural information. It relies on the fact that the three-dimensional structure of proteins is, in most cases, better conserved than their sequence and that therefore similar amino acid sequence implies similar 3D

structure. (Homology between two proteins strictly speaking indicates only that two proteins have a common evolutionary ancestor and does not therefore directly imply a similar fold.) The sequence of the unknown (query) protein is compared systematically to the sequences of all proteins with known 3D structures; those with high sequence similarity then serve as templates to model the 3D structure of the query protein. The development of better homology modeling methods is still an active field of research.

Among the 20,000 known 3D structures there are only 300 distinct protein folds. Structural genomics projects aim specifically at “filling the fold space”, at determining experimentally specifically those protein structures that cannot be modeled by homology and would in turn allow many more protein structures to be predicted.

If the sequence similarity is too weak to be detected by standard methods alone, threading (or fold recognition) techniques can be used, which compare the query sequence directly to all known protein folds and evaluate the “fitness” of a particular sequence for a fold. Recently, decisive advances have also been made in the field of “*ab initio*” protein fold prediction, that is prediction of the 3D structure without a structural template.

Methodology

In many cases, homology modeling has become routine work and automated or semi-automated procedures and even WWW services exist. There are two basic difficulties. The alignment between the query sequence and the template structure(s) has to be of very good quality since errors in the alignment cannot be corrected by the modeling procedure and parts of the query protein that have no direct counterparts in the template (for example loops) need special attention. Independently of the particular algorithm or program that one is using, the overall procedure usually consists of a series of steps: (1) identification of protein template(s) with known three-dimensional structure; (2) alignment of the query sequence with the template(s); (3) building a three-dimensional model of the query protein; (4) validation (evaluation of the quality of the model).

Identification and Selection of Template Structures

The principal resource for homology modeling is the protein data bank (PDB, ►<http://www.rcsb.org/pdb>) (2), which contains the 3D structures of all experimentally determined structures of biological macromolecules. Each entry in the PDB has two sections. The first contains general information about the molecule and its structure determination, such as the organism, the amino acid sequence, the experimental method (X-ray crystallography, nuclear magnetic resonance, electron

microscopy), the authors, related scientific publications, data base links and the resolution in the case of X-ray crystal structures. The second contains the atomic coordinates themselves, with some information on the dynamics of each atom. The latter can serve as a rough measure of the reliability of different regions of the structure.

In the simplest case, the query protein has relatively high sequence homology with at least one protein in the PDB such that it can be identified with a standard pairwise sequence alignment method such as BLAST (3). More sensitive methods use multiple sequence alignments. A multiple sequence alignment can be built from a database search of a sequence database with the query sequence. The program PSI-BLAST allows automated iterative creation of multiple sequence alignments. Once a multiple sequence alignment is generated, it can be used to search the PDB. Alternatively – and faster – one can search existing databases of multiple sequence alignments (such as PFAM, ►<http://www.sanger.ac.uk/Software/Pfam/>, or SMART, ►<http://smart.embl-heidelberg.de/>, which contain alignments of protein or protein domain families). These databases contain links to structures in the PDB. Among the most sensitive searches are those against multiple sequence alignments derived from the alignment of similar structures (for example, 3DPSSM, ►<http://www.sbg.bio.ic.ac.uk/~3dpssm/>) If several templates can be identified, one needs to choose the ones that are most appropriate for modeling. The choice can be based on the sequence identity or similarity, the score given by the alignment program or the location of query and template on a phylogenetic tree of the protein family. But the choice should also depend on other information, for example a similar biological function or a similar environment (e.g. if the template has a ligand or is in the free form). The quality of the structure, which is also important, can be estimated from the resolution and the R-values for X-ray crystal structures.

Alignment of the Query Sequence with the Template(s)

The most critical phase of the homology modeling procedure is the alignment of the query sequence with the identified templates. A homology model can only be as good as the sequence alignment. Unless the sequence identity between query and template is very high, this step should always be based on multiple sequence alignment. In contrast to a simple alignment between two sequences, a multiple sequence alignment contains evolutionary information (for example which residues are conserved in the course of evolution and therefore important for structure or function). Even though only one model is to be built, this alignment would contain several or many similar sequences, among them one or several templates. Some programs

can improve the quality of the alignment by using structural information, e.g. if several templates are known, an independently obtained structural alignment of the templates can be used to guide the sequence alignment. New and better multiple sequence alignment methods and strategies are still being developed. As a rule of thumb, a good alignment is easy to obtain once one has around 60% identity. However, it is possible to have 50% identity between two carefully designed protein sequences with a different fold (the so called JANUS protein). To obtain a correct alignment may become challenging for 40% and manual revision of the alignment may be necessary. In the so-called twilight zone of only 20–30% sequence identity, the information from multiple alignments becomes particularly important, since in a pair-wise alignment only 20% of residues can be expected to be correctly aligned if the sequence identity is below 30%.

Building a Three-Dimensional Model of the Query Protein

In building the 3D structure of the query protein based on the template, one can distinguish two different tasks. The first, easier task is to build the parts of the protein that could be well aligned. This consists mostly of replacing the amino acid side chains of the template protein with those of the query protein, using the main chain as a scaffold. The other, more difficult task concerns building those parts of the backbone where no good template can be used, the loops on the surface of the protein. These are unfortunately often the most interesting parts of the protein, containing parts of active or interaction sites of the protein.

Even modeling side chains on the main chain is, in principle, a very complex task, since the number of conformations that has to be evaluated grows exponentially with the number of side chains (it is computationally a so-called NP-hard problem). Side-chain conformations in the interior of a protein are largely determined by packing interactions, which simplifies the energetic evaluation of different conformations. Among the many methods available are interactive data base searches, the use of libraries with preferential conformations for each amino acid (rotamer libraries) and specific algorithms that circumvent the exponential explosion of conformations to be evaluated (dead-end elimination). Heuristic algorithms are based on minimization of a cost function and can be based on Monte Carlo, molecular dynamics, self-consistent mean field or distance geometry. At the end of the placement of the side chains, the backbone may need to be adjusted slightly. This is usually done by minimization with a molecular dynamics force field.

Modeling protein loops can be seen as a small “*ab initio*” prediction problem, more difficult because a

large number of possible conformations for the loop have to be evaluated and because the conformation of the loop depends on many more factors than simply packing. Searches of a database of loop conformations and the use of specialized cost functions that incorporate knowledge of likely loop conformations are most valuable for this task.

A popular homology-modeling package is SwissModel, based on a World Wide Web service (► <http://www.expasy.org/swissmod/SWISS-MODEL.html>) and interactive molecular graphics (SwissPDBViewer) to validate the alignment of the sequence with the 3D template and build the loops by database search. The service and program is associated to the SwissProt database (1). Another program is MODELLER (<http://salilab.org/modeller/modeller.html>) (4), a fully automated program that uses minimization of a cost function to build the structure of the query protein. The cost function is made up of several parts coming from sequence homology, a molecular dynamics force field and a special scoring function for loops. Sequence homology is incorporated by spatial restraints derived from a statistical analysis of protein structures, which bias the predicted structure towards that of the template with weights depending on the local degree of sequence similarity.

Validation and Evaluation of Quality

The criteria for quality assessment are the same as those used for experimental structures and range from simple geometric criteria (such as deviations from covalent bond lengths) to the assessment of the probability of environments of amino acids (e.g. a hydrophobic amino acid is more likely to be found in the interior of the protein and a hydrophilic amino acid in contact with the solvent). In general, properties derived from the homology models should not deviate much from those found in the experimental structures in the PDB. Examples of programs evaluating the quality of protein structures are WHATIF (► <http://www.cmbi.kun.nl/whatif/>), PROCHECK (► <http://www.biochem.ucl.ac.uk/~roman/procheck/procheck.html>) or PROSA (► <http://lore.came.sbg.ac.at/>). Larger errors in models of protein structures are usually due to sequence alignment errors or to parts of the protein where the template is not similar to the query protein (e.g. loops). If several different alignments between query and template are similarly possible one can build several models and evaluate all of them.

Clinical Applications and Therapeutic Consequences

Understanding the 3D structure of a macromolecule is crucial for understanding its function. Many properties of the 3D structure cannot be deduced directly from the

primary sequence, for example surface properties and electrostatic potentials. These properties are important for understanding the interactions of the protein with other molecules, for example with other proteins. Single nucleotide polymorphisms can be mapped on 3D structures of proteins in order to elucidate specific structural causes of disease.

Receptor-based or structure-based drug design exploits knowledge of the 3D structure of the binding site to construct potential drugs, for example inhibitors of a receptor protein. This can be an important first step in the development of a new therapeutic agent. Good homology models can serve as basis for drug design. The 3D structure of the protein can be used in several ways. Based on a detailed model of the protein-ligand interaction, one can propose modifications of the ligand to modify its binding characteristics. These modifications, proposed and characterized in the computer, can then be chemically synthesized and tested experimentally. The structure can also be used in virtual screening applications to screen a library of (sometimes millions of) compounds, for example to find likely inhibitors of the protein. In this way, the number of molecules that need to be screened chemically can be reduced.

Host Genome

► [Genetic Background](#)

Hotspot Mutation

Definition

The term describes mutations occurring at a chromosomal region, which is more susceptible to genetic damage/change than average sequences, or contains sequences that are more likely to be altered by spontaneous mutations, such as ► [CpG dinucleotides](#).

► [Heritable Skin Disorders](#)

► [Tumor Suppressor Genes](#)

Housekeeping Genes

Definition

Housekeeping genes refer to a set of genes that are expressed in all cells regardless of type, and which serve to maintain the basic functions of the cell.

► [CpG Islands](#)

► [Mutagenesis Approaches in Yeast](#)

Hox Cluster

Definition

Hox cluster refers to an array of ► [Hox genes](#) that arose from rounds of tandem duplication. In insects and vertebrates, the Hox genes are arranged into a cluster in the genome. Invertebrates have one Hox cluster, while mammals have four. The expression of these genes along the anteriorposterior axis usually correlates with their arrangement in the genome. Genes close to the 3' end of the cluster are expressed more anterior while genes towards the 5' end more posterior.

► [Mutagenesis Approaches in Medaka](#)

Hox Code

Definition

The Hox code describes a number of rules regarding the expression of ► [Hox](#) (homeobox) genes and their effects on segment identity. For example, a larger number of homeobox genes are usually expressed in more posterior regions. Loss-of-function mutations cause loss of structures and development of anterior structures where more posterior structure should have formed. However, the homeotic transformation occurs only in the anterior-most regions, where that Hox gene is normally expressed, and not within regions where a more posterior Hox gene is expressed.

► [Homeobox Transcription Factors](#)

Hox Genes

Definition

Hox genes comprise of a subset of ►[homeobox genes](#). In mammals, they are typically organized into 4 clusters (A–D), each spanning approx. 100 kb of DNA and containing 8–11 Hox genes. HOX genes have a primitive role in the regulation of anterior-posterior axis development. They regulate patterning during limb development, probably functioning in the determination of the timing and extent of local growth rates. A polyalanine stretch in the amino-terminal region of the HOXD13 gene causes synpolydactyly.

HPRT Vector

Definition

There are two ‘HPRT [hypoxanthine phosphoribosyl-transferase] vectors’ that are used in chromosomal engineering: the 5′ HPRT vector and the 3′ HPRT vector. The 5′ vector consists of the 5′ portion of the HPRT cassette that contains exons 1–2 of the *Hprt* gene, a single *loxP* site and the selectable marker NeoR. The 3′ vector consists of the 3′ portion of the HPRT cassette (containing exons 3–9 of the *Hprt* gene), a single *loxP* site and the PuroR selectable

HSQC

Definition

The large variety of multidimensional NMR experiments are distinguished by abbreviations of their names which reveal something about the kind of NMR sequence employed. The HSQC (Hetero-nuclear Single Quantum Coherence) is a two-dimensional NMR experiment that correlates the frequencies of either

^{15}N and ^1H nuclei in amide groups, or ^{13}C - ^1H pairs. In the case of proteins, HSQC spectra require isotopic labelling. HSQC spectra yield a pattern of signal characteristic for a particular protein, and are often used as fingerprint spectra to quickly assess the complexation state of a protein.

- NMR-Based Screening

HSRs

Definition

HSRs (homogenously staining regions) is a cytogenetic term that describes extended regions with uniform staining in G-banded chromosomes. Homogenously staining regions result from amplification of small parts (a few genes) of chromosomes.

- DNA Amplification

HSSP Database

Definition

HSSP-database displays a database of homology-derived secondary structure of proteins (HSSP), generated by aligning to each protein of known structure all sequences deemed homologous on the basis of the threshold curve.

- Protein Databases

HTF Islands

Definition

HTF island refers to HpaII tiny fragments, or CpG Islands.

- CpG Islands

HTH

- Helix-Turn-Helix

HTLV

► Human T-Cell Leukemia Virus

Htr

Definition

Halobacterial transducer of rhodopsin (Htr) is a two membrane spanning helix protein which binds in a 2:2 complex to cognate sensory rhodopsins. The cytoplasmic domain is highly homologous to the corresponding domain of chemotaxis receptors. Together with an adaptor protein CheW CheA, a His-kinase is activated.

► Photoreceptors

HTS

Definition

HTS stands for High-throughput-screening. It denotes an automated method that allows the analysis of a manifold of species from a molecular library with regard to a certain property. For example, the interaction of ligands from a library of small organic compounds to a cellular receptor may be probed by a fluorescence-based binding assay.

► Protein-Ligand-Interaction by NMR

HuCAL[®]

Definition

HuCAL[®] stands for Human Combinatorial Antibody library. It represents a fully synthetic phage display antibody library which consists of fully human Fab sequences for the generation of human antibodies.

► Immunological Methods, the Use of Antibodies to Discover the Function of Novel Gene Products

Human Genome (Sequence) Project

Definition

The human genome (sequence) project was an international effort that aimed to identify all the approximately 30,000 genes in human DNA, to determine the sequences of the 3 billion chemical base pairs that make up human DNA, and to store this information in databases (<http://www.gene.ucl.ac.uk/hugo/>). The Human genome project ended in 2003 with the completion of the human DNA sequence.

Human Leukocyte Antigens

Definition

These polypeptides are genetically encoded in the ► major histocompatibility complex (MHC) on the

short arm of chromosome 6. These highly polymorphic antigens are not only expressed on leukocytes, but on almost all cells containing a nucleus. HLA molecules are expressed on the surface of cells, and are important for the recognition of the body's own and foreign cells by the immune system. Their main function is to help the immune system to defend against invaders such as bacteria, viruses and parasites. The immune system can also recognize as foreign the histocompatibility antigens of other people's cells and will attend them, causing rejection of grafts. There are many different HLA antigens (e.g. class I, II; HLA-A, HLA-B, HLA-DR, rendering the individual immunologically unique). Therefore, they are particularly important for transplantation medicine and play an important role in autoimmune disorders.

Human Repetitive DNA

ADAM PAVLICEK, VLADIMIR V. KAPITONOV,
JERZY JURKA

Genetic Information Research Institute,
Mountain View, CA, USA
jurka@girinst.org

Definition

Repetitive DNA is usually defined as DNA present in multiple copies in the genome, without a clearly defined biological function. There are two main groups of ► **repetitive elements**, tandem repeats and interspersed repeats. ► **Tandem repeats** are repetitions of the same sequence motifs arrayed in a head-to-tail fashion. They occupy a significant fraction of heterochromatin and centromeric regions. ► **Interspersed repeats** are remnants of ► **transposable elements** (TEs), and constitute approximately 45% of the human DNA (1). TEs are either autonomous, i.e. encoding proteins necessary for their amplification, or nonautonomous, amplified by proteins encoded by autonomous elements. Most interspersed repeats are highly mutated ancient TEs, incapable of transposition. However, there are a few families of non-LTR retrotransposons including Alu and LINE1 (L1) elements that still actively proliferate in the human genome and occasionally insert into human genes (2). Interspersed repeats can also promote

chromosomal instabilities by homologous recombination between dispersed copies, causing various congenital defects and cancer (3). On the protein level, antigens produced by the translationally competent elements, particularly by endogenous ► **retroviruses**, can trigger an autoimmune reaction against affected tissues (4).

Characteristics

Tandem repeats are divided into microsatellites, minisatellites, centromeric satellites, and telomeric and subtelomeric repeats (Fig. 1). ► **Microsatellites** are tandem repetitions of short (1–9 bp) units. ► **Minisatellites** are composed of longer (10 and more bp) units. The 10 bp boundary separating micro- and minisatellites is somewhat arbitrary as it ranges from 6–13 bp in the literature. Micro- and minisatellites are traditionally also referred to as simple sequence repeats (SSRs) or variable number of tandem repeats (VNTRs), respectively. In the human genome, microsatellites composed of short 1–2 bp units are most frequent. Minisatellites, particularly those with longer units, are relatively rare. The total length of micro- and minisatellite arrays varies from a dozen or hundreds of bp for the shortest microsatellites to dozens of kb for minisatellites. ► **Satellites** are minisatellite-like units spanning up to 10^6 bp and located in well-defined chromosomal regions such as heterochromatin and centromeric regions (5). Alpha satellites representing repetitions of 171 bp units assembled into higher-order structures (Fig. 1b) are most abundant.

► **Telomeric repeats** are located at the ends of human chromosomes called telomeres. They are composed of the tandemly repeated conserved TTAGGG hexamer creating 3–20 kb long arrays (6). Telomeres play an essential role in protecting chromosomes from damage and degradation. In addition, telomeres can act as regulators of cell life span and affect cancer predisposition.

Human Repetitive DNA. Figure 1 Structure of human tandem repeats. (a) Schematic structure of an array of tandem repeats. (b) Higher-order structure of centromeric alpha satellites. The human genome contains about 12 distinct types of alpha satellite units (small arrows with different intensity of gray). A repetition of specifically ordered different units is called a higher-order structure (marked by boxes).

►**Subtelomeric repeats** are satellite-like sequences located at the 100–300 kb long boundary between the telomere and the rest of the chromosome. These repeats are generally derived from the telomeric TTAGGG hexamer, but are much less conserved and may differ between chromosomes (6).

Interspersed repeats are created by germline insertions of transposable elements (TEs). Copies of different TEs share founder-specific mutations and are classifiable into families or subfamilies of repeats. Most human interspersed repeats were active 30–150 million years ago; the oldest known repeats are older than 200 million years. Currently there are only a few active families of non-LTR retrotransposons in the human genome (1, 2, 7).

The human genome harbors three major groups of interspersed repeats derived from DNA transposons, non-LTR retrotransposons and retrovirus-like LTR-retrotransposons (1, 7). ►**DNA transposons** amplify via so-called cut-and-paste transposition, i.e. excision from one (usually freshly replicated) genomic site and insertion of the excised DNA into a new location. Autonomous DNA transposons code for an enzyme transposase that binds terminal inverted repeats and catalyses transposition (Fig. 2). The vast majority of human DNA transposons are inactive relics of ancient insertions with no elements capable of ►**transposition** detected (Table 1).

Non-LTR ►**retrotransposons** and retrovirus-like LTR-retrotransposons proliferate via an RNA intermediate reverse transcribed into complementary DNA (►**cDNA**). The ►**retrotransposition** process is catalyzed by ►**reverse transcriptase** (RT), an RNA-dependent DNA polymerase encoded by autonomous elements. LTR-retrotransposons, including human endogenous retroviruses (HERVs), structurally resemble exogenous retroviruses (Fig. 2). Autonomous LTR-retrotransposons contain several open reading frames (ORFs) homologous to retroviral *gag*, *pol* (*pro*) and, in some cases, *env* and other auxiliary genes (4). A tRNA primer encoded by the host cell initiates reverse transcription of LTR-retrotransposons, which takes place in cytoplasmic retrovirus-like particles. The retroviral reverse transcription produces a DNA copy that differs from the original RNA by the presence of long terminal repeats (LTRs) containing pol II promoters and other regulators of transcription. The DNA copy inserted into the genome is called a ►**provirus**. Currently, there are no retrotransposition-competent LTR-retrotransposons in the human genome and no insertion of LTR-retrotransposons is reported in human mutation databases. However, one member of the HERVK family with intact ORFs is polymorphic in the human population. In addition, several elements of young HERV families may contain individual ORFs

capable of translation and production of functional proteins.

The main characteristics distinguishing non-LTR from LTR retrotransposons is the lack of long terminal repeats and their utilization of DNA target-primed reverse transcription. The DNA genome of non-LTR retrotransposons is structurally collinear with RNA (Fig. 2). Transcription of these elements is initiated from internal pol II promoters. Autonomous non-LTR retrotransposons are called ►**long interspersed repeats** (LINEs). The human genome contains three families of LINEs: L1 (LINE1), which includes active subfamilies, and the extinct L2 and L3 LINEs similar to CR-1 elements from birds, fishes, and reptiles. Active L1 elements are around 6 kb long and contain two open reading frames, *ORF1* and *ORF2* (2). *ORF1* encodes a nucleic acid binding protein of uncertain function. *ORF2* encodes a single protein with reverse transcriptase and endonuclease domains (Fig. 2). The coupled nuclear process of reverse transcription and integration is primed by the 3' end of the initial nick created during cleavage of the genome by L1 endonuclease. The vast majority of the ~500,000 L1 copies in the haploid human genome (Table 1) are inactive, and there are only about 50 copies with intact reading frames capable of retrotransposition. The active copies are mostly from the L1-Ta subfamily.

Nonautonomous non-LTR retrotransposons are called ►**short interspersed elements** (SINEs). SINEs are transcribed by pol III polymerase (Fig. 2). The most abundant human SINEs are Alu elements, mobilized by the reverse transcriptase/endonuclease of L1 elements. Human Alu elements are approximately 300 bp long, dimeric sequences derived from 7SL RNA, which is a component of the ►**signal recognition particle** (SRP). Over one million Alu elements are present in the human genome (Table 1) and some AluY subfamilies still continue to retrotranspose (2). Apart from Alu elements, the human genome contains another active family of SINEs called SVA. SVA repeats are composite elements containing one complete Alu, one Alu monomer, fragments of HERVK endogenous retrovirus including one LTR and a microsatellite region. SVA elements are probably L1-dependent, since they share similar structural features, including the TTAAAA target site, 5–20 bp long target site duplication and the 3' polyA tail. In addition to SINEs, L1 elements can also occasionally retrotranspose cellular RNAs, such as intronless copies of human genes called ►**processed pseudogenes**. Due to the lack of promoters in mRNA, processed pseudogenes are not functional. Two other families of human SINEs are remnants of extinct MIR and MIR3 families that coamplified with L2 and L3 LINEs respectively, 200–300 millions years ago.

a DNA transposons**b LTR retrotransposons****c Non-LTR retrotransposons**

Human Repetitive DNA. Figure 2 Structure of human interspersed repeats. (a) DNA transposons. Human DNA transposons contain a single ORF flanked by terminal inverted repeats (TIRs) and by 2-10 bp long target site duplications (TSDs). (b) LTR retrotransposons. Autonomous elements contain an internal coding sequence with two or more open reading frames. Retroviral RNA and DNA differ from each other by the presence of 0.3-3 kb long terminal repeats (LTRs) in DNA. LTR harbors an RNA polymerase II promoter (black TATA box) and polyadenylation signal (white AATAAA or ATATAA signal). Elements are flanked by 4-6 bp long TSDs. (c) Non-LTR retrotransposons. Active autonomous L1 contains an internal RNA polymerase II promoter (black box) and two ORFs. In contrast to LTR retrotransposons, DNA of non-LTR retrotransposons is a perfect copy of RNA. Nonautonomous Alu elements are dimers composed of two monomeric units separated by short AT-rich linker. An internal RNA polymerase III promoter is composed of conserved boxes called A and B (in black). Elements are flanked by 5-20 bp long TSDs.

Detection of repetitive elements is a routine part of annotation and analysis of DNA sequences. Several specialized programs and databases have been developed for this purpose (Table 2).

Clinical Relevance

Expansions of trinucleotide repeats and other microsatellites may cause several genetic disorders (see Repeat Expansion Diseases). In addition to repeat

Human Repetitive DNA. Table 2 Programs and databases for analysis of human repeats

Database/Program	Description
Repbase Update	Database of eukaryotic repetitive sequences, including more than 600 families of human repeats. ► (http://www.girinst.org/Repbase_Update.html)
HERVd	Database of human endogenous retroviruses, maps all known endogenous retroviruses in the human genome. ► (http://herv.img.cas.cz/)
Human TE Insertion	The database collects reported insertions of repetitive elements into the human genome associated with human genetic diseases. ► (http://www.med.upenn.edu/genetics/labs/kazazian/human.html)
Censor	Program for identification of interspersed and tandem repeats in both nucleic and amino acid sequences. Both on-line and local versions are available. ► (http://www.girinst.org/Censor_Server.html)
RepeatMasker	Program for identification of interspersed and tandem repeats in nucleic acid sequences. Both on-line and local versions are available. ► (http://www.repeatmasker.org/)
Tandem Repeat Finder	Specialized program for detection of tandem repeats in DNA sequences. Both on-line and local versions available. ► (http://tandem.bu.edu/trf/trf.html)
EMBOSS	A general package for analysis of biological sequences includes programs etandem and quicktandem for detection of tandem repeats. ► (http://www.hgmp.mrc.ac.uk/Software/EMBOSS/index.html)

expansions, tandem repeats can induce genetic disorders by recombination between different arrays. Recombinations between both centromeric and telomeric satellites are involved in chromosomal rearrangements including chromosome fragility or jumping chromosomal translocations.

TE-derived interspersed repeats can also contribute to genetic instability. Active retrotransposons can occasionally insert into genes and inactivate them (► [insertional inactivation](#)). The estimated rate of genomic

retrotransposition is around 1 insertion per 4–100 individuals (2). New inserts often introduce frame-shifts, premature stop codons, or both. RNAs with ► [premature termination codons](#) (PTCs) are usually destroyed by ► [nonsense-mediated RNA decay](#) (NMD) and the corresponding defective protein is not produced. The only recently inserted elements are either L1 elements (15 cases), or L1-dependent Alu (24 cases) and SVA SINEs (4 cases). Table 3 lists insertions of TEs connected with human diseases. Many cases listed

Bruton agammaglobulinemia tyrosine kinase	BTK	Xq22.1	X-linked agammaglobulinemia

in Table 3 are *de novo* insertions, i.e. detected in children of parents without the insertion. L1 insertions are exclusively derived from the most active subfamilies L1-Ta (or L1-preTa) and Alu insertions are from the most active AluY subfamilies. Except for one somatic L1 insertion into the *adenomatous polyposis coli* (*APC*), all other cases listed in Table 3 are germline insertions. Not all insertional inactivations cause a strong negative phenotype. Insertions into nonessential genes may be under weak negative selection and eventually become fixed. For example, an AluYb8 insertion that inactivated *CMP-N-acetylneuraminic acid hydroxylase* (*CMAH*) is fixed in the human lineage, but other primates including chimp contain a functional copy of *CMAH* without the Alu insert. Distribution of TE insertions is nonuniform across the genome (2). Some genes such as the X-linked *coagulation factors VIII* and *XI* and the *dystrophin* gene have been targeted by several independent events. As much as 49% (21 out of 43) of all documented insertions have occurred in genes located on chromosome X, which represents only 5% of the human genome. This bias is even stronger for L1 insertions of which 86% (12/14) occur on chromosome X. The bias is probably caused by the dominant character (loss of function) of mutations on chromosome X, since only one of its functional copies is present in somatic cells. Males have only one X copy and in females the second copy is silenced by **X-chromosome inactivation**. Thus X-linked mutations have a dominant effect, while autosomal gene inactivation can be compensated by the copy on the sister chromosomes and no disease is detected in heterozygotic individuals.

Insertional inactivations listed in Table 3 target both exons and introns, indicating that even intronic insertions can be damaging. Insertions into splicing regulatory regions can cause exon skipping, i.e. deletion within mRNA or insertion of noncoding

intronic sequences into mRNA (intron inclusion). Intronic inclusions can also be produced by activation of **cryptic splice signals** in existing intronic repeats. Notably, Alu elements contain cryptic splice donor and acceptor sites in the antisense orientation that, after specific mutations, can give rise to new Alu-derived exons. Such Alu cassettes can be alternatively spliced and typically produce premature termination codons. However, if the new exon becomes constitutively spliced into mRNA, the NMD control prevents efficient synthesis of the protein. So far, there are two known cases of disease-related Alu splicing into cellular mRNAs. An Alu inclusion into mRNA coding for ornithine-delta-aminotransferase (OAT) led to OAT deficiency. The second case was reported for a patient with autosomal recessive Alport syndrome, caused by an Alu inclusion into the precursor of alpha 3 type IV collagen mRNA.

Similar copies of TEs interspersed with genomic DNA may promote homologous recombinations leading to genetic instabilities. Table 4 lists loci with reported deletions, duplications and chromosomal translocations related to human diseases that are caused by recombination between repetitive elements. While for some loci only a single event of recombination between interspersed repeats is detected, other loci represent hotspots for recombinations and many independent cases have been reported. For example the *complement component 1 inhibitor precursor* (*C1NH*), *low-density lipoprotein receptor* (*LDLR*), *alpha-globin* and *adenomatous polyposis coli* (*APC*) genes are frequently affected by TE-induced recombinations. Analogously to insertions, detected recombinations are biased towards X-linked genes; 12 out of 54 (22%) deletion/duplication events were detected on chromosome X. Recombinations listed in Table 4 occurred in both germline and somatic cells. Somatic recombinations are involved in many leukemia- or other cancer-related

Human Repetitive DNA. Table 4 Repeat-induced recombinations and human diseases

Locus	Symbol	Chr.	Phenotype
<i>Deletions by Alu-mediated recombination</i>			
alpha(1,2)fucosyltransferase	FUT2	19q13.33	ABO-Bombay phenotype

cases. Crossovers between repeats leading to DNA deletions have been reported in 54 genes, whereas duplications have been reported for only five loci.

Alu elements are by far the most active repeats involved in known rearrangements (Table 4). Alu-mediated recombinations have been reported for 55 out of 61 genes, L1 recombinations for three and endogenous retroviruses for one. One deletion and one translocation were induced by nonhomologous Alu-L1 recombinations. Alu elements are the most abundant repeats in GC- and gene-rich regions and frequently form clusters of highly identical copies prone to recombination in the gene-rich regions.

Alu repeats have also been implicated in the etiology of recurrent somatic chromosome translocations, particularly in several forms of acute and chronic leukemias (3). Repeat-induced recombinations associated with large rearrangements can lead to the **loss of heterozygosity** (LOH) in cancers and, therefore, to cancer progression. In the germline, constitutional congenital disorders can be caused by nonlethal cytogenetically balanced chromosomal translocations. For example, a patient with cranial deformations and mental retardation had a t(1;19)(q21.3;q13.2) congenital translocation, stimulated by nonhomologous Alu-L1 recombination. In another case, a familial form of the

bipolar affective disorder (manic depression) was caused by the congenital Alu-mediated translocation t(9;11)(p23;q23).

In rare situations, rearrangements induced by TEs may even protect against harmful recombinations. For example, primitive neuroectodermal tumors, including Ewing's sarcoma, are strongly linked to the reciprocal translocation t(11;22)(q24;q12) fusing the *Ewing's sarcoma (EWS)* gene on 22q.12 with the *Friend leukemia virus integration region 1 (FLII)* gene on 11q.24. A small (2.4 kb) Alu-mediated deletion inside *ESW* intron 6 located close to the translocations breakpoints seems to inhibit the t(11;22)(q24;q12) translocations. African human populations that carry this deletion have a tenfold decreased incidence of Ewing's sarcoma compared to other populations.

So far, it is estimated that insertions and recombinations between interspersed repeats are responsible for 0.1% and 0.3% of human genetic disorders, respectively. However, the mechanism of large DNA rearrangements representing ~7.4% of all human mutations remains to be elucidated.

Apart from obvious genetic rearrangements caused by repetitive elements, proteins encoded by transposable elements can also induce pathological processes in human cells and tissues. In particular, TE-encoded

protein antigens may trigger an immune reaction against affected tissues leading to autoimmune abnormalities (4). The relevant research was done mostly on human endogenous retroviruses. HERV expression has been linked to several autoimmune diseases such as multiple sclerosis, rheumatoid arthritis, systemic lupus erythematosus or insulin-dependent diabetes mellitus. A link to schizophrenia and some types of cancer has also been proposed. Retroviral mRNAs, and in some cases even entire retroviral particles were detected in affected tissues. It is possible that production of retroviral antigens such as the *gag* (group-specific antigen) may provoke an autoimmune response. However, since increased expression of TEs is associated with many pathological processes this relationship may be coincidental.

Human T-Cell Leukemia Virus

Definition

Human T cell leukemia virus (HTLV) is a member of the retrovirus family. HTLV type 1 causes adult T-cell leukemia/lymphoma, a malignancy of T-lymphocytes. HTLV-2 is less pathogenic. The virally encoded Tax oncoprotein can transform T-cells *in vitro*. Biochemically, ►Tax acts as a transcriptional transactivator of NF- κ B and CREB pathways, and stimulates the cell

cycle in the G1-phase by binding to cyclin-dependent kinase holoenzymes.

►Viral Oncogenesis

Humanization

Definition

Humanization refers to a process where mouse DNA sequences are replaced with equivalent human DNA sequences; e.g. in ES cells and hence in mice.

Definition

Huntington's Disease (HD) is a progressive neurodegenerative disorder with autosomal **▶dominant** inheritance and usually adult onset (4th to 5th decade of life). Clinical findings include motor, psychiatric and cognitive abnormalities. HD is caused by an abnormal elongation of a polymorphic (CAG)_n trinucleotide block beyond a critical threshold within the first exon of the *huntingtin* gene (*htt*, *IT15*). Postmeiotic instability of the (CAG)_n block, leading to further expanded **▶alleles**, accounts for the clinical phenomenon of **▶anticipation**, i.e. earlier onset and possibly more severe disease course in subsequent generations. As in related disorders, e.g. spinobulbar muscular atrophy (**▶SBMA**), dentatorubral-pallidoluysian atrophy (**▶DRPLA**) and different types of spinocerebellar ataxia (**▶SCA**), the resulting elongated polyglutamine (polyQ) stretch within the protein causes a complex alteration of its interactions with crucial factors of cell integrity, many of which are still not completely understood. Morphological studies in HD reveal substantial loss of neuronal cells, predominantly occurring in the caudate, subthalamic nucleus and putamen. On a microscopic level characteristic cytoplasmic and intranuclear huntingtin-positive inclusion bodies are detectable.

Characteristics

Clinical Features

HD, first described by George Huntington in the 19th century, is a complex neurological disorder providing variable clinical manifestations. The most impressive symptom is deteriorating loss of motor control, often reported as beginning slightly with awkwardness or fidgetiness, difficulties in swallowing or control of eye movements. With disease progress, motor symptoms often worsen to continued, uncontrollable jerking movements of numerous body parts involving limbs, trunk, neck and head while the muscle tone is generally decreased. These movements cannot be repressed voluntarily; they advance with physical or mental stress and abate only during sleep. Weight loss, caused by immense energy consumption, disturbed food intake

and possibly other factors directly linked to the pathogenesis of the disease, is a complicating factor in HD and often a critical issue in late stages. As the disorder advances, more rigid motor dysfunction with increased muscle tone and bradykinesia may come to the fore and patients are usually confined to bed. As a second aspect, psychiatric disturbances are a common feature of HD and may be the first symptom to be presented. Affective or schizophrenic psychosis may be preceded by behavioural changes like aggressiveness and impulsive behaviour, abjection and apathy, unsociability and alcohol abuse. The risk of suicide is increased among HD patients. The third major clinical feature in HD is a cognitive decline, which, although not obligatory, is present in most patients starting mildly at early stages of the disease. Deficits in memory and concentration as well as decreased ability to perform complex thought processes are reported. It may result in distinct dementia in late stages of the disorder. Patients usually die after 10 to 15 years of disease progression from complications of immobility and body wasting, with aspiration pneumonia being a typical cause of death. The prevalence of HD among Caucasian populations is about 3–5 per 100,000 and the age of onset lies within the fourth or fifth decade in most patients. There is, however, major variability and first symptoms are reported in adolescents as well as in elder people.

Genetics

HD is inherited in an autosomal dominant manner, usually with full **▶penetrance**. By linkage analysis the HD causing **▶mutation** was mapped to chromosome 4p16.3 in 1983. In 1993 the pathological expansion of the polymorphic (CAG)_n block in the first **▶exon** of the *huntingtin* (*htt*, *IT15*) gene was defined as molecular cause of the disorder (1). The *htt* gene consists of 67 exons spanning 180,000 nucleotides with the mature huntingtin protein comprising 3,144 amino acids (350 kD). In the normal population the size of the trinucleotide motif varies between 10 and 35 CAG copies with most chromosomes comprising up to 26 CAG copies and the (CAG)₁₇ allele being most common. In contrast, pathologically expanded (CAG)_n stretches between 36 and >120 copies are found in patients with HD. While alleles \geq (CAG)₄₀ show full penetrance, reduced penetrance has been observed for the rare intermediate alleles between (CAG)₃₆ and (CAG)₃₉. Since the genetic defect is known, **▶predictive genetic testing** is available for persons at risk for HD. There is a strong statistical correlation between the size of the (CAG)_n stretch and the average age of onset. Large alleles predispose to an earlier onset of first symptoms and a more severe disease course. However, within the most common group comprising 40–45 CAG copies the age of onset varies considerably and

the number of CAG copies must not be used for predicting clinical features in most cases. Yet, patients with alleles $>(\text{CAG})_{60}$ usually present first symptoms in adolescence and rare cases with childhood onset and trinucleotide blocks $>(\text{CAG})_{200}$ copies have been reported. The clinical features in adult onset usually differ from the ones in early onset HD, the latter showing more Parkinson-like **▶phenotype** with high, rigid muscle tone and bradykinesia or akinesia, severe cognitive decline and rapid disease progression. The origin of large $(\text{CAG})_n$ stretches is likely to be caused by postmeiotic expansion of an already enlarged allele in one of the patient's parents, usually the father. This mechanism constitutes the genetic correlate of the clinical finding of anticipation, i.e. an average decrease of age of disease onset in subsequent generations. In rare cases this may lead to the situation that a child shows first symptoms before its parent carrying the HD mutation, implying a case of a new mutation or skipping of a generation. This phenomenon is found far more often in families with paternal inheritance and is thought to have its origin in a higher mutation rate during spermatogenesis. Patients homozygous for the HD mutation do not show an earlier mean age of onset compared to heterozygous ones but recent studies indicate more severely affected phenotypes in homozygous patients.

Cellular and Molecular Regulation Huntingtin and Associated Proteins

Since the discovery of the molecular genetic defect in HD several animal (e.g. mice, rats, *Drosophila*) and cellular models have been developed to examine the possible pathways leading to cell death. These models and additional examinations in humans have revealed ample data not only of great value for understanding of HD but also several other disorders. HD is one of the most intensively studied diseases and has become a veritable model disease.

Located in the first exon of *htt* the $(\text{CAG})_n$ block is translated into a polyQ stretch close to the N-terminus of the mature huntingtin protein. The *htt* gene is expressed ubiquitously. Little is known about its physiological function but it is likely to be of great importance during neuronal development as homozygous *hdh* (the mouse homolog of human *htt*) knockout mice die early during embryogenesis shortly after gastrulation. There are numerous proteins associated with huntingtin, including HIP1, HIP2, HAP1 and GAPDH, a major component of cell glycolysis. HIP1 (huntingtin interacting protein) is a membrane-associated protein linked to the cytoskeleton, which is probably involved in mechanisms of endocytosis. Its interaction with huntingtin is impaired by the expansion of the polyQ stretch, indicating disturbed membrane-cytoskeletal integrity in HD.

Over-expression of HIP1 results in activation of apoptosis *via* caspase 3. While HIP2 may be involved in huntingtin degradation, HAP1 (huntingtin associated protein) is also associated with the cytoskeleton. Recently, the interaction of another protein, HIP14, with huntingtin has been shown to be dependent on the length of the polyQ stretch. HIP14 is likely to play a role in cell trafficking and its interaction with huntingtin may contribute to the pathogenesis of HD.

Protein Aggregation—A Crucial Step in the Pathogenesis

The polyQ expansion causes a pathological **▶gain-of-function** in the huntingtin protein, reflecting the dominant mode of inheritance. A hallmark of the pathological processes underlying HD is the occurrence of cytoplasmic and, in particular, of intranuclear inclusions comprising huntingtin and ubiquitin. These are assumed to emanate from the intranuclear aggregation of N-terminal huntingtin fragments, possibly generated by caspase cleavage, to amyloid fibrils *via* the formation of oligomers. This process may be mediated either by transglutaminases or, more probably, by the potential of polyQ stretches to self-assemble, e.g. acting as polar zippers. While full-length wild-type huntingtin harbours a nuclear export signal at the C-terminus of the protein, intranuclear accumulation of N-terminal fragments of mutant huntingtin may be promoted by the lack of this motif. Notwithstanding, the impact of visible intranuclear inclusions has not been clarified sufficiently in the pathogenesis of HD. The original hypothesis that intranuclear inclusions constitute the major pathogenetic factor in HD has recently been disputed, and models of these inclusions have been discussed as being an epiphenomenon or even a protective factor established by the cell. Although the presence of intranuclear inclusions has been shown to lack correlation with huntingtin induced cell death, expanded polyQ stretches and even those of physiological huntingtin proteins have the potential to cause cell death when delivered to the nucleus (2). Thus, the toxic potential of intranuclear polyQ elements is generally accepted, but the stage of aggregation initiating the cascade to cell death remains to be elucidated. Oligomerization of polyQ elements may be crucial (3).

From Aggregation to Pathology

Various complementary models suggest how the intranuclear occurrence of polyQ elements causes cell death. Mutant huntingtin is not only able to build complexes with itself but also with other proteins including transcription factors like cAMP-response element binding protein (CREB) binding protein (CBP) and TATA binding protein (TBP), both containing polyQ elements, and SP1, harbouring a glutamine-rich

Huntington's Disease. Figure 1 The polymorphic (CAG)_n motif within the first exon of the *huntingtin* gene is translated into a polyglutamine stretch at the N-terminus of the huntingtin protein. Aggregation of polyglutamine elements beyond a critical threshold results in altered interaction of the huntingtin protein with various cellular elements including the mitochondria. Impaired degradation and nuclear accumulation of polyQ elements causes cell death predominantly in striatal neurons.

domain. However, in mouse models these transcription factors are not trapped within the intranuclear inclusions to a great extent, emphasizing the potential importance of the intermediate stages of polymerization. There is evidence for a reduced expression of signalling genes in a mouse model of HD (4). Mutant *htt* exon 1 protein binds to the acetyltransferase domain of CBP and p300/CBP associated factor (P/CAF) resulting in decreased levels of acetylated histones H3 and H4. Thus, impairment of protein expression controlled by huntingtin-interacting transcription factors may be important. Wild-type huntingtin up-regulates transcription of brain derived neurotrophic factor (BDNF) whereas mutant huntingtin lacks this ability (5). BDNF was found to be reduced in the putamen of HD patients. As BDNF is required for both differentiation and survival of neuronal cells, decreased BDNF activity may represent a ►**loss-of-function** pathway in HD pathogenesis. There is evidence that pathogenesis in HD is partly related to mitochondrial dysfunction. Enzymatic activities of different mitochondrial proteins have been shown to be decreased in HD neurons, affecting different complexes of the respiratory chain. Decreased metabolic capacity is proposed to enhance the susceptibility of the cell to chronic damage caused by oxidative stress and excitotoxicity subsequently leading to apoptosis. Huntingtin fragments are degraded by the proteasome complex in a polyQ length-dependent manner with fragments containing shorter polyQ stretches being

metabolized more efficiently. The ability of proteasomes to react with other proteins may be impaired by the binding of mutant huntingtin. It has been shown that proteasomal dysfunction is associated with disrupted mitochondrial membrane potential, cytochrome c release from the mitochondria, and activation of caspase-9 and -3-like proteases resulting in apoptotic cell death.

Point of Origin – Expansion Mechanisms in HD

Intermediate alleles carrying 27–35 CAG units show a greater tendency to expand into a pathological range, i.e. $\geq(\text{CAG})_{36}$, than the common alleles $\leq(\text{CAG})_{26}$, probably accounting for the rare cases of true new mutations in HD. Mechanisms by which this expansion is generated are not fully understood, nor is the process of how pathologically enlarged (CAG)_n blocks undergo further expansion during gametogenesis. Probably closely linked to these mechanisms is the occurrence of age-dependent somatic ►**mosaicism** with larger (CAG)_n stretches found in the striatum of HD patients (6). Recently a model has been established suggesting that expansions in germ cells are not due to mitotic mechanisms like homologous ►**recombination** or replication slippage of the DNA polymerase. In contrast, the expansion mechanism appears to be located within the postmeiotic haploid cell, i.e. during the maturation of spermatids to spermatocytes, and is likely to be mediated by a complex containing Msh2, a DNA mismatch repair protein. This complex may

stabilize DNA loops, which emerge after single-strand or double-strand breaks in the DNA, and facilitate their integration into the DNA by gap filling. As neuronal cells are generally post-mitotic and HD Msh2-knock-out mice do not show somatic instability of the (CAG)_n stretch, expansion mechanisms within tissues other than germ cells are likely to underlie a similar pathogenetic model.

Clinical Relevance

Due to its fatal course and the lack of a sufficient causal therapy, HD constitutes a great challenge for interaction with patients and their families. Predictive genetic testing for persons at risk for HD requires profound genetic counselling including psychological and social support in order to provide the individual with the best possible ability to cope with the test result, be it positive or negative. Current medication protocols for patients with manifest HD improve psychiatric symptoms using antidepressants, neuroleptics or anxiolytic drugs, respectively. Motor symptoms may be reduced by antidopaminergic neuroleptics like tiaprid or tetra-benazine whereas patients with hypokinetic features (e.g. Westphal variant) may even benefit from low doses of dopaminergic drugs. Additionally, physical, occupational and logopedic therapy constitute fundamental concepts in HD care.

Based on the pathogenetic mechanisms in HD, several new therapeutic approaches have been suggested. Prevention of aggregation is an obvious principle to overcome the probable basis of HD pathology. Certain heat shock proteins (HSP40 and HSP70) are able to bind polyQ proteins and alter their solubility. Over-expression of HSP40 and HSP70 results in reduced *htt* exon 1 protein aggregation in mammalian cells. Histone deacetylase inhibitors (HDAC) have been shown to slow down neurodegeneration in a Drosophila model of HD. Caspase inhibitors like minocycline, inhibiting the pathological cleavage of huntingtin, slow down disease progression in a HD mouse model. A recent finding is the neuroprotective potential of tauroursodeoxycholic acid (TUDCA), a hydrophilic bile acid, in HD mice, which is of particular interest as it may provide a therapeutic concept which is likely to show only minor side effects.

It is highly remarkable that HD symptoms and occurrence of nuclear inclusion bodies was shown to be reversible in mice expressing exon 1 of mutant *htt* after the mutant gene was switched off. Thus, the aforementioned approaches may be a basis not only for the prevention but also for a cure of HD symptoms in humans in future times.

Hybridization Probes

Definition

In the context of molecular biology, a probe traditionally refers to the labelled, soluble partner in a nucleic acid hybridization experiment such as a Southern, northern or dot blot. More recent usages in the field of microarrays confusingly invert the usage, and call the partner bound to the solid support the “probe” and the soluble, labelled partner the “target”.

►YAC and PAC Maps

Hybridization

Definition

Hybridization is the process of binding complementary single-stranded DNA molecules (or DNA and RNA)

resulting in a helical structure (Watson-Crick base pairing). The hybridization process is temperature and salt dependent.

Hydrophobic Interactions

Definition

Hydrophobic interactions are molecular interactions that are driven by the exclusion of water from non-polar groups of atoms that are not able to participate in hydrogen bonding.

► [Protein/DNA Interaction](#)

Hydrophobicity

Definition

Hydrophobicity characterizes a thermodynamic scale that indicates whether a considered molecule has affinity for water or not. Due to their atomic composition, hydrophobic molecules are incapable of forming substantial hydrogen bonds with water. In such polar solvents, these molecules tend to bind together, because this phenomenon is accompanied by a decrease of the Gibbs free-energy.

Hyper- and Hypoparathyroidism

GEOFFREY N. HENDY

Calcium Research Laboratory, Royal Victoria Hospital, and Departments of Medicine, Physiology and Human Genetics, McGill University, Montreal, Canada
geoffrey.hendy@mcgill.ca

Definition

Hyperparathyroidism

► [Primary hyperparathyroidism](#) – the increased secretion of parathyroid hormone (PTH) – is due to neoplasms or idiopathic hyperplasia of the parathyroid glands. ► [Secondary hyperparathyroidism](#) associated with hyperplasia of the parathyroids arises as a result of disordered metabolism producing hypocalcemia, as in chronic uremia due to renal disease, malabsorption, ► [rickets](#) or ► [osteomalacia](#). The focus of this review is on primary hyperparathyroidism.

Hypoparathyroidism

Hypoparathyroidism is due to diminution or absence of the secretion of PTH. Pseudohypoparathyroidism is a disorder resembling hypoparathyroidism, with high serum phosphate and low calcium levels, but normal or elevated serum PTH levels due to lack of end-organ responsiveness to PTH. The focus of this review is on hypoparathyroidism.

Characteristics

Hyperparathyroidism

The important biochemical features of primary hyperparathyroidism are elevated serum calcium, decreased fasting serum phosphate, increased serum ► [parathyroid hormone](#) (PTH) and hypercalciuria. Eighty-five percent of cases involve a single benign parathyroid adenoma, while hyperplasia (multiple hypercellular glands) is present in 15%. Parathyroid carcinoma is seen in less than 1% of cases and ectopic secretion of PTH by nonparathyroid tumors is extremely rare.

Although primary hyperparathyroidism is most often detected by its biochemical features, ►nephrolithiasis due to hypercalciuria is a frequent clinical manifestation. Nephrolithiasis with kidney stones occurs in 20% of patients. Other organ systems can be involved, including skeleton, gastro-intestinal tract and central nervous system. Formerly a classic feature, overt bone disease (►osteitis fibrosa cystica, ►brown tumors or pathological fractures) is now rare. Gastrointestinal manifestations (nausea, vomiting or constipation) are common but nonspecific, while ►pancreatitis and peptic ulcer disease are now rare. Hypercalcemia and hypercalciuria lead to increased urinary frequency and progressive nocturia is common. Even mild elevations of calcium can be associated with weakness and a feeling of lassitude. Major mood disturbances and psychotic behavior can be seen with more severe hypercalcemia.

Primary hyperparathyroidism is one of the common causes of hypercalcemia in adults. With the advent of multichannel autoanalyzer screening, the population incidence was shown to be 1 in 1,000. Although the disorder can occur at any age, it is most frequent in the sixth decade. More women than men are affected, the ratio being about 3:1. When found in children, primary hyperparathyroidism is likely to be a component of a ►familial endocrinopathy and a sex bias is not observed.

Hypoparathyroidism

In hypoparathyroidism, serum calcium concentrations are decreased, serum phosphate levels are increased and serum PTH concentrations are low or undetectable. The signs and symptoms of hypoparathyroidism include evidence of latent or overt neuromuscular hyperexcitability. There is wide variation in the severity of the symptoms, and patients may have ►circumoral numbness, ►paresthesias of the distal extremities or muscle cramping, which can progress to ►carpopedal spasm or ►tetany. ►Laryngospasm or ►bronchospasm and seizures may occur. Other less specific manifestations include fatigue, irritability and personal disturbance. Severe hypocalcemia may be associated with a prolonged ►Q-Tc interval on ►electrocardiography, which reverses with treatment. Patients with chronic hypocalcemia may have calcification of the ►basal ganglia or more widespread intracranial calcification. Also seen are extrapyramidal neurological symptoms, subcapsular cataracts, ►band keratopathy and abnormal dentition.

Cellular and Molecular Regulation

Hyperparathyroidism

Molecular analyses have determined that most, if not all, parathyroid ►adenomas and ►carcinomas are ►monoclonal cell expansions. Alterations in two

genes, ►cyclin D1 and the ►multiple endocrine neoplasia type 1 (MEN1) gene, have been implicated in the development of some sporadic parathyroid adenomas. Cytogenetic loss of 13q containing the ►retinoblastoma (RB) and other tumor suppressor genes has also been implicated in parathyroid carcinoma. ►Karyotypic abnormalities involving several other chromosomal regions have been observed in parathyroid adenomas, but the genes remain to be identified.

One in ten cases of primary hyperparathyroidism is hereditary, occurring as an isolated form or associated with other abnormalities. Genetic linkage studies have confirmed the hereditary nature of these syndromes and in some cases identified specific mutations responsible for parathyroid hyperfunction. These entities include familial hypocalciuric hypercalcemia (FHH)/neonatal severe hyperparathyroidism (NSHPT), MEN1 and multiple endocrine neoplasia type 2 (MEN2), the hyperparathyroidism-jaw tumor syndrome (HPT-JT) and familial isolated hyperparathyroidism (FIHP).

Hypercalcemia and elevated serum PTH levels are the biochemical hallmarks of primary hyperparathyroidism. It is recommended that more than one measurement of these parameters be made, as values may be within the normal range early in the disease. Changes in serum proteins affect the ionized (biologically active) calcium fraction and total calcium values should be corrected for albumin concentration or direct measurement of the ionized calcium made. Serum PTH should be assayed by a ►two-site immunoradiometric assay that detects the intact molecule. Elevated PTH levels occur in 90% of primary hyperparathyroid patients, but a high normal PTH level in the face of hypercalcemia indicates lack of suppression and is consistent with hyperparathyroidism. Serum phosphate is usually at the lower end of the normal range because of the phosphaturic action of PTH. Hypophosphatemia occurs in about 25% of patients. To be diagnostically useful, serum phosphate measurements should be made in the fasting state to avoid postprandial fluctuations. Serum bone-specific alkaline phosphatase is a practical measure of skeletal involvement. Mild hyperchloremic acidosis is common because of the effects of PTH on renal chloride and bicarbonate handling. Urinary calcium is frankly elevated in one-third of patients. The effect of PTH on the renal 25-hydroxyvitamin D-1 α -hydroxylase enzyme is reflected in serum 1,25-dihydroxyvitamin D levels at the upper end of the normal range or frank elevations in a third of cases.

Hypoparathyroidism

Primary hypoparathyroidism most commonly results from surgical excision of, or damage to, the parathyroid glands. However, genetic forms of hypoparathyroidism are known. Familial isolated hypoparathyroidism may show autosomal dominant, autosomal recessive or

X-linked inheritance. In a few instances of either autosomal dominant or recessive disease, mutations in the PTH gene have been found. Gain-of-function mutations in the CASR gene have been identified in several families with autosomal dominant hypocalcemia or hypoparathyroidism. In the parathyroid gland, the activated CASR suppresses PTH secretion and in the kidney, it induces hypercalciuria, which may contribute to the hypocalcemia. A patient with neonatal hypoparathyroidism was homozygous for a partial deletion of the glial cell missing-2 gene (GCMB). This gene, which is expressed in the PTH-secreting cells of the developing parathyroid glands, encodes a transcription factor that is critical for their development. Hypoparathyroidism with multiple malformations can occur, for example, as part of a 22q11 microdeletion. This is a common cause of the DiGeorge syndrome as well as isolated congenital heart disease and velocardiofacial (VCF) syndrome. With DiGeorge syndrome, patients may present with neonatal hypocalcemic seizures due to hypoparathyroidism, severe infections due to thymic hypoplasia and conotruncal heart defects. However, it is not unusual for the hypoparathyroidism to remain asymptomatic until adolescence or require provocative testing to confirm the decreased parathyroid reserve in normocalcemic adults. Craniofacial abnormalities include cleft palate, pharyngeal insufficiency and mildly dysmorphic facies. The syndrome complex arises from a failure to develop the derivatives of the third and fourth pharyngeal pouches leading to agenesis or hypoplasia of the parathyroid glands and thymus. The identification of novel developmental genes in the 22q11 region is being keenly pursued. The Tbx1 transcription factor has been implicated although the full expression of DiGeorge syndrome may involve loss of other contiguous genes.

Hypoparathyroidism is part of the Barakat or HDR (hypothyroidism, nerve deafness and renal dysplasia) syndrome. Deletions of two non-overlapping regions of chromosome 10p contribute to a DiGeorge-like phenotype—the DiGeorge critical region II on 10p13-14 and the HDR syndrome (10p14-10pter). Haploinsufficiency of the transcription factor GATA3 has been implicated by the finding of heterozygous loss-of-function mutations in HDR patients. Thus, GATA3 appears essential for normal embryonic development of the parathyroids, auditory system and kidney.

Hypoparathyroidism is found variably associated with the typical picture of Kenny-Caffey syndrome of growth retardation, ▶osteosclerosis, cortical thickening of the long bones and delayed closure of the anterior fontanel. Both dominant and recessive modes of inheritance have been observed but it is likely that some of the latter cases are examples of Sanjad-Sakati syndrome. This is a recessive condition characterized by congenital hypoparathyroidism, seizures, growth

and developmental retardation and characteristic dysmorphic features. The defect had been localized to 1q43-44 and recently mutations in the ▶TBCE gene have been identified in affected individuals. TBCE encodes a chaperone protein important for the proper functioning of the tubulin assembly pathway important for development of the parathyroid.

Hypoparathyroidism can be due to metabolic disease. It is, for example, a variable component of the neuromyopathies caused by mitochondrial gene defects. Among these are the Keams-Sayre and Pearson marrow pancreas syndromes and mitochondrial encephalomyopathy. Long-chain hydroxyacyl-CoA dehydrogenase deficiency is a metabolic disorder of fatty acid oxidation that may be accompanied by hypoparathyroidism. Parathyroid insufficiency and symptoms of hypocalcemia are occasionally seen in inherited metabolic disorders leading to excess storage of iron (thalassemia, Diamond-Blackfan anemia, hemochromatosis) or copper (Wilson disease).

▶Autoimmune parathyroid gland ablation or destruction can occur. Antibodies directed against parathyroid tissue have been detected in over one-third of patients with either isolated hypoparathyroid disease or combined with other endocrine deficiencies. Antibodies that bind to and activate the parathyroid CASR have been found in patients with either type 1 autoimmune polyglandular syndrome (APS-1) or acquired hypoparathyroidism associated with autoimmune hypothyroidism. In APS-1, the most common associated manifestations are hypoparathyroidism with ▶mucocutaneous candidiasis and ▶Addison's disease. The phenotype is highly variable and patients may not express all elements of the basic triad. The disease, also known as the autoimmune polyendocrinopathy-candidiasis-ectodermal dystrophy syndrome (APECED), presents in infancy or early childhood. It may show sporadic or autosomal-recessive inheritance. The mutated gene, called the autoimmune regulator (AIRE), maps to chromosome 21q22 and encodes a putative transcriptional regulator.

Clinical Relevance

Hyperparathyroidism

With the frequent detection of hypercalcemia in biochemical screening programs, the differentiation of primary hyperparathyroidism from other conditions causing hypercalcemia has become increasingly important. Causes of non-parathyroid hypercalcemia include humoral ▶hypercalcemia of malignancy, vitamin D or A intoxication, ▶milk-alkali syndrome, granulomatous disorders (especially sarcoidosis), immobilization of patients with a pre-existing high bone turnover state such as adolescence, thyrotoxicosis, ▶Paget's disease and treatment with thiazide diuretics or lithium. ▶Parathyroid hormone-related protein

(PTHrP) is the major causative agent in the humoral hypercalcemia of malignancy, although many other circulating factors may contribute. New immunoassays for PTH and PTHrP have greatly facilitated the differential diagnosis of primary hyperparathyroidism from malignancy-associated hypercalcemia.

Study of the relatives of patients with hypercalcemia can contribute to establishing the diagnosis in the 10% of all cases of primary hyperparathyroidism that prove to be hereditary. The finding of another relative with hypercalcemia furnishes evidence of primary hyperparathyroidism if FHH is not suggested by a relatively low urinary calcium-to-creatinine clearance ratio or definitively diagnosed by the identification of a mutation of the calcium-sensing receptor (CASR) gene. The finding of a hypercalcemic relative also requires investigation of the patient for manifestations of the MEN or HPT-JT syndromes.

Criteria for surgery in hyperparathyroidism have been established by a consensus conference and a follow-up workshop of the National Institutes of Health. Candidates for surgery are those having one or more of the following: hypercalcemia >11.6 mg/dL; hypercalciuria >400 mg/day; kidney stones; reduced bone density or age >50 years). Asymptomatic patients who are managed conservatively with twice yearly serum calcium and urinary calcium excretion determinations and annual bone densitometry generally do well since the progression of the disease is usually quite slow.

Hypoparathyroidism

Acute hypocalcemia can be life threatening and present with seizures, tetany or cardiac arrhythmias. Intravenous calcium can alleviate these symptoms rapidly although this should be done cautiously to minimize risks associated with this route of administration. With chronic hypocalcemia, oral supplementation with calcium and vitamin D analogues is usually employed. Careful monitoring of the patient's calcium homeostatic status is necessary as, with under replacement, cataracts and symptoms of numbness and tingling can occur. With over replacement, there is the risk of ►nephrocalcinosis and nephrolithiasis.

Hypercalcemia of Malignancy

Definition

Hypercalcemia of malignancy is the most common metabolic consequence of skeletal metastases and/or tumor. HCM is based on humoral factors released by the tumors that mediate accelerated bone resorption.

►Hyper-and Hypoparathyroidism

Hyperferritinemia Cataract Syndrome

Definition

Hyperferritinemia cataract syndrome refers to a disease that is characterized by increased serum ferritin levels and the early formation of cataracts. The molecular defect is explained by mutations in the iron responsive element (IRE), which blocks iron regulatory protein (IRP) binding and results in aberrant translation control.

►Translational Control in Eukaryotes

Hyperglycemia

Definition

Hyperglycemia is an increase in plasma glucose ("blood sugar") above normal. It can turn into a complex medical condition, for example, diabetic ketoacidosis and coma. Hyperglycemia is usually the first sign of diabetes mellitus.

►Diabetes Mellitus, Genetics

Hyperkeratosis

Definition

Hyperkeratosis is a term which denotes abnormal cornification and thickening of a stratified squamous epithelium, usually the epidermis. An increase in cornification usually arises as a defence against chronic abrasion and hyperkeratosis is often a reflection of cell fragility, possibly resulting from a chronic wound response. It is unrelated to the collagen accumulation of scarring, which is a dermal response.

Hyperphosphorylation

Definition

Hyperphosphorylation refers to phosphorylation of a given protein at multiple phosphorylation sites leading to altered function. For example, phosphorylation of serines 63/73 and threonines 69/71 of c-Jun and ATF-2, respectively, results in enhanced transactivation function in response to extracellular signals. Hyperphosphorylation may be involved in the pathogenesis of neurodegenerative disorders. For example, several proteins such as tau, neurofilaments, β -tubulins or β -catenins are hyperphosphorylated in Alzheimer's disease brains.

►Jun/Fos

Hyperpolarization

Definition

Hyperpolarization denotes the overshoot response of the repolarization phase of the action potential in a neuron.

►Ion Channels/Excitable Membranes

►Idiosyncratic Drug Reactions

Hypertension

Definition

Hypertension is a chronic elevation of blood pressure, which is a major risk factor for cardiovascular and renal disease. Hypertension is strongly associated with stroke, myocardial infarction, aneurysm, progression of renal disease and other vascular disturbances. Current opinion is that blood pressures $>140/90$ mm Hg are labeled "hypertensive", while blood pressures $>135/85$ but $<140/90$ mm Hg are termed "prehypertensive".

Cases of hypertension can be classified as primary (►essential hypertension) when no secondary causes such as renovascular diseases, renal failure, hyperaldosteronism or pheochromocytoma are present. Those cases of hypertension account for 95% of all cases of hypertension. This condition is a heterogeneous disorder with different patients having different causal factors leading to high blood pressure, and usually requires pharmacological treatment. Essential primary or idiopathic hypertension is defined as high blood pressure in which causes of ►secondary hypertension or monogenic (mendelian) forms are not present.

►Mendelian Forms of Human Hypertension and Mechanisms of Disease

Hyperthyroidism

Definition

Hyperthyroidism is caused by excessive production of thyroid hormones. Symptoms of hyperthyroidism include: nervousness, irritability, sweating and too warm skin, fatigue, rapid heartbeat, and hand tremors.

Hypertriglyceridemia

Definition

Hypertriglyceridemia describes a state of excess triglyceride level in plasma. Plasma lipoproteins of chylomicron VLDL (very low density lipoprotein; 0.950 – 1.006 g/ml) and IDL (intermediate density I; 1.006 – 1.019 g/ml) contain a large amount of TG (triglyceride). Overproduction of VLDL (Type IV hyperlipoproteinemia in WHO classification), decreased lipolysis of chylomicron or VLDL (Type I and type V hyperlipoproteinemia), or decreased receptor-mediated uptake of IDL (Type III hyperlipoproteinemia), result in hyper-triglyceridemia.

Synonyms

Hypopituitarism; Panhypopituitarism; Combined Pituitary Hormone Deficiencies

Definition

Genetic diseases of the hypothalamus and pituitary gland, or hypopituitarism, are characterized by one or more pituitary ►**hormone** deficiencies. The hormone deficiencies result in target organ dysfunction and disease. The pituitary gland is a tiny gland (0.5 g and 10–15 mm in adult humans) that has an anterior and a posterior lobe called the adenohypophysis and the neurohypophysis, respectively. The pituitary gland is located in the sella turcica (Turkish saddle) of the sphenoid bone of the skull. The hypothalamus is a small wedged-shaped gland located superiorly to the pituitary gland and has multiple complex functions in addition to regulation of the pituitary gland.

The pituitary hormones that can be deficient in hypopituitarism are synthesized in and released from five cell types in the anterior pituitary gland. These hormones include somatotropin (growth hormone, GH), thyrotropin [►**thyroid stimulating hormone** (TSH)], ►**prolactin** (PRL), ►**adrenocorticotropin** (ACTH), ►**follicle stimulating hormone** (FSH), and ►**luteinizing hormone** (LH). These anterior pituitary hormones are regulated by stimulatory/inhibitory hormones and neurotransmitters produced in the neurons

of the hypothalamus. These hormones are transported from the hypothalamus *via* a capillary plexus in the pituitary stalk to the anterior pituitary gland (see Table 1).

The posterior pituitary gland stores hormones, ►**oxytocin** and ►**vasopressin** (ADH), originally produced in the supraoptic and paraventricular nuclei in the hypothalamus. Then, the hormones are transported to the posterior pituitary gland *via* neural tracts to be released into the vasculature.

The etiology of the congenital pituitary hormone deficiencies is usually idiopathic but the molecular and/or genetic basis of some of them has been clarified. The genetic and/or molecular defects affect the pituitary gland during embryogenesis and can result in pituitary aplasia or hypoplasia. The anterior and posterior lobes of the pituitary gland are derived embryologically from different sources, and are usually affected separately by different molecular defects. The molecular abnormalities that have been discovered to cause hypopituitarism include pituitary transcription factor mutations, GHRH receptor mutations, GH-1 gene mutations, vasopressin gene mutations (neurophysin II component) and Wolfram syndrome gene mutations (WFS1 gene). The mutations cause deficient/decreased function of the target organ (depending on which hormones are deficient): ►**hypothyroidism** (TSH deficiency), ►**growth hormone deficiency**/short stature (GH deficiency), ►**gonadotropin deficiency**/delayed puberty/infertility (LH and/or FSH deficiency), ►**adrenal insufficiency** (ACTH deficiency), and ►**diabetes insipidus** (ADH deficiency).

Characteristics

Pituitary Transcription Factor Mutations

There are multiple transcription factors (Pit-1, Hesx-1, Ptx-2, Lhx-3, Lhx-4 and Prop-1) known to be involved in the determination of the five anterior pituitary hormone producing cells: thyrotrophs (TSH), somatotrophs (GH), corticotrophs (ACTH), gonadotrophs

Hypothalamic and Pituitary Diseases, Genetics. Table 1 Hypothalamic Regulation of Anterior Pituitary Hormones

Hypothalamic Regulation of Anterior Pituitary Hormones	Action – Anterior Pituitary Gland
Corticotropin-releasing hormone (CRH)	Stimulates ACTH synthesis and release
Thyrotropin-releasing hormone (TRH)	Stimulates TSH & PRL synthesis and release
Gonadotropin-releasing hormone (GnRH)	Stimulates LH & FSH synthesis and release
Growth hormone-releasing hormone (GHRH)	Stimulates GH synthesis and release
Growth hormone-release-inhibiting hormone (Somatostatin)	Inhibits GH & TSH synthesis and release
Prolactin-releasing factor (PRF) (possibly VIP or TRH)	Stimulates PRL release
Prolactin-inhibiting hormone (PIH) (actually Dopamine)	Inhibits PRL synthesis and release

(LH/FSH), and lactotrophs (PRL). These factors initiate a cascade of developmental events in a temporal and spatial pattern that results in mature anterior pituitary cell types (see Fig. 1). A mutation in one of the genes encoding these transcription factors results in anterior pituitary hormone deficiencies (see Table 2). Pit-1 (also called GHF-1 and now officially called POUF1) is a **POU transcription factors** that has a POU-specific (POU-S) and a POU-homeo (POU-H) protein domain. Pit-1 has been shown to be essential for somatotroph, lactotroph and thyrotroph development, cell specific gene expression and regulation. Thus, Pit-1 mutations result in GH deficiency, PRL deficiency and TSH deficiency. There have been at least 17 different point mutations found in the Pit-1 gene in humans resulting in GH, PRL and TSH deficiency (see Fig. 2) with the majority the result of an amino acid substitution (missense mutation), but deficiencies have also been found to be due to a nonsense mutation or a base pair deletion. The arginine to tryptophan mutation at codon 271 (R271W) is the most common Pit-1 mutation. Most of these mutations have been found to be sporadic, although some are inherited in an autosomal recessive manner.

Hesx-1 (also called Rpx-Rathke's pouch homeobox) is one of the paired-like homeobox genes and is an acronym for homeobox gene expression in embryonic stem cells. Since it is the earliest known marker for the pituitary primordium, it may have a role in the differentiation of the pituitary gland. Hesx-1 transcripts also disappear as the pituitary cell continues to differentiate. At least four different Hesx-1 mutations discovered in humans are known to cause hypopituitarism in the form of isolated GH deficiency combined pituitary hormone deficiency, panhypopituitarism or septo-optic dysplasia (S.O.D.). S.O.D. is a heterogeneous condition with any combination of optic nerve hypoplasia, pituitary gland hypoplasia (resulting in pituitary hormone deficiency), and midline brain abnormalities (such as absence of the **corpus callosum** or **septum pellicidum**). Hesx-1 mutations have been found to be heterozygous and homozygous missense mutations secondary to amino acid substitutions (arginine to cysteine (R53C and R160C), serine to leucine (S170L), and asparagine to serine (N125S)).

Ptx-2 (also called Pitx2, P-otx2, or RIEG) is a paired-like **homeodomain** transcription factor that is present in the fetal and adult anterior pituitary gland. It is expressed in thyrotrophs, gonadotrophs, somatotrophs and lactotrophs, but not in corticotrophs. It is also expressed in other adult organs including kidney, lung, testis, and tongue. There have been at least 18 mutations found in the Ptx-2 gene (RIEG gene) inherited in an autosomal dominant pattern. These mutations have resulted in variable manifestations of hypopituitarism, anomalies of the anterior chamber of

Hypothalamic and Pituitary Diseases, Genetics.

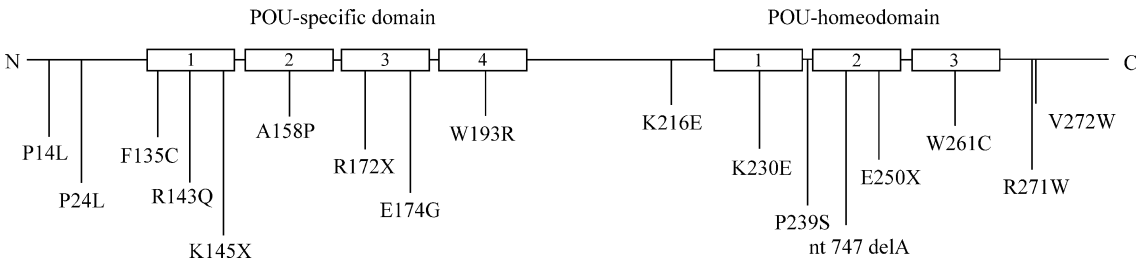

Figure 1 Pituitary-specific transcription factors involved in anterior pituitary development. The homeodomain factors play a role in the determination of specific pituitary cell lineages. Rpx is the earliest known specific marker for the pituitary primordium. Pitx is present in the fetal pituitary and in most cells of the adult pituitary, albeit at different levels. Lhx3 and Lhx4 are expressed in gonadotrophs, thyrotrophs, somatotrophs, and lactotrophs. Prop-1 determines Pit-1 cell lineages and may play a role in directing some of the precursors of the Pit-1 cell lineage into the gonadotroph lineage, prior to terminal differentiation events. Pit-1 has been shown to be essential for the development of somatotrophs, lactotrophs, and thyrotrophs. There is a Pit-1-independent population of thyrotrophs in the rostral tip of the developing anterior pituitary gland that disappears by the day of birth. There are other specific transcription factors involved in the determination of the anterior pituitary cell lineages abbreviated in the figure that have no known mutations resulting in GH deficiency or CPHD. These transcription factors are beyond the scope of this review (including SF-1 (steroidogenic factor-1), α -GSU (alpha subunit of common G-protein), NeuroD1, and GATA-2 (a member of the GATA family of transcription factors with a common core nucleotide sequence - first found to be W-GATA-R with W = A or T and R = A or G)).

the eye, dental hypoplasia, protuberant umbilicus and mental retardation collectively called Rieger's syndrome. Some of the Ptx-2 mutations were missense with amino acid substitution in the homeodomain, some were splicing mutations in the intron dividing the homeobox sequence and one was an in-frame duplication of 21 base pairs (causing a seven amino acid duplication (7aakup of residues 6–12) threonine to lysine in the homeodomain).

Lhx-3 (also called **LIM-3** and P-Lim) is a LIM-type homeodomain protein. The LIM proteins contain two repeat cysteine/histidine LIM domains and a homeodomain. The LIM domains are thought to be involved in regulation of transcription but do not bind DNA. Lhx-3 is expressed in fetal and adult anterior pituitary cells (gonadotrophs, thyrotrophs, somatotrophs and

Hypothalamic and Pituitary Diseases, Genetics. Table 2 Hormone Deficiencies associated with the respective Transcription Factors

Deficient Factor	ACTH Deficiency	GH Deficiency	LH/FSH Deficiency	Prl Deficiency	TSH Deficiency
Rpx	yes	yes	yes	yes	yes
Ptx-2	no	yes	yes	yes	yes
Lhx-3	no	yes	yes	yes	yes
Prop-1	+/-	yes	+/-	yes	yes
Pit-1	no	yes	no	yes	yes

Hypothalamic and Pituitary Diseases, Genetics. Figure 2 Schematic representation of the Pit-1 protein with mutations. The 4 α -helices of the POU-specific domain and the 3 α -helices of the POU-homeodomain are depicted as boxes, and mutations are noted at their locations. The E250X mutation results from both a missense mutation at codon 250 and from a 1 bp deletion at nt 747, which also causes a missense mutation at codon 249.

lactotrophs), as well as in the ventral hindbrain and spinal cord during embryogenesis. Lhx-3 mutations have been found to cause hypoplasia or hyperplasia of the anterior pituitary gland (with secondary LH/FSH deficiency, TSH deficiency, GH deficiency and prolactin deficiency) and a rigid cervical spine (limiting head rotation). Mutations caused by a missense mutation with an amino acid substitution of tyrosine for cysteine at codon 116 (Y116C) result in a hypoplastic anterior pituitary gland, whereas an intragenic deletion of 23 amino acids results in an enlarged pituitary gland of unknown mechanism and a severely truncated protein without the homeodomain. Lhx-4 is another LIM-type homeodomain protein involved in early pituitary development. One Lhx-4 mutation was found in a family cohort (penetrated over 3 generations) that results in a phenotype consisting of CPHD (GH deficiency, TSH deficiency and ACTH deficiency), small sella turcica, hypoplastic anterior pituitary gland, ectopic posterior pituitary gland and herniation of the cerebellar tonsils (called Arnold-Chiari malformation type1). This mutation was inherited in an autosomal dominant pattern. The mutation was a heterozygous point mutation (G to C substitution) in the intronic region before exon 5.

Prop-1 is a paired-like homeodomain transcription factor expressed in the anterior pituitary only during embryogenesis and thus, is named as the prophet of pit-1. Several prop-1 mutations (at least 14) have been discovered that result in hypopituitarism with GH deficiency, PRL deficiency, TSH deficiency and LH/FSH deficiency (see Fig. 3). Most patients have a hypoplastic pituitary gland. The gonadotropin deficiency (LH/FSH deficiency) in some humans with prop-1 mutations prevents the start of puberty, however, in others, puberty is delayed with diminished LH/FSH secretion with increasing age. The mutations found include intronic point mutations, one base pair deletions, two base pair deletions and 12 base pair deletions that result in amino acid substitutions and stop codons.

GHRH Receptor Mutations

GHRH receptor mutations have been found in at least two separate groups. A consanguineous Indian Moslem family demonstrated a nonsense mutation with a substitution of glutamate at codon 72 for a stop codon. The group described as “Dwarfism of Sindh” showed a nonsense mutation with a substitution of glutamate at codon 50 for a stop codon.

Hypothalamic and Pituitary Diseases, Genetics. Figure 3 Schematic representation of the *Prop-1* gene. Exons are depicted as shaded areas, and the homeodomain is noted in black. Mutations are noted at their locations. The S109x mutation results from both a 2 bp deletion between nt 296-301, and a 2 bp deletion at codon 50 (nt 149-150) that causes divergence of amino acid sequence from codon 52. The P164X mutation results from a 1 bp deletion at codon 50, which causes divergence of amino acid sequence from codon 53. The P160X mutations results from a 13 bp deletion between nt 112-124, which causes divergence of amino acid sequence from codon 38.

GH-1 Gene Mutations

GH-1 gene mutations result in isolated GH deficiency and are classified as Type IA, Type IB, Type II and Type III.

Type IA GH deficiency is caused by a complete GH-1 gene deletion that is the result of autosomal recessive inheritance. Thus, there is complete absence of GH with growth retardation present in infancy.

Type IB GH deficiency is caused by point mutations of the GH-1 gene that are also inherited in an autosomal recessive manner. Type IB GH deficiency mutations include G to C or G to T transversion in intron 4 (causing splice deletion of one-half of exon 4 and frameshift within exon 5) and other nonsense, splicing and frameshift mutations. These individuals demonstrate a partial GH deficiency.

Type II GH deficiency is the result of intronic transitions (T to C) in intron 3 of the GH-1 gene that inactivate the donor splice site and delete exon 3. Type II GH deficiency has an autosomal dominant inheritance and results in partial GH deficiency.

Type III GH deficiency is caused by mutations of the X chromosome, and thus, is inherited in an X-linked manner. These mutations result in partial GH deficiency. Some individuals may also have [hypogamaglobulinemia](#).

Vasopressin Gene Mutations

Vasopressin gene mutations result in central diabetes insipidus (ADH deficiency) and are inherited in an autosomal dominant pattern, although one point mutation (amino acid substitution proline for leucine at codon 7 (P7L)) was found to be the result of autosomal recessive inheritance. Mutations (nonsense, missense, deletion and frameshift) have been found at more than 30 different sites in the precursors of the vasopressin hormone (vasopressin pre-prohormone).

The majority of mutations have been found in the neurophysin portion of the precursor of vasopressin, although some have been found in the signal peptide and vasopressin peptide region of the gene.

WFS-1 (Wolframin) Gene Mutations

WFS-1 gene mutations result in DIDMOAD syndrome (diabetes insipidus (ADH deficiency), [diabetes mellitus](#), optic atrophy and sensorineural deafness) that is also referred to as Wolfram syndrome (hence, the gene name Wolfram Syndrome-1). The WFS-1 gene encodes a transmembrane protein consisting of 890 amino acids with unknown function. Multiple single nucleotide mutations in the WFS-1 gene have been found to cause Wolfram syndrome or DIDMOAD. The mutations included stop, frameshift and amino acid deletions and insertions, suggesting loss-of-function mutations as the cause of Wolfram syndrome.

Cellular and Molecular Regulation

Pituitary Transcription Factor Mutations

The Pit-1 gene mutations vary in the molecular mechanisms that cause hypopituitarism. In the most common Pit-1 mutation, R271W, Pit-1 binds normally to DNA, but the mutant Pit-1 inhibits transcription in a dominant manner and may impair dimerization. In the K216E Pit-1 mutation, Pit-1 binds to DNA, does not inhibit basal activation of the GH and PRL genes, but is unable to produce retinoic acid induction of the Pit-1 gene distal enhancer. The A158P Pit-1 mutation results in a protein with a slightly decreased ability to bind DNA and a lack of (or minimal) transcriptional activation of the GH, PRL, and Pit-1 promoters. The P239S Pit-1 mutation binds to DNA normally but has decreased activation of the GH promoter. The F135C mutation is located in the hydrophobic core of the POU-S domain near the dimer interface of the POU-S

domain. Since the normal F135 residue appears to be the key in assembling and stabilizing the first, third, and fourth α -helices of the POU-S domain according to molecular models, the mutant F135S Pit-1 prevents proper assembly and stabilization of α -helices of the POU-S domain, which prevents normal interaction with other pituitary transcription factors. There are some Pit-1 mutations (E174G, R172X, W193R, nt747delA, E250X) located at amino acids critical for DNA binding, which thus impair transcriptional activation. The other Pit-1 mutations that have been found have yet to be characterized.

Rpx-1 mutations have not been well characterized. The R53C Rpx-1 mutation has been shown to decrease DNA binding. Other Rpx-1 mutations were inherited from an unaffected parent and may represent ►poly-morphisms that do not affect normal Rpx-1 function or low penetrance of the phenotype.

Ptx-2 mutations result in several different molecular causes of hypopituitarism. The L54Q Ptx-2 mutation in helix 1 of the homeodomain results in an unstable protein. The T68P Ptx-2 mutation has decreased affinity for DNA and does not permit enhanced binding to Pit-1. The V45L has a slight decrease in DNA binding but actually increases transcriptional activity by 200-fold. This increased transcriptional activity is postulated to cause hypopituitarism but this has not been proven. The Ptx-2 mutation that is secondary to 7aa duplication of residue 6–12 of the homeodomain has significantly decreased DNA binding (100-fold) and no transactivation of a target promoter construct. The K88E Ptx-2 mutation has reduced DNA binding and transactivational activity which suppressed its synergism with Pit-1. This may represent a dominant-negative effect.

The two Lhx-3 mutations result in reduced gene activation. However, the Y116C Lhx-3 mutation binds DNA, but the intragenic 23 amino acid deletion does not bind DNA.

The Lhx-4 mutation abolishes normal Lhx-4 splicing and activates two exonic cryptic splice sites. The first splice site leads to an in-frame deletion of four highly conserved amino acids in the third helix of the homeodomain (deletion of VWFQ at positions 47–50 in the homeodomain). The second splice site alters the reading frame in the homeodomain at position 47 that results in a premature stop codon in exon 5. Thus, two different proteins with deletions in their homeodomain are produced and have altered function.

Prop-1 mutations characterized reveal various molecular defects. S83P Prop-1 mutation results in an 8-fold decrease in DNA binding at two sites in the Pit-1 early enhancer required for Pit-1 gene activation. This indirectly causes diminished transactivation at these

two DNA binding sites. The 296 delGA Prop-1 mutation changes the reading frame and results in a stop codon (S109X). This truncated product does not have promoter binding or transcriptional activation. There are other Prop-1 mutations that have resulted in a truncated product from a premature stop codon ((P160X, S109X, P164X, R99X). The F117I and R120C Prop-1 mutations cause diminished DNA binding and activation of target gene reporter constructs. The A-T nt343 Prop-1 mutation in the intronic region preceding exon 3 abolishes normal splicing and ultimately causes loss of the first 12 nucleotides of exon 3.

GHRH Receptor Mutations

GHRH-R mutations result in a truncated GHRH receptor without the membrane spanning regions and a G-protein site.

GH-1 Gene Mutations

The GH-1 gene is flanked by long stretches of highly homologous DNA that predispose it to mutations that result in Type IA GH deficiency. Mutations that cause Type IB deficiency have been characterized as affecting the stability and biological activity of the mutant GH protein that may derange targeting of the GH peptide into secretory granules. The mechanism of the autosomal dominant Type II GH deficiency is unknown. Type III GH deficiency is the result of interstitial (q13.3-21.1) deletions or microduplications (certain regions) on the X chromosome.

Vasopressin Gene Mutations

The multitude of vasopressin gene mutations (in the pre-prohormone) cause vasopressin deficiency by an unknown mechanism.

WFS-1 Gene Mutations

Studies suggest the *wolframin* gene encodes a novel transmembrane protein and mutations result in loss of function.

Clinical Relevance

There have been many mutations discovered that cause pituitary and hypothalamic diseases originally regarded as “idiopathic.” Present characterization of these mutations and correlation with the phenotypes have started the journey to unravel the genetic basis for hypopituitarism. Further understanding of the genetic basis of pituitary and hypothalamic diseases along with advances in medicine show promise to eventually lead to earlier diagnosis, treatment or prevention and ultimately decrease the morbidity and mortality associated with these diseases.

Hypothyroidism

Definition

Hypothyroidism refers to a condition in which the body lacks thyroid hormone (T4 and T3), which is produced by the thyroid gland (underactive thyroid gland). It results in fatigue, weight gain, dry skin, cold intolerance, constipation, depression and menstrual cycle irregularity. It is termed primary, secondary or tertiary depending on where the thyroid hormone deficiency stems from (primary-thyroid gland itself; secondary-pituitary gland/TSH deficiency; tertiary-hypothalamus/TRH).

Hypoxanthine-Guanine-Phosphoribosyl-Transferase

Definition

Hypoxanthine-guanine-phosphoribosyl-transferase (HGPRT) is an enzyme involved in the salvage pathways of nucleotide synthesis. The enzyme catalyzes conversion of ►hypoxanthine to IMP, and guanine to GMP. When HGPRT is present in low levels, affected persons usually experience gout, due to precipitation of uric acid in the joints. Complete absence of HGPRT causes Lesch-Nyhan syndrome, characterized by increased uric acid concentration in the serum and by neurological problems.

Hypoxia Inducible Factors

TILL ACKER

Edinger Institute, Neuropathology, Johann-Wolfgang Goethe University, Frankfurt, Germany
till.acker@med.uni-frankfurt.de

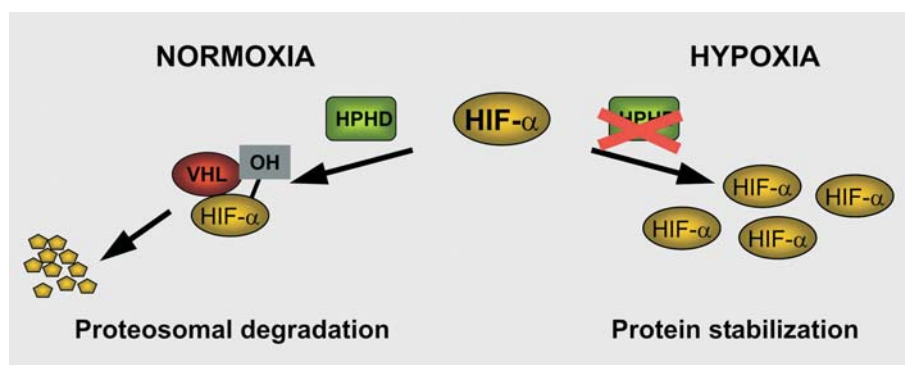

Definition

The maintenance of oxygen homeostasis, i.e. the balance between oxygen consumption and delivery, represents an essential cellular and systemic function, requiring the coordinate regulation of a wide array of genes. It is only within the past few years that the underlying molecular mechanisms have been elucidated. The identification of the HIF transcription system in 1995 constituted a milestone in our understanding of oxygen physiology (1). Since then the HIF system has emerged as a key regulatory system of responses to hypoxia both on a local as well as a systemic level in a variety of developmental, physiological and pathological conditions.

Characteristics

The HIF transcriptional complex is a heterodimer composed of HIF- α and HIF- β subunits belonging to the ►bHLH (basic helix loop helix)-PAS family of transcription factors, conserved among mammalian cells and invertebrate model organisms such as *Drosophila melanogaster* and *Caenorhabditis elegans*. The bHLH domain contains the basic DNA-binding domain and the primary dimerization interface HLH. The adjacent PAS-domain with two conserved regions termed PAS A and PAS B contains the second dimerization motif. Both HIF- α and HIF- β proteins exist as isoforms (HIF-1 α , HIF-2 α , HIF-3 α and ARNT, ARNT2 and ARTN3, respectively). Whereas HIF- β subunits are constitutively expressed and partly involved in other transcriptional responses, specificity to hypoxia-mediated responses seems to be conferred by HIF- α subunits. At least two mammalian α subunits, HIF-1 α and HIF-2 α , are regulated by oxygen in a similar fashion.

Transcriptional activity of HIF- α subunits seems to be mainly regulated by cellular O₂ concentrations involving two mechanisms, namely protein levels and transactivation domain functions. Under normoxic conditions HIF- α subunits are subject to rapid ubiquitination and proteasomal degradation. Upon hypoxia, ubiquitination is dramatically reduced and protein levels increase rapidly (Fig. 1). Deletion analysis revealed that HIF- α contains two transactivation regions, termed the amino- and carboxy-terminal transactivation domains (►N-TAD, ►C-TAD), which

Hypoxia Inducible Factors. Figure 1 Schematic representation of structure, function and posttranslational modification of HIF-1 α , affecting protein stability (ODD) or transactivation activity (N-TAD).

upon reduced oxygen levels are relieved of a negative control. Thus, decreasing oxygen levels lead to a progressive stabilization of HIF- α subunits, which translocate into the nucleus and dimerize with HIF- β subunits, allowing binding to the conserved consensus DNA-binding motif RCGTG residing in the hypoxia-responsive elements (HRE) of many oxygen regulated genes. Transactivation is subsequently initiated by recruitment of co-activators such as CBP (CREB binding protein)/p300, SRC (steroid receptor coactivator)-1 and TIF2 (transcriptional intermediary factor), which is promoted by the redox regulatory protein Ref (redox effector factor)-1. Though oxygen-dependent regulation seems to provide the prevailing control mechanism of HIF function, receptor mediated signals *via* binding of various growth factors and cytokines including angiotensin II, epidermal growth factor (EGF), platelet derived growth factor (PDGF), tumour necrosis factor (TNF) α , insulin and insulin-like growth factors (IGF) 1 and 2, represent an alternative way to enhance HIF activity under normoxia. This induction is generally less intense than that mediated by reductions in oxygen tension.

Cellular/Molecular Regulation

Regulation of HIF activity is complex, involving multiple mechanisms of control at the level of mRNA expression, protein stability, nuclear translocation and transactivation activity, which combine co-operatively to activate HIF to maximal levels under decreasing oxygen concentrations. On the molecular level this is mediated by subjecting HIF- α subunits to multiple modes of modification including two different types of hydroxylation, acetylation and phosphorylation (Fig. 2).

Oxygen Dependent HIF Activation

O₂-regulated degradation of HIF- α subunits is mediated by a functional domain of approximately

200 amino acids, termed the oxygen-dependent degradation domain (\blacktriangleright ODD). This domain confers hypoxic stabilization on HIF-1 α and HIF-2 α , the feature being transferable to various fusion partner proteins. pVHL (von Hippel Lindau protein), loss of function of which is implicated in \blacktriangleright VHL-disease, acts as the recognition component of an E3 ubiquitin-protein ligase that binds to subsequences within the ODD, thus targeting HIF- α subunits for proteasomal degradation. HIF- α protein stability seems to be also regulated by ubiquitin ligases other than VHL, e.g. p53 has been implicated in promoting HIF degradation and decreasing transactivation of HRE-bearing genes, possibly by promoting binding of the ubiquitin ligase MDM-2 and competing for the co-activator p300.

Interaction of VHL with HIF- α requires an O₂- and iron-dependent hydroxylation of specific prolyl residues (Pro 402, Pro 564) within the HIF- α ODD. This posttranslational modification is conferred by a distinct, conserved subclass of 2-oxoglutarate-dependent-oxygenases termed \blacktriangleright HIF-prolyl hydroxylases (HPHD) (2). So far, four isoforms of HPHD have been described (HPHD I-IV). A second oxygen dependent switch involves an iron and 2-oxoglutarate dependent hydroxylation of an asparagine residue within the C-TAD of HIF- α subunits by a recently identified HIF asparaginyl hydroxylase called \blacktriangleright factor-inhibiting HIF (FIH-1). Asparagine hydroxylation apparently interferes with recruitment of the coactivator p300 resulting in reduced transcriptional activity. Both, HPHD and FIH, belong to a superfamily of \blacktriangleright 2-oxoglutarate dependent hydroxylases that employ non-haem iron in the catalytic moiety. They require oxygen in the form of dioxygen with one oxygen atom being incorporated in the prolyl or asparagyl residue and the other into 2-oxoglutarate yielding succinate and CO₂ (3). Thus, the hydroxylation reaction is inherently dependent on ambient oxygen pressure, providing a direct link between oxygen-dependent enzymatic activity and

Hypoxia Inducible Factors. Figure 2 Regulation of HIF-protein stability by oxygen dependent activity of HIF-prolyl-hydroxylases and VHL-mediated ubiquitination and proteosomal degradation.

the regulation of hypoxia-inducible responses, a crucial criterion for an oxygen sensor.

Recently, a novel mode of posttranslational modification of HIF- α subunits under normoxia has been identified, which involves acetylation of a lysine residue (Lys 532) within the ODD domain by an acetyl-transferase termed ARD1. Lysyl acetylation has been shown to modulate HIF- α protein stability by promoting VHL-binding and subsequent proteasomal degradation. With decreasing oxygen tensions acetylation is gradually reduced due to decreased ARD1 mRNA levels and decreased affinity of ARD1 for HIF- α subunits.

Alternative Mechanisms of HIF Activation under Normoxic Conditions

Receptor mediated enhancement of HIF activity seems to involve two major intracellular signal transduction pathways, namely the phosphatidylinositol-3 kinase (PI3K-PTEN-AKT-FRAP) and the mitogen activated protein kinase (RAS-RAF-MEK-ERK) pathways, the latter including the p42/p44 MAP kinase (4). Both signalling cascades have been found to influence HIF activity *via* mechanisms differing from those induced by reductions in oxygen tension with the former directly inducing HIF- α protein synthesis and the latter HIF- α transcriptional activity. As a consequence of PI3K-AKT-FRAP pathway signalling, translational regulatory proteins such as eIF-4E and p70S6K are activated, enhancing translation of HIF- α mRNA. Thus, AKT leads to an increase in HIF transcriptional

activity by increasing the pool of available HIF- α protein. In contrast, direct phosphorylation of HIF- α subunits within the \blacktriangleright C-TAD region by MAPK has been reported to increase HIF transcriptional activity by relieving transcriptional repression, possibly due to interference with FIH-binding and FIH-mediated hydroxylation. There seems to be some cross talk between both pathways as e.g. H-RAS transformation appears to increase HIF- α levels under normoxia and hypoxia *via* recruitment of the PI3K signalling cascade.

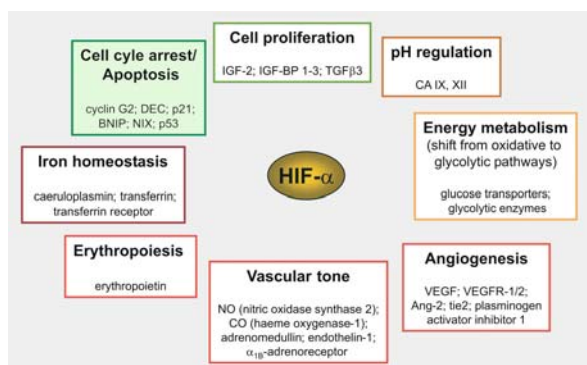

Regulatory Mechanisms

The HIF transcriptional system acts as a master regulator of oxygen-regulated gene expression inducing adaptive mechanisms that serve the common purpose of maintenance of oxygen homeostasis. To date more than 30 HIF-target genes have been identified (Fig. 3).

HIF-regulated Genes and Function

\blacktriangleright Angiogenesis and Erythropoiesis

The vascular system is tightly regulated by oxygen tension. Various molecular players have been identified which are involved in orchestrating specific stages and mechanisms of vascular growth in response to developmental, physiological and pathological hypoxia. Among these, members of the VEGF (vascular endothelial growth factor) and the angiopoietin (Ang) family seem to have a predominant role. In addition, different mechanisms have been identified which control local blood flow by regulating the vascular

Hypoxia Inducible Factors. Figure 3 HIF-regulated target genes and function.

tone through production of NO, CO, adrenomedullin and endothelin-1, all of which involve up-regulation of HIF target genes. Red blood cell production (erythropoiesis) by the bone marrow underlies tight feedback control by oxygen-regulated EPO (erythropoietin) production by the liver and kidney. Taken together, coordinated up-regulation of different sets of genes enhances O₂ delivery to the cell by increasing vascular density, thus decreasing oxygen diffusion distance and increasing oxygen transport capacity by boosting red blood cell mass.

Iron Homeostasis

Iron is required for haem formation, being the most common limiting factor for erythropoiesis. Interestingly, HIF-target genes regulate different steps in iron homeostasis from iron uptake to iron transport and iron storage. The implication of iron in [▶oxygen sensing](#) by 2-oxoglutarate dependent hydroxylases and the involvement of iron in oxygen toxicity through the Fenton reaction gives an additional need for tight iron regulation, making the interaction between oxygen and iron homeostasis physiologically highly appropriate.

Energy Metabolism and pH Regulation

Hypoxia leads to a metabolic adaptation of the cell by inducing a shift from oxidative to glycolytic pathways with anaerobic glycolysis becoming the predominant mode of cellular ATP generation. HIF mediates coordinate up-regulation of genes of the glycolytic pathway ranging from glucose uptake to lactate production. Enhanced lactate production by up-regulation of glycolysis is thought to be the major source of protons under limited oxygen conditions, resulting in decreases in pH. However, pH homeostasis is tightly controlled by various proton extrusion mechanisms. Among these the transmembrane carbonic anhydrases (CA) 9 and 12, recently identified as a new class of HIF- α regulated genes, provide a potential link between

metabolism and pH regulation. They catalyze the reversible hydration of carbon dioxide to bicarbonate and protons. Taken together, these findings suggest that HIF controls fundamental metabolic changes in response to hypoxia by inducing a shift from oxidative to glycolytic pathways whilst at the same time providing means to deal with the resulting increase in proton load by up-regulation of CA.

Proliferation/Apoptosis

Recent studies support the view that apart from inducing pro-proliferative proteins, such as IGF (insulin-like growth factor)-2, IGF-BP (binding proteins) 1-3 and TGF (transforming growth factor) β 3, the HIF pathway includes responses with adverse effects on cell function by inducing cell-cycle arrest specific and pro-apoptotic proteins such as DEC (defective chorion)-1, BNIP (Bcl2/adenovirus E1B 19kD-interacting protein)-3, its homologue NIX (Nip3-like protein X) and cyclin G2. In addition, direct stabilization of the proapoptotic protein p53 has been suggested by studies demonstrating physical and functional interaction between HIF-1 α and p53.

Thus, the HIF system transactivates an extended physiological pathway, which encompasses a wide array of physiological responses to hypoxia ranging from mechanisms that increase cell survival to those inducing cell-cycle arrest or even apoptosis.

Clinical Relevance

Disruption of oxygen homeostasis and activation of HIF have been implicated as essential features in the pathophysiology in a multitude of diseases including cardio- and cerebrovascular disease, chronic obstructive lung disease and tumour formation (5, 6). Though HIF-1 α is ubiquitously expressed in all cells and HIF-2 α in a wide range of cells, the level of HIF- α protein detectable in normoxia and the capacity of HIF- α up-regulation by hypoxia varies in different cell types, making the disease specific contribution of each subunit difficult to discern. To date, current belief suggests that while HIF might play a major role in the prevention of ischemic disease it is involved in the pathogenesis of pulmonary hypertension and cancer; e.g. myocardial ischemia is a potent inducer of HIF-activity and VEGF expression, eliciting an angiogenic response, which, however, is often not sufficient to prevent infarction. In contrast, essential HIF target genes such as endothelin-1, angiotensin II or PDGF have been linked to pulmonary artery remodelling leading to pulmonary hypertension. Similarly, widespread HIF activation in tumours as a consequence of tumour hypoxia and genetic alterations has been associated with tumour progression, invasion and increased resistance to chemo-/radiotherapy. Thus, small molecule inducers of HIF activity might provide

protection against ischemic disease, while small molecule inhibitors might be employed to prevent pulmonary hypertension and cancer. However, with the above outlined dual functions of HIF in cell survival and death it becomes clear that HIF action is far more complex. Depending on the individual components that are induced in response to tissue hypoxia, activation of the HIF system can result in deleterious or beneficial effects, arguing for a cautious application of therapeutic strategies aimed at the general manipulation of the HIF pathway.

Hypoxia/Normoxia

Definition

Hypoxia is a condition of low oxygen tension, typically in the range 1–5% O₂, and is often found in the central region of tumours due to poor vascularisation. Normoxia is used to describe oxygen tensions between 10–21%, and hyperoxia for those above 21%.

ICAT

Definition

ICAT designates a method of quantitative proteome analysis (proteomics) based on a class of reagents termed isotope-coded affinity tags (ICAT). The ICAT reagent incorporates three elements: a specific chemical reactivity (usually cysteine-specific), two different isotopically coded linkers (light form and heavy form), and an affinity tag. Proteins of cell state 1 and 2 are derivatized with the isotopically light and heavy forms, respectively. The two samples are combined enzymatically, cleaved (trypsin), and the tagged peptides are isolated and analyzed by capillary liquid chromatography mass spectrometry. The relative amounts of the original proteins are determined by isotope peak ratios of identical peptide sequences which differ in mass only due to different isotopically coded modifications. Identification of the proteins is performed by tandem mass spectrometry which yields amino acid sequence information.

I-Cell Disease

Definition

I-cell disease (Mucopolipidosis Type II) is an autosomal recessively inherited lysosomal storage disorder with

clinical manifestations at birth or in the first few months of life. The disease is characterized by the presence of inclusion bodies in cultured fibroblasts (I-cells). Lysosomes lack hydrolases due to a deficiency of N-acetylglucosaminyl-1-phosphotransferase. The functional deficiency of lysosomal enzymes results in abnormal cell architecture. The most severely affected system is the skeletal system, in which trabeculation of bone and cartilage structures are abnormal. Muscular tissue, including cardiac muscle, is relatively spared; however, significant vacuolization is present in the connective tissue cells that are in the heart valves. This leads to thickening of the valves, which results in clinically significant valvular disease. Affected individuals usually die from pneumonia or congestive heart failure within the first decade of life.

Idiosyncratic Drug Reactions

JACK UETRECHT

Pharmacy and Medicine, University of Toronto,
Toronto, Canada

jack.uetrecht@utoronto.ca

Synonyms

Hypersensitivity drug reactions; type B reactions; allergic drug reactions

Definition

Idiosyncratic drug reactions are adverse drug reactions that do not occur in most patients at any dose and do not involve the known pharmacological properties of the drug. Using this definition, adverse reactions, such as

cardiac arrhythmias caused by drugs that affect potassium channels, would not be idiosyncratic because they involve known pharmacological properties of the drug. However, many people would reasonably call these latter reactions idiosyncratic because they only occur in a small fraction of the population whose polymorphisms in the potassium channel make them more susceptible.

Characteristics

There are an almost infinite number of adverse drug reactions because every drug can interact with the body in many different ways. It would be too difficult to describe them all and the focus of this entry will be on idiosyncratic drug reactions. These reactions share common characteristics and although the exact mechanism is probably different for different reactions, most such reactions appear to be immune-mediated. Characteristically there is a delay between starting a drug and the onset of an idiosyncratic drug reaction on initial exposure to the drug. The length of delay varies with the type of adverse reaction. Idiosyncratic drug reactions can affect virtually any organ but skin, liver and bone marrow as well as generalized reactions are the most common. With most skin rashes and antibody-mediated reactions, the delay is usually from a week to a month, with agranulocytosis and hepatic necrosis the delay is usually 1 month to 6 months and with drug-induced lupus the delay is often more than a year. In contrast, on reexposure to the offending drug, the adverse reaction is usually immediate (minutes to a few days) although there are exceptions. Idiosyncratic drug reactions are usually more common in women than in men, but the basis for this difference is unknown, although other types of immune-mediated diseases, such as thyroid disease and lupus, are also more common in women. The reactions are usually said to be dose-independent, but all effects are dose dependent; it is just that the relationship is made more complex by the fact that most people will not have an idiosyncratic reaction at any dose of the drug. In addition, the dose required to cause an idiosyncratic reaction is often smaller than the dose required to exert the desired pharmacological effect. This is especially true in a sensitized patient where the dose required to cause an idiosyncratic reaction is often lower than the dose required on initial exposure. However, the dose-response curve for idiosyncratic drug reactions in susceptible patients is often similar to that for the desired effect and a dose can always be found that does not cause an idiosyncratic reaction. In fact, drugs that are given at a dose of 10 mg/day or less are not usually associated with a significant incidence of idiosyncratic drug reactions.

Cellular and Molecular Regulation

With a few notable exceptions, the mechanism of most idiosyncratic drug reactions is not known with certainty. One notable exception is the allergic reactions that some people have to penicillin. These reactions are known to be due to the covalent or irreversible binding of penicillin to protein. In some patients this induces IgE antibodies in response to the modified or “foreign” protein and these antibodies are responsible for the allergic reaction. Some other idiosyncratic drug reactions are also mediated by antibodies. Some antibodies are directed against the drug, such as aminopyrine-induced agranulocytosis, while others are autoantibodies, as in the case of α -methyldopa-induced hemolytic anemia, which recognize normal red blood cells. Other idiosyncratic drug reactions, such as severe skin rashes (e.g. toxic epidermal necrolysis) are probably mediated by cytotoxic T lymphocytes. Some idiosyncratic drug reactions may be mediated by the innate immune system, which is made up of cells such as [macrophages](#) and natural killer (NK) cells (1).

Penicillin is chemically reactive and can directly bind to proteins. Most drugs are not chemically reactive, but many are metabolized to chemically reactive species, which can bind to protein and there is a large amount of circumstantial evidence that such reactive metabolites are responsible for many idiosyncratic reactions (2). This is the basis for the classic hapten hypothesis, i.e. small molecules are not immunogenic but if they bind to biological macromolecules, usually proteins, these modified proteins can be immunogenic. This binding must be essentially irreversible or covalent in order to survive antigen processing. A small molecule that modifies a protein leading to an immune response is referred to as a hapten. However, there are many drugs that form reactive metabolites and yet are not associated with a significant incidence of idiosyncratic reactions. There are several possible reasons for this observation. One is that the amount of covalent binding is simply too low to induce an immune response. Although covalent binding can be quantified under certain circumstances, it is not possible to quantify covalent binding *in vivo* in humans in the usual target organs of idiosyncratic drug reactions. Therefore, we do not know how good a correlation exists between the degree of covalent binding and the risk that a drug will cause idiosyncratic drug reactions. Another possible reason is that covalent binding to certain types of proteins may be more likely to cause an idiosyncratic reaction than binding to others and we still do not know what proteins are modified by most drugs. Finally, it is possible that covalent binding is necessary but not sufficient, or possibly not even necessary, for the induction of an idiosyncratic drug reaction.

It has been known for some time that foreign proteins do not usually induce a significant immune response in the absence of an ►[adjuvant](#). The purpose of the adjuvant is to up-regulate costimulatory molecules on antigen presenting cells and this is necessary for the induction of an immune response. Matzinger proposed that it is not the foreignness of something that determines whether it will induce an immune response but rather whether it causes some type of danger to the organism. This is referred to as the danger hypothesis (3). Applying this hypothesis to idiosyncratic drug reactions, it may be that a reactive metabolite must induce some type of danger signal in order to induce an immune response (1). By their very nature, reactive metabolites usually cause some type of cell damage and this could act as a danger signal. In fact, the ability of the reactive metabolite to act as a hapten may not even be important (4). These hypotheses have yet to be adequately tested. At the present time there is no accurate way to test drug candidates for their potential to cause idiosyncratic drug reactions. However, if there are biological markers of cell damage or cell stress that predict that a drug will cause idiosyncratic drug reactions, this would have a major impact on drug development. It is unlikely that such effects could be accurately mimicked in cell cultures and *in vivo* tests would be required. Furthermore, there is likely to be more than one pattern of cell stress that is associated with an increased risk of adverse reactions and in some cases there will probably be differences between animals and humans, so such predictive tests are unlikely to be simple.

As suggested by the name, most people do not have an idiosyncratic drug reaction to a drug that is associated with such reactions. If “danger” plays an important role in the mechanism of idiosyncratic drug reactions, then environmental factors, such as infections or surgery would probably increase the risk of such reactions. This appears to be the case. Patients who have HIV infections are at increased risk of idiosyncratic drug reactions. Furthermore, it appears that patients who are started on procainamide immediately after open-heart surgery have a 10 fold higher incidence of procainamide-induced agranulocytosis than those started on the drug under more usual circumstances. However, it is important to point out that even in the presence of open-heart surgery, 95% of the patients do not develop agranulocytosis. It appears that the immune systems of individuals who do not have an idiosyncratic reaction do respond to the drug but the response is ►[immune tolerance](#) (5). The risk of idiosyncratic reactions to some drugs can be decreased by treating a patient with a lower dose of the drug for 2 weeks; this promotes tolerance. Although not proven, surely genetic factors must play a dominant role in the interindividual differences in the risk of an idiosyncratic drug reaction. Many of the

enzymes responsible for metabolizing drugs, including the conversion of drugs to reactive metabolites, are genetically polymorphic and this could be the basis for interindividual differences in risk (6). The effect of genetic polymorphisms in drug metabolizing enzymes has received much attention as a basis for the large differences observed in the response of different individuals to drugs. However, genetic polymorphisms in drug transporters and the therapeutic targets of drugs are also very important (7). In the case of idiosyncratic drug reactions, there are several examples where genetic polymorphisms in drug metabolizing enzymes have been shown to be important (8). For example, the slow acetylators are at higher risk of idiosyncratic reactions to sulfonamides and isoniazid-induced liver necrosis. However, in most cases when such associations are sought they are usually not found. It is important to note that many of the genes coding for specific components of the immune system are extremely polymorphic. Our survival as a species may have been very much dependent on such polymorphism because if the immune system were monomorphic we might have been wiped out by some pathogen. For the same reason the immune system must also be complex and redundant. Therefore there are many more polymorphic genes involved in the control of the immune system than there are involved in drug metabolism and, on a statistical basis, there will probably be more “immune” polymorphic genes that are associated with idiosyncratic drug reactions than polymorphic genes involved in drug metabolism. The genes that have been studied the most as a risk factor for idiosyncratic reactions are the ►[major histocompatibility complex](#) genes (8), which are highly polymorphic and are also involved in the presentation of antigens to T lymphocytes. For example, clozapine-induced agranulocytosis has been linked to the several ►[human leukocyte antigen](#) (HLA) genes and the associations were different in different ethnic groups. However, these genes are also linked to genes controlling expression of ►[tumor necrosis factor](#) and ►[heat shock proteins](#) and this type of gene linkage makes mechanistic inferences difficult. Although there may be cases in which one gene polymorphism plays a dominant role in the risk of an idiosyncratic drug reaction, it is likely that in most cases hundreds if not thousands of genes will be involved, each making only a small contribution to the risk. If this is the case, it will be very difficult to determine the risk of a specific individual having an idiosyncratic drug reaction to a specific drug. In most cases the history of an idiosyncratic reaction to one drug does not predict an increased risk of an idiosyncratic reactions to other drugs. Although some individuals believe they are “allergic” to all drugs, this does not appear to be true. However, there are some examples where an idiosyncratic

reaction to one drug is associated with an increased risk of an idiosyncratic reaction to another drug, presumably because the structures are very similar, such as different penicillins, or because the mechanism is similar. An example of the latter is that if a patient has a reaction to one aromatic anticonvulsant, i.e. phenytoin, carbamazepine or phenobarbital, they are at increased risk of having a similar idiosyncratic reaction to the others in this group. It was initially believed that there was a type of reactive metabolite, specifically an arene oxide, common to these three anticonvulsants and an increased risk of an idiosyncratic reaction was due to defective detoxication of this reactive metabolite by epoxide hydrolase. However, this does not appear to be the case.

Clinical Relevance

It has been estimated that adverse drug reactions in general, are the 4th to 5th leading cause of death in North America. This is probably somewhat misleading because it is easy to argue about the cause of death in a patient. For example, if someone has cancer, is treated with anticancer agents that suppress the bone marrow and make the patient susceptible to infections and they develop pneumonia and die, what was the cause of death? If the death is blamed on cancer or pneumonia, then adverse drug reactions are not the 4th leading cause of death, but if the death is blamed on drugs, i.e. the anticancer drugs, then adverse drug reactions may be the 4th leading cause of death. Most of the deaths in these studies involved anticancer drugs and drugs used to treat severe heart problems and these patients were at very high risk of dying no matter what the treatment. Even though I suspect that the incidence can be overstated, idiosyncratic drug reactions are certainly very important. Most adverse drug reactions are not idiosyncratic, but about 20% are and these are very difficult to deal with because of their unpredictable nature. They are often severe. They also greatly impede the development of new drugs because a major part of the expense of drug development is trying to ensure drugs are safe and yet idiosyncratic reactions are usually not detected by preclinical testing and clinical trials. In the last quarter of the 20th century, 10.2% of drugs that were released on the market either had to be withdrawn from the market or received a “black box” warning that severely limited the use of the drug. As indicated above, if biological markers could be found that predicted the risk of idiosyncratic drug reactions, it would have a major impact on drug development.

IEF

Definition

Isoelectric focusing refers to the separation of molecules according to their isoelectric point. A pH gradient of molecules (ampholytes) with low Mr (relative molecular mass) is built up by an electric field. The analytes migrate until they reach their isoelectric point, where they are uncharged and therefore focus at this position.

► [Two-Dimensional Gel Electrophoresis](#)

Ig Domain

Definition

Ig (immunoglobulin) domain is a common structural motif of many proteins. The Ig domain consists of a compact structure with two cysteine residues, separated by 55–75 amino acids that are arranged as two antiparallel beta sheets.

Imatinib Mesylate

Definition

Imatinib mesylate is a selective small molecule inhibitor of a small family of tyrosine kinases including the Bcr-Abl fusion protein. Imatinib mesylate induces high remission rates in patients with chronic myelogenous leukemia (CML).

- Leukemia

Imidazolium

Definition

Imidazolium is a five member heterocyclic compound in histidine.

- Proteases and Inhibitors

Immediate Early Genes

Definition

Immediate early genes are genes that are characterised by a rapid and transient activation of transcription in response to changes of environmental conditions, such as growth factors, cytokines, tumour promoters, carcinogens and expression of certain oncogenes. Immediate early genes can also describe viral genes that are expressed first after infection.

- ▶ Jun/Fos
- ▶ Transcription Elongation

Immobilized Metal-Affinity Chromatography

Definition

IMAC is based on the interaction between a transition metal ion (Co^{2+} , Ni^{2+} , Cu^{2+} , Zn^{2+}) immobilized on a matrix and specific amino-acid side chains.

- ▶ Protein Tags

Immobilized pH Gradients

Definition

Immobilized pH gradients (IPG) are based on the principle that the pH gradient within the gel is generated by a limited number (6–8) of well-defined chemicals (immobilines), which are co-polymerized with the acrylamide matrix. The gradient is built up by a gradient mixer. IPGs allow the generation of pH gradients of any desired range (broad, narrow or ultra-narrow) between pH 3 and 12.

- ▶ Microvilli

Immune System

- ▶ Immunity/Immune System

Immune Tolerance

Definition

Immune tolerance is the specific failure of a normally responsive individual to make an immune response to a known antigen. It results from previous contact with the antigen by an immunologically immature individual (fetus or neonate), or by an adult who has been exposed to extremely high- or low-dose antigen, ▶ radiation, antimetabolites, antilymphocytic serum, etc.

Immunity

Definition

Immunity is the ability of an organism to repel and stop the spread of disease-causing agents such as viruses, bacteria, and fungi or other foreign materials, and protect the body from infection. The immune system is a complex of organs – highly specialized cells and a

lymph circulatory system – all of which work together to ensure immunity and clear infection from the body. As a first line of defense, non-specific responses block the entry and spread of disease-causing agents. As a second line of defense, highly specific (antibody- and cell-mediated) responses, generate specific responses to an individual threat. Dysregulation/defects of the immune system can cause severe diseases like autoimmune diseases, allergies, immune deficiency syndromes and transplant rejection.

► [Innate Immunity](#)

► [Interleukins and Their Receptors, a Role in Regulating Hematopoietic Stem Cells](#)

Immunization, Active and Passive

Definition

Passive immunization is the treatment of a non-immune individual with antibodies from an immunized donor. This results in a state of transient immunity in contrast to active immunization which activates the host's own immune system and results in long-lasting immunity.

► [Monoclonal Antibodies](#)

Immunoblot

Definition

Immunoblot defines a method by which the transferred proteins on a western blot are probed with an appropriate antibody and the resulting bands visualised using fluorescence, chemiluminescence or autoradiography.

Definition

Immunochemical methods are processes utilizing the highly specific affinity of an ► [antibody](#) for its antigen to detect the distribution of a given protein (antigen) in tissues or cells. This methodology is highly important in the clinical context, as the normal localizations of a large number of proteins are known to be altered in various disease states, particularly in cancer.

Characteristics

Important ideas regarding the function of newly identified or uncharacterized proteins are often obtained by identifying the normal environment in which a given protein resides, by determining in which species or tissue it is expressed, in which cell type and ► [subcellular compartment](#) this protein can be found or whether there is some variation in expression of the protein during development or in different stages of, for example, the cell-cycle. In addition, some alteration in the normal expression pattern of a particular protein may be indicative of a particular disease state, information that may be useful for diagnosis and decisions regarding treatment.

Because many proteins have highly specialized functions within an organism, identifying the particular organs and tissues in which a protein is expressed provides valuable insight into the normal functions of the protein. For example, a protein expressed only within the brain is possibly involved in some aspect of nervous or sensory system regulation or in signaling pathways directing higher processes such as cognition or memory. Likewise, determining the specific cell type within a tissue in which a given protein is expressed further defines its normal function. For example, proteins only found within pancreatic islet cells may play some role in endocrine hormone production (proinsulin, glucagon, gastrin etc), whereas proteins found exclusively within pancreatic exocrine cells are more likely to be associated with pathways for digestive enzyme production. Similarly, identifying the subcellular compartment in which a protein normally resides provides more detailed information regarding its molecular function. For example, this may involve structural roles, such as gap junction or cytoskeletal components or being part of various metabolic pathways like DNA replication/maintenance and protein trafficking. This also provides an indication of the direction of future analyses.

Numerous methodologies have been developed to enable the localization of proteins within tissues and cells. Most rely upon immunochemical techniques, whereby a directly or indirectly labeled antibody (generated by exposing animals such as rabbits to doses of the protein of interest, or part thereof) specific for the protein of interest binds to this protein. The localization of bound antibody is then detected microscopically. Immunohistochemical methods, as the name suggests, are principally involved in the analysis of proteins within tissue sections, whereas immunocytochemical methods are employed for analyzing proteins within a cellular context.

Either direct or indirect immunochemical techniques are employed for localization of proteins within tissues or cells. Direct immunohistochemistry involves using an antibody specific for the protein of interest coupled to a particular label, whereas indirect immunohistochemistry involves the use of an unlabeled primary antibody specific for the protein of interest, which is then detected using a labeled secondary antibody recognizing immunoglobulin (IgG) from that species in which the primary antibody was generated. Indirect immunohistochemistry is more widely used, as this approach results in amplification of the resulting signal and does not raise the potential problem of inhibition of antibody binding as a result of the label. Additionally, individual labeling of each primary antibody is not necessary. Instead, most users have a series of labeled species-specific secondary antibodies that are used to detect many primary antibodies, e.g. a labeled anti-mouse-IgG antibody generated in goat will detect any murine-specific primary antibody (1). A comparison of

direct versus indirect immunochemistry is given in Fig. 1.

Three different types of labels are primarily used for immunochemistry, ►enzymes, metallic compounds and ►fluorochromes. Enzymatic labeling of antibodies is applied almost exclusively to tissue sections. This approach provides the advantage of increased sensitivity of detection and permanence of staining. The basic principle of enzymatic immunohistochemistry involves coupling an enzyme such as ►alkaline phosphatase or ►horseradish peroxidase to a secondary antibody. These enzymes catalyze the conversion of a colorless substrate to a colored precipitate, which is then readily detected using a regular transmitted light microscope, in an extra reaction step following the immunostaining procedure. When highly detailed information is required regarding the localization of a protein within a subcellular compartment, electron microscopy may be the method of choice. This highly specialized technique requires the use of electron dense labels, such as colloidal gold or silver coupled to a primary or secondary antibody for detection of proteins.

Fluorochromes are the usual label of choice for most immunochemical methods, particularly immunocytochemistry. Many different fluorescent markers with different emission spectra are available, allowing considerable flexibility in experimental design. Furthermore, simultaneous detection of multiple proteins within the same cell or tissue section using antibodies labeled with different fluorochromes is possible, provided primary antibodies from different species are used to prevent "cross-reactivity". Table 1 shows a list of commonly used fluorochromes.

Immunochemical Methods, Localization. Figure 1 Comparison of direct and indirect immunochemistry.

Immunochemical Methods, Localization. Table 1 Fluorochromes commonly used in immunochemical techniques. This list is not exhaustive

Fluorochrome	Excitation wavelength (nm)	Emission wavelength (nm)
5-Carboxyfluorescein (5-FAM)	492	518
5-Carboxytetramethylrhodamine (5-TAMRA)	542	568
5-Hydroxy Tryptamine (HAT)	370-415	520-540
Acid Fuchsin	540	630
Acridine Red	455-600	560-680
Acridine Yellow	470	550
APC (Allophycocyanin)	630, 645	655, 660
Astrazon Brilliant Red 4G	500	585
Astrazon Orange R	470	540
Astrazon Red 6B	520	595
Astrazon Yellow 7 GLL	450	480
Beta Lactamase	409	447, 520
Calcein	494	517
Calcium Green	501, 506	531
Calcium Orange	549	575, 576
Chromomycin A	436-460	470
CMFDA	494	520
Cy3™	514	566
	552	570
	554	
Cy5™	649	666, 670
Dansyl Chloride	372	518
DAPI	359	461
Eosin	524	545
Ethidium Bromide	510, 523	595, 605
Fast Blue	360	440
Fluorescein isothiocyanate (FITC)	490, 494	520, 525
Hoechst 33258	345	487
Hoechst 33342	347	483
Hoechst 34580	392	440
Lissamine Rhodamine	572, 577	591, 592
Lucifer Yellow	425, 428	528, 536, 540
Phycoerythrin R [PE]	565	578
Propidium Iodide (PI)	(305), 536, 538	617
Rhodamine	550	573
Tetramethylrhodamine (TRITC)	555	576
Texas Red™	595	620

In addition, the protein can be detected directly with a fluorescence microscope or perhaps with a ►fluorescence-activated cell sorter (FACS), without the need for additional, sometimes inconsistent enzymatic reactions (2). The primary disadvantage of fluorochromes is their sensitivity to light, which means that their signal is only detectable for a certain time period, depending on the properties of the individual molecule. Some more unstable dyes require special handling to prevent inactivation by light exposure.

When no antibody against a protein of interest is available, over-expression of the protein fused to a peptide or protein tag, either at the beginning (N-terminal) or end (C-terminal) of the protein provides a practical alternative for localizing the protein at a subcellular level. This methodology is especially appealing for high-throughput approaches. Two key types of ►fusion tag are available, ►epitope tags and fluorescent proteins, such as ►green fluorescent protein (GFP). An epitope tag consists of a short, specific stretch of amino acids known to be immunogenic and often derived from well-characterized proteins for which primary antibodies are readily available. Because these sequences are short, they are less likely to affect the normal folding or function of the protein of interest. Table 2 shows a summary of some of the common epitope tags currently in use (3).

GFP and its family of spectral variants – for example blue, cyan, red and yellow fluorescent proteins (BFP, CFP, DsRed and YFP respectively) – have become widely used in recent years as fusion tags. These tags have a number of useful properties, such as high stability, low toxicity and fluorescence without additional experimental steps. The existence of these different spectral variants, which were originally generated by substitution of certain amino acids within GFP, allows concurrent analysis of several different proteins. Many researchers now utilize these fluorescent proteins as fusion tags for the localization of novel

proteins (4). An example of this is shown in Fig. 2, where a novel protein was shown to be located in the mitochondria, due to the co-localization of a C-terminal YFP fusion of this protein with Hsp60, a known mitochondrial protein. It must be noted however, that the presence of GFP fused to a protein may cause incorrect localization results if the necessary sequence motifs are hidden within the tertiary structure of the protein by the presence of GFP.

As no antibody staining steps are required to view GFP fusion proteins within cells, these fluorescent proteins are also highly suitable for use in live cell imaging. This has become an important field of research in recent years, providing valuable information about the natural environment of proteins. Highly specialized techniques, such as ►fluorescence resonance energy transfer (FRET), and ►fluorescence recovery after photo bleaching (FRAP), have been developed in order to analyze properties such as interactions between proteins and intracellular protein movement.

Due to the highly structured, three-dimensional nature of organs and tissues and indeed cells, certain techniques are required to enable good detection and visualization of proteins. Primarily, the tissue must be fixed for long-term storage and use, which involves preservation of tissue morphology and immobilization of the various cellular components while still maintaining the antigenicity of proteins. Various advantages and disadvantages are associated with each of the many available fixation techniques and it is common practice to optimize the technique to suit the antibody and antigen of interest. Fixation procedures for tissues and cells commonly involve chemical alteration of cellular components to preserve their structural integrity, using ethanol to precipitate cellular proteins or formaldehyde and its derivatives, which cross-link various structural proteins. Another technique commonly applied to whole tissue sections, particularly in the clinical environment, involves snap freezing of the tissue in

Immunochemical Methods, Localization. Table 2 List of common epitope tags available for localization of fusion proteins using immunochemical methods

Tag	Peptide sequence	Origin
c-myc	EQKLISEEDL	Amino acids 411-420 of human c-myc protein
FLAG	DYKDDDDK	Synthetic peptide
HA	YPYDVPDYA	Amino acids 98-106 from human influenza virus hemagglutinin, HA1
His6	HHHHHH	Synthetic peptide
HSV	QPELAPEDPED	Peptide from herpes simplex virus glycoprotein D
Protein C	EDQVDPRLIDGK	Human protein C

Immunochemical Methods, Localization. Figure 2 Example of immunochemical methods used to co-localize two mitochondrial proteins. **A.** A novel protein expressed in HEK 293 cells is detected via a C-terminal YFP fusion tag. **B.** Expression pattern of Hsp60, a known mitochondrial protein, in the same cells. The protein was detected by incubation with a primary antibody specific for Hsp60 generated in mouse, followed by an anti-mouse IgG antibody coupled to Texas Red. **C.** Overlay of the two images to demonstrate co-localization of the two proteins within the mitochondria. Transfected cells were fixed on glass slides with 4% paraformaldehyde and permeabilized with a solution of 0.1% Triton X-100 to allow uptake of antibody. After antibody staining, slides were mounted with Mowiol to preserve structures. Images were obtained using a Zeiss LSM510 Meta laser-scanning microscope.

liquid nitrogen. After fixation of an entire tissue or organ, it is necessary to prepare ultra-thin sections from the fixed tissue for subsequent immunohistochemical staining and visualization, usually using a microtome.

Clinical Relevance

Immunochemical methods, particularly immunohistochemical techniques have been shown to be indispensable for the correct identification of the origin and stage of many tumor types, for distinguishing benign from malignant neoplasms and for diagnosing and understanding many other disease states, particularly immune system disorders, by virtue of the fact that the localization of key proteins is known to change in a highly tissue- and cell type-specific manner during these disease processes. Detailed knowledge of the precise nature of an illness is essential for a clinician in directing treatment and determining a patient's prognosis. For example, the presence of κ or λ immunoglobulin light chain in lymphocytes is indicative of either malignant B-cell lymphoma or myeloma/plasmacytoma. An important marker for distinguishing certain thyroid tumors is thyroglobulin. Tumors staining positive for this antigen are most likely to be papillary or follicular thyroid tumors, whereas medullary and metastatic thyroid tumors generally do not express thyroglobulin. Often, a panel of antigens is tested in clinical samples in order to diagnose a condition correctly. For example, specific expression patterns of IgG, IgA, IgM, C3 and κ and λ light chains are used to differentiate between numerous kidney diseases such

as glomerulosclerosis, glomerulonephritis, forms of lupus and amyloidosis (6).

As a result of detailed functional and structural information about proteins being increasingly available following the sequencing of the human genome, as well as with improved markers and detection systems for immunochemistry, the importance of these techniques as diagnostic and prognostic markers will undoubtedly increase in the future.

Immunological Methods, the Use of Antibodies to Discover the Function of Novel Gene Products

MARKUS ENZELBERGER, THOMAS VON RÜDEN
MorphoSys AG, Martinsried, Germany
enzelberger@morphosys.com,
vonRueden@morphosys.com

Definition

Antibodies are specific molecules of the vertebrate immune system, which are produced upon contact with an ► **antigen**. They bind the antigen with both high affinity and specificity and have thus become the reagents of choice for identifying and quantifying single proteins in complex protein mixtures. Antibodies are an essential tool in understanding the role of the individual gene and its function in complex

networks; they enable the detection and quantification of the gene product, they can reveal the localization of gene products *in situ* and they can be used for functional characterization of gene products (1). The combined benefit of high specificity and broad applicability in a variety of biological assays makes antibodies valuable tools. High throughput methods for antibody generation, antigen production and antibody characterization have been developed.

Characteristics

The primary questions when elucidating the function of novel proteins are where, when, in what amount, in which modification and for what purpose is the protein expressed?

How is this pattern altered under pathological circumstances?

Antibodies specific for the protein of interest can answer these questions by their use in various methods.

Detection and Quantification of Soluble Proteins

► **Enzyme Linked Immuno-Sorbent Assay (ELISAs)** are used for quantifying the protein of interest. The assays might be multiplexed by using ► **antibody arrays** on planar or bead surfaces (3); on planar arrays, the antigen is identified by the position of the signal on the array, on bead-based arrays, the antigen is detected by either the color or the size of the bead running by a detection module.

Four different ELISA protocols have been described for quantification and detection of antigen on these arrays (Fig. 1). (a) The protein of interest is labeled and detected in the lysate by binding to the antibody

directly; (b) the first antibody binds the antigen in the lysate and the second antibody carries the label; (c) the lysate is immobilized and different labeled antibodies bind to the lysate or (d) to speed up the assay development process drastically one can detect antibody/antigen binding to large antibody arrays by ► **surface plasmon resonance (SPR)** without labeling either of the binding partners.

In all cases, the challenge is to find an antibody that has a very low potential to cross react with other proteins in the lysate that are also applied to the chip.

There is a trend for using specific antibodies against posttranslational modifications of proteins, e.g. phosphorylation, instead of using radioactive methods. Besides their ease of use, this offers the possibility to multiplex and analyze complex pathways in a single experiment.

Detection and Quantification of Proteins in Tissue Extracts

General protein expression of the novel protein of interest is studied by ► **Western blot (WB)** analysis. This method usually denatures the protein of interest, thus, the antibody used for detection has to be able to detect linear epitopes. Laborious sample preparation, difficulties in quantification and the comparatively large amount of protein needed for Western blot analysis make it only moderately suited for high throughput analysis of protein expression.

In Situ Localization of the Protein

► **Immunohistochemistry (IHC)** is used to identify the site of protein expression in tissue sections or on

Immunological Methods, the Use of Antibodies to Discover the Function of Novel Gene Products.

Figure 1 Protein and antibody array formats: (a) Antigen capture; antibodies are immobilized on a solid support in a known pattern. All the proteins of the lysate are labeled with a fluorescent dye. The lysate is incubated with the solid support and, after washing, the proteins contained can be identified. (b) Sandwich ELISA: (capture) antibodies are immobilized on a support in a known pattern, after addition of lysate, a second (detection) fluorescently labeled antibody and washing, the proteins contained are identified. (c) Reverse phase: the lysate is immobilized on a surface and the proteins contained are detected using differently labeled antibodies. (d) Surface plasmon resonance (SPR) detection: (Capture) antibodies are immobilized on an SPR surface in a known pattern; lysate is added and, after washing, binding can be detected by a change in the resonance angle. No labeling is needed for this method.

► **tissue microarrays** (2). The latter allow the parallel study of expression in tissues from different sites, diseases or developmental stages in parallel.

► **Fluorescence activated cell sorting (FACS)** analysis is used to determine the distributions of cell surface proteins and their variations in different cell populations.

For both methods, IHC and FACS, the antibody must be able to detect the protein in its native conformation.

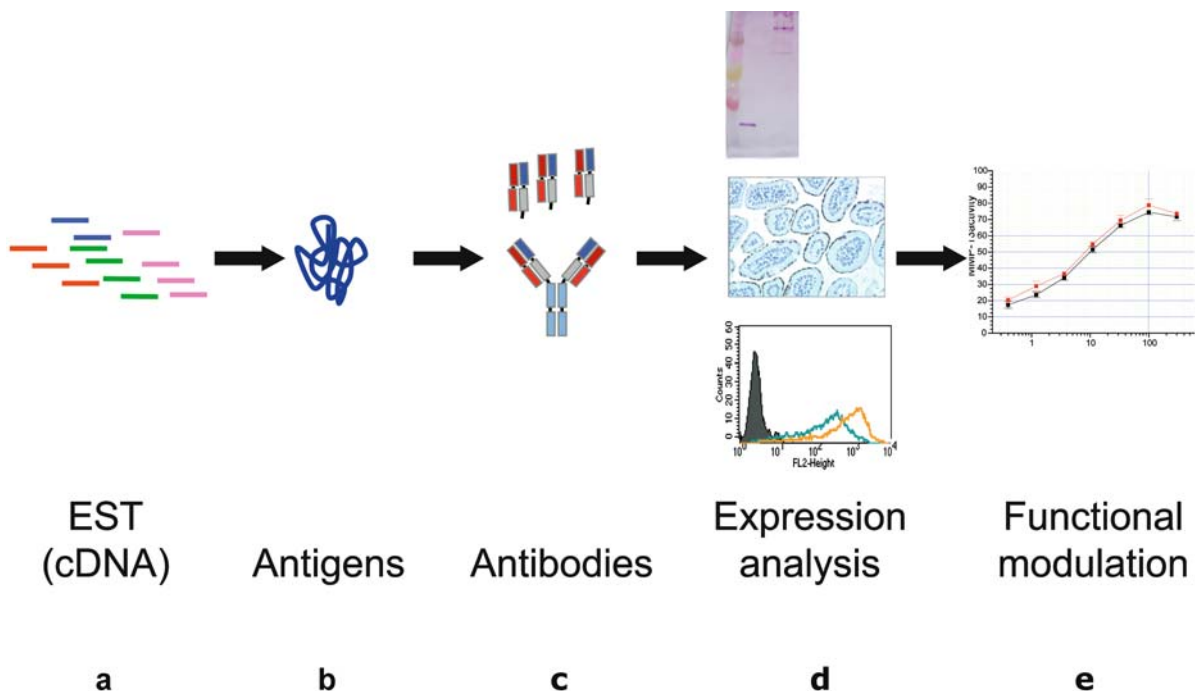

Functional Characterization of the Protein

The binding of an antibody to an antigen can disrupt the functionality of the antigen, thus leading to an understanding of the protein function. Antibodies can neutralize soluble mediators, block the interaction between ligand and receptor, bind to the active site of an enzyme or change the conformation of a biocatalyst reducing its enzymatic activity. Antibodies can also block the binding of inhibitors of a biocatalyst leading to neutralization of enzyme inhibitors. Most critical for all these applications are antibodies that are similar to the natural ligand and hence act as competitors.

Antibodies can further be used to trigger the signaling function of unknown proteins. Binding of the antibody to cell surface receptors can lead to dimerization of the receptor molecules and thus activate cell signaling cascades leading to cell proliferation or cell death. Antibodies can be expressed inside the cell and inhibit protein function intracellularly by interacting with the protein of interest in the native *in vivo* environment (4). However, the difficulty of expressing functional antibodies in the reducing environment of the cytoplasm and nucleus limits the application of this technique.

Traditional Generation of Antibodies

The classical way of producing antibodies was discovered over a hundred years ago when Behring and Kitasato observed the presence of antigen-specific antibodies in the blood of animals (mostly mice) that had been immunized with the antigen. Such an “antiserum” contains a mixture of different antibodies binding to different ► **epitopes** on the antigen. The non-defined epitope binding of the mixture and its

Immunological Methods, the Use of Antibodies to Discover the Function of Novel Gene Products.

Figure 2 Typical workflow for in vitro antibody generation for proteome or target research antibodies: Subsequent to identifying a differentially expressed gene (a) peptides, polypeptide encoded ESTs or purified proteins are produced (b). In multi selection rounds, binders from a diverse pool are enriched and afterwards screened for binding against the antigen used for selection. The format of the antibodies can now be changed to the one (e.g. IgGs or dimeric Fabs) best suited for the consecutive assays (c). To check expression of the protein of interest, Western blot, IHC, ELISA or FACS analysis is used (d) before functional assays are performed (e). Following characterization and validation, human antibodies can enter the optimization procedure for a therapeutic antibody seamlessly.

dependence on the individual animal used for immunization raise a problem with regard to the reproducibility and specificity of the desired antibody. Since the mid 1970's, this problem has been overcome with hybridoma technology. Here, one single epitope-specific antibody-producing B-cell is isolated from the spleen and fused to cancer cells to achieve immortality. Each "hybridoma" cell can then divide and produce a single epitope-specific antibody.

High Throughput Generation of Antibodies

High throughput methods for antibody generation use recombinant antibody libraries with *in vitro* selection methods like ►phage display or ►ribosomal display. Advantages of this approach are the potential availability of antibodies against "self antigens" and the ease of modifying antibodies, i.e. the addition of specific detection and purification tags.

In all cases, the antibodies are directly coupled to the gene sequence. The fusion protein is exposed to the antigen under selective pressure, e.g. binding to the antigen of interest. Non-binding members of the library are removed. Then, the remaining binding members are amplified. Methods such as PCR are used when employing ribosomal display, whereas infection of bacteria is used when using phage display methods. The amplification can be repeated several times, yielding a polyclonal pool of highly specific and high affinity binders. The polyclonal pools can be cloned and clones screened for specific binders e.g. by ELISA. Short cycle times and standardized protocols make *in vitro* methods well suited for automation and high throughput. A typical workflow for antibody generation is shown in Fig. 2 (6, 7).

A major challenge for the high throughput generation of antibodies is the need for sufficient amounts of high quality antigen. One approach for overcoming this obstacle is the use of synthetic peptides derived from the primary structure of the protein of interest as antigen (8). An alternative is the so-called ►HuCAL® EST-technology, a direct expression of the EST sequences in bacterial systems (9). Stretches of 40–400 amino acids derived from cDNA are fused to a His-tagged protein and expressed as inclusion bodies in *E. coli*. After purification and refolding of the inclusion bodies, the antigen can be used for the antibody generation process. Like the peptide-based approach, EST-encoded polypeptides can be used as surrogate substrates in the antibody generation process, yielding binders with good affinities recognizing the full length protein in its denatured form (Western blot), as well binders recognizing the native protein (IHC & FACS) (10).

Clinical Relevance

Rapid elucidation of the function, distribution and pathological relevance of a novel gene product yields data necessary for an early judgment on the potential therapeutic value of a target protein. An intriguing possibility exists that human antibodies may serve as lead compounds in the development of a drug directed against such a target. Antibodies will also be used as biosensors for patient selection and/or for monitoring specific biomarkers to improve diagnosis of human disease.

Immunophilins and Cyclophilins

Definition

Immunophilins are a family of soluble receptors capable of binding to one of two major immunosuppressant agents; cyclosporin A (CsA) or FK506.

Proteins that bind to FK506 are termed FK506 Binding Proteins (FKBPs), and those that bind to cyclosporin A are called cyclophilins (CyP). Immunophilins function as cis-trans peptidyl-prolyl isomerases (PPIase), whose activity is inhibited by their respective immunosuppressant compounds. Thus, immunophilins accelerate folding of some proteins both *in vivo* and *in vitro*, by catalyzing slow steps in the initial folding and rearrangement of proline-containing proteins.

► [Nuclear Hormone Receptors: Regulators of Gene Transcription and Cellular Signaling](#)

Immunoprecipitation

Definition

Immunoprecipitation refers to an experimental technique to identify the subunits of oligomeric proteins. It requires a specific antibody of high affinity, which captures its antigen together with any bound proteins from a cell or tissue extract. Protein A of *Staphylococcus aureus* is used to cross-link and precipitate the antibody-protein complexes which are then isolated by centrifugation. Alternatively, Protein A bound to agarose beads is used.

Impedance

Definition

Impedance is a measure for the manner and degree a component resists the flow of electrical current if a given voltage is applied. It is usually denoted by the symbol Z and is measured in Ohm $[\Omega]$.

► [PNA Chips](#)

Importin

Definition

Importins are soluble transport receptors mediating macromolecular transport processes across the nuclear envelope. They recognize their substrates in the cytoplasm by a nuclear localization signal (NLS) and transport them through nuclear pores into the nucleus. In the nucleoplasm, RanGTP binds to importins, inducing the release of import cargoes. For comparison, see ► [exportins](#), which interact with their substrates only in the nucleus in the presence of RanGTP, and release them after GTP hydrolysis in the cytoplasm, causing disassembly of the export complex.

Definition

Understanding the development of the nervous system, the establishment and functioning of neural circuits, as well as the cure of brain diseases are probably the most exciting questions for a neuroscientist. The generation and use of appropriate animal models provides new vistas not only on brain function, but also on therapeutic approaches of CNS diseases. Recently, genes encoding for ▶fluorescent proteins (FPs) have been cloned from sea animals like jellyfish or corals, and optimized for the expression in mammals. The combination of cell-type specific promoters with FP genes allows the generation of transgenic mice, in which distinct cell populations are selectively labelled, and can be visualized in their complexity within their native environment (1). Many spectral variants of FPs

are now available, so that different cell-types can be co-labelled in different colors. Applied to the nervous system, FP expression in transgenic mice provides a variety of advantages. Living brain cells can be identified in acutely isolated tissue slices by conventional ►fluorescence microscopy, without prior tissue fixation and the need for laborious immunohistochemical staining techniques. Labelled cells can be selected and analyzed by patch-clamp recording, or isolated by ►fluorescence-activated cell-sorting. Since FPs outline the cellular morphology, long-term recordings can reveal structural dynamics of the cells, e.g. cell migration or motility of their processes. Common to all these paradigms is the unequivocal identity of cells under study, neurons, astrocytes, microglia or oligodendrocytes.

In parallel to the establishment of FPs as cellular markers, recent advances in microscopy technology now make it possible to visualize FP-expressing cells in living animals (*in vivo*). In particular, application of two-photon laser-scanning microscopy (2P-LSM) (2) allows fluorescence imaging at high spatial resolution several hundred microns deep in intact tissue, enabling the visualization of structural dynamics and physiological activity in the living brain. In the following, we describe several advantages of the combination of 2P-LSM and transgenic mice with FP expression.

Characteristics

Two-Photon Microscopy

A major breakthrough during recent years have been imaging techniques, which allow the direct observation of the brain in living laboratory animals, particularly in rats, but also in mice. The most common and least invasive technique is functional magnetic resonance imaging (►fMRI). For *in situ* and *in vivo* analysis, the animals are anesthetized and placed into the observation chamber equipped with the appropriate magnets. A major limitation of fMRI is, however, the relatively low spatial resolution (about 150 µm), which prevents resolving individual cells. Compared to fMRI, 2P-LSM provides a more than hundred-fold higher spatial resolution (<1 µm), and therefore is well suited for cellular imaging, in particular in the intact brain (3). 2P-LSM is based on the simultaneous absorption of two infrared excitation photons by a fluorophore, instead of one photon of visible wavelength (2). Following excitation, the molecule fluoresces in the usual way, irrespective of the mode of excitation. As 2-photon absorption depends non-linearly (quadratically) on light intensity, fluorescence is only generated where the photon density is high, and thus is typically confined to the focal volume. These special features give 2P-LSM several advantages over conventional (one-photon) confocal microscopy for biological imaging (4):

- a) a better depth-penetration of infrared excitation photons into the specimen, due to the reduced scattering of infrared light by tissue;
- b) intrinsic optical sectioning and better image contrast, due to the localisation of excitation and the ineffectiveness of scattered infrared photons to generate fluorescence;
- c) reduced out-of-focus photobleaching, permitting long-term observations, and
- d) effective collection of scattered fluorescence from deeper tissue regions.

2P-LSM does, however, require an expensive pulsed laser source, most commonly an externally pumped Ti:Sapphire laser oscillator, which emits laser pulses of ~100 femtosecond (10⁻¹⁵ s) length at a frequency of ~80 MHz, with a tunable wavelength between 750 and 1000 nm. Pulsed laser light is of paramount importance to generate very high peak intensities.

2P-LSM has become the principal technique for high-resolution imaging deep inside intact biological tissues, in particular for structural and functional analysis of cellular dynamics in the brain of living mice. Typically, imaging is performed in anesthetized animals, either through a small craniotomy of a few millimeters diameter (4) or through the thinned skull (5,6). A prerequisite of *in vivo* 2-photon imaging is specific labeling of the structures of interest with a fluorescent marker. Various fluorescent labeling techniques have been introduced, including staining of the blood plasma by tail-vein injection of fluorescent dyes (7) intracellular loading of individual neurons with calcium indicators (8) or bulk-loading of neuronal and glial cell populations with membrane-permeable calcium indicators (8). Alternatively, and perhaps most conveniently, 2P-LSM can be applied to transgenic mice expressing FPs in specific cell types (either neurons or glial cells). These animals are particularly well suited to investigate structural changes of cells and cellular processes both during development and adulthood. By multiple repeated imaging of the same cells in the same animal structural dynamics can be followed on various time scales ranging from minutes to several months (1,6).

Transgenic Mice with Fluorescent Protein Expression

Transgenic mice with cell-type specific FP expression represent an important advancement for the analysis *in situ* and *in vivo*. Cell-type specific promoters are used to target FPs with different spectral properties into cells of interest (Fig. 1). For example, in one mouse line a Thy1.2 promoter induces expression in a variety of neurones in several brain regions including cortex and hippocampus (9); in other mouse lines the human glial fibrillary acidic protein ►promoter causes expression in ►astrocytes (10) and the mouse proteolipid protein

promoter in ►**oligodendrocytes** (11). In addition, by using a knock-in strategy to place the enhanced green fluorescent protein (EGFP) gene into the fractalkine receptor (CX3CR1) locus, a mouse line was generated in which virtually all ►**microglia** cells of the brain parenchyma were fluorescently labelled (12).

These and similar transgenic mouse lines are currently being used to investigate whether cell morphologies are stable or plastic in adult animals, and under what conditions they might change. Imaging of neuronal dendrites and axons showed that overall neuronal morphologies were stable, but that synaptic structures

***In Vivo* Imaging of Transgenic Mice with Fluorescent Protein Expression.** **Figure 1** Cell-type specific *in vivo* imaging of brain cells in transgenic mice with fluorescent protein expression. All images were acquired using 2P-LSM. The cartoons below the images depict the combination of cell-type specific promoter and fluorescent protein gene to generate the genetically modified mouse lines. (a) Pyramidal cells in the mouse neocortex expressing the yellow fluorescent protein YFP under control of the mouse Thy1.2-promoter. The image is a side-projection of a stack of fluorescent images acquired from about 400 µm below the brain surface up to the pial surface. (b) A single astrocyte enwrapping a brain capillary. 2P-LSM recording in the cortex of a TgN(hGFAP-EGFP) mouse. (c) Visualization of a resting microglia cell with its numerous branched processes sensing the parenchymal environment in the cortex of a TgH(CXC3R1-EGFP) mouse.

(dendritic spines and presynaptic endings) were turned over at a certain rate, indicating plastic (possibly experience-dependent) changes of neuronal connectivity. Similarly, astrocytes appear to preserve their gross morphology, at least over the time course of weeks. In marked contrast, recent findings demonstrate that microglial cells display an extraordinary high level of structural dynamics. The cell processes of these immune cells of the brain are highly motile, apparently continually surveying the brain tissue (6). Consistent with a protective function, the motile processes immediately targeted damaged areas, e.g. shielding local disruptions of blood vessels.

Another application of 2P-LSM for the analysis of transgenic mice is the visualization of amyloid plaques in a transgenic mouse model of [▶Alzheimer's Disease](#) (5). To this end, a fluorescent [▶thioflavin T](#) derivative was injected into the tail vein of an anesthetized mouse. After 20 min. the dye had crossed the blood-brain barrier, and had exclusively stained amyloid plaques at the vessels and within the brain parenchyma. This method permits the study of plaque growth and disease progression, as well as the analysis of potential treatments (13). Crossbreeding of these mice with other mice showing specific FP expression may also permit detailed analysis of the involvement of surrounding cells.

In summary, during the past years, the fields and numbers of applications of 2P-LSM in living animals have expanded enormously, including *in vivo* studies on brain tissue, but also on skin, tumors, lymph nodes and kidney. The combination of 2P-LSM with transgenic mice expressing FPs has proven particularly well suited for studies of short- and long-term morphological changes during normal and pathological conditions.

Definition

What is an inflammatory response? ► [Inflammation](#) is a general term for the local accumulation of fluid, plasma proteins and white blood cells that is initiated by physical injury, infection or a local immune response. More extensive tissue damage or infection may result in additional systemic reactions including fever and induction of certain genes mounting the acute phase response. These largely uniform responses of higher multicellular organisms to various injuries/infections are also known as the inflammatory response. The cells that invade tissues undergoing inflammatory responses are often called inflammatory cells or inflammatory infiltrates.

Acute inflammation is the term used to describe early and often transient episodes, while chronic inflammation occurs if the infection persists or during atherosclerosis or autoimmune responses. Many different forms of inflammation are seen in different diseases.

Characteristics

► Innate Immunity and Inflammation

Barriers keep harmful materials from entering your body. Some of these barriers are the skin, stomach acid, mucus (traps microorganisms and small particles), the cough reflex and enzymes in tears and skin oils. If a pathogen gets past the external barriers, it is attacked and destroyed by the immune system. Host defense mechanisms of the innate immune system represent the first immunological protection line.

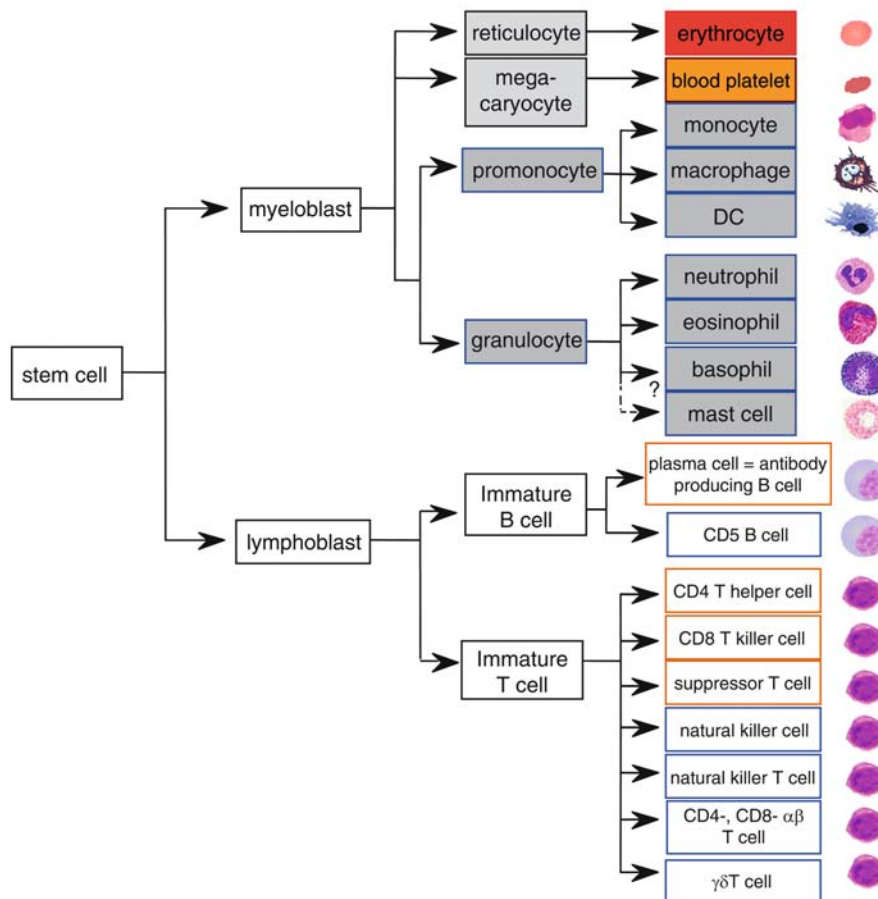

The immune system consists of certain types of white blood cells. It also includes biochemicals and proteins in the blood such as complement proteins, interferons and cytokines. Some of these directly attack foreign substances in the body and others work together to help the immune system.

The inflammatory response (inflammation) is part of innate immunity. It occurs when tissues are injured by bacteria, trauma, toxins, heat or any other cause. Proinflammatory mediators including histamine, bradykinin, serotonin and others are released by damaged tissue. These chemicals cause blood vessels to leak fluid into the tissues, resulting in localized swelling. This helps to isolate the invading substance or pathogen from further contact with tissues.

Certain proinflammatory mediators also attract white blood cells that “eat” microorganisms and dead or damaged cells. The process whereby these white blood cells surround, engulf, and destroy foreign substances is called ► [phagocytosis](#) and the cells are collectively referred to as phagocytes. Some of the phagocytes eventually die. Pus is formed from a collection of dead tissue, dead bacteria and live and dead phagocytes.

But not everything that enters the body is harmful, as can easily be understood by the example of food. So, in this line of defense, differentiation of pathogens from non-pathogens is crucial. The first line of defense is always directed by the innate immune system (Fig. 1). The innate immune system expresses a large amount of so called “pattern recognition receptors” which detect basic pathogen molecules or patterns (pathogen-associated molecular pattern [► [PAMP](#)]; Table 1). Only the activation of one or more of these pattern recognition receptors activates the second line of defense, which is performed by the adaptive immune system consisting of T and B cells (Fig. 1).

Initially, the adaptive immune system generates its receptors randomly. So, it does not know what it will bind. This leads to enhanced flexibility but also the

Inflammatory Response. Figure 1 The tree of blood cell types starting from hematopoietic stem cells. Stem cells are multipotent and may differentiate into each cell type in the figure. A strict borderline is demarked after differentiation either to lymphoblasts or myeloblasts. No way back! All adaptive immune cells (brown lining) are derived from lymphoblasts. Cells belonging to the innate immune system (blue lining) are from both branches, lymphoblasts and myeloblasts.

possibility that it might bind self-structures is high. Therefore, T and B cells undergo stringent selection processes to avoid unwanted destruction of self. If these selection processes fail, ►[autoimmune diseases](#) or allergies prevail.

Much is known about the first line of selection, especially about T cell selection, whereas less is known about B cell selection. The immunoreceptor selection processes and the whole of ►[adaptive immunity](#) are not covered by this essay. In the second line of selection processes, the innate immune system governs the fate of adaptive immunity by means of its pattern recognition mechanisms.

There are many ways to die. Cells, however, usually meet their destiny in one of two ways – death by ►[necrosis](#) or death by ►[apoptosis](#).

The decision to initiate an inflammatory response also has to be made for dying cells, which arise by hundreds

of billions each day. They carry valuable information with respect to the possible influence of pathogens. Dying cells are usually phagocytosed by specialized macrophages (tingeable body macrophages, Kupffer cells, alveolar macrophages, tissue macrophages) or less frequently dendritic cells (DC). If the differentiation between apoptosis and necrosis fails, for instance when apoptotic cells are not swiftly phagocytosed and, therefore, reach a state of secondary necrosis, autoimmune reactions against components of the lysed cells may arise. Therefore, impaired engulfment of dead cells is supposed to play an important role in the etiopathogenesis of autoimmune diseases such as ►[systemic lupus erythematosus](#) (SLE).

Necrosis

Necrosis can be viewed as a sort of violent cell death. Cells that may not have yet reached their full life span

Inflammatory Response. Table 1 Selected innate recognition receptors

Receptor	Ligand (innate response)
TLR 1 - 10	LPS, flagellin, CpG DNA, dsRNA, and many others
CD14	LPS, peptidoglycan
Complement receptor 3 (Mac-1, integrin $\alpha_M\beta_2$, CD11b-CD18)	iC3b-opsonized particles
Complement receptor 2 (CD21)	iC3b-opsonized particles
Fc-receptor (FcR)	"Natural antibodies"
Scavenger receptor AI/II	LPS, lipoteichoic acid, bacteria
MARCO	Bacteria
Integrin $\alpha_v\beta_3$ (macrophages), integrin $\alpha_v\beta_5$ (DC)	Fibronectin
Dectin-1	β -glucan
Mannose receptor	Mannan
DC-SIGN	ManLAM
FMLP receptor	N-formylated bacterial peptides

are hit by an external noxa that interrupts some of their vital functions or disrupts their physical integrity and the intracellular contents are spilled into the micro-environment. This process is often due to the influence of a pathogen or mechanical or oxidative stress.

Cells do not die violent deaths unnoticed. The intracellular fluids, proteins and organelles released into the extracellular spaces exert a proinflammatory function, attracting inflammatory cells and cytokines from the nearby vessels and tissues. What ensues is an inflammatory reaction that may be more or less damaging to the tissues.

The Apoptotic Program

Apoptosis is seen as a form of graceful death. The name itself suggests it – it is the ancient Greek term for the falling of leaves. Once the internal program is activated, the cell shuts down its internal networks and activates a series of enzymatic reactions that lead to an autoprolytic breakdown. Enzymes, proteins and DNA are cleaved internally in a "silent" fashion. In contrast to necrotic cells, apoptotic cells maintain their membrane integrity for a relatively long time, thereby

preventing the release of intracellular components that may directly damage the tissue or may induce inflammatory or immune responses. In addition, apoptotic cells undergo very early membrane changes to ensure immediate recognition and timely engulfment of the dying cells prior to secondary necrosis and cells lysis (see below).

Apoptosis plays a critical role not only during embryogenesis, pregnancy, delivery and development, when the rate of tissue modeling and remodeling is at its highest. Normal tissue homeostasis relies substantially on removal of old cells by apoptosis (eg granulocytes, gut epithelium) to allow new, young cells to take their place. Apoptotic check points are also critically involved in preventing overgrowth, once adult tissues start proliferating to repair a cell loss or extensive cell damage.

Apoptotic and Necrotic Signals to Phagocytes

Cells undergoing apoptosis subtly signal their demise to the extracellular environment. They expose "eat me" signals and bind a variety of adaptor molecules, features important for recognition and uptake by specialized phagocytes (Table 2). The receptors are highly redundant and are ordered hierarchically, reflecting the necessity for fine-tuning of the recognition process. Some recognize apoptotic cells in the early phase of cell death, others rather represent backup systems. Some recognition pathways differentiate among apoptosis, necrosis and cellular debris, while others do not. A variety of specialized phagocytes have developed in humans due to organ-specific requirements. The macropinocytosis of apoptotic cells by macrophages triggers the production of **transforming growth factor β** , a cytokine that suppresses inflammatory processes. When monocytes or immature DC encounter apoptotic cells they are triggered by CD36 to produce IL-10, which is also an anti-inflammatory cytokine. In addition to the enhanced secretion of anti-inflammatory cytokines, the production of proinflammatory cytokines such as TNF α , IL-1 and IL-12 is markedly inhibited in the presence of apoptotic cells. Phospholipids are asymmetrically distributed among the inner and outer leaflets of the intact cell membrane; the outer leaflet primarily contains sphingomyelin and phosphatidylcholine (PC), whereas the inner leaflet harbors most of the phosphatidylserine (PS) and phosphatidylethanolamine (PE). Maintenance of this asymmetry is energy dependent and requires adenosine triphosphate (ATP). In the absence of ATP as in necrosis, the phospholipids of the inner and outer leaflets undergo exchange (so-called 'flip-flop'). Another condition that induces a membrane flip-flop is apoptosis. Phosphatidylserine can be recognized by phagocytes, mostly macrophages, leading to quick

Inflammatory Response. Table 2

Receptor		Ligand and adaptor (innate response)
Phosphatidylserine receptor (PSR) => triggers the production of transforming growth factor β		Phosphatidylserine (PS)
Integrins	CR3, CR4	iC3b
	$\alpha_v\beta_3$ / CD36	PS , Tsp
	$\alpha_v\beta_5$	
	$\alpha_3\beta_5$	MFG-E8
Collectin receptors		C1q, C3, C4, MBL, SP-A, SP-D
CD14		PS , ICAM-3
CD21/35		Complement
ABC1		PS
β_2 -GPI receptor		PS , β_2 -GPI
Scavenger receptors	CD36	PS , oxLDL
	SR-A	PS , oxPL
	CD68	PS , oxLDL
	LOX-1	PS
	SR-B1	PS
Lectins		Sugar moieties, altered carbohydrates
FcγR		IgG, CRP, SAP, PTX3, HRG; Anti-S,-M,-L, oxPL, CRP
c-mer		Gas-6
CD91 / calreticulin		Calreticulin, collectins, heat shock proteins
gas-6		PS
asialoglycoprotein receptor		Glycoproteins
CD31-R (PECAM-1-R)		CD31 (PECAM-1)

removal by phagocytosis. The recognition of PS by the PS receptor (PSR) is of major importance for phagocytosis of early apoptotic cells.

The Last Order of an Apoptotic Cell: “Anti-Inflammation, Please”

Cells dying by apoptosis are not immunogenic because they are self-material that is not subject to pathogen attack. It must be finely differentiated from necrosis by apoptotic cell-associated molecular patterns (►ACAMP). The mechanisms of this differentiation are a matter of intense discussion.

In contrast to apoptotic cells, necrotic cells initiate inflammatory responses and can mediate maturation of DC. As described above, the fine-tuning of responses against dying cells is of major importance. Even primary and secondary necroses involve the display of

different inflammatory signals. Primary necrotic cells release the inflammatory high mobility group B1 (HMGB1) protein that is “frozen” on the chromatin of apoptotic cells and remains immobilized even under conditions of secondary necrosis. This might be considered one reasonable mechanism of fine-tuning. In addition, the release of heat shock proteins, substances of mitochondrial origin (which still display certain bacterial features), and other molecules appear to contribute to the proinflammatory response.

Secretory Phospholipase and ►C-Reactive Protein in Apoptosis and Necrosis

In humans, another relevant secretory protein that strongly binds PS floats freely in the serum. Its name is secretory phospholipase A2 (sPLA2) IIA. sPLA2 IIA is not able to hydrolyze the phospholipids of the outer

membrane leaflet of normal intact cells efficiently. Thus, sPLA2 IIA is only able to react with phospholipids in the outer leaflet of normal cells if they have undergone a flip-flop from the inner leaflet as in apoptosis or necrosis. After interaction with sPLA2 IIA, cells are left with an increased proportion of lysophospholipids (phospholipids that have lost free fatty acids at the *sn*-2-ester bond) like lysophosphatidylcholine (lyso-PC) in the outer membrane leaflet. This modification disturbs the packing of the phospholipids and generates binding sites for the pentraxin ►C-reactive protein (CRP) in the outer leaflet.

CRP is capable of binding to cells provided that they contain a substantial amount of lyso-PC in the outer leaflet of their membranes. Thus, in inflamed tissues, it is proposed that binding of CRP initially occurs to cells containing a significant proportion of lysophospholipids in the outer leaflet of their membranes due to the activity of sPLA2 IIA. Once bound, CRP induces complement activation *via* the classical pathway, which in turn triggers the influx of neutrophils, decorates the surface of the ligand with opsonising complement fragments and enhances phagocytosis of the cells that have bound CRP and complement. CRP also interacts with Fc receptors on phagocytic cells and acts as an opsonin. Because the occurrence of lyso-PC is dependent on the exposure of PS, CRP, in this chronological view, efficiently decorates late apoptotic cells.

In addition to the membrane of intact injured cells, CRP also binds to membranes and nuclear constituents of necrotic cells. Several nuclear constituents, including histones, small nuclear ribonucleoproteins and ribonucleoprotein particles have been shown to bind CRP in a calcium-dependent fashion. Deposition of CRP onto nuclei of necrotic cells at sites of inflammation has been observed, while CRP does not cross the plasma membrane of apoptotic cells. This might be considered a second reasonable mechanism for fine-tuning the differentiation between apoptosis and necrosis.

The ►Acute Phase Reaction: Secretory Phospholipase and C-Reactive Protein in Infection

CRP is an acute-phase protein featuring a homopentameric structure and Ca-binding specificity for phosphocholine and lyso-PC. The wide distribution of phosphocholine in polysaccharides (C-polysaccharide) of pathogens and in cellular membranes allows CRP to recognize a range of pathogenic targets as well as membranes of damaged and necrotic host cells. Thus, the main biological function of CRP appears to be host defense against bacterial pathogens and clearance of apoptotic and necrotic cells.

The acute phase response (APR) of inflammation is a well-known clinical phenomenon characterized by leukocytosis, fever, alterations in the metabolism of many organs and changes in the plasma concentrations of various so-called acute phase proteins (APPs). The prototypal APP in humans is CRP. Plasma levels of this APP start to rise as early as about 8–10 h after challenge with the inciting stimulus. In addition, circulating levels of another APP, the enzyme sPLA2 IIA start to rise approximately 6–8 h after challenge.

CRP is widely used as a biomarker of systemic inflammation due to the fact that its concentration correlates considerably with the inflammatory state. Examples are infection, sepsis, severe wounds and vast areas of necrotic cells as after myocardial infarction or stroke. The swift rise of its serum concentration during the acute phase, the magnitude of the response approaching 1000-fold increase within 24–48 h, and the equally quick return to the very low normal concentration of a few µg/ml are the most impressive biological characteristics of CRP as an inflammation marker. CRP-synthesis within the liver accounts for its blood concentration. Hepatic synthesis of CRP occurs upon stimulation by inflammatory cytokines (IL-1β, IL-6) produced in response to tissue injury. In an analogous fashion, inflammation induces a 10–100-fold increase in circulating sPLA2 IIA, starting within 3–4 h and reaching peak levels after approximately 10 h.

Transcriptional Regulation of the Inflammatory Response

Multiple cell types and genes are involved in the complex inflammatory process, whereas only a few transcription factors govern the transcriptional regulation of the inflammatory response. The promoter/enhancer sequences of most genes that are involved in inflammatory and immune responses contain binding sites for ►NF-κB, activating protein 1 (AP-1), ETS-domain transcription factors and CAAT/enhancer-binding proteins (C/EBP). Binding of at least one, often several, of these transcription factors is usually required for the efficient transcription of most genes involved in the inflammatory response. Among these transcription factors, NF-κB appears to play a key role, since it can be rapidly activated and is essential for the efficient expression of many inflammatory genes. Therefore, NF-κB can be regarded as a main switch of the inflammatory response and host defence. Pharmacological inhibition of NF-κB might represent a powerful therapeutic target in inflammatory diseases.

Concluding remark

As a basic view, an inflammatory response is governed by paranoia. This paranoia is two-fold.

Paranoia 1 is the well founded suspicion that an enemy might enter or might have entered the body.

Paranoia 2 is that adaptive immunity will accidentally react to self and so raise an autoimmune disease. This is also well founded and the reaction of the immune system to this fact is that it uses the differentiation between friend and foe to raise, upon contact with self, anti-inflammatory signals. These signals are transported by DC to T cells and establish a cohort of regulatory or suppressor T cells to gain tolerance for self.

Informational Property Right

Definition

Informational property right is a legally protected personal right, similar to other property rights; individuals may share properties with others for personal benefit and within legal or regulatory frameworks or contract.

► [Ethical Issues in Medical Genetics](#)

Informed Consent

Definition

Informed consent of patients and probands is an essential moral, regulatory, and legal prerequisite for medical examination and treatment, as well as in

clinical research; researchers are morally and legally obligated to inform adequately and to seek consent without pressure or promises; patients and probands must be given the right to ask for termination of treatment or involvement in research.

► [Ethical Issues in Medical Genetics](#)

Informed Contract

Definition

Informed contract between citizens seeking health care guidance, medical treatment or volunteering in clinical research, and health care professionals, scientists, and their sponsors, outlines the rights and obligations of stakeholders involved.

► [Ethical Issues in Medical Genetics](#)

In-Frame Deletion

Definition

An in-frame deletion is a mutation in the coding region of a gene, resulting in the loss of normal DNA sequence, which does not alter the normal triplet reading frame between the mutation site and the carboxyterminus of the polypeptide.

Inherited Mental Retardation Syndromes

NIELS TOMMERUP

Department of Medical Biochemistry and Genetics, Wilhelm Johannsen Center for Functional Genome Research, University of Copenhagen, Copenhagen, Denmark
tommerup@imbg.ku.dk

Definition

Mental retardation (MR) is defined as “significant subaverage intellectual functioning and limitation in adaptive skills with onset before 18 years”. In relation

to the intelligence quotient (IQ), MR is defined as IQ below 70, which is 2 standard deviations below the mean IQ of 100. MR can be divided into moderate to severe MR (IQ <50) with a prevalence of 0.3–0.5%, and mild forms (IQ = 50–70), affecting an estimated % 1–2% of the population.

Genetic factors, caused by visible chromosomal defects, cryptic genomic alterations or gene mutations may underline most MR. MR can occur as an isolated trait (non-►**syndromic** MR) or in association with other features (syndromic MR). Both types may be inherited. However, the distinction between syndromic and non-syndromic MR is only clear-cut in a few cases. Once an apparently non-syndromic form is defined by a specific molecular defect, it often leads to the detection of additional clinical features and hence to a new syndromic form of MR. Furthermore, MR has common genetic origins with other symptoms of brain dysfunction, e.g. autism and epilepsy.

Characteristics

How Many Syndromes with MR, How Many Genes in MR?

There is an extreme ►**genetic heterogeneity** of MR. There are more than 900 registered entities associated with MR (1), and loss or gain of almost any segment of the genome can lead to MR, indicating that a proper dosage of hundreds to thousands of genes is needed for normal brain development, maturation and function.

Etiologies

Chromosomal and Genomic Disorders

Robertsonian Translocations

►**Down syndrome** (trisomy 21), the most common cause of MR is usually sporadic, caused by an extra, free chromosome 21 due to ►**chromosomal non-disjunction**, with a strong association with elevated maternal age. However, in ~4% of the cases, the underlying cause is an unbalanced Robertsonian translocation involving chromosome 21 and another acrocentric chromosome, most frequently a 14;21-translocation. Clinically, there is no difference whether the extra chromosome 21 is a free one or is part of a Robertsonian translocation. In ~40% of the cases the translocation is inherited from a balanced carrier parent, usually the mother. The risk of carriers of Robertsonian translocations having a Down syndrome child varies with gender; males have only a slightly increased risk, whereas it ranges from 10–20% in female carriers. However, if the Robertsonian translocation involves both homologous chromosomes 21, then the carrier cannot produce normal gametes and can only expect to have live born children with Down syndrome.

Reciprocal Translocations

Carriers of balanced reciprocal ►**translocations** have a high risk of producing unbalanced gametes due to aberrant segregation of the derivative translocation chromosomes during meiosis. The clinical symptoms associated with unbalanced reciprocal translocations vary, depending on the chromosomal segments involved, but MR is the most frequent single trait, often associated with multiple congenital anomalies (MCA). MR may occur sporadically in translocation families, but the mode of inheritance may occasionally mimic either an autosomal dominant (with reduced penetrance) or an autosomal recessive trait. Since the same translocation may lead to different types of imbalances in the gametes, two or more MR/MCA syndromes may occur in the same family.

An increased frequency of apparently balanced *de novo* reciprocal translocations are seen in association with mental retardation. One reason for this is, that some of these breakpoints disrupt genes where ►**haploinsufficiency** results in abnormal brain development. Another explanation is that some of these apparently balanced translocations may turn up to be associated with microdeletions/-duplications (see below).

Submicroscopic Genomic Disorders

Technical improvements, especially in fluorescence *in situ* hybridization (►**FISH**) and lately array based Comparative Genomic Hybridization (CGH) have resulted in the description of a growing number of cryptic translocations and inversions, microdeletions and duplications which may be responsible for inherited MR syndromes.

Subtelomeric Cryptic Translocations

The chromosomal subtelomeric regions are gene rich and associated with a high meiotic recombination. This recombinatorial property also involves illegitimate recombination and subtelomeric deletions or duplications can be detected by FISH in 5–8% of patients with idiopathic MR (2). The subtelomeric imbalance can often be traced back to a parental carrier of a cryptic balanced reciprocal translocation, with an associated recurrence risk. Some of the subtelomeric deletions, e.g. involving chromosome 1pter, 22qter and 17pter can be recognized as specific MR/MCA syndromes, and screening for subtelomeric integrity (e.g. by FISH, Fig. 1) is now a routine procedure in MR/MCA syndromes.

Micro-Deletion and -Duplication Disorders

Almost 5% of the human genome is composed of duplicated sequences that share more than 95% identity at sequence level. These segmental duplications may facilitate recurrent deletion/duplications of the

Inherited Mental Retardation Syndromes.

Figure 1 FISH with a probe for the subtelomeric region on the short arm of chromosome 4 (4p) labelled green and a probe for the subtelomeric region on the long arm of chromosome 4 (4q) labelled red. By systematic hybridization of probes specific for all 43 unique subtelomeric regions, minute deletions, duplications and translocations involving these regions can be revealed. Courtesy Isabel Carreira, Coimbra.

intervening sequences by non-homologous crossing-over. The resulting clinical symptoms, determined by the imbalance of the genes located between the flanking duplicons, often include MR. Most of these deletions are sporadic, but a few may be inherited, including the most common deletion of 22q11 associated with DiGeorge and velo-cardio-facial syndromes, with an estimated prevalence of 1:4,000. The list of known microdeletion and duplication syndromes is growing; the first results from genome-wide screening by array based Comparative Genomic Hybridization (CGH) suggest that submicroscopic microdeletions and –duplications scattered all over the genome will be detected in a substantial proportion of patients with idiopathic MR.

Monogenic Disorders

There are numerous autosomal recessive, autosomal dominant, X-linked and mitochondrial disorders where MR is the only symptom, part of a more complex clinical spectrum or seen in a fraction of the affected individuals. The underlying genetic defects have been identified in many of these disorders, providing direct molecular proof of the extreme genetic heterogeneity in MR. Furthermore, inherited MR diseases illustrate an abundance of basic genetic mechanisms, and have revealed several novel ones.

X-linked Mental Retardation

More males than females are mentally retarded, with a M:F sex ratio of 1.5, a skewing which is likely due to

Inherited Mental Retardation Syndromes.

Figure 2 Metaphase from a male with fragile X syndrome. Arrow on the fragile site at Xq27.3 (FRAXA).

the many X-linked forms of MR (XLMR). A current estimate is that of the total genetic morbidity 30% are X-linked and 70% are autosomal forms. There are more than 150 known X-linked syndromes associated with MR and an unknown but growing number of non-specific XLMR loci, many of which have been dissected at the molecular level (3).

The ►Fragile X Syndrome

The fragile X syndrome, characterized by early hyperactivity, MR, speech defect, an elongated facies with large ears, prominent jaw and macroorchidism, is the most common cause of inherited MR. It has its name from the association with a chromosomal fragile site at Xq27.3 which can be seen in a proportion of the metaphases from affected males and heterozygous carriers (Fig. 2). This fragility is caused by elongation of a polymorphic CGG trinucleotide repeat at the 5' UTR region of the *FMR1* gene (Fig. 3). A remarkable feature of this X-linked disorder is that males with only a slight elongation of the CGG repeat (up to ~200 CGGs = a premutation) have normal intelligence and will transmit the premutation unaltered to their likewise phenotypically normal obligatory carrier daughters; however, in the gametes of these daughters, the

Inherited Mental Retardation Syndromes.

Figure 3 Southern blot of the fragile X locus: (a) A full mutation in an affected male; (b, j) premutations in phenotypically normal transmitting males; (c, f, g, h) the normal female pattern with two bands, corresponding to the active X chromosome (lower band) and inactive X chromosome (upper band); (d, e) female carriers of a premutation; (i) female carrier of a full mutation.

premutation has a high risk of expanding many fold into a full mutation, which becomes hypermethylated, resulting in transcriptional inactivation of *FMR1*. These daughters then have a high risk of having affected sons and daughters. At least some of the normal male transmitters with premutations may later develop Parkinson-like neurodegenerative symptoms. The mutation behind the fragile X syndrome is the prototype of a dynamic mutation and it provided the first molecular explanation for anticipation, i.e. that the severity and/or onset of some disorders worsen from generation to generation. All male carriers and almost half of the female carriers of a full mutation are affected, indicating that the fragile X syndrome is an X-linked dominant disease (with incomplete penetrance in the female carriers).

Rett Syndrome and Factors Affecting Male:Female Ratios in X-linked Disorders

Mutations in genes associated with X-linked dominant disorders may be male lethal *in utero*, in which case only affected females are observed and there will be an excess of females born in such families. Rett syndrome (RS), which is caused by mutations in the X-linked gene *MECP2*, almost exclusively affects females. In its classic form, RS has a stage of normal development for $\frac{1}{2}$ – $1\frac{1}{2}$ years then, after developmental stagnation, rapid progressive deterioration to dementia, autism, ataxia and loss of motor skills, followed by a stable plateau which can last for many years. Some females with

MECP2 mutations may have a phenotype resembling Angelman syndrome (see below) with mild MR and autism. *MECP2* mutations in males have been reported in association with severe encephalopathy, but there is no evidence that mutations in *MECP2* are male lethal. One explanation for the almost exclusive occurrence of RS in females could be that almost all cases are due to new mutations and that these mutations occur during spermatogenesis and hence will be transmitted to females exclusively. However, there may be other causes of occasional female excess in MR. In a family with X-linked epilepsy and MR limited to females with normal carrier males, an equal sex ratio was seen among live births. In this family, male sparing rather than male lethality seems to be involved. The mechanism behind this is unknown.

The Prototype Autosomal Recessive MR Disorders: Inborn Errors of Metabolism

In some disorders, MR is due to a primary developmental defect, in others it is caused by a progressive neuronal degeneration, which may ultimately be lethal. The latter is a frequent course in many inborn errors of metabolism. These are typically rare, autosomal recessive conditions caused by mutations in genes encoding for enzymes. Based on the biochemical and cellular defects, these disorders are classified e.g. into mucopolysaccharidoses, lysosomal storage disorders, peroxisome biogenesis disorders, etc. For each of these enzymopathies there is often a wide variability in onset and progression of clinical symptoms, which has led to the description of different clinical forms, e.g. neonatal, infantile and adult forms. The molecular basis of this clinical variability can frequently be related to different mutations in the specific disease gene, some being associated with a milder course, others with a more severe form of the disease. Homozygosity for a severe mutation will lead to severe, maybe early onset and lethal disease, homozygosity for milder mutations to a milder course, whereas a combination of two different mutations (compound heterozygosity), one a severe and one a mild form, may be observed in patients with an intermediate form of the disease.

Linking an Autosomal Recessive Enzyme Defect with Dysmorphology

Smith-Lemli-Opitz syndrome (SLO) is an autosomal recessive, multiple malformation and MR syndrome, caused by mutations in the gene encoding 7-dehydrocholesterol reductase (*DHCR7*). *DHCR7* deficiency interferes with cholesterol biosynthesis, and cholesterol is necessary for the activation of the protein Sonic hedgehog (SHH). SHH is an important secreted molecule, a ►morphogen, involved in a variety of developmental processes, including normal brain formation. Thus, SLO illustrates how an enzymatic

defect merges with dysmorphology. SLO may be more common than anticipated, and even a major unrecognized cause of fetal loss. Other defects in the SHH-pathway are implicated in other developmental disorders, some of which are associated with MR, the most striking being ►**holoprosencephaly**. Holoprosencephaly can be caused by mutations in *SHH* itself, in *PTCH*, encoding the receptor for SHH and in several downstream target genes in the SHH-signaling cascade.

Modification of Autosomal Recessive Inheritance: Bardet-Biedl syndrome (BBS)?

BBS is characterized by MR, obesity, retinopathy, polydactyly, renal malformations, hypogenitalism and predisposition to diabetes mellitus. There is extensive genetic heterogeneity in BBS, with at least eight genes, all of which have been identified. Although BBS is an autosomal recessive disorder, some patients have been reported to carry three mutated alleles (two at one locus and a third at a second locus). A likely explanation is that BBS proteins which are involved in cilia assembly or function may interact with each other at the cellular level. Although this inheritance pattern, termed triallelic or oligogenic inheritance, has not been confirmed in other studies, it is intriguing to speculate that the clinical variability observed in many monogenic disorders, even within the same family, may reflect the concerted action of variation in additional, modifying genes.

Autosomal Dominantly Inherited Diseases

Since individuals with severe MR rarely reproduce, autosomal dominant MR syndromes are less common than autosomal recessive and X-linked recessive syndromes. In some autosomal dominant disorders, mildly affected individuals may reproduce, revealing the dominant nature of the condition. ►**Tuberous sclerosis** (TSC), affecting 1 in 10,000 individuals, is an autosomal dominant disorder characterized by the growth of ►**hamartomas** in many organs, including the brain, where it is associated with MR, epilepsy, learning difficulties and behavioral problems, but with a high degree of clinical variability. Affected children may be severely retarded, whereas a carrier parent may only display microsigns (variable expressivity). Two TSC genes have been identified, *TSC1* on chromosome 9 and *TSC2* on chromosome 16. More than half of the affected children are sporadic cases, which indicates a high frequency of new mutations in TSC. The high mutation rate in *TSC1* and *TSC2* is also illustrated by a high degree of ►**gonadal mosaicism** in TSC and part of the clinical variability can be explained by a frequent presence of ►**mitotic mosaicism**. Both *TSC1* and *TSC2* are ►**tumor suppressor genes** and part of the clinical variability could also be related to

the need for a second mutational hit to occur, in accordance with Knudson's two-hit hypothesis for oncogenesis.

Modification of Autosomal Dominant Inheritance by Genomic Imprinting

►**Angelman syndrome** (AS) is characterized by severe MR, lack of speech, ataxia, a happy disposition and dysmorphism. Most cases (~75%) are sporadic, caused either by a microdeletion of 15q11, which always involves the maternal chromosome 15, or by ►**uniparental disomy** of paternal origin. A similar microdeletion of paternal origin, or uniparental disomy of maternal origin, causes Prader-Willi syndrome with a completely different phenotype. The reason is that only part of the deleted region is active on the paternal chromosome 15 (corresponding to the genes that are responsible for Prader-Willi syndrome), whereas only another part, corresponding to the single gene *UBE3A*, is active on the maternal chromosome 15 (genomic imprinting). In AS, 10% of the patients have mutations within *UBE3A*, in which case the disease can be inherited. AS illustrates that dominant transmission of a phenotype can be explained by the inheritance of one mutated allele which is expressed into an inactive product, while the other allele is silenced by genomic imprinting, in effect creating functional nullisomy. One consequence of the gender specificity of genomic imprinting is that if the mutated allele in *UBE3A* is inherited from a father, who in any case would have donated an inactive allele, the offspring will be phenotypically normal. However, if this is a daughter, her children will have a 50% risk of being affected since she reactivates the mutated allele in her gonads.

Cellular and Molecular Regulation

At the functional level, the identified genes involved in MR confirm that the extreme genetic heterogeneity reflects an extreme functional heterogeneity. However, some interesting trends have emerged: Several of the identified genes in nonspecific XLMR encode for proteins involved in regulation of small GTP-binding proteins of the Ras superfamily cycle, which mediate organization of the cytoskeleton, cell shape and migration and outgrowth of axons and dendrites. The fragile X syndrome protein FMR1 may interact with the small GTPase Rac1 and there is evidence that tuberlin (*TSC2*), defective in tuberous sclerosis, is a putative GTPase-activating protein for Rap1 and Rab5. It is likely that others of the more than 150 genes encoding for small GTP-binding proteins may be associated with MR.

The Sonic hedgehog pathway may not be the only developmental pathway involved in MR. Studies in *Drosophila* indicate that developmental pathways are

particularly sensitive to dosage effects. Thus, chromosomal imbalance and haploinsufficiency syndromes may provide links to other pathways involved.

Several MR-associated syndromes have defects in genes involved in chromatin structure or modification. These include X-linked dominant conditions (RS in females with defects in *MECP2*), X-linked recessive conditions (Coffin-Lowry syndrome (*RSK2*) and the various allelic disorders caused by defective *ATRX*), autosomal dominant (Rubinstein-Taybi syndrome (*CBP*)) and autosomal recessive syndromes (ICF syndrome (*DNMT3B*)). In these disorders, the primary defect probably leads to dysregulation of other genes, which will also be candidate MR genes.

Dissection of the genetic causes of MR may tell us how the human brain evolved so rapidly. In autosomal recessive primary microcephaly (MCPH), a grossly normal but small cerebral cortex is associated with mild to moderate MR. In the most common type, MCPH5, the affected gene *ASPM* is involved in normal mitotic spindle function, showing that mitotic spindle activity is an important factor for determining brain size. Intriguingly, there is evidence suggesting that during evolution the numbers of a specific repetitive “IQ” domain in *ASPM* have increased along with the size of the brain.

Clinical Relevance

The importance of the identification of a specific molecular defect in MR should not be underestimated. It allows for a specific diagnosis, improves the genetic counseling of the individual family, provides options for prevention of recurrence in the family and is often the first step towards an understanding of the pathophysiology of the disorders and hence hope for future therapy. In the post-genomic era, with molecular techniques that can reveal even the tiniest needle (mutation) in the genomic haystack, the importance of careful clinical investigations should not be underestimated, either. One important aspect of the clinical studies in MR will be to identify those patients who can provide clues to the finding of novel MR genes. This will include patients from the rare, large families, from inbred populations with an increased rate of consanguinity, from geographically isolated populations with founder effects and the sporadic patients with chromosomal breakpoints that have inactivated specific MR genes.

Definition

► [Integrins](#) are transmembrane receptors that promote cellular attachment to the ► [extracellular matrix](#) (ECM) and to counter-receptors on the surfaces of neighboring cells. Integrins are responsible for mediating cell adhesion and migration, and for maintaining tissue integrity. They are expressed at the surface of virtually all multi-cellular animal cells as non-covalent heterodimers of α and β subunits. Integrins are named based on their α and β subunit composition, e.g. $\alpha_1\beta_1$, $\alpha_{IIb}\beta_3$. The integrin family in humans consists of eighteen α and eight β subunits, which are each encoded by unique genes. Each α subunit pairs with a restricted set of β subunits, resulting in a total of twenty-four known functional integrin heterodimers. Each pairing, in turn, is expressed on a limited array of cell types. Thus, each cell has its own particular repertoire of integrins. Since different integrins display distinct ligand-binding preferences, these repertoires specify adhesive preferences of different cell types. In some cases, multiple integrins can recognize the same ligand. For example, many integrins bind to the extracellular matrix protein, fibronectin. Even within the same ECM protein, integrins can vary in recognition specificity. Integrin $\alpha_v\beta_3$, for example, binds to an Arg-Gly-Asp (RGD)

motif in fibronectin, while integrin $\alpha_4\beta_1$ binds to a Leu-Asp-Val (LDV) motif present in a different part of fibronectin. Furthermore, these short peptide motifs can occur in evolutionarily unrelated proteins, where they can serve as recognition sites for many different integrins. The **RGD motif** occurs in many proteins and can bind to many integrins (e.g. $\alpha_{IIb}\beta_3$, $\alpha_v\beta_3$, $\alpha_v\beta_5$, $\alpha_5\beta_1$). This integrin-binding motif interaction is conserved in phylogeny; for example, the *Drosophila* PS2 integrin recognizes an RGD sequence in tigrin, a matrix protein. The occurrence of integrin-binding motifs, such as RGD, is an example of convergent evolution dictated by the recognition specificity of adhesion receptors.

All integrin subunits possess a single transmembrane domain, which separates the large extracellular, N-terminal ligand-binding domain from the typically short (less than 60 amino acids) C-terminal cytoplasmic domain or **cytoplasmic tail**. Besides acting as cellular “glue” to support adhesion and “feet” to facilitate migration, integrins initiate signaling pathways, which regulate processes such as embryogenesis, cell development, proliferation, apoptosis and the immune response.

Integrins derive their name from their role of integrating the extracellular matrix with the insoluble cellular skeleton (**cytoskeleton**). Binding of ligands to the extracellular portion of integrins leads to both conformational changes in the receptors and to receptor clustering. This combination of events initiates intracellular signals such as protein tyrosine phosphorylation, activation of small GTPases and changes in phospholipid biosynthesis. This process is commonly referred to as “outside-in” integrin signaling. In addition, integrins are subject to so-called “inside-out” integrin signaling. Integrins can fluctuate between three functional states, an “active” state that manifests high affinity for binding ligands, a high affinity state that is bound to ligand or a distinct “inactive” state, which has a low affinity for ligands. Inside-out signaling is defined as modulation of the functional state of integrins *via* intracellular signaling processes. It is frequently mediated by interactions of intracellular components with the integrins’ cytoplasmic tails. Furthermore, signals from one integrin can regulate the activation state of another in a phenomenon referred to as integrin trans-regulation or cross-talk. Through trans-regulation, multiple integrins can be linked, *via* a combination of both outside-in and inside-out signaling (1).

Characteristics

The switch from an inactive to an active state is the result of alterations in the conformation of the integrin extracellular domains. These conformational changes

can be triggered by protein-protein interactions at the integrin cytoplasmic face. These protein-protein interactions are regulated by different signaling pathways in different cells. However, in many contexts, activation of key intermediates such as the GTPase Rap1 or protein kinase C, promote increased integrin affinity. Conversely, activation of Raf-1 kinase often suppresses integrin activation. The activation states of individual integrin subtypes can be differentially regulated to affect integrin-specific cell adhesiveness. Therefore mechanisms of activation and suppression of individual integrins exist, in addition to common mechanisms affecting all integrins. Whatever the upstream events, it is likely that the final common events involve changes in interactions at the integrin cytoplasmic domain (Fig. 1).

Physiological Roles of Integrin Activation

Integrin Activation in Hematopoietic Cells

Integrin activation plays a crucial role in the biology of blood-borne cells. For example, the platelet integrin, $\alpha_{IIb}\beta_3$, is usually maintained in the inactive state, with very low affinity for its extracellular ligands, fibrinogen, fibronectin and von Willebrand factor. Upon platelet stimulation, the integrins are quickly activated, leading to fibrinogen binding and consequent platelet aggregation, an early step in hemostasis. Thus, loss of $\alpha_{IIb}\beta_3$ integrin activation impairs hemostasis. Conversely, platelet aggregation is central in arterial thrombosis, which is responsible for the majority of heart

Integrin Signaling. Figure 1 “Inside-out” signaling activates integrins. Binding of an integrin activating complex (IAC) to the cytoplasmic tails of an integrin heterodimer produces conformational changes in the extracellular head domains, leading to activation and high affinity binding to ligand (L).

attacks and strokes. Pharmacological blockade of the activation of integrin $\alpha_{IIb}\beta_3$ by agents such as aspirin or ticlopidine is therefore often used to treat patients at risk for these diseases. Similarly, rapid activation of dormant integrins on leukocytes allows these cells to attach firmly to the endothelial vessel wall and resist strong shear forces from the flowing blood. This step is essential for leukocyte migration into sites of inflammation. For this reason, loss of leukocyte integrin activation can lead to enhanced susceptibility to infections and its blockade may be useful in anti-inflammatory therapies.

Integrin Activation in Tissues

For adherent cells in tissues, such as ►fibroblasts or ►epithelial cells, stable cellular attachment to the ECM is necessary for maintaining tissue integrity. Many of the best-studied integrins in these cells, such as the α_5 , α_v and α_6 integrins, are indispensable components of cell-substrate attachment structures, ►focal adhesions, ►hemidesmosomes, and podosomes. In addition to attaching to the extracellular matrix, integrins participate in formation and remodeling of the ECM. Activation of tissue integrins can regulate the assembly and structure of the extracellular matrix and control the stability of integrin-matrix attachments. The migration of these cells in tissues is also regulated by the ability of integrins to become activated. Furthermore, integrin activation may be topographically localized across the basal cell surface. For example, activated $\alpha_v\beta_3$ integrins are preferentially localized to the leading edge of endothelial cells during cell migration.

Molecular Interactions

Tail-binding Proteins

Numerous cytoplasmic integrin-binding proteins have been described, and several have been reported to contribute to activation through binding to the integrin tails. The best-characterized example is the cytoskeletal linker protein ►talin, which promotes integrin activation by binding to a subset of integrin β subunit tails at a highly conserved ►NPxY motif. Mutational evidence suggests that integrin α - β subunit tail interactions inhibit activation. The ability of talin to activate the integrins has been attributed to competition with the α subunit for β tail binding. In addition to talin, other integrin-binding or talin-binding proteins may affect the activation states of integrins.

Membrane Proximal Residues

Deletion of the tail sequences adjacent to the putative transmembrane regions in either the α or the β tail can activate integrins, indicating that these residues are

essential for maintaining integrins in an inactive state. One model for activation entails a breaking of a salt bridge in this region that holds the tails together, leading to an “opening” of the tails *via* a scissor-like mechanism (Fig. 1). This leads to an allosteric rearrangement in the extracellular domain and a shift to the active state (1).

Extracellular Domain Conformational Changes

Precise conformational shifts at the ligand binding face of integrins result in high affinity binding to ligands. Integrin-ligand interactions require an essential Asp or Glu residue in the integrin recognition sequence in the ligand, as well as the presence of a divalent cation. Some of the integrin α subunits have an “inserted” or ►I/A domain near the N-terminus; these integrins contact ligand solely through the α subunit, although the β subunit plays an accessory role. The I/A domain manifests a metal ion-dependent adhesion site (►MIDAS). Key residues in the ligand cooperate with the MIDAS to coordinate the cation and allow integrin-ligand interaction. Conformational changes in the MIDAS during cation coordination and ligand binding subsequently result in secondary changes in the rest of the integrin, including a downward shift of a α -helix C-terminal to the I/A domain, thereby switching the integrin from the “closed” inactive state into the “open” active state. For integrins with a α subunit that does not contain an I/A domain, the I/A-like domain in the β subunit cooperates with the α subunit in a somewhat different fashion to mediate ligand interaction, but also through coordination of a divalent cation (2).

Connections to Intracellular Signaling Pathways

Although integrins themselves do not manifest any catalytic activity, they transmit signals through binding partners such as integrin-associated protein (IAP, CD47), integrin-linked kinase (ILK) and members of the tetraspanin transmembrane protein family. Integrin ligation activates members of the Ras family of GTPases and can also lead to activation of kinases such as JNK, PAK, and ERK/MAP kinase – the latter two are localized to integrin-rich adhesion sites. These enzymes can subsequently regulate the expression of genes involved in cell proliferation and differentiation. Furthermore, integrins play a role in the inhibition of detachment-induced apoptosis, called “anoikis”, through regulation of the PI3-kinase/Akt signaling pathway. Activation of these and other signaling pathways following integrin ligation must be precisely coordinated to affect productive cellular phenotypes. Thus, the integrin signaling proteome undergoes dynamic alterations depending on the cellular state.

Regulatory Mechanisms

“Inside-out” Signaling

Modulation of integrin function can occur by changes in ligand binding affinity or by changes in the clustering of these receptors. The former mechanism is often referred to as integrin “activation” and the latter as a change in avidity. These functional changes can be caused by signaling pathways initiated by agonist-receptor interactions at the plasma membrane. The appropriate regulation of integrin activation is required for the formation and maintenance of normal tissue architecture (3).

“Outside-in” Signaling

Occupancy of integrins leads to conformational changes that can propagate over long distances in the extracellular domain. It has been proposed that these allosteric rearrangements can be transmitted across the plasma membrane, changing the interactions of the α and β cytoplasmic domains with each other and thus heterodimer interactions with intracellular signaling molecules. Furthermore, occupancy leads to integrin clustering, which can also change the physical relationships of the integrin cytoplasmic domains with each other. This combination of occupancy and clustering is believed to initiate signals from integrins. These signals regulate the formation and strengthening of adhesion sites, the dynamics of cytoskeletal structure, cell shape

and size, cell polarity and cell migration. In addition to controlling morphological activities of cells, signaling through integrins also regulates gene expression, cell proliferation and apoptosis and many integrins are required for the development of particular cell lineages. Thus a more complete picture of the cellular responses to integrin ligation at the genomic level is necessary for a fuller understanding of the breadth of integrin signaling (3).

Avidity Modulation

In addition to affinity modulation through conformational changes in individual integrin molecules, cell adhesion can also be enhanced by increasing the density of ligand binding sites through integrin clustering, *via* an affinity-independent mechanism known as avidity modulation. Many [▶ integrin ligands](#) are multivalent; thus integrin clustering can promote adhesion through cooperative ligand binding. In many cases, a combination of affinity and avidity modulation both contribute to the regulation of cell adhesion (3).

Integrin Cross-talk

Ligand binding to one subtype of integrins can affect the activation state of another integrin subtype on the same cell, by modulating the ligand-binding affinity and/or avidity of that integrin. For example, outside-in signaling through ligand binding of $\alpha_4\beta_1$ integrin can

Integrin Signaling. Figure 2 Focal contacts and hemidesmosomes. Two types of integrin-ECM contacts are shown. (a) Focal contacts are visualized by labeling $\alpha_{11b}\beta_3$ integrin clusters in a fibroblast expressing $\alpha_{11b}\beta_3$ attached to fibrinogen. Arrowheads indicate two focal contacts. (b) Transmission electron micrograph of a cross section of bovine tongue. Hemidesmosomes (arrowheads) are seen as electron-dense structures at the basal surface of the tongue epithelial cells (EC), connecting the intermediate filaments (arrow) to the extracellular matrix (ECM). Image courtesy of Gregory W. deHart and Jonathan C.R. Jones.

affect $\alpha_L\beta_2$ -dependent lymphocyte adhesion and migration by regulating signaling through $\alpha_L\beta_2$. Furthermore, integrins are involved in cooperative signaling with other non-integrin receptors, such as the EGF receptor and the T cell receptor complex.

Contributions to Cellular Phenotypes

By connecting the ECM to the intracellular cytoskeleton, integrins also act as mechanosensors, transmitting information about the physical state of the extracellular matrix into the cell and altering cytoskeletal dynamics. Integrin ligation can activate key signaling components, such as the small GTPases Rho, Cdc42 and Rac, which promote cytoskeletal rearrangements leading to the formation of actin stress fibers, filopodia and lamellipodia respectively. Within focal adhesions, integrins can activate kinases important for downstream signaling, such as focal adhesion kinase (FAK) and Src tyrosine kinases. Activation of these enzymes results from signals initiated at the integrin cytoplasmic tails. Integrin tails also affect cytoskeletal rearrangements through other mechanisms, e.g. activation of Syk tyrosine kinase through its direct binding to the β_3 tail, which promotes Vav1-induced GTP loading of Rac and subsequent lamellipodial formation. Through such mechanisms, integrins regulate cell polarity, migration, shape and size (4).

Integrins in Adhesion Sites

Most integrins are physically linked to the actin cytoskeleton *via* interactions of the β tail with actin-binding proteins such as α -actinin, talin and filamin. By connecting the extracellular matrix with the actin cytoskeleton, clustered integrins form the essential core of complexes of structural and signaling molecules such as focal complexes and adhesions (contacts), and osteoclast structures called podosomes (which have many of the same protein components as focal adhesions). $\alpha_6\beta_4$ Integrins associate with the intermediate filament cytoskeleton through other linker proteins, BP180 (BPAG2), BP230 (BPAG1) and plectin in hemidesmosomes (5), which are specific to basal epithelial cells (Fig. 2).

Ligand binding and integrin clustering promote nucleation of nascent cell adhesion sites. Numerous cytoskeletal adapters and signaling molecules are subsequently recruited to the clustered integrin tails. These complexes serve as the initiation points for signaling by integrins to affect cellular phenotypes. Focal complexes “mature” to become focal adhesions (focal contacts) as more integrins and signaling molecules associate, thereby strengthening cellular attachments to the ECM. The intricate network of protein-protein interactions within focal adhesions contributes to signaling pathways regulating various cellular phenotypes (4).

Adhesion sites are dynamic structures, which undergo remodeling to fit the needs of the cell or of the region of the cell in contact with the extracellular matrix. Focal complexes form at the leading edges of lamellipodia and filopodia in migrating cells, where they mediate new attachments but do not mature to focal adhesions. Instead, these smaller complexes are subject to rapid turnover as the cell continues to extend protrusions in the direction of migration. Concomitantly, integrins in focal adhesions at the rear of the cell are recycled to the front *via* a treadmill-like mechanism. Focal adhesions, hemidesmosomes and podosomes break apart and reform by severing and re-establishing integrin-ECM contacts under conditions in which cells are motile, such as during development and in wound healing (4).

Integrin-Associated Protein

► IAP

Integrins

Definition

Integrins are major receptors for cell-cell adhesion and cell binding to extracellular matrix. They are a family of transmembrane proteins composed of noncovalently linked heterodimers of an α and a β subunit. In mammals, 8 β subunits can dimerize with 18 α subunits to form 24 distinct integrins. These can be considered to belong to several subfamilies based on evolutionary relationships. All integrins containing an α_v or a β_1

subunit bind extracellular matrix proteins, which activates a signaling pathway, gene transcription and modifies cell behaviour. Inside the cell, integrins bind signalling molecules and other proteins connecting to actin, thus linking the extracellular matrix to the cytoskeleton.

Definition

▶Cytokines are low molecular weight proteins that are of great importance in the regulation of ▶hematopoiesis, ▶immunity, ▶inflammation and other processes. The earliest reports on the biological activity of cytokines in the 1960/1970s revealed that substances emanating from cells or present in conditioned medium could stimulate the growth and/or differentiation of hematopoietic colonies in semi-solid medium. Hence, these substances were referred to as ▶colony stimulating factors (CSFs). Several specific factors from different sources were identified that, for example, could stimulate macrophage colony formation, granulocyte colony formation or the formation of colonies containing both macrophage and granulocytes. The significance of the first hematopoietic colony forming assays facilitated the molecular isolation and

characterization of many colony stimulating factors in the late 1970s/early 1980s. Mainly for historical reasons, some CSFs acquired quite different names, e.g. erythropoietin, interleukins. Although they have little meaning with regard to classification, some of these names have been retained, particularly the interleukin designation.

The cytokine superfamily is usually divided into three subfamilies, the interleukins (ILs), the colony-stimulating factors and the tumor necrosis factors (TNFs). Cytokines are produced by many different cell types, both hematopoietic and non-hematopoietic, and can perform their function either in a local or systemic fashion by stimulating the target cells through interaction with specific cell surface receptors. Additionally, some cytokines act in an autocrine fashion, stimulating the cell by which they were produced. Cytokines have a wide range of biological activities, including the regulation of proliferation and/or differentiation, chemo-attraction and survival/apoptosis depending upon the target cell type (3).

Interleukins act as communication signals between leukocytic cells, hence the name meaning “between ▶leukocytes”. To date, more than 30 interleukins have been identified and this number is still increasing. The interleukin family consists of a structurally and functionally diverse group of proteins, but all interleukins are, in one way or another, regulators of the hematopoietic system (1, 3).

Despite the wide variety of cytokines, this review will focus on the interleukins and CSFs that have predominant effects on the pivotal cells of the hematopoietic system. In particular, we will focus on the cytokines that play an important role in the regulation of inflammatory reactions (i.e. IL-1, IL-6 and IL-18), in the regulation of the immature hematopoietic cells within the hematopoietic hierarchy, namely ▶hematopoietic stem and progenitor cells (i.e. IL-1, IL-3, IL-6 and IL-11 and GM-CSF), and those involved in the proliferation and/or differentiation of T and/or B ▶lymphocytes (i.e. IL-2, IL-4 and IL-7). Summaries of these cytokines and their receptors are presented in Tables 1 and 2, respectively. Included within Table 2 are the more recent nomenclature designations for molecules elaborated by cells in lineage differentiation hierarchies, i.e. clustering of differentiation or ▶CD numbers. These are provided for most of the cytokine receptors discussed in this review.

Characteristics

Interleukins: Expression and Biological Activity

Several subfamilies of interleukins are discussed in this section. The interleukins are grouped into subfamilies on the basis of their biological function within the hematopoietic system. Figure 1 shows the position and the cell type within the hematopoietic hierarchy upon

Interleukins and Their Receptors, a Role in Regulating Hematopoietic Stem Cells. Table 1 Characteristics of Interleukins (1, 3)

which the specific interleukins act and Table 1 provides detailed information on each interleukin (1, 3).

Interleukin-1/Interleukin-18 (IL-1/IL-18)

IL-1 and IL-18 play an important role within the innate immune system and in the regulation of ►inflammation reactions. IL-1 and IL-18 are predominantly produced by macrophages and monocytes, but also by keratinocytes, endothelial cells, fibroblasts and lymphocytes. IL-1 and IL-18 mediate inflammatory reactions by recruitment and activation of neutrophils and macrophages. IL-1 regulates adhesion molecule expression on endothelial and hematopoietic cells thereby facilitating trans-endothelial transport. Interestingly, IL-1 is also a known regulator of immature hematopoietic cells. IL-1 stimulates (sometimes in synergy with other cytokines) the proliferation and/or differentiation of immature CD34⁺ hematopoietic cells and can further regulate hematopoiesis by inducing the expression of cytokines/growth factors by cells of the hematopoietic microenvironment. Similarly, IL-18 is a known regulator of lymphoid cells and plays a role in the proliferation and differentiation regulation of Th1 and B-cells. IL-18 is also a potent inducer of interferon-gamma (IFN γ) expression in T and B-cells.

Interleukin-2/Interleukin-4/Interleukin-7 (IL2/IL4/IL7)

The subfamily of interleukins that includes IL-2, IL-4 and IL-7 (and IL-9/IL-15) plays an important role in regulating lymphocytes within the hematopoietic system. IL-2 and IL-4 are produced predominantly by (sub)populations of T-cells and IL-7 is produced by BM stromal and thymic cells and keratinocytes. IL-2 and IL-4 regulate the proliferation and differentiation process of T-cells and B-cells respectively. IL-2 also plays an important role in the clonal expansion of antigen-activated T-cells in immune reactions. IL-7 is an important regulator of the immature ►common lymphoid progenitor (CLP), which gives rise to both B- and T-cells. The importance of these interleukins within the immune system was demonstrated by studies investigating immunodeficiency in humans and mice. Severe combined immunodeficiency results from defects in the gene encoding for the receptor gamma-common (γ c) subunit, which is commonly used by the receptors of the IL-2/IL-4/IL-7 subfamily. The γ c receptor gene is also known as the X-linked severe combined immunodeficiency (SCID-X) gene.

Interleukin-3/Interleukin-5/Granulocyte-macrophage Colony Stimulating Factor (IL-3/IL-5/GM-CSF)

IL-3, IL-5 and granulocyte-macrophage colony stimulating factor (GM-CSF) form a subfamily of interleukins that are important regulators of hematopoietic progenitor and myeloid cell development. Activated T-cells are the main physiological source of IL-3 and

IL-5, but stimulated mast and endothelial cells, fibroblasts and monocytes also produce these interleukins. IL-5, and to a lesser extent IL-3, is a regulator of eosinophil proliferation/differentiation and murine IL-5 plays a role in immature B-cell differentiation/proliferation. Additionally, IL-3 and GM-CSF are best known for their important roles in regulating HSC and hematopoietic progenitor cell proliferation and the differentiation of these cells towards the myeloid/erythroid lineage. Furthermore, IL-3 plays a pivotal role in regulating the survival of hematopoietic cells, *via* the up-regulation of the anti-apoptotic Bcl-2 gene and the down-modulation of the pro-apoptotic factors.

Interleukin-6/Interleukin-11 (IL-6/IL-11)

The IL-6 subfamily of cytokines includes IL-6 and IL-11, oncostatin M (OSM), leukemia inhibitory factor (LIF), ciliary neurotrophic factor (CNTF) and cardiotrophin-1 (CT-1). IL-6 and IL-11 are produced by several cell types, including lymphocytes, monocytes, epithelial cells and keratinocytes. IL-6 and IL-11 regulate the differentiation of megakaryocytes and macrophages and, to a lesser extent, the differentiation and proliferation of T-cells and B-cells respectively. However IL-6 and IL-11 are better known for their ability to induce expression of ►acute phase proteins, such as C-reactive protein (CRP), serum amyloid A (SAA) and fibrinogen, in the liver. Moreover, IL-6 and IL-11 can act in a synergistic manner to induce proliferation of multipotent HSCs and progenitor cells.

Interleukin Receptors

A wide variety of interleukin receptors have been identified. Some interleukins have very distinct receptors, while other interleukins utilize common receptor subunits. Here we discuss some of the biochemical features of the interleukin receptors. Figure 2 provides a schematic representation of several receptors and Table 2 provides additional details on their characteristics (1, 2, 3).

Within the interleukin receptor family, the IL-1 and IL-18 receptors are very distinct from other receptors. The IL-1 and IL-18 receptors contain several extracellular immunoglobulin (Ig)-like repeats and an intracellular ►Toll-IL1 receptor (TIR) domain involved in receptor proximal signal transduction events (Fig. 2a). The IL-1 receptor consists of ligand-binding subunit (receptor type 1; IL-1RI) and an accessory subunit (receptor associating protein; IL-1RAcP) that increases the affinity of the IL-1RI for its ligand. The type 2 receptor (IL-1RII) contains a short intracellular tail and lacks signal-propagating properties. In addition, soluble isoforms of the receptors have been identified and these receptors probably play a role in the availability of IL-1. Both the IL-1 and the IL-18 receptors activate similar ►signal transduction pathways, which could

Interleukins and Their Receptors, a Role in Regulating Hematopoietic Stem Cells. Table 2 Characteristics of Interleukin Receptors (1, 3)

Interleukin	Protein size (kD)	Human chromosome	Mouse chromosome	CD number	Expression pattern	Remarks
IL-1RI	80	2	1	CD121a	T-cells mesenchymal cells	Signaling subunit associated with IL-1RAcP
IL-1RII	60	2	1	CD121b	B-cells granulocytes macrophages	Non-signaling subunit/ decoy receptor
IL-RAcP	66	3	16		see IL-IRI and RII	Accessory subunit
IL-2R α	55	10	2	CD25	(activated) T and NK cells	Ligand binding subunit
IL-2R β	75	22	15	CD122		Ligand binding subunit
IL-2R γ (yc chain)	64	X	X	CD132		Signaling subunit gamma-common chain
IL-3R α	150	X	14	CD123	Macrophages mast cells eosinophils/ basophils megakaryocytes HSCs/ HPCs	Ligand binding interacts with CSF2-R β
CSF2-R β (β c chain)	120	22	15	CD131		β common chain of IL-3R, IL-5R and CSF-R signaling subunit
IL-4R α	140	16	7	CD124	B-and T-cells NK cells HPCs	Ligand binding Extracellular domain is related to EPO-R, IL-6R and IL-2R β Associated with IL-2R γ chain
IL-5R α		3	6	CDw125	hematopoietic cells lymphoid cells	Ligand binding interacts with the β common chain of IL-3 receptor
IL-6R α	80	7	3	CD126	T-cells activated B-cells monocytes hepatocytes	Ligand binding subunit Resembles M-CSF, PDGF receptor interacts with gp130
IL-6 ST (gp130)	130	5	13	CD130		Signaling chain glycoprotein
IL-7R α	76	5	15	CD127	Activated T-cells T/ B-cell progenitors BM macrophages	Ligand binding associated with yc chain
IL-8R α (CXCR1)	59	2	-	CD128	neutrophils NK cells T-cells monocytes	Dimeric glycoprotein G-protein coupled receptor Important for chemotaxis related to stromal derived factor (SDF) and macrophage-inflammatory protein (MIP) receptors

Interleukins and Their Receptors, a Role in Regulating Hematopoietic Stem Cells. Figure 1 Hematopoiesis is regulated by interleukins. A schematic representation of the hematopoietic hierarchy in the adult human and mouse providing an overview of the most prominent target cells of the interleukins discussed in this review. The hematopoietic hierarchy is founded by the hematopoietic stem cells (HSCs), which have the capacity to extensively self-renew and produce all the different mature hematopoietic cell types. HSCs, together with the hematopoietic progenitor cells (HPC), the common lymphoid progenitor (CLP) and the common myeloid progenitor (CMP), form the compartment of the immature hematopoietic cells. Cytokines that are involved in regulating HSCs and HPCs include interleukin (IL)-1, 3, 6 and 11, stem cell factor (SCF; also known as kit-ligand) and granulocyte-macrophage colony-stimulating factor (GM-CSF). For differentiation along the lymphoid lineages IL-7 plays an important role in regulating the CLP as well as T and B precursors. IL-2/4 and IL-4/5 play important roles in regulating respectively T-cell and B-cell proliferation and/or differentiation. IL-3/5/6 and GM-CSF play an important role in myeloid differentiation. IL-3 and 5 play a role in neutrophil/ eosinophil differentiation, while IL-6, GM-CSF and M-CSF regulate macrophage/ megakaryocyte differentiation. Although not addressed in this review, for clarity the central regulator of erythrocyte differentiation, erythropoietin-1 (Epo), is indicated.

Interleukins and Their Receptors, a Role in Regulating Hematopoietic Stem Cells. Figure 2 Interleukin Receptors. Schematic representation of several interleukin receptors and their structural and biochemical motifs. (a) The interleukin (IL)-1/18 receptor family has distinct features from the other interleukin receptors. The IL-1 receptor consists of two subunits, the type 1 receptor (IL-1RI) and the IL-1 receptor associating protein (IL-1RAcP). Both subunits contain several immunoglobulin (Ig)-like domains in the extracellular part of the receptor. Upon binding of IL-1 to the IL-1RI, the IL-1RAcP subunit is recruited to the receptor complex. IL-1RAcP increases the binding affinity of IL-1 for the IL-1RI and is involved in signaling. Upon ligand binding and receptor activation the signal transduction mediators interact with the IL-1RI and IL-1RAcP via the intracellular Toll/IL-1 receptor (TIR) domains. The MyD88 is an essential adapter protein for initiating signaling and this protein also contains a TIR domain to allow interactions with downstream signaling components. The IL-1 receptor type 2 (IL-1RII) and the soluble IL-1R (sIL-1R) receptor lack signal propagating properties and act as decoy receptors regulating the availability of the biological active ligands. (b) The IL-2/4/7, IL-3/5, IL-6/11 receptors all contain a ligand-interacting subunit, the α -chain and a signaling subunit. For the IL-2/4/7 subfamily the signaling subunit is the γ c chain. For the IL-3/5 and the IL-6 subfamilies these signaling subunits are the β c and the gp130 protein respectively. The extracellular part of the receptors consists of fibronectin type III and Ig-like structural domains with WSXWS motifs (forming a hinge structure) and the cysteine-rich motifs. The intracellular signal mediating domains include the box 1 and 2 motifs, to which the Janus kinases (JAKs) can bind. Moreover, several tyrosine residues are located in the intracellular tail of the receptors and upon phosphorylation these sites become docking sites for SH2-domain containing proteins.

explain the extensive overlap in the biological effects induced by these interleukins.

The receptors for IL-2/IL-4/IL-7, IL-3/IL-5/GM-CSF and the IL-6 subfamily share a number of characteristics (Fig. 2b). All the receptors consist of a specific ligand-binding α -chain, a common signal mediating receptor subunit and, in some cases, one or more auxiliary receptor subunits. For IL-2/IL-4/IL-7 the common subunit is named the gamma-common (γ c) chain, for the IL-3/IL-5 the signal mediating subunit is the beta-common (β c) subunit and the gp130 protein is the signaling subunit of all IL-6 subfamily receptors. These interleukin receptors share a number of structural (fibronectin type III), biochemical (WSXWS, cysteine-rich) and signaling (box motifs) domains (Fig. 2b). Since all interleukins within a subfamily signal *via* a common receptor subunit and the signaling domains in the intracellular part of the receptors are similar for all

mentioned subfamilies, it is not surprising that these receptors activate similar signaling pathways and overlap in biological function. In addition, it has been reported that soluble variants exist for several of these interleukin receptors. In most cases such soluble receptors are thought to play a role in regulating the bioavailability of the interleukins.

Molecular Interactions

Upon ligand binding, the intracellular domain of interleukin receptors becomes involved in signal transduction. However, interleukin receptors lack intrinsic kinase activity. Thus, other molecules, such as non-receptor protein kinases, are required to activate the signal transduction cascade. ► **Interleukin-1 receptor associated kinases (IRAKs)**, ► **Janus kinases (JAKs)** and members of the ► **Src kinase** family, such as Lck, Fyn and Lyn are located in close proximity to

interleukin receptors on the cytoplasmic side of the plasma membrane. These protein kinases are activated upon ligand binding and receptor activation. Subsequently, these kinases can directly phosphorylate and activate downstream signal transduction proteins. Alternatively, some kinases phosphorylate tyrosine residues on the intracellular part of the receptor to allow docking of SH2-domain signaling proteins that will in turn activate downstream targets (2, 4, 5).

IL-1/IL-18 Receptor Signaling

The IL-1/IL-18 receptors transduce a signal *via* a TIR domain that is a docking site for signaling proteins. Among the first proteins recruited to the activated receptor are the adapter protein MyD88 and IRAK family kinases, of which IRAK-4 seems to play a crucial role in IL-1 signaling. Once IRAKs are activated, ►TRAF (TNF receptor associated factors) adapter proteins and members of the ►MAPK family, such as ►TAK1 are recruited and activated. These signaling mediators will activate downstream signaling pathways, i.e. the nuclear factor kappa-B (NFκB) and the Jun kinase (JNK) pathways, which in turn will regulate the expression of IL-1 and IL-18 target genes.

IL-2, IL-3 and IL-6 Subfamily Receptor Signaling

Upon binding of these interleukins to their cognate receptors, one of the main signaling cascades activated is the Janus kinase/signal transducer and activator of transcription (►JAK/STAT) pathway. The ►Janus kinases are located in proximity to the intracellular tail of the interleukin receptors (near the box 1/2 motifs). They are activated upon receptor activation and phosphorylate their ligands, the STAT proteins. STAT proteins then translocate to the nucleus, bind to gene regulatory sites with the consensus sequence TTNCNNNAAA and subsequently activate their target genes. To date, four different mammalian JAKs (JAK 1/2/3 and Tyk2) and at least eight different STATs have been identified. A specific combination of JAK and STAT proteins is activated upon receptor activation by its cognate interleukin. This results in an activated signaling cascade and ultimately in a specific biological response. For example, the IL-2 receptor signals *via* JAK1/3 and STAT5, while the related IL-4 receptor signals *via* JAK1/2 and STAT6.

Besides the JAK/STAT pathway, Src-family kinases are also located in close proximity to interleukin receptors and are involved in the activation of downstream signaling mediators upon receptor activation. For example, the Src-kinases Lck, Lyn and Fyn play a role in IL-2 and IL-3 receptor signaling by phosphorylating tyrosine residues in the intracellular parts of these interleukin receptors. These phospho-tyrosine residues then become docking sites for SH2-domain signaling proteins (such as Shc and Grb2) that will activate

downstream targets (such as Ras-Raf). In addition, the Src-family kinases can directly phosphorylate downstream signal mediators.

Regulatory Mechanisms

As interleukins have a broad range of biological activities as well as numerous target cells, their expression requires tight regulation. Therefore, most interleukins are not expressed constitutively, but their expression is induced upon stimulation/activation of the producing cell with growth factors, cytokines or immune response inducing substances, such as pathogenic proteins. Moreover, some interleukins (including IL-1) regulate their own expression levels and that of their receptor, resulting in auto-regulatory feedback loops within the target cells. The expression of interleukins is regulated at several molecular levels, including the transcriptional and translational and at the protein level (glycosylation, proteolytic cleavage etc) (1, 3).

At the transcriptional level, several transcription factors were shown to regulate the gene expression of interleukins and their receptors. Among these are the ubiquitous gene expression regulators, such as members of the AP-1 family (jun, fos) and the CCAAT/enhancer binding protein (C/EBP). Transcription factors more restricted to the hematopoietic system are regulators of interleukin expression. For example, the ETS family member PU.1 plays an important role in the gene regulation of IL-1 and the β_c receptor. Another important hematopoietic transcription factor, Runx-1 (also known as AML-1) regulates IL-3 and GM-CSF expression. STAT and NFκB transcription factors play a role in the gene expression of multiple interleukins. Several interleukins are also regulated at the translational level. The mRNA for IL-1 contains stretches of AU rich sequences that prevent mRNA translation into functional IL-1 protein. However, upon activation of target cells with specific stimuli, this inhibitory effect can be overcome and functional protein can be produced. Similar mechanisms of regulation have been shown for other interleukins. Additionally, several interleukins require post-translational processing in order to become biologically active. For example, several interleukins contain signal peptides that direct the interleukins to the plasma membrane to allow secretion. Others are produced as precursor proteins and require proteolytic cleavage in order to be secreted or become biologically active. Proteolytic cleavage also regulates the subsequent degradation of the interleukins.

In addition to the regulation of gene expression, the affinity of interleukins receptors for their ligands can be regulated. Both high and low affinity receptors for a similar ligand have been described. Moreover, soluble receptors exist which in most cases compete with the

membrane-bound receptors for ligand binding and thereby prevent ligand-induced signaling. However, the soluble IL-6 receptor is an exceptional case. This soluble receptor can bind IL-6, interact with membrane-bound gp130 proteins and allow signaling in cell types that normally do not express the IL-6 receptor.

Summarizing Remarks

Prior to their molecular characterization, the biological activities of several interleukins and related cytokines and their effects on hematopoietic cells were already well known. Despite extensive research over the years, our knowledge of interleukins is incomplete and new interleukins and receptors are still being identified. Also, it is becoming more apparent that interleukins, besides their redundant biological functions, possess highly specific functions *in vivo*. Current interleukin research focuses on the elucidation of the interleukin signaling events and the regulation of interleukin target genes. The major challenge for the future will be to understand the interplay between interleukins and other cytokines and developmental factors within the hematopoietic system *in vivo*, especially within the compartment of the immature hematopoietic progenitor and stem cells.

Intermediate Filaments

E. BIRGITTE LANE

Division of Cell & Developmental Biology, University of Dundee School of Life Sciences, MSI/WTB Complex, Dundee, UK
e.b.lane@dundee.ac.uk

Definition

►Intermediate filaments are polymeric protein structures of the ►cytoskeleton and are found in most

animal cells. Most types of intermediate filament proteins form a network of cytoplasmic filaments that are each about 10 nm in diameter and usually very long; ends are rarely seen. Their name comes from their intermediate size between actin and myosin filaments in muscle. They form one of the three fibrous systems of the cytoskeleton, the other two being microtubules (of tubulin) and actin microfilaments. Intermediate filament proteins differ from actin and tubulin systems in forming more stable filaments than either of them. They do not bind nucleotides and are not dependant on nucleotide hydrolysis to regulate their polymerisation and depolymerisation. The amount of intermediate filament protein in a cell varies widely, from less than 1% in hepatocytes of liver to around 80% of the total cell protein in differentiated ►keratinocytes of skin. Intermediate filaments are encoded by a large gene family and have distinct tissue expression patterns. They are found in nearly all cells of motile multicellular organisms and their common function is believed to be to provide physical resilience to cells in tissues. The best direct evidence for this comes from human skin fragility disorders caused by mis-sense mutations in the genes encoding ►keratin intermediate filament proteins. It is likely that different intermediate filament proteins possess different tissue-specific properties.

Characteristics

All intermediate filament proteins share the same basic secondary structure characteristics, shown in Fig. 1. Each has a central α -helical rod domain of around 310 residues, which coils to form an α -helix some 45 nm long. Only one group, the lamins, shows a significantly different rod length as these proteins have an additional 42 amino acid residues in helix 1B. The rod domains have a very consistent structure. They fall into 4 helical sections (1A, 1B, 2A, 2B) interspersed by 3 non-helical stretches (L1, L12, L2) and a fourth irregularity in 2B known as the "stutter". These non-helical linker domains are well conserved and are probably important for filament formation and flexibility. At either end of the rod domain are key conserved ►helix boundary motifs (Fig. 1) also needed for assembly; the helix termination motif has even been used to identify unknown intermediate filament genes.

The rod domain is flanked by non-helical amino-terminal head and carboxy-terminal tail domains, containing a region of quasi-repeats (V1 and V2) between charged end domains (E1, E2) and helix flanking regions that usually contain phosphorylation sites (H1, H2; see Fig. 1). The head and tail domains can vary hugely in size and are thought to determine the tissue-specific characteristics of different filament proteins.

The family of intermediate filament proteins is divided overall into six distinct types or classes,

Intermediate Filaments. Figure 1 Characteristics of intermediate filament proteins as illustrated with a type II keratin. All intermediate filament proteins have the basic structure as shown, with a central rod domain (pink: 1A, 1B, 2A, 2B), interspersed and flanked by non-helical regions (yellow, orange, pink). The conserved rod ends (dark pink) or helix boundary motifs are referred to as the helix initiation motif (HIM) and the helix termination motif (HTM) and are important for establishing the correct filament properties. Within the head and tail domains, E1 and E2 are the charged extreme ends; V1 and V2 are the variable quasi-repeat regions and H1 and H2 are the hypervariable regions that usually contain phosphorylation target sites for remodelling filaments by disassembly and reassembly. The non-helical linker domains are shown as L1, L12 and L2 and the stutter discontinuity in helix 2B is shown by the line labelled S. Numbers above the domains denote the number of published pathogenic mutations in keratins reported in that domain. Below is indicated the position of the intron-exon boundaries.

type I-type VI, based on similarities in their DNA coding sequences and the primary amino acid sequences of their proteins.

Expression

The spectrum of intermediate filament proteins and their expression in tissues was mapped using gel electrophoresis and antibodies (1, 2). Many well-characterised monoclonals are now available commercially as differentiation markers and tools for diagnostic pathology. There are over 60 intermediate filament proteins whose expression range in tissues is now known. The diversity of their expression is one of the most striking characteristics of the intermediate filament protein family and one of the most useful. Table 1 gives a brief overview of the diversity of known intermediate filament proteins and their expression in tissue differentiation, although a full account of tissue expression mapping of intermediate filament proteins is far beyond the scope of this article.

Type I and type II proteins are the keratins, or cytokeratins, the intermediate filament family expressed by the cells of **epithelia**. The classification of keratins as type I (smaller, acidic) and type II (larger, neutral to basic) proteins arises from original studies on wool proteins and this nomenclature has been expanded to cover all the intermediate filament proteins (3). There are thought to be 54 functional keratin sequences in the human genome and a significant proportion encode specialised hair keratins (trichocyte

keratins). The keratins are traditionally catalogued numerically by their charge and molecular weight. Hair keratins have a slightly different nomenclature. Keratins in tissues are coexpressed as pairs, from the largest type II keratin pairing with the largest type I keratin (K1 + K10, in differentiating epidermis), the next largest ones also pair, etc., down to the smallest pair (K8 + K18, in early embryos and simple epithelia). A potential revised nomenclature is currently under discussion (4).

Type III proteins are the vimentin-like group, expressed mostly in mesenchymal cells. Type IV are the neurofilament proteins in neurones. Type V are lamin proteins, expressed in the **nuclear lamina** of all cells and the only non-cytoplasmic group. The type VI group encompasses proteins that are clearly intermediate filament proteins but do not show obvious homology to the other groups; this group currently includes the divergent lens intermediate filament proteins, CP49 and filensin. Different members of each group are selectively expressed in different tissues and the intermediate filament expression profile of a cell is an indicator of the cell's differentiated state. This information is summarised in Table 1.

Intermediate filament genes are found widely throughout the animal kingdom, and proteins with related properties may occur elsewhere (e.g. some bacteria). They appear to be limited to motile multicellular organisms and cytoplasmic intermediate filaments are underrepresented in tissues protected by an exoskeleton.

*Calculated molecular mass; otherwise molecular weights are given as relative migration on gels. Eight further type I and five further type II gene sequences are present but their expression range is unclear

Genes

The genes are generally small and compact, with 8–9 exons in most genes separated by 7–8 introns. Within each type the gene organization is very similar. Keratin genes are located within two dense gene clusters but other intermediate filament genes are scattered

elsewhere throughout the genome (Table 1). Genes have now been identified for all known intermediate filament proteins. A systematic search of the human genome database in 2001 identified 65 sequences as intermediate filament genes (5), although not all of these had yet been identified in tissues. In the human

genome, type I keratins are on chromosome 17q and type II genes are all except one on chromosome 12q12-13. The gene for type I keratin 18 lies next to its co-expressed partner keratin K8 and is the only type I keratin on chromosome 12. The chromosomal location of the intermediate filaments genes is summarized in Table 1.

It now seems likely that all the intermediate filament genes have been identified. Genome analyses have confirmed that there are multiple genes for K1, K5, K6, and K2. Alternative splicing is found in the lamin A/C gene, LMNA, (which encodes both lamin A and lamin C), and in peripherin, nestin, syncoilin and synemin. Polymorphisms mostly involve the variable head and tail domains. Intronless, or processed, **pseudogenes** for the two embryonic keratins K8 and K18 are abundant and dispersed throughout the human genome and account for 90% of all the keratin sequences in the draft human genome sequence. A small number of pseudogenes have also been identified for K17, K19, K14 and K16.

It is thought that the mammalian intermediate filament genes probably evolved from a lamin-like precursor in a pre-vertebrate ancestor, as invertebrates have filament genes with a lamin-like extended helix. It is suggested that loss of the isoprenylation target sequence that leads to anchoring of lamins in the nucleus might have been sufficient to initiate the evolution of a cytoplasmic type of intermediate filament. Proteins with resemblance to type I/II keratins and type III intermediate filaments are certainly all present in early chordates.

Molecular Interactions

By electron microscopy, intermediate filaments in cells all look rather similar, forming long, sinuous filaments that traverse the cell cytoplasm, singly or in bundles, with visible free ends hardly ever seen in a normal cell. The filaments themselves are **apolar**, unlike actin filaments or microtubules and they do not have a directional “organising centre” in the cell. They do however interact with cell-cell junctions (**desmosomes**, through desmoplakin) and cell-substrate junctions (**hemidesmosomes**, through BP230 and plectin **plakins** or cytolinker proteins) at the cell membrane. Interactions with the cytolinker/plakin proteins also occur elsewhere in the cytoplasm.

Assembly

Studies with recombinant intermediate filament proteins confirm that they can polymerize spontaneously and rapidly without the need for additional cofactors or chaperones. Keratin assembly is especially fast. The α -helical rod domain forms the building block for assembly of the 10 nm-thick filaments. It is highly charged, with alternating positive and negative patches

on its surface, and has a strip of hydrophobic residues curving round its length. It is therefore unstable until it forms a dimer or higher order structure. Monomeric intermediate filament polypeptides start to assemble by dimerisation, 2 polypeptides forming a left-handed coiled-coil, parallel and in register, along their α -helical rods. This is through a conventional “**leucine zip**” mode of progressively interdigitating hydrophobic residues down the helical coil, probably initiated by key sequences at the ends of the rod domain. It is at this dimer formation stage that type I and type II keratins have to interact, as keratin homodimers are unstable and short-lived, and cannot assemble into filaments, thus keratins are obligate heteropolymers. Transfection experiments in cells have shown that if no complementary partner protein is available for a keratin to assemble with, the protein is rapidly degraded. The dimeric molecules associate into tetramers with a preferred antiparallel half-stagger configuration. Tetramers assemble laterally and longitudinally into filaments in a sequence of events that is not yet clear. From studies *in vitro*, Herrman and colleagues have proposed that this assembly passes through a stage of forming short fat “unit length filaments” which connect longitudinally as a string of beads, and finally undergo a compaction stage to form a 10 nm thick intermediate filament (6).

Certain other intermediate filament proteins also require mixtures of protein to form filaments efficiently. Neurofilaments NF-M and NF-H need NF-L, although NF-L can polymerise alone; eye lens proteins filensin and CP49 need each other, but with different stoichiometry from the keratins. Current thinking on the identity of preferred assembly partners for different intermediate filament proteins is indicated in Table 1.

Regulatory Mechanisms

Cellular and Molecular Regulation

Intermediate filaments are relatively stable structures in comparison to microtubules and actin filaments, yet there is clearly a lot of flux of subunits on and off the length of filaments in living cells. Filament assembly is controlled inside cells by phosphorylation (favouring disassembly) and dephosphorylation, mostly on serine and threonine residues located in the non-helical head and tail domains, close to the ends of the rod domain. Although many potential phosphorylation sites and kinases can be identified it is less clear which ones are important *in vivo*. Lamins are phosphorylated by p34 cdc2 at mitosis on sites in the head and tail domains for disassembly of the nuclear lamina at mitosis and during interphase they are targets for protein kinase A and C sites in the tail domain. The lamins are also subject to isoprenylation at their C terminus, which is necessary

for their correct intranuclear localization. Several serine phosphorylation sites in keratin heads and tails are now known [see review by Omary et al (7)] and again their main purpose seems to be remodelling during the cell-cycle. Phosphorylation may also regulate keratin interaction with chaperones. Neurofilament proteins can be heavily phosphorylated, especially NF-H, on repeated KSP sequence motifs in the tail domain. This leaves the tail domain highly charged so that it extends at right angles from the axis of the filament and this may be important for spacing filaments in the axon. At least some of the keratins are also subject to glycosylation, possibly affecting their solubility, and some intermediate filament proteins interact with chaperone molecules such as 14-3-3 or α B crystallin.

Disorders of Intermediate Filaments

Mutations in intermediate filament genes cause a wide range of genetic disorders. A web database has been set up to collate information on these mutations (at ►<http://www.interfil.org>), maintained at the University of Dundee. The first discoveries of intermediate filament mutations were made in a skin disorder, ►[epidermolysis bullosa simplex](#) (EBS). EBS is a skin blistering disease in which the keratinocytes of the epidermis are fragile due to mutations in the genes for either K5 or K14, the two keratins expressed in basal cells of the epidermis. Cells with these pathogenic mutations may lyse on scratching, rubbing or any traumatic contact, leading to intraepidermal fluid-filled blisters and sores on the skin. ►[Hyperkeratosis](#) also often develops on the hands and feet. These blisters will normally heal without scarring.

Pathogenic mutations are distributed non-randomly along the protein, as shown in Fig. 1. The most severe cases are caused by mutations arising in the helix boundary motifs that mark the ends of the rod domain, especially the type-specific helix initiation motif, and give rise to the Dowling-Meara form of EBS. Milder clinical phenotypes (Koebner and Weber-Cockayne forms) are associated with mutations in different hotspots in K5/K14, presumably reflecting regions where the detrimental effect on filament function is not quite so drastic.

Fragility of other epithelial cells is linked to mutations in different keratin genes (see www.interfil.org and references therein for accumulated information on keratin mutations). In the epidermis, mutations in the secondary (differentiation-specific) keratins K1 and K10 lead to bullous congenital ichthyosiform erythroderma (BCIE), so-called because of the formation of blisters and later the thickened ichthyotic (fish scale like) appearance of the skin, plus the reddening (erythroderma) that often accompanies this condition especially in children. K1/K10 disorders are also

sometimes called epidermolytic hyperkeratosis, referring to the major phenotypic characteristic of this disorder. Mutations in K2e cause ichthyosis bullosa of Siemens (IBS), whereas in K3 or K12 they cause Meesman corneal dystrophy. In K4 or K13, mutations cause oral and genital mucosal lesions of white sponge naevus (WSN). In K6a/K6b genes or K16 or K17, mutations are responsible for two forms of ►[pachyonychia congenita](#), PC-1 and PC-2, or the related and usually milder disorder of steatocystoma multiplex. Mutations in the palm- and sole-specific keratin K9 cause palmoplantar keratoderma. Nearly all of these are dominantly inherited and are caused by missense or nonsense mutations, but there are also several documented cases of recessive knockout mutations in K14 and some cases of compound heterozygotes. Some mutations in intron sequences have also been reported. The clustering of mutations, which tend to be the same regions in different keratin genes, must reflect the importance of conserving sequence to retain function. Therefore there must be other mutations in the rest of the keratin sequences that do not give rise to significant pathology.

Mutations have also been identified in the simple epithelial keratins K8 and K18, associated with disorders in liver, pancreas and intestinal epithelium (inflammatory bowel disease), but here the genetic link with disease is less clear. Inflammatory bowel disease is known to be of polygenic aetiology and moreover does not present clinically until the damage to the epithelium is already substantial, leaving less opportunity for morphological analysis. Finally, a number of mutations in the hair keratins that cause hair defects are also being uncovered. Disease-associated mutations remain to be uncovered in keratins K7, K15, K19 and K20. Hair disorders are also now beginning to be linked to keratin mutations. There are now altogether more than 400 published keratin mutations (www.interfil.org) and the field has recently been reviewed by several authors [e.g. Irvine & McLean (8)].

Outside the keratins the list of intermediate filament disease associations is also growing. Mutations in the type III desmin gene are associated with cardiomyopathies, disorders in which the stresses induced by constant contraction and relaxation of the muscles are thought to lead to cellular disruption analogous to the situation in skin keratinocytes. Type III mutations have also been seen in GFAP in patients with Alexander disease, a severe neurodegenerative condition that seems to be triggered and accelerated by incidences of brain trauma in the susceptible. Brain injury induces glial cell activation as part of the wound healing process and glial cells without intermediate filaments have been shown to behave aberrantly, which is

probably at the heart of the Alexander disease phenotype. Type V (lamin) genes are also implicated in disease. Mutations in the nuclear lamin A (A/C) gene are clearly responsible for a variety of pathologies ranging from familial partial lipodystrophy through Charcot-Marie-Tooth disease type 2B1 to Hutchinson-Gilford progeria: presumably loss of the reinforcement of the nuclear envelope in dividing cells leads to lethal cell damage in the presence of other undetermined stochastic factors.

Abnormalities in neurofilaments are seen in ALS and a number of other neurodegenerative disorders but the role of neurofilament mutations is mostly still obscure, as these are often late onset, variable severity disorders not amenable to genetic analysis. However mutations in NF-L have now been definitively linked to human Charcot-Marie-Tooth disease type 2E, a progressive muscle wasting disorder. In the eye lens, deletion of the CP49 gene in mice leads to loss of clarity of the lens, although no pathogenic mutations in the lens intermediate filament genes have yet been found in humans. Listing of mutations reported in intermediate filament genes can be found at ►<http://www.interfil.org>, and details on the individual disorders are recorded in ►OMIM (On-line Mendelian Inheritance in Man).

Intermediate Mesoderm

Definition

Intermediate mesoderm describes a specific region of embryonic mesoderm that forms the kidney and the sex organs.

►Kidney

Intermembrane Space

Definition

Intermembrane space is the region between the outer and the inner membrane of mitochondria.

►Mitochondria

Internal Ribosomal Entry Sites

Definition

Several eukaryotic cell and viral mRNAs initiate translation by an alternative mechanism, which involves internal initiation rather than cap-dependent translation initiation. These mRNAs contain complex nucleotide sequences, called internal ribosomal entry sites (IRES) where ribosomes bind in a cap-independent manner and start translation at the closest downstream AUG codon. As an IRES element can direct binding of ribosomes to the start codons of multiple genes on a single message, it can support coexpression of more than one protein under the control of a single promoter.

Interneuron

Definition

In general, the term ‘interneuron’ is used for neurons with a local axon plexus (projection approximately 0.5 mm) in the brain. Interneurons in the brain may show axonal projection both within a lamina and between laminae. In the neocortex, the majority of interneurons are inhibitory and use (-amino butyric acid as a

neurotransmitter. Exceptions to this rule are e.g. neocortical spiny stellate neurones and cerebellar granule cells, both of which are excitatory neurons.

► [Neurons](#)

Internode

Definition

Internode describes a myelinated axon segment between two nodes of Ranvier, up to 1 mm in length.

► [Glial Cells and Myelination](#)

Interphase

Definition

Interphase describes the long period of the cell cycle following mitosis, in which chromosomes are decondensed and general metabolism occurs. Interphase includes G1, S and G2 phases.

- [Cell Cycle – Overview](#)
- [Mitotic Recombination](#)
- [Nuclear Compartments](#)

Interpolar Microtubule

Definition

Interpolar microtubule refers to antiparallel microtubules that originate from opposite poles, and overlap at the midzone of mitotic spindles.

- [Cytoskeleton: Microtubules and Intermediate Filaments](#)
- [Mitotic Spindle](#)

Interspersed Repeats

Definition

Interspersed repeats are randomly inserted copies of transposable elements.

- [Repetitive DNA](#)
- [Transposons](#)

Intervertebral Disc

Definition

Intervertebral disc is a connective tissue that is located between the individual skeletal elements of the vertebrae.

- [Bone and Cartilage](#)

Intrabodies

Definition

Intrabodies are specifically designed antibodies which can be expressed intracellularly (e.g. in the cytoplasm).

- [Monoclonal Antibodies](#)

Intron

Definition

Intron refers to a DNA segment of a eukaryotic gene that is not represented in the mature mRNA transcript, because it is removed from the primary transcript in a process known as splicing. Introns often make up the bulk of sequence in the genes of higher eukaryotes.

Definition

Investigation of electrical excitability in vertebrates has a long history. It started with the pioneering experiments of Alessandro Volta on frog muscles in the 18th century. Today electrical excitability of tissues or cells still fascinates life scientists, irrespective of whether they are physiologists, neurobiologists or biochemists. Thanks to numerous studies, we now have a rather detailed knowledge about the molecular and cellular mechanisms of electrical activity as well as their functional consequences (1).

Membrane potential changes and secretion are the most prominent ways of information transfer in living organisms. Almost all cell types exhibit a voltage

difference, i.e. an electrical potential difference, across their membranes, which is negative at the cytoplasmic side compared to the extracellular space. This membrane potential (normally ranging from -90 to -50 mV) is mainly due to an uneven distribution of Na^+ , K^+ and Ca^{2+} ions at the extra- and intracellular sides of the plasma membrane, which harbors ion selective pores. Under resting conditions, the membrane potential is the equilibrium result of ion fluxes along chemical and electrical gradients. The negative voltage prevents small negative anions from entering the cytoplasm and thereby causing cell swelling. The electrochemical gradient is used by several transporters as an energy source for transporting metabolites or ions across the cell membrane. In electrically excitable cells (predominantly neurons and myocytes), transient potential changes and secretion of transmitters, hormones or growth factors convey cell-to-cell signaling, which represents the main mechanism for communication between these cells and their neighbors. The action potential, which defines the electrical excitability of a cell, is a fast redistribution of electrical charge across the membrane. In neurons and in myocytes, it can be divided into several phases which are characterized by different ion fluxes (Fig. 1): (a) sudden depolarization after reaching a certain voltage threshold, (b) repolarization, (c) hyperpolarization and (d) rest or equilibrium. In some cases, the repolarization phase is preceded by a plateau phase, which lasts a few ms in neurons and can last several 100 ms in cardiac myocytes.

Here we will focus on the molecular entities mediating these membrane potential changes underlying neuronal and muscle activity, i.e. voltage-gated Na^+ , K^+ and Ca^{2+} ion channels.

Characteristics

Neuronal action potentials can be initiated either at the afferent synapses or at the axon hillock of efferent ► [neurons](#), the most proximal part to the neuronal cell soma. The depolarizing upstroke of the action potential is mediated by Na^+ channels, the repolarization by K^+ channels. At synaptic terminals, action potentials activate voltage-gated Ca^{2+} channels. The subsequent influx of Ca^{2+} ions is a prerequisite for the vesicular release of transmitters, resulting in an activation of postsynaptic receptors. In non-myelinated axons, action potentials propagate as waves (diffusion of Na^+ ions) with a speed of about 1 m/s. In myelinated fibers, axons are electrically insulated by several neighboring lipid-rich myelin sheaths (a few hundred μm in length) intermitted by nodes of Ranvier. These nodes are characterized by a high-level expression of voltage-gated Na^+ and K^+ channels. Myelinated fibers are characterized by saltatory action potential propagation from one node to the other at ten- to hundred-fold higher

Ion Channels/Excitable Membranes. Figure 1 Time course of a neuronal and a cardiac action potential. Both types of action potentials (orange: neuron, blue: cardiac myocyte) are characterized by the same phases: (a) threshold-dependent depolarization, (b) repolarization (fast for a neuron, slow for the myocyte), (c) period of hyperpolarization and (d) resting state.

speeds compared to unmyelinated fibers. In cardiac myocytes, additional Ca^{2+} channels prolong the length of the depolarizing phase and mediate the substantial Ca^{2+} increase needed for muscle contraction.

Molecular Interactions
Voltage-gated Ion Channels

The superfamily of human voltage-gated and voltage-gated-like ion channels comprises a large set of 143 membrane-bound proteins that can be divided in 11 subfamilies according to sequence similarity (2), Na_v , Ca_v , K_v1-9 , K_v10-12 , K_{ir} , K_{Ca} , K_{2P} , CNG, HCN, TRP and TPC. They can all contribute to the membrane potential by their different selectivities for mono- and di-valent cations, depending on subcellular, cell- and age-selective expression, as well as by their modulation *via* accessory subunits and/or intracellular second messenger systems. According to their structure, these channels exhibit four variations (Fig. 2). (i) The Na_v and Ca_v channels consist of a principle, channel-forming α subunit composed of four homologous domains (Fig. 3). Each domain contains six membrane-spanning α helices (termed S1 – S6) and a membrane-reentrant loop (P loop) between the S5 and S6 segment, constituting the wall of the central ion pore. The S4 segment is an important part of the voltage sensor. (ii) K_v channels are composed of tetramers of subunits, which each resemble a single homologous domain of Na_v or Ca_v channels. (iii) K_{ir} channels display the simplest structure constituted by two transmembrane regions M1 and M2 separated by a P

Channel	Structure

K_{2P}	

Ion Channels/Excitable Membranes. Figure 2 Structural building blocks of voltage-gated and voltage-gated-like ion channels. Na_v and Ca_v channels are formed by a single pore-forming α subunit only. Although evolutionarily separated, K_v as well as transient receptor potential (TRP) channels are composed of tetramers containing six transmembrane regions and the pore forming re-entrant loop. The voltage-sensing S4 segment is less conserved in TRP channels. Ca^{2+} -activated (K_{Ca}), cyclic nucleotide-gated (CNG) channels and hyperpolarization-activated, cyclic nucleotide-gated (HCN) channels are similarly constructed. Their α subunits carry a regulatory domain at the C-terminus. Recently discovered two-pore channel (TPC) proteins seem to be fusions of two TRP proteins. Inwardly rectifying K_{ir} channels represent the simplest ion channel family. Two-pore region (K_{2P}) channels form functional channels as dimers (adopted from 2).

Na_v channel

Ion Channels/Excitable Membranes. Figure 3 Detailed view of the Na_v channel α subunit. The long polypeptide chain of more than 260 kD is composed of four homologous domains each containing the pore-forming reentrant loop between α -helical segments S5 and 6. The voltage sensor is located in S4.

loop. (iv) Linking two of these structures together generates the architecture of K_{2P} channels. Only those channels that possess the S4 segment are voltage-gated in the strict sense. These are the Na_v, Ca_v and K_v channels.

Gating of Voltage-gated Ion Channels

During their activity, these proteins undergo conformational changes that are a prerequisite for ion permeation and thereby crucial for their physiological function. Under resting conditions, voltage-gated ion channels are usually in a closed conformation. Upon activation, the ion channel undergoes a conformational change ("gating") that opens a permeation pathway for cations (the pore) resulting in a selective permeation of Na⁺, K⁺ or Ca²⁺. From this so-called open state, these proteins can go into an inactivated state by an additional conformational change in which the protein is non-conductive. Upon repolarization to resting conditions, these proteins are deactivated by returning into the closed state.

The physiologically relevant ion channels are protein complexes that are known to interact with and be regulated by a whole variety of different proteins and other signaling molecules. Accessory subunits are

known to alter the current characteristics of a given channel but they are not usually part of the ion channel pore.

Na_v Channels

At resting potential, the probability of Na_v channels being in the open state is very low. Upon depolarization, the open channel probability increases, which under physiological conditions leads to the permeation of Na⁺ ions into a cell, which in turn leads to a depolarization of the membrane potential. Upon opening, Na_v channels inactivate fast. Accordingly, the proper kinetics of activation and inactivation of Na⁺ currents are crucial for the occurrence of the upstroke depolarization (Fig. 1a) and the shape of the action potential. To date, 10 different isoforms of α subunits with different developmental and tissue distributions have been identified and 9 of them fall into a single gene family.

K_v Channels

K_v channels are a heterogeneous group of ion channel proteins that are involved in many cellular properties. Accordingly, about 40 genes encoding different K_v channels have been identified and several families of

voltage-gated K_v channels ($K_{v1.x}$, $K_{v2.x...}$) are known. Under physiological conditions, the opening of K channels leads to an efflux of K^+ ions, which leads to a repolarization of the cell. Voltage-gated potassium channels are therefore crucial for the electrical excitability of cells, determining the repolarizing phase during an action potential (Fig. 1b, c).

Ca_v Channels

Ca_v channels mediate the Ca^{2+} influx in response to depolarizations. The physiologically relevant channel complex of this diverse group of proteins consists of three or four different subunits in addition to the pore-forming α subunit. Originally, Ca_v channels were grouped according to their different pharmacological properties and current characteristics into T-, L-, N-, P-, Q- and R-type channels. More recently, the genetically derived nomenclature for the different Ca_v channel families ($Ca_{v1.x}$, $Ca_{v2.x}$, etc.) is used. Since the intracellular Ca -concentration is much lower than the extracellular one, a transient rise in intracellular Ca^{2+} , which can be mediated by the activity of Ca_v channels, acts as a second messenger within intracellular signaling.

Regulatory Mechanisms

Pharmacology/Disease

A whole variety of different substances are known to interact with voltage-gated ion channels. Besides physiological substances such as ATP, Ca^{2+} , cyclic nucleotides, prostaglandins and biogenic amines, this also includes an enormous variety of different toxins from venomous organisms like snakes, scorpions, spiders and cone snails (3). In addition, ion channels are the prime target for numerous clinically relevant drugs like local anesthetics, antiarrhythmics or anti-convulsants. In recent years, several hereditary neurological, motor or cardiac diseases that are correlated with mutations in voltage-gated ion channels have been identified, for example special forms of epilepsy, deafness, migraine or heart arrhythmia. Certain malfunctions of ion channels have been identified for these so-called channelopathies. Ion channels, however, can also be affected by autoimmunity or acquired disorders of RNA processing.

The feature that mutations of different channels can cause very similar phenotypes such as cardiac arrhythmia in the case of some mutated Na_v and Ca_v channels is common to many channelopathies. In addition, different mutations of the same gene (e.g. $Na_v1.4$) may cause a broad bandwidth of myotonic disorders (4).

Interestingly, for diseases that are linked to mutations of Na_v channels, it can be shown that even subtle changes in the current kinetics can be responsible for

the clinical picture. This strongly demonstrates how well adjusted the “concert of activity” of the different ion channel proteins has to be for the proper electrical activity of a given cell.

While we already have a detailed knowledge of Na_v , Ca_v and K_v channel physiology, we are just at the beginning of understanding the diverse properties of the other channels (K_{2P} , TRP, TPC etc.) belonging to this exciting group of membrane proteins.

Ion Trap

Definition

Ion trap describes an electrostatic lensing system (a three-dimensional quadrupole filter using a ring-electrode) that focuses ions created by electrospray (ESI), or matrix-assisted laser desorption (►MALDI), for analysis of their biophysical properties.

►Quadrupole Mass Analyser

►SNP Detection and Mass Spectrometry

Ion Trap Mass Spectrometer

Definition

The ion trap mass spectrometer uses three electrodes to trap ions in a small volume. The mass analyzer consists of a ring electrode separating two hemispherical electrodes. A mass spectrum is obtained by changing the electrode voltages to eject the ions from the trap. The advantages of the ion trap mass spectrometer include compact size, and the ability to trap and accumulate ions to increase the signal-to-noise ratio of a measurement.

►Mass Spectrometry: ESI

Ion-Exchange Chromatography

Definition

A chromatographic separation method based on the differences in electric charge of the components of the analyzed mixture. The column of ion-exchange chromatography consists of a synthetic resin containing fixed charged groups. In cation-exchange resins, negatively-charged groups are fixed to the resin, usually sulfonates, whereas anion-exchange resins bear positive-charged groups, usually alkyl-derivatives of ammonium. Ion-exchange separation is widely used to separate amino acid and protein mixtures.

Isomorphic Replacement

Definition

Multiple Isomorphic Replacement (MIR) uses crystals of a macromolecule with additional atoms (mostly heavy metals) soaked in or co-crystallized to determine the phases. Only the normal scattering of the heavy atoms is used for phasing. The most striking problem is the isomorphism of the derivatized crystal with respect to the native crystal. Lattice parameters must not change by more than 1% to allow determination of the partial structure of the heavy atoms and the protein phases.

► [MAD Phasing](#)

Isopeptide Bond

Definition

Isopeptide bond describes an amide bond formed between a carboxyl group of one amino acid and an amino group of another amino acid with the exception of the conventional peptide bond, e.g. the C-terminus of ubiquitin is connected with the ϵ -amino group of a lysine-residue.

Isothermal Titration Calorimetry

TIMM REINISCH, HANS-JURGEN HINZ
Institute for Physical Chemistry, WWU Münster,
Münster, Germany
hinz@uni-muenster.de

Definition

Isothermal Titration Calorimetry is one of the most powerful analytical techniques in modern drug design. It exploits the method of thermal titrations to obtain the number of bound ligands per mole of protein (or biopolymer in general), i.e. the stoichiometry, as well as the relevant thermodynamic parameters such as standard reaction enthalpy ΔH^0 , standard reaction entropy ΔS^0 and the standard Gibbs energy change ΔG^0 which relates to the equilibrium constant. Isothermal measurements can be performed in the temperature range from close to 0°C up to 80°C. This permits to obtain the important information on the variation with temperature of all parameters.

Description

Binding phenomena are the essence of biological regulation. The quantitative understanding of these

interactions in molecular terms forms therefore the basis of all pharmaceutical and medicinal activities to evolve strategies for coping with malfunctions of organisms. The indispensable vital parameters for the characterization of binding reactions are the number and molar ratio of interacting molecules (termed the stoichiometry, n), the binding constant K_B , (or dissociation constant $K_D = 1/K_B$); the standard reaction enthalpy, ΔH^0 , the standard reaction entropy ΔS^0 , the standard Gibbs energy change ΔG^0 and the variation with temperature of ΔH^0 , the so called heat capacity change ΔC_p^0 . An elegant, simple and fast method for the determination of these parameters is provided by high sensitivity isothermal titration calorimetry (ITC). As implied by the name a solution is titrated at constant temperature with another solution containing the potential ligand. The heat resulting from the interaction is used as an indicator of the degree of complex formation. As practically all reactions are associated with heat release (exothermic reaction) or heat absorption (endothermic reaction) the field of application of ITC is nearly unlimited. Even reactions that are apparently athermal at the temperature chosen for the experiment are likely to involve non-zero heat changes at a higher or lower temperature.

This feature renders ITC a very useful technique for the determination of physical properties of binding reactions. They include interactions between macromolecules such as DNAs, RNAs and proteins or between these molecules and small ligands, drugs and coenzymes or inhibitors as well as binding reactions to membranes and receptors, to name a few.

Figure 1 shows the schematic view of an ITC instrument. It generally consists of two identical reaction cells, one serving as reference the other as sample cell. At specified time intervals a small volume of the ligand solution (red) [typically 5–20 µL] is injected into the sample solution (blue) [0.5–2 mL] under stirring to provide rapid mixing of the solutions. The ITC instrument registers the compensatory power (J/s) required to maintain a “zero temperature difference” between the reference and sample cell as a function of time. Depending on the reaction being exothermic or endothermic the compensatory power of the instrument will be negative or positive relative to the zero reaction level. Figure 2 shows the simulation of an ITC titration based on the parameters given in the figure legend.

Integration of the individual power peaks over the time interval defined by the time elapsed between the start of the injection and the return of the power signal to the original baseline provides the heat change per injection, δq . The magnitude of the heat change per injection is largely determined by the change in the number of moles of ligand bound, δn_B , and the molar binding

Isothermal Titration Calorimetry. Figure 1 Schematic view of an ITC instrument.

enthalpy ΔH^0 , however, it also contains heat contributions from stirring and dilution of both ligand and sample. $\Delta q = \Delta H^0 \cdot \Delta n_B + (q_{\text{stirring}} + q_{\text{dilution}})$ The latter heat contributions shown in brackets must be corrected for by separate experiments in which a) buffer is injected into the sample solution and b) ligand solution is injected into the sample free buffer. Usually the correction resulting from the small dilution of the sample solution is negligible, while the heat associated with the dilution of the ligand can be significant. Division of the corrected heat change, δq , by the number of moles of ligand bound, δn_B , results in the value for the binding enthalpy per mole of ligand ΔH^0 . Optimal conditions for the determination of the binding enthalpy are therefore a high binding constant and an excess of sample over ligand concentration in the cell, i.e. conditions that guarantee complete binding of the injected ligand. This situation often prevails during the first injections at the beginning of a titration and is apparent by the identical magnitude of the initial power peaks as seen in Fig. 2. The enthalpy change ΔH^0 calculated in this manner can be further broken down into an intrinsic enthalpy value ΔH_{int} and an enthalpy contribution resulting from protonation or deprotonation effects, ΔH_{H^+} , if a change in the degree of protonation originates from ligand binding. The relevant equation is

$$\begin{aligned} \Delta H^0 &= \Delta H_{\text{int}}^0 + \Delta H_{\text{H}^+} \\ &= \Delta H_{\text{int}}^0 + n_{\text{H}^+} \cdot (\Delta H_{\text{ion, sample}} + \Delta H_{\text{ion, buffer}}) \end{aligned} \quad [1]$$

ΔH_{H^+} is given by the number n_{H^+} of protons transferred, times the sum of the ionization enthalpies

(with the proper sign) of the groups of the sample and that of the buffer used.

Performing the titration under otherwise identical conditions in a series of buffers with different heats of ionization the number of protons involved in the binding reaction can be obtained. If in addition conditions can be found where ligand binding is pH independent ($n_{\text{H}^+} = 0$) the observed enthalpy is equal to the intrinsic binding enthalpy.

Favourable conditions for the determination of binding enthalpies and the number of protons involved are unfavourable for the determination of binding constants. Extraction of binding constants from titration curves requires a significant change in the degree of ligation of the sample in the course of the titration which is equivalent to having a sizeable amount of unbound ligand in solution. A good estimate of the proper sample concentration that will yield analyzable titration curves can be obtained from the equation

$$a = K_B \cdot [\text{bs}]_{\text{total}} \quad [2]$$

where K_B is the site binding constant and $[\text{bs}]_{\text{total}}$ is the total concentration of binding sites. In the range of a values between 1 and 1000 the binding isotherms can be deconvolved to obtain binding constants; best accuracy is achieved with a values in the range of 5 to 500.

There is an elegant mathematical procedure to analyze both ITC and DSC experiments. We shall consider here the part relevant to ITC measurements. We give the derivation for proteins but the formalism applies of course also to all other macromolecules or binding partners. The enthalpy change of a reaction relative to a [reference state](#), for example the unliganded protein, can be obtained from the derivative with respect to temperature of the logarithm of the relative partition function Z as shown in Eq. 3:

$$H - H_N = \Delta H = -\frac{\partial}{\partial \beta} (\ln Z) = R \cdot T^2 \frac{\partial \ln Z}{\partial T} = \frac{RT^2}{Z} \frac{\partial Z}{\partial T} \quad [3]$$

β is defined as $1/RT$, $R = 8.3145 \text{ JK}^{-1}\text{mol}^{-1}$ is the Avogadro constant and T is absolute temperature.

Generally the relative partition function depends on the free ligand concentration x_{free} , which can be calculated from the mass conservation equation

$$x_{\text{total}} = x_{\text{free}} + \bar{x}_{\text{bound}} \cdot c_{\text{prot}} \quad [4]$$

x_{total} refers to the total and x_{free} to the free and ligand concentration in the calorimetric cell, \bar{x}_{bound} is the average number of ligands bound per mole of protein and c_{prot} is the total protein concentration. x_{free} can be calculated once \bar{x}_{bound} is known, as c_{prot} and x_{total} are

Isothermal Titration Calorimetry. Figure 2 Simulation of an ITC-Experiment: $K = 10^7$, $c_{\text{cell}} = 0,380 \text{ mM}$, $c_{\text{injector}} = 4.2 \text{ mM}$, $\Delta H = 10 \text{ kJ/mol}$, time between 10 μl injections: 120 s.

the accessible analytical concentrations of protein and ligand, respectively. For simplicity we write in the following x instead of x_{free} .

The average number of ligands bound per mole of protein is easily calculated from the relative partition function Z according to the equation

$$\bar{x}_{\text{bound}} = \frac{\partial \ln Z}{\partial \ln x} = \frac{x}{Z} \frac{\partial Z}{\partial x} \quad [5]$$

Thus once the relative partition function Z can be formulated for the various binding equilibria both the binding enthalpy ΔH^0 and the binding constant K_B can be obtained from non-linear curve fitting algorithms.

Binding to Independent Sites

A widely used theoretical model for the analysis of binding phenomena in biology is based on the assumption of multiple sets of independent binding sites. For generality we assume k classes of binding sites, each of which is characterized by its own binding constant K_y . This is indicated by the index y varying from 1 to k . Each of the k classes can have an arbitrary number of independent binding sites m_y ($y = 1$ to k) and each of the k binding sites of one class accommodates n_y ligands ($y = 1$ to k). Though in many cases n_y will be equal to 1 in biological systems, we

allow here for values different from the sake of generality.

The partition function Z_y for the single site reaction is described by the equation:

$$Z_y = (1 + K_y x^{n_y}) \quad [7]$$

x is the free ligand concentration and K_y is the binding constant of the class.

For m_y identical independent sites with the same binding constant K_y the corresponding class partition function Z_y^{class} is the product of the individual partition functions.

$$Z_y^{\text{class}} = (Z_y)^{m_y} = (1 + K_y x^{n_y})^{m_y} \quad [8]$$

Finally, if there are m_y independent classes, the overall partition function Z is the product of the class partition functions

$$\begin{aligned} Z &= (1 + K_1 x^{n_1})^{m_1} (1 + K_2 x^{n_2})^{m_2} \dots (1 + K_k x^{n_k})^{m_k} \\ &= \prod_{y=1}^k (1 + K_y x^{n_y})^{m_y} = \prod_{y=1}^k Z_y^{\text{class}} \end{aligned} \quad [9]$$

Isothermal Titration Calorimetry. Figure 3 Illustration of the terms used in the independent and equal sites model.

Knowledge of the overall partition function for the general “multiple sets of independent binding sites model” permits now the calculation of the binding enthalpy using Eq. 10:

$$\Delta H^0 = \frac{RT^2}{Z} \frac{dZ}{dT} \quad [10]$$

With Z from Eq. 9 one obtains:

$$\begin{aligned} \Delta H^0 &= RT^2 \sum_{y=1}^k \frac{1}{Z_y^{\text{class}}} \frac{dZ_y^{\text{class}}}{dT} \\ &= RT^2 \sum_{y=1}^k \frac{1}{Z_y^{\text{class}}} m_y q_y^{m_y-1} \cdot x^{n_y} \cdot \frac{K_y \Delta H_y^0}{RT^2} \quad [11] \\ &= \sum_{y=1}^k m_y \Delta H_y^0 \frac{K_y x^{n_y}}{1 + K_y x^{n_y}} \end{aligned}$$

The average number of bound ligands \bar{x}_{bound} is determined from Eq. 5

$$\begin{aligned} \bar{x}_{\text{bound}} &= \frac{\partial \ln Z}{\partial \ln x} = x \sum_{y=1}^k \frac{1}{Z_y^{\text{class}}} \frac{\partial Z_y^{\text{class}}}{\partial x} \\ &= \sum_{y=1}^k \frac{1}{Z_y^{\text{class}}} m_y Z_y^{m_y-1} \cdot n_y K_y \cdot x^{n_y} \quad [12] \\ &= \sum_{y=1}^k n_y q_y^{-1} \cdot m_y K_y x^{n_y} \\ &= \sum_{y=1}^k m_y \cdot n_y \cdot \frac{K_y x^{n_y}}{1 + K_y x^{n_y}} \end{aligned}$$

With the use of the expression for \bar{x}_{bound} the free ligand concentration x_{free} can be obtained for each total ligand concentration x_{total} employing the mass conservation constraint

$$0 = x_{\text{free}} + \left(\sum_{y=1}^k m_y \cdot n_y \cdot \frac{K_y x^{n_y}}{1 + K_y x^{n_y}} \right) \cdot c_{\text{prot}} - x_{\text{total}} \quad [13]$$

As this equation has no analytical, closed form solution for $k > 3$, iterative numerical procedures must be used to solve the equation for x_{free} .

On the basis of this general algorithm the measured total enthalpy change as well as the individual enthalpy change per injection can be expressed as a function of the known parameters: total ligand and total protein (sample in general) concentration in the calorimetric cell.

Sequential Binding

Obligatory sequential binding can be modelled by the following binding scheme:

The relative partition function representative of this equilibrium is

$$Z = 1 + K_1x + K_1K_2x^2 + K_1K_2K_3x^3 + \sum_{i=4}^n x^i \prod_{y=1}^i K_y \quad [15]$$

The K_i values refer to the microscopic binding constants characteristic for each binding equilibrium. The treatment of the partition function is facilitated, if instead of these microscopic constants K_i the stoichiometric constants \tilde{K}_i are introduced. They are defined by the relation

$$\begin{aligned} \tilde{K}_i &\equiv \prod_{y=1}^i K_y \\ (\tilde{K}_1 &= K_1; \tilde{K}_2 = K_1K_2; \tilde{K}_3 = K_1K_2K_3 \text{ etc.}) \end{aligned} \quad [16]$$

Introducing the stoichiometric binding constants transforms the partition function into

$$Z = 1 + \tilde{K}_1x + \tilde{K}_2x^2 + \tilde{K}_3x^3 + \sum_{i=4}^n x^i \prod_{y=1}^i K_y \quad [17]$$

Differentiation of $\ln Z$ with respect to the logarithm of free ligand concentration, yields the average number of ligands bound \bar{x}_{bound} :

$$\bar{x}_{\text{bound}} = \frac{\partial \ln Z}{\partial \ln x} = \frac{\sum_{y=0}^n i \tilde{K}_y x^y}{1 + \sum_{y=1}^n \tilde{K}_y x^y} \quad [18]$$

Introduction of this expression into the mass conservation equation results in the conditional equation for the free ligand concentration

$$0 = x_{\text{free}} + \left(\frac{\sum_{y=0}^n i \tilde{K}_y x^{ny}}{1 + \sum_{y=1}^n \tilde{K}_y x^{ny}} \right) \cdot c_{\text{prot}} - x_{\text{total}} \quad [19]$$

There is no analytical solution to this equation for $n > 2$ but numerical methods are available that allow for the extraction of the equilibrium constant, the binding enthalpy and the stoichiometry.

Thermodynamic Relationships

The change in Gibbs energy, ΔG , determines the direction of a spontaneous reaction at constant pressure and temperature.

$$\Delta = G - G^0 + RT \ln \frac{\prod_i [c_i]_{\text{products}}}{\prod_i [c_i]_{\text{educts}}} \quad [20]$$

$R = 8.3145 \text{ J K}^{-1} \text{ mol}^{-1}$ is the gas constant, T is the absolute temperature, c_i is the molar concentration of educts and products, respectively. ΔG^0 is the standard state Gibbs energy change, if all c_i are kept at 1 M. At that condition $\Delta G = \Delta G^0$. In case the c_i 's assume arbitrary values and experimental conditions are such that these analytical concentrations are kept constant by removal or replenishment of material, ΔG is the driving force of the reaction at the specified concentrations.

In a titration experiment the binding reaction tends to approach equilibrium. As no work can be performed at equilibrium ΔG equals zero at equilibrium and one obtains from Eq. 20 the important relationship between the equilibrium constant K_{eq} and the standard Gibbs energy change, ΔG^0 .

$$\Delta G^0 = -RT \ln \frac{\prod_i [c_i]_{\text{products,eq.}}}{\prod_i [c_i]_{\text{educts,eq.}}} \equiv -RT \ln K_{\text{eq}} \quad [21]$$

The Gibbs energy change is related to the enthalpy (ΔH) and entropy (ΔS) change of the reaction by the eq.22

$$\Delta G = \Delta H - T\Delta S \quad [22]$$

This is a significant relationship, since interactions with similar affinities can have a largely different energy and entropy signature. Generally both ΔH and ΔS vary with temperature and for biological reactions a linear dependence of δH satisfies usually the observations.

$$\begin{aligned}
 \Delta H(T) &= \Delta H(T_R) + \Delta C_p \int_{T_R}^T dT \\
 &= \Delta H(T_R) + \Delta C_p (T - T_R) \\
 \Delta S(T) &= \Delta S(T_R) + \Delta C_p \int_{T_R}^T \frac{dT}{T} \\
 &= \Delta S(T_R) + \Delta C_p \ln\left(\frac{T}{T_R}\right)
 \end{aligned} \quad [23]$$

T_R is a convenient reference temperature, for example, 25°C (298.16 K). Allowing for the temperature dependence of ΔH and ΔS the equation for ΔG assumes the form

$$\begin{aligned}
 \Delta G(T) &= \Delta H(T_R) - T\Delta S(T_R) \\
 &+ \Delta C_p \left(T - T_R - T \ln \frac{T}{T_R} \right)
 \end{aligned} \quad [24]$$

In analogy the same relation written in terms of standard properties can be used as fit equation to determine the dependence on temperature of the equilibrium constant.

$$\begin{aligned}
 -RT \ln K_{eq} &= \Delta G^0 = \Delta H^0(T_R) - T\Delta S^0(T_R) \\
 &+ \Delta C_p \left(T - T_R - T \ln \frac{T}{T_R} \right)
 \end{aligned} \quad [25]$$

The heat capacity change on binding, ΔC_p , can be obtained conveniently by performing ITC measurements at different temperatures. Calculation of the slope of the ΔH^0 versus T plot yields

$$\Delta C_p = \left(\frac{\Delta H^0(T_2) - \Delta H^0(T_1)}{T_2 - T_1} \right) \quad [26]$$

Depending on whether ΔH^0 increases or decreases with temperature, ΔC_p can be positive or negative. It has been observed frequently that ligand binding reactions to proteins are characterized by negative values of ΔC_p in the range of a few $\text{kJ mol}^{-1} \text{K}^{-1}$.

Application of ITC in the Life Sciences

Enthalpy changes are a characteristic and universal property of chemical and biological reactions and can therefore be utilized to follow the degree of complex formation without the requirement of modification of the samples under study. A major field of application is in drug discovery, target validation and assay development. As the chemical nature of the compounds plays virtually no role, both samples and ligands can consist of small molecules or polymers. Thus protein-protein, protein-DNA, protein-polysaccharide interactions are equally accessible as the reactions of these biopolymers

with small ligands such as ions, drugs, enzymes, allosteric effectors, protons and water. Another wide field of application is the characterization of vesicular micellar systems, the analysis of ligand-induced protein folding mechanisms, and the identification of **co-operativity** of ligand binding.

Determination of Kinetic Parameters of Enzyme Reactions Using ITC

Enzyme kinetics can be determined by ITC because the thermal power generated as the reaction proceeds is a direct probe of the reaction velocity. The total heat involved in the conversion of n moles of substrate into product P is

$$Q = n\Delta H^0 = [P]_T \cdot V_{\text{cell}} \Delta H^0 \quad [27]$$

$[P]_T$ is the total molar concentration of product in the calorimetric cell having the volume V_{cell} . ΔH^0 refers to the enthalpy change per mole of product generated.

Assuming Michaelis-Menten kinetics the reaction rate r is determined by the equation

$$r = -\frac{d[S]_{\text{inst}}}{dt} = \frac{k_{\text{cat}} \cdot [E]_T \cdot [S]_{\text{inst}}}{K_M + [S]_{\text{inst}}} \quad [28]$$

k_{cat} is the catalytic rate constant, $[E]_T$ is the total enzyme concentration in the calorimetric cell, and $[S]_{\text{inst}}$ is the instantaneous substrate concentration. The rate of disappearance of substrate $-\frac{d[S]_{\text{inst}}}{dt}$ is equal to the rate of product formation $\frac{d[P]}{dt}$. The power $[J s^{-1}]$ generated by the reaction is given by the equation

$$\frac{dQ}{dt} = \frac{d[P]}{dt} \cdot V_{\text{cell}} \cdot \Delta H^0 \quad [29]$$

Rearrangement of the equation provides the dependence of the reaction rate on the measured power signal dQ/dt , the cell volume V_{cell} and the enthalpy change ΔH^0 per mole of substrate transformed into product. The latter can be determined in a separate experiment, in which the heat for a known, completely converted amount of substrate is measured.

$$r = \frac{d[P]}{dt} = \frac{\frac{dQ}{dt}}{V_{\text{cell}} \cdot \Delta H^0} \quad [30]$$

Calculation of k_{cat} and K_M on the basis of eq.(28) becomes possible by fitting routines if $[S]_{\text{inst}}$ is known. Under continuous assay conditions $[S]_{\text{inst}}$ can be obtained using the relation

$$[S]_{\text{inst}} = [S]_{t=0} - \frac{\int_0^t \left(\frac{dQ}{dt} \right) dt}{V_{\text{cell}} \cdot \Delta H^0} \quad [31]$$

$[S]_{t=0}$ is the analytical substrate concentration at the beginning of the experiment, the integral is proportional to the area under the power-time curve (the output signal) t seconds after the start.

The resulting instantaneous substrate concentrations together with the measured reaction rates, r , can be employed to extract k_{cat} and K_M values from the Michaelis-Menten rate equation using non-linear fitting routines. Activation parameters can be obtained from performing these measurements at different temperatures. Different buffer systems can be used for signal amplification in reactions where proton evolution is coupled to product formation. (Eq. 1)

Summary

Isothermal Titration Calorimetry is an extremely useful, universally applicable, non-invasive technique to quantify interactions by providing all necessary thermodynamic parameters. These include reaction enthalpies, ΔH^0 , their temperature dependence, ΔC_p , and the binding constant K_B . The second rapidly growing field of application of ITC is the determination of kinetic parameters of enzyme reactions. There are no assay requirements other than the fact that the reaction be associated with enthalpy changes. This condition is practically universally met or can be arranged by a proper choice of the experimental temperature.

Definition

The term “Fos/Jun” is used for a number of structurally and functionally related members of the Fos and Jun protein families of transcription factors, collectively described as activating protein-1 (► **AP-1**). AP-1 mediates gene regulation in response to cytokines, growth factors and stress signals during cell proliferation, differentiation and apoptosis or transformation and tumorigenesis.

Characteristics

Much of our present knowledge about transcription factors comes from the discovery and study of the activating protein-1 (AP-1) family. AP-1 has served to detect the first decisive DNA binding motifs required for gene regulation by a variety of extracellular signals including growth factors, cytokines, tumour promoters, such as the phorbol ester TPA (12-O-tetradecanoyl-phorbol-13-acetate) and carcinogens, for example UV irradiation and other DNA damaging agents. One AP-1 subunit, the heterodimer Fos-Jun was found in the mid 80s to contain the viral oncogene product Fos. AP-1 was defined as an activity that controls both basal and inducible transcription of several genes containing AP-1 sites (5'-TGAG/CTCA-3'), also known as TPA-responsive elements (► **TRE**).

Within one year it became evident that the AP-1 containing polypeptides correspond to the products of members of the *jun* and *fos* gene families and that the first member of the Jun family, c-Jun, represents

the cellular homologue of the transforming oncogene (v-Jun) of the chicken retrovirus ASV-17.

At present, the Jun protein family consists of c-Jun, JunB and JunD; the Fos protein family comprises c-Fos, FosB, Fra-1 and Fra-2. During the past decade additional proteins, such as members of the ATF family (ATFa, ATF-2, ATF-3) have been identified (mostly by yeast-two-hybrid screening) that share structural homologies and form heterodimeric complexes predominantly with Jun proteins (see below) to bind to TRE-like sequences.

General Structure of the AP-1 Subunits

For its function in controlling gene expression, the prototype of a transcription factor has to include at least two structures; one region of the protein that is responsible for binding to a specific DNA recognition sequence (DNA binding domain) and a second region that produces transcriptional activation (transactivation domain) once the protein is bound to DNA.

DNA Binding Domain

The DNA binding domain is evolutionarily conserved between the Jun, Fos and CREB/ATF proteins, thus defining the protein family called “► **bZip**” proteins. bZip stands for the amino acid sequences of the two independently acting sub-regions of the DNA binding domain, the “basic domain” rich in basic amino acids which are responsible for contacting the DNA and the “leucine-zipper” region characterised by heptad repeats of leucine, part of the well known “4–3 repeats” forming a coiled-coil structure, which is responsible for dimerisation and is a pre-requisite for DNA binding (Fig. 1). In addition to the leucines, other hydrophobic and charged amino acid residues within the leucine zipper region are responsible for the specificity and stability of homo- or hetero-dimer formation between the various Jun, Fos or CREB/ATF proteins. The Fos proteins do not form stable homodimers but heterodimerise efficiently with the Jun proteins. The Jun proteins can form homodimers, although with reduced stability compared to Jun/Fos or Jun/ATF. Jun-Jun and Jun-Fos dimers preferentially bind to the 7bp motif 5-TGAG/CTCA-3' whereas Jun-ATF dimers or ATF homodimers prefer to bind to a related, 8 bp consensus sequence 5'-TTACCTCA-3'. Therefore, individual AP-1 dimers are expected to regulate specific subsets of AP-1 target genes depending on the characteristics of the AP-1 site in their promoter.

Transactivation Domain

In contrast to the well-defined DNA binding domain, the structural properties of the domains in the AP-1 proteins mediating transcriptional activation of target genes (transactivation domain, TAD) are less well

Jun/Fos. Figure 1 Structural organisation of the Fos and Jun proteins.

understood. The activity of the TAD can be transferred to heterologous DNA binding domains, such as the yeast transcription factor GAL4. By employing such chimeric proteins (which, in contrast to the wild type proteins do not depend on a dimerisation partner) critical amino acids in the TADs were identified. Moreover, it became clear that the various Jun, Fos and ATF proteins significantly differ in their transactivation potential. For example, c-Fos, FosB and c-Jun are strong transactivators, whereas JunB, JunD, Fra-1 and Fra-2 exhibit only weak transactivation potential. Under specific circumstances, the latter may even act as repressors of AP-1 activity by competitive binding to AP-1 sites or by forming inactive heterodimers with c-Fos, FosB or c-Jun. Most importantly, transactivation studies using fusion proteins led to the identification of protein kinases that bind to and phosphorylate AP-1 proteins in the TAD in response to extracellular signals, thereby controlling expression of AP-1 target genes (see below).

Molecular Interactions

In addition to the “classical” AP-1 members (Jun, Fos, ATFs), several new bZip proteins have been defined on the basis of DNA sequence specificity and heterodimer formation with Jun and Fos proteins. These include Maf and Maf-related proteins, Nrl, Smads and Jun-dimerising partners (JDs). The function of these proteins in AP-1-regulated processes remains to be determined. Binding of AP-1 to DNA may also support binding of other transcription factors to adjacent or

overlapping binding sites (composite elements) to allow the formation of quaternary complexes. The interaction of NFAT and Ets proteins with DNA on the IL-2 and collagenase promoters respectively, may serve as paradigms for this type of protein/protein interaction. The mutual interference between AP-1 and steroid hormone receptors, particularly the glucocorticoid receptor (GR) represents another extensively analysed example of protein-protein interaction-based cross-talk. There is evidence that the anti-inflammatory and immunosuppressive activities of glucocorticoids are mediated, at least in part, by GR-mediated repression of AP-1 activity. In addition to GR, transcription factors NFκB, MyoD, the LIM-only protein FHL2 and YY1, as well as other types of cellular proteins, such as DExD/H-box RNA helicase RHH/Gu, BAF60a subunit of the chromatin remodelling complex SWI/SNF, CBP and p300 have been found to modulate AP-1 activity. In most cases, the exact mechanism of interaction between AP-1 and these proteins remains to be determined. The N-terminus of JunD is the site of interaction with the tumour suppressor menin, which represses JunD-activated transcription through interference of ERK-dependent phosphorylation and/or association with an mSinA-histone deacetylase complex.

Regulatory Mechanisms

Transcriptional Regulation of *fos* and *jun* Genes

The *jun* and *fos* genes are members of a class of cellular genes, termed early response or “immediate-early”

genes which are characterised by a rapid and transient activation of transcription in response to changes in environmental conditions, such as growth factors, cytokines, tumour promoters, carcinogens and expression of certain oncogenes. Since this type of regulation of promoter activity is also observed in the absence of ongoing protein synthesis, it is generally accepted that pre-existing factors, whose activity gets altered by changes in post-translational modification (described in detail in the subsequent section), are responsible for the regulation of promoter activity.

Most of our current knowledge on transcriptional activation of ►immediate early genes is derived from studies on deletion and point mutations in the *c-fos* and *c-jun* promoters, combined with *in vitro* and *in vivo* footprinting analyses. The serum response element (SRE) is required for the majority of extracellular stimuli, including growth factors and phorbol esters. This element is bound in a ternary complex containing the transcription factor p67-SRF and p62-TCF (which stands for a class of related proteins described as Elk, SAP). Changes in the phosphorylation pattern of SRF and, predominantly, TCF regulate *c-fos* promoter activity by these stimuli. Other elements include the c-AMP response element (CRE) and the Sis-inducible enhancer (SIE), which is recognised by the STAT group of transcription factors, which are at the receiving end of the Jak/Stat signalling pathway initiated by specific classes of cytokines. In contrast, the element responsible for negative autoregulation of the *c-fos* promoter has not yet been identified conclusively.

Analysis of deletion mutants of the *c-jun* promoter identified two AP-1-like binding sites (Jun1, Jun2), which are recognised by Jun/ATF heterodimers or ATF homodimers and which are involved in transcriptional regulation in response to the majority of extracellular stimuli affecting *c-jun* transcription. In response to G-protein coupled receptor, EGF and other growth factors, the AP-1 sites and an additional element in the *c-jun* promoter recognised by MEF2 proteins cooperate in transcriptional control of the *c-jun* gene. Like the factors binding to the *c-fos* promoter, the activity of factors binding to the *c-jun* promoter is regulated by their phosphorylation status.

Post-Translational Control of AP-1 Activity

The most important members of the class of protein kinases regulating the activity of AP-1 in response to extracellular stimuli are mitogen-activated protein kinases (MAPKs). Depending on the type of stimuli these proline-directed kinases can be dissected into three subgroups. The extracellular signal-regulated kinases (Erk-1, Erk-2) are robustly activated by growth factors and phorbol esters, but only weakly activated by cytokines and cellular stress-inducing stimuli (UV irradiation, chemical carcinogens). In contrast

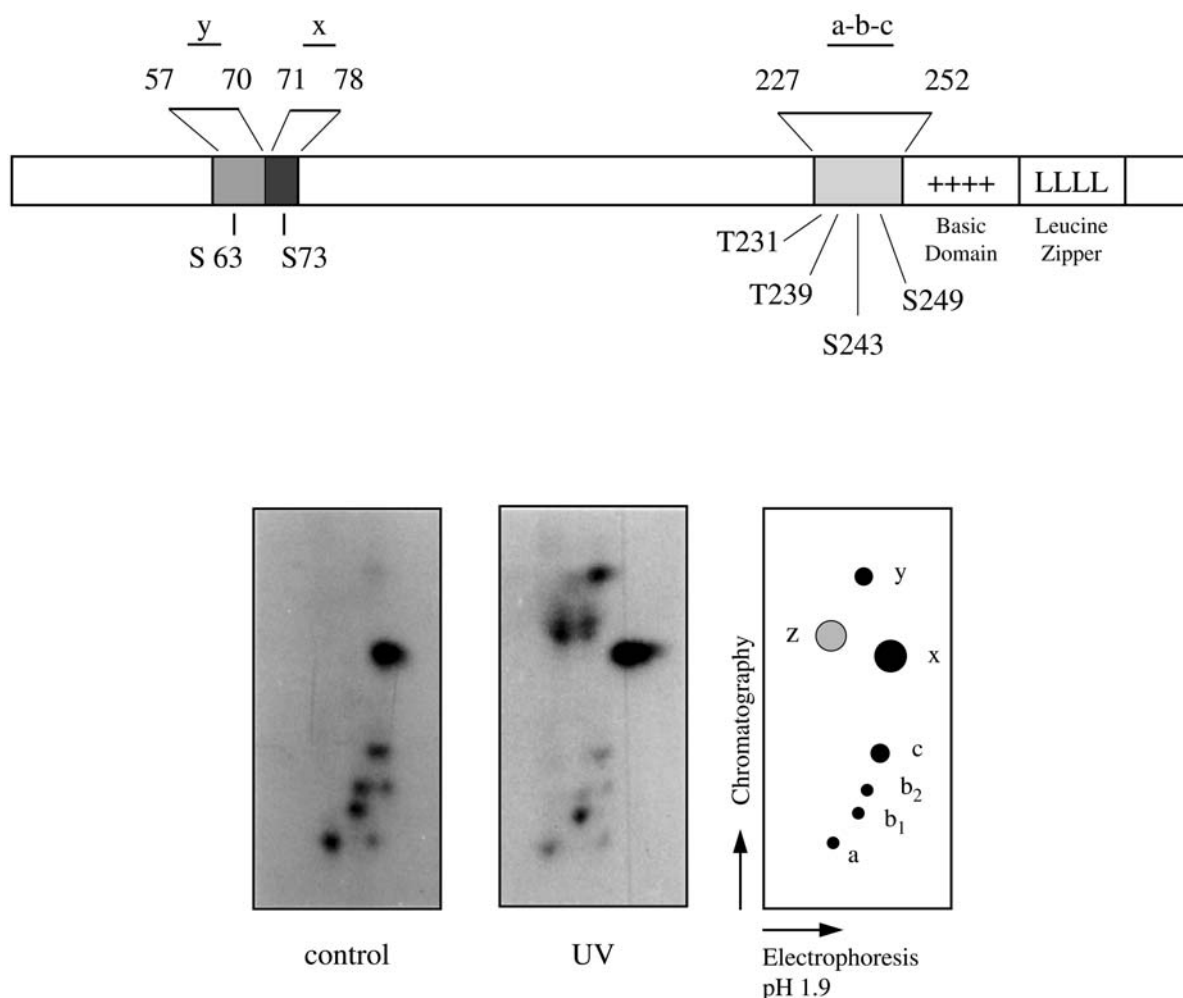

Jun-N-terminal kinases (►JNK-1, -2, -3), also known as stress-activated kinases (SAPK) and a structurally related class, p38 MAP kinases (p38 α , - β , - γ), are strongly activated by cytokines and environmental stress, but are poorly activated by growth factors and phorbol ester.

These kinases themselves are under the strict control of upstream kinases and phosphatases, which are part of individual signalling pathways initiated by specific classes of extra- and intra-cellular stimuli (growth factors, DNA damaging agents, oncoproteins). This network, which exhibits a high degree of evolutionary conservation between yeast, *Drosophila* and mammals is, however, far too complex to be discussed in greater detail in this review (for in-depth information on this subject see 7, 10, 11, 12).

Erk1 and Erk2 carry out mitogen-stimulated phosphorylation of Elk/SAP proteins. The sites phosphorylated by Erks reside in the TAD of TCF proteins and have a positive regulatory role in transactivation. The JNK/SAPKs were originally identified by their ability to specifically phosphorylate c-Jun at two positive regulatory sites (Ser-63, Ser-73) residing within the transactivation domain (Fig. 2). ►Hyperphosphorylation of both sites, which was originally identified by 2D-phospho-amino acid-peptide mapping (peptides x, y; Fig. 2), as well as additional sites at Thr-89 and -91 is observed in response to stress stimuli and oncoproteins and is responsible for transcriptional activation of c-Jun target genes. The JNKs can also phosphorylate and stimulate the transcriptional activity of ATF-2 and, to a lesser extent, TCF proteins. The same positive sites on ATF2 also serve as phospho-acceptor sites for p38, while Ser-63 and -73 of c-Jun are not affected by p38. Most probably, hyperphosphorylation of Jun, ATF and TCF proteins results in a conformational change in the TAD, allowing more efficient interaction with co-factors, such as CBP, which facilitate and stabilise the connection with the RNA polymerase II/ initiation complex to enhance transcription of target genes. Interestingly, in addition to enhanced transactivation, hyperphosphorylation of the TAD of c-Jun also regulates the stability of c-Jun by reducing ubiquitin-dependent degradation of c-Jun. Similarly, phosphorylation-dependent changes in the half-life of c-Fos have been observed.

In unstimulated cells, the DNA binding domain of c-Jun becomes phosphorylated at multiple sites (Fig. 2) by GSK-3 and/or casein kinase II (CK-II) resulting in reduced DNA binding. In response to extracellular stimuli, such as UV, phosphorylation is reduced, leading to enhanced DNA binding. The mechanism (reduced activity of the kinase or enhanced activity of a phosphatase) has not yet been defined conclusively.

In addition to phosphorylation, other mechanisms have been identified which regulate AP-1 activity. These

Jun/Fos. Figure 2 Top: schematic diagram of the human c-Jun protein. Amino acids are numbered. The numbers on top refer to the trypsin cleavage sites that lead to the appearance of phosphopeptides after *in vivo* labelling of cells with ^{32}P -orthophosphate. The location of the tryptic peptides “a-c” in the DNA binding domain and peptides “x” and “y” in the transactivation domain are indicated. Bottom: Autoradiogram of *in vivo* labelled c-Jun protein, isolated by immunoprecipitation from untreated and UV-treated cells, digested with trypsin and separated by gel electrophoresis into two dimensions. On the right the positions of the tryptic peptides are schematically illustrated. Peptide “z” most probably represents a peptide containing residual phosphorylation at threonine-89 and/or threonine-91 of c-Jun.

include redox-dependent DNA binding and regulation of nuclear localisation. Moreover, positive and negative interferences between AP-1 and other cellular proteins (in addition to the protein kinases and coactivators described above) have been identified (see “Molecular Interactions”).

In Vivo Functions of Fos and Jun Proteins in Physiology and Pathology

As described above, AP-1 activity is enhanced when cells are stimulated by mitogens. Moreover, oncogenic versions of c-Jun and c-Fos have been isolated from retroviruses and various membrane-associated or

cytoplasmic oncogenes (Ras, Src, Raf) permanently up-regulate AP-1 abundance as part of their transforming capacity, suggesting that AP-1 members play an important role in cell proliferation and transformation. Initial evidence for this assumption has been obtained by over-expression studies in various cell lines, by blocking AP-1 activity either through expression of a transdominant-negative c-Jun mutant, by expression of antisense sequences or by microinjection of Jun- and Fos-specific antibodies. Under these conditions, cell-cycle progression was disturbed and the efficiency of oncoprotein-mediated cell transformation was reduced. *In vivo* in transgenic mice, expressing a

Jun/Fos. Table 1 Summary of the phenotypes of mice containing loss-of-function mutations (introduced by gene targeting)

AP-1 member	Knockout/Knockin mice	References
c-Jun	Complete loss: embryonic lethal E12.5, hepatic failure, heart defect Liver-specific loss (albumin-cre): viable, impaired postnatal hepatocyte proliferation and liver regeneration Ubiquitous mosaic loss (Bal1-cre): malformations of axial skeleton Notochord and sclerotome-specific loss (collagen2a1-cre): increased apoptosis of notochordal cells, fusion of vertebral bodies, scoliosis of axial skeleton Epidermis-specific loss (K5-cre, K14-cre): eye lid closure defect	Reviewed by (1, 4, 8)
c-Jun ^{AA/AA}	Loss of N-terminal phosphorylation of c-Jun: viable, resistant to epileptic seizures and neuronal apoptosis induced by the excitatory amino acid kainate	
<i>junB</i> in <i>c-jun</i> locus	Rescue of <i>c-jun</i> ^{-/-} phenotype by JunB (cardiac and liver defects); rescue of c-Jun/c-Fos-, but not c-Jun/ATF- dependent gene expression	
JunB	Complete loss: embryonic lethal E8.5-E10.0, placentation defect Myeloid cell lineage: myeloproliferative disease T cells: altered Th2 cytokine expression, impaired allergen-induced airway inflammation Compromised expression in epiphyseal growth plate chondrocytes and bone lining osteoblasts: defective endochondral ossification Epiblast-specific loss (MORE-cre): osteopenia, myeloproliferative disease Macrophage/osteoclast-specific loss (lysozyme-cre): osteopetrosis	Reviewed by (2, 3, 4, 5, 8)
JunD	Viable, reduced postnatal growth, age-dependent defects in male reproductive function dysregulated T helper cell cytokines	(4, 6)
c-Fos	Viable, defective bone remodelling, osteopetrosis, light-induced apoptosis of photoreceptors CNS-specific loss: impaired long-term memory, NR2A-type NMDA receptor-dependent synaptic plasticity, resistant to chemically induced skin carcinogenesis Trp53/c-fos double knock out: development of rhabdomyosarcomas	(1)
<i>fra-1</i> in <i>c-fos</i> locus	Dose-dependent rescue of the <i>c-fos</i> ^{-/-} phenotype (bone remodeling, photoreceptor apoptosis)	
FosB	Viable, nurturing defect	(4, 8)
Fra-1	Embryonic lethal E10, placenta defect	
ATF-2	Hypomorph allele: decreased postnatal viability and growth, defects in endochondral ossification, ataxic gait, hyperactivity, decreased hearing, decreased number of Purkinje cells, decreased immediate inflammatory gene induction Complete loss: Neonatal lethality, Meconium aspiration syndrome, decreased cytotrophoblasts in placenta	

transdominant-negative mutant of c-Jun (which compromises total AP-1 activity) in keratinocytes interferes with chemically induced skin carcinogenesis. Already in these systems, different lines of evidence, including variations in the expression pattern and phosphorylation status of AP-1 members during the cell-cycle, had suggested that the members of the Jun and Fos families play specific roles during these processes or may even antagonise each other. The generation of mice

harbouring genetic disruption and/or transgenic over-expression (Tables 1, 2), as well as the availability of genetically defined mutant cells isolated from these animals represent a major breakthrough in our understanding of the regulatory functions of AP-1 subunits. The distinct phenotypes of the individual **knock out** mice (Table 1) induced by defects in cells or tissues in which the subunit was particularly important or where its absence became rate-limiting, support the notion that

Jun/Fos. Table 2 The consequences of over-expression of Fos and Jun proteins in mice (gain of function) are listed

AP-1 dimers exhibit specific and independent functions *in vivo*. As a general rule derived from all studies, the AP-1 subunits must be present in a complementary and co-ordinated manner in order to ensure proper development or physiology of the organism.

Embryonic development of c-Fos, FosB or ATF-2 null mice is normal. Adult *fos*^{B^{-/-}} females, however, nurture insufficiently. ATF-2-deficient mice die shortly after birth and suffer from a disease resembling a severe type of human meconium aspiration syndrome. Loss of c-Jun, JunB or Fra-1 results in embryonic lethality. While c-Jun null embryos die at midgestation (E12.5 to 13.5) due to failure in liver and heart development, lethality of JunB (E8.0 to E10) and Fra-1 (E10.5) deficient embryos is caused by placentation failure due to multiple defects in the extraembryonic tissues. These data suggest that JunB and Fra-1, possibly as heterodimers, address common target genes responsible for the generation of a functional placental labyrinth. Despite the general association of AP-1 with proliferation, these developmental phenotypes are caused by differentiation failures rather than aberrant cell proliferation. Tissue- and cell-type specific ablation confirmed initially seen phenotypes but also revealed non-overlapping as well as common functions within preferred cellular programs. While c-Jun plays a unique role in liver regeneration in response to partial hepatectomy, loss of JunB results in a transplantable myeloproliferative disease resembling human chronic myeloid leukaemia. Viable JunD null mice develop age-dependent defects in reproduction, hormone imbalance and impaired spermatogenesis. Specific functions in skeletal and bone morphogenesis can be

assigned to a majority of the AP-1 subunits; presence of c-Jun in notochord and sclerotome protects from scoliosis of the axial skeleton, while compromised expression of JunB as well as of ATF-2 results in defective endochondral ossification. Epiblast-specific and macrophage/▶osteoclast-specific loss of JunB caused osteopenia or osteopetrosis respectively, due to failure in ▶osteoblast and osteoclast differentiation and physiology. c-Fos null mice are viable and also show defective bone remodelling, suggesting common target genes or even a genetic program affecting bone homeostasis regulated by c-Fos, JunB and ATF-2. Indeed, c-Fos is a major regulator of osteoclastogenesis, while deregulated transcriptional regulation of cyclin A in the absence of either ATF-2 or JunB has been associated with defective chondrogenesis. T cells represent another cell type addressed by various AP-1 members. JunB and JunD are required for the regulation of T helper cell specific cytokine expression and ATF-2 is needed for immediate inflammatory gene induction.

AP-1 activity is greatly enhanced upon treatment of cells with genotoxic agents, implying that AP-1 target genes are involved in the cellular ▶stress response, such as ▶DNA repair, induction of survival functions or initiation of the apoptotic program. While JunD participates in an anti-apoptotic pathway, JunB appears to be part of a pro-apoptotic pathway through negative regulation of anti-apoptotic genes, at least in myeloid cells. However, it is important to note that AP-1 subunits, depending on the cell type and stimuli, may be involved in both anti-apoptotic and pro-apoptotic responses. When N-terminal phosphorylation of c-Jun

is lost upon mutation of ser-63 and -73 to alanine *via* ►knock-in, mutant mice become resistant to epileptic seizures and neuronal apoptosis induced by the excitatory amino acid kainate. Moreover, JunAA fibroblasts from these mice show proliferation defects as well as apoptotic defects upon stress induction. By contrast, T-cell proliferation and differentiation appears to be independent of c-Jun N-terminal phosphorylation whereas efficient T-cell receptor-induced thymocyte apoptosis is affected. Several pro- and anti-apoptotic functions have also been described for c-Fos depending on the cell type and nature of the inducing signal. Light-induced apoptosis of retinal photoreceptors requires c-Fos, yet in fibroblasts loss of c-Fos results in hypersensitivity to UV-induced DNA damage. Reduced apoptosis in response to genotoxic agents was also observed in mice lacking members of the JNK/SAPK family of protein kinases, suggesting that c-Jun and ATF proteins are the major substrates of JNK/SAPKs in mediating the cellular stress response. The findings that the AP-1 members can exert ambiguous functions as pro- or anti-apoptotic proteins or as transcriptional activators or repressors depending on the target gene, the cellular context and the inducing extracellular signal open an avenue for understanding the high level of complexity surrounding AP-1.

Interestingly, knock-in approaches revealed that some members are able to substitute at least for some functions of a near relative, when expressed at sufficient levels. Knock in mice having the *c-jun* allele replaced by *junB* undergo normal embryogenesis and develop a normal liver and heart. Analysis of indicative marker genes showed that expression of genes regulated by Jun/Fos, but not those regulated by Jun/ATF dimers, are restored, thereby rescuing c-Jun-dependent defects *in vivo* as well as in primary fibroblasts and foetal hepatoblasts *in vitro*. Fra-1-deficient embryos can be rescued from embryonic death by JunB over-expression. The c-Fos-dependent functions in bone cells can be substituted by Fra-1, when the *fos* locus is deleted and replaced by the *fosl1* gene encoding Fra-1. *Fosl1* is a transcriptional target of c-Fos during osteoclast differentiation and can fully complement for the lack of c-Fos in bone development in a gene-dosage-dependent manner. However, Fra-1 is not able to induce expression of c-Fos target genes in fibroblasts derived from the knock in mice, suggesting the need for additional tissue-specific factors.

Genetically altered mice represent an excellent system for the isolation of mutant cells. Primary and immortalised fibroblasts were isolated from almost all mice lacking individual AP-1 members. Analysis of these cells revealed that c-Jun acts as a positive regulator of the cell-cycle by suppressing ►p53 and, indirectly, the p53 target gene p21. Moreover, loss of

c-Jun results in reduced ►cyclin D1 activity. JunB, on the other hand, serves as both a negative and a positive regulator of cell-cycle progression by induction of the cyclin-CDK inhibitor p16, down-regulation of c-Jun and cyclin D1 expression and transcriptional activation of cyclin A. Data from fibroblasts lacking both c-Fos and FosB established a critical role for these AP-1 subunits in cyclin D expression. Moreover, fibroblasts lacking either *c-jun* or *c-fos* cannot be transformed by oncogenes, such as Ras and Src. JunD-deficient fibroblasts exhibit specific alterations in cell proliferation, depending on p53 and p19-ARF expression. In addition to these cell-autonomous effects, critical and antagonistic functions of c-Jun and JunB in cell proliferation and differentiation *in trans* were observed. c-Jun and JunB-dependent expression of critical cytokines (KGF, GM-CSF) could be demonstrated in an *in vitro* skin equivalent model system composed of primary keratinocytes and mouse embryonic fibroblasts of wild type, *c-jun*^{-/-} or *junB*^{-/-} genotypes. This system mimics many characteristics of cutaneous wound healing.

Gain-of function studies have been performed with various AP-1 members using promoters that mediate ubiquitous gene expression, such as the H2kB, the human ubiquitin C and the CMV promoter as summarised in Table 2. In principle, for some subunits these studies were in accordance with the knockout data, showing the opposite phenotype. Tissue-specific over-expression of JunB in T lymphocytes induced an enhanced T helper cell maturation. C-Fos, Fra-1 and δ FosB over-expression resulted again in bone phenotypes causing osteosarcoma in c-Fos and osteosclerosis in either Fra-1 or δ FosB transgenic mice.

Despite the fact that AP-1 was identified more than a decade ago, it still maintains much of its mystery. Further research on tissue-specific inactivation of AP-1 members and the identification of subunit-specific target genes may yield an even more complex picture of the function and regulation of AP-1.

Karyopherins

Definition

Karyopherins (or importins/exportins) are nuclear transport receptors (Ran-binding transport receptors), which are responsible for the translocation of their specific cargo in or out of the cell nucleus through the nuclear pores. They act as an “adaptor” to bind or target a signal bearing cargo to the nuclear pore complex. Karyopherins bind to either nuclear localization signals (NLS) or nuclear export signals (NES) on cargo proteins, respectively.

Keratin

Definition

Keratins are a large family of intermediate filament proteins encoded by more than 50 genes in humans. About half of these are the epithelial keratins that are found in soft epithelial tissues of the human body. The rest are high-sulphur, hard keratins of which hair and nail are composed. Keratins are subdivided into Type I and Type II proteins based on their charge, and form heteropolymers consisting of a specific pair of Type I and Type II keratins in well-defined tissuespecific and differentiation-specific patterns. Keratins share a central alpha-helical rod domain, which is important for dimerization through coiled-coil interaction between a Type I and a Type II protein. These dimers form tetramers which undergo further stages of assembly to produce 10nm keratin intermediate filaments.

Definition

The kidney is one of the main excretory and homeostatic organs of the body. It performs two essential functions; it excretes most of the end-products of metabolism, removing them from the blood to produce urine and it controls the concentration of certain constituents of the body's fluids, such as salt and uric acid, by controlling their excretion and reabsorption. The kidney has served as a model organ for developmental studies for over 40 years. Like many other organs kidney develops as a result of sequential and reciprocal tissue interactions (1, 2). Many basic developmental events are associated with kidney organogenesis. These include epithelial branching morphogenesis, inductive tissue interactions, differentiation, cell polarization, mesenchymal-to-epithelial transformation and pattern formation. One of the aims in the field is to identify the signals that determine inductive tissue interactions, trigger nephrogenesis and later pattern the [nephron](#). Generation of mutant animals has been useful in addressing molecular mechanisms of kidney assembly and such animals have proved to be useful models of inherited human kidney disorders (1, 2).

Characteristics

Morphogenesis of the Kidney

The adult mammalian kidney, the metanephros, develops from the Wolffian duct and the metanephric mesenchyme. Both of these derive from the [intermediate mesoderm](#). The metanephric kidney begins to develop when the [Wolffian duct](#) has produced an outgrowth called the ureteric bud (Fig. 1). The ureteric bud is an epithelial tissue that invades the [metanephric blastema](#), which occurs around E10.5–11 in the mouse and E35 to E37 in humans. On invading this mesenchymal tissue, the ureteric bud induces the mesenchymal cells that surround it to condense to form a cap of closely associated cells in the [nephrogenic mesenchyme](#) (Fig. 1). The [stroma](#) develops initially at the periphery of this mesenchyme and later also in between the ureteric branches. The condensed mesenchymal cells induce the ureteric bud to branch to form two new ureteric tips and to begin to

Kidney. Figure 1 The morphological stages and essential genes of early kidney development. (a) The mouse kidney starts to develop when the ureter bud forms at the caudal end of the Wolffian duct at ~E10.5 in mice. (b) The ureter bud grows into the metanephric mesenchyme and induces the mesenchyme adjacent to the tips of the ureter bud to condense and to form the stomal mesenchymal zone. (c) The condensed mesenchyme (dark area) induces the ureter bud to branch from E11.5 onwards. (d) In association with ureter branching morphogenesis, mesenchymal cells are induced in each epithelial tip region to undergo a mesenchymal to epithelial transformation and to form the nephron. U, ureteric bud.

form pretubular aggregates that undergo a mesenchyme-to-epithelial transition to form epithelial tubules *via* S-shaped and comma-shaped bodies. [Endothelial cells](#), which invade the kidney at the initiation of its development and also develop from the kidney mesenchyme, contribute to the formation of the functional nephron (Fig. 2) (1, 2).

Molecular Interactions

Induction of Kidney Development by Mesenchymal Signals

The metanephric mesenchyme is currently thought to initiate organogenesis by inducing the formation of the ureteric bud that forms the [collecting duct](#). The initiation signals are still largely unknown.

The Wilm's tumour suppressor gene, *Wt1*, encodes a transcription factor that is an important initiation factor. *Wt1* is first expressed in the condensing mesenchymal cells and, in the *Wt1* knockout mouse, the metanephric mesenchyme forms but the ureteric bud fails to grow out of the Wolffian duct. Due to lack of ureteric growth, the metanephric blastema will degenerate *via* apoptosis. Amphiregulin, a member of the epidermal growth factor (EGF) family of secreted signals is a direct target of *Wt1* at the initiation of kidney development and mirrors its expression. The details of the mechanism of *Wt1*'s action at the initiation of kidney development remain unclear.

Wt1 regulates another gene, the paired homeobox gene *Pax2*. *In vivo*, *Pax2* expression is reduced in kidney mesenchyme in *Wt1* deficient embryos, suggesting regulatory interactions. *Pax2* controls the initiation of kidney development as it controls the expression of the gene that encodes glial cell line-derived neurotrophic factor (*Gdnf*), a member of the transforming growth factor (TGF) β family of signalling molecules. *Gdnf* also has an important role in ureteric bud induction. The absence of *Pax2* causes *Gdnf* expression to be lost from the metanephric mesenchyme and *Pax2* also regulates *Gdnf* transcription in cell culture conditions (3).

Gdnf is expressed in the kidney mesenchyme prior to ureteric bud induction and lack of *Gdnf* function leads to the failure of ureteric bud formation. As the local application of *Gdnf* to the side of the Wolffian duct *in vitro* induces supernumerary ureteric buds, *Gdnf* is evidently sufficient for the induction of ureteric bud formation.

Eya1 is critical in controlling *Gdnf* expression in kidney mesenchyme. *Eya1* is a homologue of the *Drosophila* eyes absent (*Eya*) gene, which encodes another transcription factor. *EYA1* mutations in humans are associated with the branchio-oto-renal (BOR) syndrome. As with the *Wt1*, *Pax2* and *Gdnf* deficient embryos, in *Eya1* null mouse embryos the ureteric bud fails to invade the kidney mesenchyme. As the expression of *Gdnf* is lost but *Pax2* expression persists in the mesenchyme of *Eya1* mutant embryos. *Eya1* may function in kidney mesenchyme upstream of *Gdnf* but downstream of *Pax2* to initiate kidney development.

Sal1 is a new class of molecules implicated in early kidney development. *Sal1* is a mammalian homologue of the *Drosophila* region-specific homeotic gene *Spalt*. Heterozygous *SALL1* mutations in humans induce a

Townes-Brocks syndrome characterized by kidney anomalies. *Sal1* is expressed in the kidney mesenchyme and *Sal1* deficiency leads to incomplete ureteric bud growth and to a failure in nephrogenesis. Interestingly, *Sal1* deficient mesenchyme can form tubules when induced by heterologous inducer tissue. This suggests that the deficiency is transmitted to the ureteric bud. *Gdnf*, *Eya1* and *Wt1* remain expressed in *Sal1* mutant mesenchyme, which suggest that *Sal1* function lies downstream of these signals or possibly in a separate pathway.

Foxc1 is also expressed in the kidney mesenchyme and might control the location where the ureteric bud forms. *Foxc1* encodes a transcription factor of the forkhead/winged-helix family on the Wolffian duct. This conclusion is based on the fact that double ureter buds and kidneys can form in *Foxc1* knockout embryos. *Foxc1* is thought to regulate ureteric bud formation by repressing *Gdnf* and *Eya1* in the anterior region of the nephrogenic mesenchyme.

Initiation of Ureteric Bud Formation Induction of Ureteric Bud

The tyrosine kinase receptor *Ret* expressed in the ureteric bud has been implicated in the control of ureteric bud growth (2, 4). As *Gdnf* co-precipitates with *Ret*, *Gdnf* induces ureter budding in a *Ret*-dependent manner and defects in *Ret* and *Gdnf* signalling *in vivo* generate very similar kidney phenotypes suggesting that *Gdnf* contributes to ureteric bud induction via *Ret* signalling. *Gfra1*, a gene that encodes a co-receptor for *Ret*, is also expressed in the ureteric bud, and its deficiency in mice causes a phenotype related to that of *Ret* and *Gdnf* knockout mice. This *in vivo* data support the role for *Gfra1* in *Gdnf* signalling. The *Ret*/*Gdnf*/*Gfra1* system may initiate ureteric budding by promoting the growth of the ureteric bud towards the

Kidney. Figure 2 Schematic stages of nephrogenesis. (a) Ureteric bud signalling leads to formation of mesenchymal cell condensates. (b) The condensate starts to undergo mesenchymal-epithelial transformation to generate an epithelial tubule. The epithelialised tubule undergoes simple morphogenetic steps via comma and S-shape stages (c) to assemble the nephron. During nephrogenesis, endothelial cells are induced to migrate into the developing nephron that will fuse to the ureteric branch (d). The interactions between the endothelial cells and the nephron control glomerulogenesis.

mesenchymal source of Gdnf *via* a chemo attractive mechanism.

Branching of Ureteric Bud

The Ret/Gdnf/Gfra₁ system coordinates ureteric bud growth with other secreted factors, possibly pleiotrophin (Ptn, also known as HB-GAM) and Bmp4. Like *Wt1*, *Eya1*, *Sall1* and *Foxc1*, *Ptn* is expressed in the kidney mesenchyme and can stimulate the branching of isolated ureteric buds in culture together with Gdnf. *Bmp4*, a member of the ▶bone morphogenetic factor family is in turn expressed in the mesenchymal cells that surround the Wolffian duct and ureteric stalk. *Bmp4* is thus in the right place to regulate ureteric bud formation. *Bmp4*^{+/-} mouse embryos on a C57BL/6 background have kidney defects. These are thought to be due to the misregulated development of the ureteric bud. The defect mimics human congenital anomalies of the kidney and urinary tract (CAKUT).

In addition to the secreted signalling molecules, ▶extracellular matrix (ECM) proteins, such as the ▶proteoglycans (PGs), are also involved in ureteric bud development. PGs have many functions, being involved in growth factor signalling and ECM interactions. PGs consist of a core protein and sulphated ▶glycosaminoglycan (GAG) side chains. The glypican 3 (*Gpc3*) gene is mutated in humans with Simpson-Golabi-Behmel syndrome (SGBS) who have renal dysplasia. *Gpc3* contains HS GAG chains attached to the core protein, which is in turn anchored to the plasma membrane by the lipid, glycosyl-phosphatidylinositol. *Gpc3* is expressed in the ureteric bud and kidney mesenchyme. *Gpc3* inactivation leads initially to increased ureteric bud branching, while later the proliferation of the cells in the proximal collecting duct is inhibited. Hence *Gpc3* might control the cellular responses of the collecting duct to inducing or inhibitory growth factors.

Gpc3 is also a low affinity receptor for endostatin, a carboxyl-terminal proteolytic cleavage product of the extracellular matrix component type XVIII collagen. Type XVIII collagen and its fragment endostatin, are expressed in the ureteric bud and exogenously applied endostatin inhibits migration of renal epithelial cells towards hepatocyte growth factor (HGF). HGF in turn is another growth factor that, together with its oncogenic receptor c-met, is thought to regulate ureteric epithelial branching *in vitro*. Interestingly, blocking endostatin function with antibodies enhances the outgrowth and branching of isolated ureteric buds *in vitro*. This is an effect that is similar to that seen in *Gpc3* deficient mice. It is therefore possible that endostatin might normally inhibit ureteric bud branching and use *Gpc3* in the process.

Induction of Kidney Tubulogenesis

One of the central aims of the field of kidney research has been to identify the inducers of kidney tubules. Tubule formation in the mesenchyme is induced *in vivo* by the ureteric bud and *in vitro* by various ▶heterologous inducers, such as the spinal cord. The classic view has been that the mesenchymal cells that come into contact with the ureteric bud and its signal go on to form the kidney tubules.

The inactivation of *Emx2* in mice provided genetic support for the model according to which the ureteric bud secretes an initial inductive signal to trigger tubule formation *in vivo*. *Emx2* is a homeobox-containing transcription factor that is expressed initially in the ureteric bud. In *Emx2* knockout mice, the ureteric bud invades the metanephric mesenchyme normally, but no tubules are induced and kidney development fails. Although *Wt1*, *Gdnf* and *Ret* are expressed, the expression of *Wnt4* in mesenchymal cells is lost. As discussed below, *Wnt4* is believed to be an important initiating signal for tubulogenesis. *Emx2* might therefore regulate the expression of one or more unidentified ureteric bud-derived inducers that mediate epithelial signalling to the kidney mesenchyme to trigger tubulogenesis.

Wnt Signals as Inducers of Kidney Tubulogenesis

Wnts compose a large family of secreted signals that regulate key morphogenetic steps during embryogenesis. Since the discovery in 1994 that *Wnt1* can replace the spinal cord in kidney organ culture assays as an inducer of tubulogenesis, Wnts have been implicated as tubule inductive signals. However, *Wnt1* is not normally expressed in the embryonic kidney.

Of the Wnts, *Wnt4* is expressed in the condensed mesenchyme and pretubular aggregates. In *Wnt4*^{-/-} kidneys, the mesenchyme initially condenses on the ureteric bud outgrowth and expresses several early markers of mesenchymal induction, such as *Wt1* and *Pax2*, but then the mesenchymal-to-epithelial transformation fails and tubules do not form. *Wnt4* therefore appears to be a mesenchymal signal that is involved in the transition of mesenchyme to epithelium. The function of *Wnt4* signalling in triggering tubulogenesis was tested by generating NIH3T3 mouse cells to express *Wnt4*. Interestingly, both *Wnt4*-expressing cells and those expressing a panel of other Wnts were sufficient to induce tubulogenesis in the kidney mesenchyme *in vitro* (5). These studies point to an important tubule-inducing role for *Wnt4*. Interestingly, another *Wnt*, *Wnt6*, is also expressed in the developing kidney at the tips of the ureteric bud. Indeed, NIH 3T3 cell lines that express *Wnt6* can induce *Wnt4* gene expression and kidney tubules *in vitro*. *Wnt6* may

therefore function as an epithelial Wnt that triggers tubulogenesis by activating the Wnt4 signal-transduction pathway. Alternatively, Wnt6 signalling may be redundant with respect to Wnt9b and act as an inducer for this reason.

The Stroma Is Critical for Kidney Development

As discussed above, the kidney mesenchyme gives rise to cell types other than those that contribute to the nephron. One such cell type is the stromal cell, which does not differentiate into nephrons or into the collecting duct system but may be active in signalling and controlling kidney development.

The winged-helix transcription factor *Foxd1* gene (formerly called the *BF2* gene) is expressed in the stromal cell compartment. However its inactivation leads to defects in the collecting duct system and the nephrons. Hence, *Foxd1* may contribute to kidney development by regulating the expression of a stromal cell-derived signal that promotes tubulogenesis and ureteric bud development.

Vitamin A has been shown to be involved in stromal signalling as well (6). The vitamin A signal is transduced by the nuclear retinoic acid receptors (Rars). *Rara* is expressed at low levels throughout the embryonic kidney, whereas *Rarβ2* expression is restricted to stromal cells; these receptors co-localise in stromal cells. In double null *Rar* and *Rar2* mutants, ureteric bud growth is reduced, indicating a redundant function for these genes in the stroma. Consistent with this ureteric phenotype, *Ret* expression is down-regulated in the ureteric bud. When this hypothesis was tested by expressing *Ret* in the ureteric bud of double mutant mice, ectopic *Ret* expression rescued kidney development. These observations provided *in vivo* evidence that stromal cell-derived signalling maintains *Ret* expression in the ureteric bud, which in turn triggers signalling that regulates the differentiation of mesenchymal cells. These data indicate that a signalling loop might exist between the stroma, ureteric bud and kidney mesenchyme that coordinates kidney development. Indeed recent studies showed that Wnt11 (Fig. 3) and Sprouty signalling operate in a Ret/Gdnf signalling loop to contribute to ureteric branching, while Sonic hedgehog acts as an ureteric bud signal to regulate part of the smooth muscle cells' fates in kidney mesenchyme. Wnt7b is expressed in presumptive collecting duct and may regulate its development (Fig. 3).

Although the nature of the signals secreted by the early stromal cells remains elusive, there is some evidence to suggest that Fgf and Wnt signals may be involved. *Fgf7* is expressed in the stromal cells that surround the ureteric bud and developing collecting duct, whereas

Kidney. Figure 3 Expression of some important genes in the embryonic kidney. (a) At E11.5, *Wnt-11* is expressed in the ureteric bud that has initiated branching morphogenesis. (b) During subsequent ureteric bud branching, *Wnt11* is maintained at the tips of the ureteric bud tree (E13.5). (c) *Wnt7b* expression is excluded from the very tips of ureteric buds while its expression is localised mainly to presumptive collecting duct.

the *Fgf7* receptor is expressed in the ureteric bud itself. In *Fgf7*-deficient mice, the ureteric bud has branched less and ~30% fewer nephrons are formed. When FGF7 is added to organ culture *in vitro*, it stimulates the growth of isolated mutant ureteric buds. This indicates that FGF7 serves as a growth factor for ureteric bud development. *Wnt2b* is expressed in the early stromal mesenchyme of the kidney, suggesting that it might function in this kidney compartment. Indeed, kidney organogenesis can be reconstituted *in vitro* by treating isolated ureteric buds with cells that express *Wnt2b*, prior to co-culturing the ureteric buds with mesenchyme. Wnt2b may therefore function as a reciprocal mesenchymal signal that regulates early ureteric branching; its inactivation in mice may provide proof of this possibility.

Regulatory Mechanisms

Even though knowledge of the regulatory mechanisms of kidney development is still rather limited, we can draw some hypothetical models of the molecular mediators involved. Initiation of kidney development involves several transcription factors such as WT-1, Pax2, Foxc1 and Sall1. Gdnf is a critical factor together with pleiotrophin in regulating ureteric branching, while Emx2 controls ureteric growth and signalling, with modifiers of proteoglycans such as glypican 3 involved in the control of ureteric branching. Wnt11 regulates ureteric patterning at the initiation of trifurcation of the ureteric bud while Sonic [hedgehog](#) regulates smooth muscle cell fates as a ureteric bud derived signal. Wnt4 acts as a critical tubule inductive signal. The possibility of applying the technology of conditional mutagenesis will permit the next generation of experiments to target gene functions in organogenesis of the kidney to be done. A selection of the genes implicated in early kidney development is presented in Table 1.

Kidney. Table 1 Some genes that are implicated in early kidney development

Type/Name	Tissue type expressing	Phenotype
Transcription factors		
<i>Emx2</i>	U, MM	Kidneys, U, genital tract completely missing
<i>Eya1</i>	MM	Absence of U growth and failure of induction of MM
<i>Foxc1</i>	MM	Two kidneys and double U's
<i>Foxd1</i>	S	Mutant kidneys are small, few nephrons, fused longitudinally
<i>Pax2</i>	U,MM	Deficient U outgrowth, MM uninduced
<i>RARα & RARβ2</i>	U, S,MM	Hypoplasia/agenesis
<i>Sall1</i>	MM	Incomplete U outgrowth, failure
<i>Wt1</i>	MM	MM undergoes unrescuable apoptosis tubule formation, apoptosis
Growth factors		
<i>Bmp4</i>	MM	+/- Hypo/dysplastic kidneys, hydroU, ectopic uterovesical junction, double collecting duct
<i>Bmp7</i>	U, MM	Severe hypoplasia with few nephrons and collecting ducts
<i>Fgf7</i>	S	Small kidneys, fewer U branches and nephrons
<i>Gdnf</i>	MM	No kidney as U bud fails to grow
<i>Wnt4</i>	MM	Failure of kidney tubule formation
<i>Wnt11</i>	U	Defect in ureteric patterning
Sonic hedgehog	U	Defect in smooth muscle cell differentiation
Growth factor/receptor		
<i>Gfra1</i>	U, MM	Agenesis of the kidney as in <i>Ret</i> and <i>Gdnf</i>
<i>Notch2</i>	MM*	Glomerular defects
<i>Ret</i>	U	Failure of U growth
Proteoglycans and their biosynthetic enzymes		
<i>Hs2st</i>	U, MM	Renal agenesis due to lack of U branching and mesenchymal condensation
<i>Glypican3</i>	U, MM	Selective degeneration of medullary collecting duct

U, ureteric bud; MM, metanephric mesenchyme; S, stromal cells. Expression at later steps on nephrogenesis not indicated. * In maturing nephron and glomerulae

Kinase

Definition

Kinase/protein kinases are cytosolic regulatory enzymes that modify the functional properties of certain cytosolic proteins (substrates), by catalysing the transfer of phosphate groups from a high-energy phosphate-containing molecule (as ATP or ADP) to the side chains of serine, threonine or tyrosine residues. This large group of enzymes not only comprises those transferring phosphate, but also diphosphate, nucleotidyl residues, and others. Kinases have also been subdivided according to the acceptor group.

Knock-Out Mice (Null Mice)

Definition

The term knock-out or knock-out mutation characterises the inactivation of specific genes in order to study their function. Knock-out mice (also called Null mice) are derived from embryonic stem cell clones, in which a particular gene was disrupted (knocked-out) by targeted integration of a defective gene construct. If the mice differ from their normal litter mates, it is assumed that the phenotype is a consequence of the gene disruption. Knock-out mouse models allow the study of disease predisposing genes identified in humans.

Kupffer Cells

Definition

Kupffer cells are the resident macrophages of the liver located in the walls of the liver sinusoids. These cells are intensely phagocytic and – together with the liver sinusoidal endothelial cells – constitute the most powerful scavenger system in the body, removing waste macromolecules or bacteria from the blood of the portal vein. Kupffer cells are also able to secrete several types of mediators such as cytokines, oxygen and nitrogen species, and prostaglandins, mostly after stimulation through infection.

Laminar Flow

Definition

Laminar flow is defined as the state of fluid (or gas) flow wherein particles move along parallel, ordered paths.

- [Proteomics in Microfluidic Systems](#)

Laminin

Definition

Laminin designates a family of glycoproteins that form an integral part of basement membranes. All laminins are heterotrimers assembled from α , β , and γ -chains. From the known 5 α , 3 β , and 3 γ -chains in vertebrates, at least 15 different laminin trimers can be formed, which are assembled into ternary protein complexes, via coiled coil interactions. The complete trimers have been named by arabic numerals (Laminins 1 to 15), roughly in order of their discovery. They are considered important for organ development.

Langer-Giedion Syndrome

Definition

Langer-Giedion syndrome describes a rare contiguous genetic disease (1:100,000 newborns) caused by loss of the TRPS1 and EXT1 genes on one homologue of human chromosome 8q24.1. Infants show short stature, facial anomalies, redundant skin, hypotonia, and frequent infections; later signs include multiple exostoses, rheumatoid deformation of fingers and toes, and mental retardation.

- ▶ [Microdeletion Syndromes](#)

LAP

Definition

LAP stands for Latency Associated Peptide. It consists of the N-terminal part of the TGF- α propeptide, which

is proteolytically cleaved from the mature C-terminal peptide, and remains non-covalently bound to mature TGF- α and disulfide-linked to other proteins of the latent TGF- α complex, such as latent TGF- β binding proteins (▶ [LTBPs](#)). The function of the propeptide is to confer inactivity to the mature C-terminal peptide.

Large Scale ENU Mutagenesis In Mice

MARTIN HRABÉ DE ANGELIS, JOHANNES BECKERS, SIBYLLE WAGNER, DIAN SOEWARTO
GSF Research Center for Environment and Health, Neuherberg, Germany
hrabe@gsf.de

Definition

Chemical mutagenesis by ▶ [ENU](#) (ethylnitrosourea) is a method for efficient production of mouse ▶ [mutants](#). ENU-mutagenesis is used in the field of forward genetics to create mouse models with specific ▶ [phenotypes](#) (e.g. disease models) and unknown ▶ [genotypes](#). The latter are discovered by genetic-mapping and cloning strategies. ENU mutagenesis can also be used as a reverse genetics approach, creating mouse models with a known ▶ [mutation](#) and yet unknown phenotype. It can be applied on a large-scale basis and/or in combination with other mutagenesis strategies to genetically dissect phenotypes or molecular pathways. ENU is the most powerful ▶ [mutagen](#) known in mammals.

Characteristics

ENU is a highly effective mutagen in mammalian germ cells with mutations rates higher than any form of radiation mutagenesis tested to date (9). ENU was originally used to study the influences of a number of variables on germ cell mutagenicity such as gender, sensitivity of germ cell stages and dose fractionation. In the mouse, ENU is known to have its main effect on pre-meiotic stages of spermatogonial stem cells. These stages are characterized by biological parameters such as cell division (mitosis, meiosis), DNA replication and DNA lesion repair, which presumably affect the sensitivity to mutation induction by ENU mutagenesis. ENU depletes multiple stem cells, such as hematopoietic stem cells, which causes temporary sensitivity to pathogens. Therefore, ENU treated male mice not only undergo a period of sterility, but are also more susceptible to infections than untreated males and have a shorter life span.

ENU transfers its ethyl group to nitrogen or oxygen in the DNA and can lead to mispairing and base pair substitution after DNA replication if DNA repair mechanisms do not revert the mutation. ENU mainly induces point mutations, namely base pair substitutions such as A/T→T/A transversions and A/T to G/C transitions, covering about 82% of all induced mutations or small deletions. Base pair substitutions in coding regions result in missense, nonsense or mRNA

▶**splicing** defects.

When used in its optimal dose, ENU induces approximately one mutation in every 700 gametes per locus. There is a dose response correlation for ENU induced specific locus mutations in mouse spermatogonia, which have been assessed in the ▶**specific locus test** (SLT). Several studies showed that specific locus mutations were not induced when a lower threshold dose up to approximately 38 mg ENU/kg body weight was applied. This threshold is presumably due to the presence of DNA repair mechanisms that, below a certain dose, are not saturated and able to repair the ENU induced adducts efficiently. Above this threshold, a linear correlation could be demonstrated between the ENU concentration up to a dose of 400 mg ENU/kg body weight (fractionated dose of 4×100 mg/kg) and the mutation frequency.

To date, mutation frequencies for ENU have been determined mainly in specific locus experiments but can be different for other loci depending on the phenotyping assay applied.

New molecular technologies in mutation detection at the DNA level and ▶**sequencing** have revealed mutation frequencies of ENU induced mutations in mouse embryonic stem (ES-cells) of one mutation in a gene in every 150 ES cells (2).

The efficiency of an ENU mutagenesis project is dependent on different issues such as the choice of appropriate mouse strains or the optimal dose of ENU (5). It is known that certain inbred strains exhibit different sensitivities to chemical mutagens, presumably due to different characteristics of DNA repair systems in their germ cells. In most instances, inbred strains are used for mutagenesis experiments in order to avoid the difficulties of a polymorphic genetic background in chromosomal mapping or for phenotypic analysis and characterization. Another issue is the application of the optimal dose of ENU which has already been determined for some of the most common inbred strains considering a) the period of sterility, b) the percentage of male mice that regain fertility, c) the mortality rate before or after regaining fertility and d) the mutation frequency in the F1 or G3 generation.

Forward Genetics

Within the analysis of gene functions, mutant phenotypes resulting from spontaneous or induced mutations

Large Scale ENU Mutagenesis In Mice.

Figure 1 Generalized scheme of a dominant (or semi-dominant) and recessive ENU mutagenesis screen. In both cases male mice are treated with ENU to mutagenize spermatogonia and crossed to a wild type female (generally from the same genetic background). In the dominant screen, mice of the resulting F1 generation are examined for significant phenotypic variation from the wild type phenotype. The genetic (non-congenital) nature of such pheno-deviant mice needs to be established by a confirmation cross, generally to a mouse of the same inbred strain. Only if the phenotypic change is confirmed in the resulting (G2) generation (by dominant or semi-dominant inheritance) may the pheno-deviant of the F1 generation be designated as the founder of a new mutant line. The scheme shown for the recessive ENU mutagenesis screen allows the efficient identification of potential recessive alleles in a rather small number of G3 animals. Male mice from the F1 generation are crossed back with wild type females to generate females heterozygous for the mutant allele. To generate homozygous G3 animals a limited number of females from the G2 are crossed back to their father. Pheno-deviants may be identified in the third generation (G3). To establish a mutant line, the genetic inheritance of the allele needs to be demonstrated by crossing the G3 pheno-deviant to either its G2 mother or F1 grandfather (depending on the gender of the pheno-deviant). The mutated gene may be identified by inter- or back-cross; the mouse line may be analyzed for gene function, distributed to the scientific community and archived by cryopreservation of germ cells.

have always had an important role. This strategy is also called forward genetics or the phenotype-driven approach (Fig. 1). The ability of ENU to induce different types of ▶**alleles** including loss- and gain-of-function, hypo- and hyper-morphs as well as dominant negative alleles allows the creation of allelic series of single genes. Such allelic series are a valuable tool in the analysis of gene function by revealing different and novel gene functions. The main interest in such phenotype driven approaches is the implementation of appropriate procedures to assess the mutant

phenotypes of interest. Systematic ENU mutagenesis screens have successfully been performed in several non-mammalian organisms such as fruit fly or zebra fish from which most of the genes and pathways that are involved in early development have been identified. The first ENU mutagenesis screens that were carried out in the mouse focused on the specific chromosomal region of the T locus. One of the largest genome-wide screens for specific phenotypes identified dominant mutations causing cataracts in mice out of which 35 different alleles were isolated. Although several thousand different mouse mutations are available, this represents only a small fraction of the estimated total number of about 30,000 genes in mammals. To close this “phenotype gap”, several large-scale and genome-wide ENU mutagenesis programmes have been launched all over the world in recent years.

In order to identify the causative mutation of an abnormal phenotype, it is first necessary to map the chromosomal localization of the mutation by ► [linkage analysis](#) using an outcross/backcross or an outcross/intercross mapping strategy in different inbred strains. An optimal condition for linkage analysis is the use of two mouse-inbred strains having high polymorphism. A backcross strategy is preferred and more efficient:

- if the mutant allele is fully penetrant or
- if the mutant allele is recessive and homozygotes are fertile.

An intercross strategy is preferred and more efficient:

- if the homozygous individuals are not fertile and
- if the mutation is recessive and affected homozygous individuals are not fertile.

Linkage analysis is performed using a genome-wide panel of ► [microsatellite](#) markers (www.informatics.jax.org) or using single-nucleotide polymorphism (► [SNP](#)) maps (www.genome.wi.mit.edu/SNP/mouse/). Computer programs such as Map manager, GeneLink or Mapmaker are available for the analysis of mouse linkage data. The analysis of for example 100 meioses results in the determination of a chromosomal region of about 10 cM (► [centi Morgan](#)).

The mapped location of the chromosome is then applied to determine the mutation in a new or already known gene by a ► [candidate gene approach](#) or ► [positional cloning](#).

Modifier/Sensitized Screen

Modifier or sensitized screens are also phenotype-driven strategies to study specific genetic interaction in particular biological pathways. The aim of such screens is to detect new alleles that enhance or suppress the phenotype of the original mutation or transgenic model (in an allelic or non-allelic, non-complementary manner). In these sensitized screens, ENU treated

males may be mated, e.g. to female mice carrying mutations in the pathways of interest. In the G1 generation, mutant phenotypes may be recovered 1) that show a completely new dominant phenotype owing to the presence of a dominant mutation that might be dependent or independent from the pathway of interest 2) that show a less (suppressor) or more severe (enhancer) appearance compared to the original mutant phenotype due to a dominant mutation, which directly affects and modifies the pathway of interest and 3) that show a mutant phenotype caused by new alleles at the locus of the original recessive mutation.

Reverse Genetics

In contrast to the phenotype-driven approaches described above, the gene-driven approach starts with a gene of interest to analyze the effect of the mutation on the phenotype. Nevertheless, most of the induced mutations by gene targeting resulted in null alleles.

With the combination of new techniques in cryobiology and the development of DNA based mutation detection methods on a high-throughput level (1), ENU mutagenesis has become important in gene-driven approaches, also called reverse genetics. The cryopreservation of spermatozoa of male mice offers the possibility of establishing a sperm and tissue bank from a large colony of male F1 or G3 offspring whose parents have been treated with ENU. In order to get mice with a mutation in a gene of interest, it is now possible to screen large numbers of DNA samples in an efficient way. The re-derivation of interesting mutants can be carried out by *in vitro* fertilization and re-implantation of two cell embryos or blastocysts into pseudo-pregnant female mice.

Another gene-driven strategy is the treatment of embryonic stem cells with ENU. The aim is the establishment of a cryopreserved bank of ENU treated ES cells that can be screened for mutations in any gene of interest. Once the mutation is identified, the phenotypic consequences are analyzed in animals derived from the germ line contribution of the mutated ES cells.

A high mutation rate coupled with high throughput mutation detection technology renders these approaches applicable to generating mutations in any gene of interest and thereby creating an allelic series of mutations.

Clinical Relevance

The relevance of ENU mutagenesis for human diseases can be assessed on at least two levels, the relation of phenotypic screens in the mouse to human diseases and the correspondence of mutated gene and phenotype in man and mice. Some examples of both aspects are given below. In addition, it will be shown how the application of ENU mutagenesis in reverse genetic

approaches can support the isolation of new alleles of known genes with importance for human diseases and how sensitized screens allow the identification of novel genes that may be associated in particular with ►polygenic diseases.

Relevance of “Model-Phenotypes” to Disease

The majority of mouse models that have been generated in ENU mutagenesis screens are of high clinical relevance (4, 8). This is primarily due to the fact that many phenotype driven screens were and are specifically designed to examine parameters that are also affected in human diseases. The general concept of phenotype driven approaches is to identify mutant lines based on, for example, morphological, physiological or behavioral parameters that are distinct from established baselines of the corresponding wild type strain. The frequency with which disease models can be identified in genome wide mutagenesis screens may be substantially increased when a large variety of parameters are assessed for each mutant line. For these reasons new non-invasive phenotypic screens are continuously being adapted for mice from human clinical examinations.

External and non-invasive screens for dysmorphologies may reveal phenotypic abnormalities, for example of sense organs, the limb or axial skeleton, the skull, pigmentation of hair or skin or other anatomical structures, which may be relevant for the identification of genes affected in human congenital malformations. X-ray and computer tomography have been adapted to small rodents, so that they can reveal subtle dysmorphologies of the skeleton and soft tissues comparable to the precision achieved in human examinations. Simple behavioral tests including, for example, click-box-tests (for hearing), have successfully been used to identify new mouse models for congenital malformations and progressive degeneration of the sensory patches or vestibular structures of the inner ear. Examination of the eye lens using the split lamp or electro-retinograms to measure action potentials in the retina are examples of efficient tools to identify models for diseases affecting the eye. Clinical chemical and biochemical metabolite assays may assess, for example, blood plasma enzyme activities and plasma concentrations of electrolytes and metabolites using blood auto-analyzers that are comparable to those used in clinics. These parameters are of particular importance for human disorders. For example, abnormalities in glucose metabolism may be indicative of diabetes, serum urea levels may be related to gout and so on. In addition, alterations in the immune system that are characteristic of, for example, autoimmune disease, allergic reactions or pathological changes in immune cell populations in man may also be assessed in the mouse by applying fluorescence associated cell sorting

(FACS) or enzyme-linked immunosorbent assays (ELISA). Atherosclerosis, hypertension, and other cardiovascular diseases are major causes of mortality. The screening of cardiovascular disorders in mouse models involves the examination of cardiac functions, blood pressure regulation and measurement of cardiovascular hormones and lipoprotein metabolites. Primary, non-invasive screens in the mouse may include, for example, echocardiography or plethysmographic measurement of blood pressure. Exercise capacity examinations are also possible in the mouse model. Such cardiovascular screens are directly adapted from human examinations.

Other relevant screening parameters to identify mouse models for human diseases include, for example, lung function tests, metabolic screens, measurement of metabolized energy, standardized behavioral tests with relevance for human psychology and genome wide gene expression analyses to name just a few. The phenotypic screens that are being used to find novel mouse models for human diseases in ENU mutagenesis (and other mutagenesis and targeting) approaches continue to be refined and standardized. Novel screens are being adapted while the mouse model system becomes increasingly important for the study of the molecular and genetic bases of human diseases.

Relevance of “Model-Mutations” to Diseases

After having generated several thousands of mouse models in large-scale ENU mutagenesis screens, attention is beginning to shift from the generation of new disease models to the identification of the underlying mutation and the affected gene(s). Two examples will be given in which the identification of the mutated gene in the mouse was accompanied by the identification of mutations in the homologous gene in man resulting in related disease phenotypes. These findings demonstrated that the mouse provides not only a “phenotypic model” but also a direct “genetic model” for the human disease, at least for some gene/phenotype relations in both species.

The first example is an ENU induced mouse mutant line that was discovered as a congenital zonular cataract with progressive opacity (*Po*) and a semidominant mode of inheritance. The induced T to A substitution was found to affect the fourth Greek key structural motif in the β A1- and β A3-crystallins, both encoded by the *Cryba1* gene (3). A mutation in the human homologue, *CRYBA1*, is phenotypically very similar to the *po* allele. Thus, this particular mouse mutation provides an excellent model for a human congenital zonular cataract with suture opacities, caused by a mutation in the homologous gene.

The second example is the semidominant *Beethoven* (*Bth*) missense mutation in the *Transmembrane Cochlear-Expressed* gene (*Tmc1*). This mutant line

is phenotypically characterized by progressive hearing loss and degeneration of cochlear hair cells (10). At least one ►**dominant allele** (DFNA36) has been identified in the human homologue *TMC1* that is associated with progressive hearing loss (6). This makes *Bth* an invaluable model to study postlingual deafness and could also provide new insights into the factors needed for long-term survival of hair cells. The examples above stand for many other mutant lines that have demonstrated the clinical relevance of ENU induced mutations.

Application of Reverse-Mutagenesis-Genetics to Identify Novel Disease-Alleles

With the availability of high-throughput sequencing infrastructures and the hundreds of thousands of mutagenized genomes that have been archived, it has now become possible to profit from ENU mutagenesis in reverse genetic approaches also. In this strategy, selected genes of clinical relevance may be sequenced in thousands of ENU mutagenized mouse genomes to identify potentially interesting mutations in these genes. The corresponding mouse mutant lines may then be re-derived from frozen sperm or oocyte archives and the phenotype can be assessed.

Application of Sensitized Mutagenesis to Identify Polygenic Disease Genes

In sensitized screens, a known mutation in a single gene is used to simplify the identification of genes or pathways involved in polygenic diseases. In such an analysis one mouse mutant line carries a mutation that is associated with a particular disease or ►**trait**. The second line is mutagenized (but may also carry the sensitizing mutation – depending on whether modifiers are sought in the heterozygous or homozygous background). The phenotypic screen in the filial generation of both lines may identify, for example, dominant modifiers (enhancers or repressors) of a quantitative or qualitative trait (recessive modifiers may be identified in subsequent generations). The relevance for human diseases in sensitized polygenic trait analyses is through the selection of the sensitizing mutation (involved in a disease) and the (disease-relevant) phenotypic screen (7).

Large-Scale Gene Trap Approaches in Mice

PATRICIA RUIZ

Center for Cardiovascular Research, Charité University Medicine Berlin and Max Planck Institute for Molecular Genetics, Berlin, Germany
ruiz@molgen.mpg.de

Definition

Since mouse mutants are valuable resources for the study of mammalian gene function in the context of the whole organism, large-scale mouse ►**mutagenesis** programs have recently gained increasing attention. Several mutant collections have been established with this aim using either a phenotype- (1) or a gene-driven

approach (2). The development of high-throughput mutagenesis screens in the mouse using ethylnitrosourea (ENU) and gene trap vectors has enabled an efficient large-scale mutagenesis approach. The main advantages of these systems are that (i) many more genes can be mutated at once and (ii) no initial knowledge of gene structure or sequence is necessary to mutate a given gene.

Within the concept of tackling gene function with a ►gene-driven approach, there are basically two methodological ways of approaching the problem:

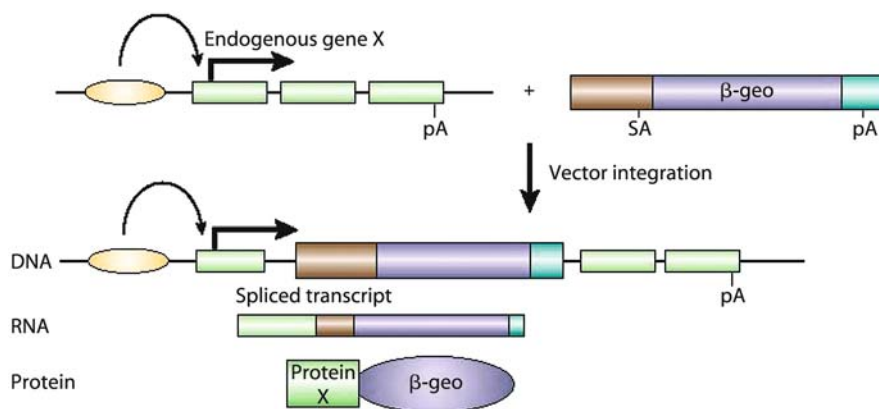

1. the generation of defined mutations in the gene(s) of interest (e.g. over-expression, ectopic expression or inactivation of a gene and knock-in of a modified gene product isoform, conditional mutations using cre-loxP).
2. the non-directed, systematic generation of mutants without any previous knowledge of the gene to be mutated (e.g. gene traps, mutagen-treated ES-cells).

Homologous recombination in ES-cells has led to the development of hundreds of mouse mutants that have aided in the annotation and functional characterization of many genes (3). Although very successful, this method is still very work- and time-consuming and has been prone to a high degree of redundancy; over the last 15–20 years ~7,000 genes have been inactivated. An overall estimation would therefore predict 70–100 years before a given mouse mutant would be available for all mouse genes (assuming the current calculation of 25–35,000 genes/transcripts). Gene trap technology was developed to contribute to the goal of saturating the mouse genome with mutations. Since it combines gene trap vector and ES-cell technologies, it offers the possibility of applying high-throughput methods to this ambitious goal.

Characteristics

The non-directed insertion of different selector cassettes with or without minimal promoters had led to the identification of many new genes and enhancer elements in bacteria, *Drosophila* and *C. elegans*. The enhancer traps were adapted to the mouse system 15 years ago, but had to be largely modified to identify and at the same time mutate genes of a much more complex organism such as the mouse. Therefore, splice-acceptor (SA) sites were inserted 5' to a reporter/selector gene cassette (2). Whenever such a vector integrates into an intron of an active gene, the cassette becomes posttranscriptionally fused to the 5' upstream exon. A fusion transcript and a fusion protein are obtained and neomycin (G418) resistant ES-cell clones can be selected (►intron trap vectors) (Fig. 1).

Gene trap vectors without an additional splice acceptor (SA) allow the insertion into exonic regions of transcriptionally active genes (►exon trap vectors). Again, a fusion protein allows the selection of neomycin-resistant ES-cell clones with the corresponding gene trap insertion and mutation. One limitation of these vectors is that only genes transcriptionally active in undifferentiated ES-cells can be trapped. In order to trap genes transcriptionally inactive in ES-cells, a new generation of vectors has recently been developed, the ►poly-A trap vectors, carrying a promoter-driven neomycin cassette but no poly-A signal. In this case, a functional neomycin-resistance gene cannot be encoded by the vector itself. Instead, a splice donor (SD) site was added 3' to the neomycin cassette. By these means an integration into an intron leads to splicing to the next 3' exon, leading to the polyadenylation and therefore to the translation of the neomycin cassette. Since expression of the neomycin cassette does not depend on the endogenous promoter,

Large-Scale Gene Trap Approaches in Mice. Figure 1 The insertion of the β geo vector generates a fusion transcript and a fusion protein from the β geo reporter gene and the upstream exon of gene X, providing that gene X is transcriptionally active in undifferentiated embryonic stem (ES) cells (adapted from Stanford et al. 2001).

genes transcriptionally inactive in ES-cells can be trapped, identified and eventually functionally characterized.

At the same time retroviral vectors were developed. These vectors carrying the SA recognition site of the adenovirus and a LacZ/neomycin fusion cassette are transferred into ES-cells *via* infection. Without regard to the vector type used, ES-cell clones can be further selected based on the expression of the reporter gene, e.g. ►LacZ. This feature will be essential later on when analyzing gene expression in the organism, e.g. at different stages of embryonic development or in different cell types. The crucial and common attributes of all the different vectors are (i) that the expression of the reporter/selector cassette is under the regulatory control of the trapped gene and (ii) that the trapped gene is mutated due to the insertion.

Many mouse mutant lines have been established meanwhile with all the different types of vectors. It has thereby been shown that the LacZ reporter gene does indeed reflect the endogenous gene expression of the trapped gene *in vitro* as well as *in vivo* (Fig. 2).

In addition, the analysis of gene trap mouse mutants has shown that the mutagenicity of the vectors seems comparable to that obtained using homologous recombination in ES-cells. The trapped genes in homozygous mutant animals were usually inactivated and in ~60% of the homozygous mutant mice an obvious ►phenotype could be detected.

The characterization of the trapped genes is indispensable for the functional analysis of the genes and for

the phenotype analysis (genotype-phenotype correlations) of mouse mutants. The trapped genes can be identified using PCR-based strategies (5' RACE, rapid amplification of cDNA ends) and in combination with ES-cell technology (e.g. injection of ES-cell clones into host blastocysts or aggregation chimeras) a mouse mutant line can be generated. In the first instance, RNA from neomycin-resistant ES-cell clones is isolated, cDNA synthesized using either random or poly-d(T) primers and primed with vector-specific as well as with synthetic primers in a nested-PCR approach. The obtained PCR products contain at their 5' ends sequences corresponding to the exons of the endogenous gene. By direct sequencing of these PCR products and sequence comparison analysis using publicly available databases the trapped genes are identified. Currently available databases (e.g. Ensembl, GeneCards, SwissProt, OMIM) enable the characterization of many of the trapped genes at genomic, transcript and protein levels, offering a wealth of information and a basis for the identification of genes relevant for e.g. human disease in general and developmental processes in particular.

Gene trap vectors have been developed and modified more or less extensively according to many prerequisites (4). For instance, an induction-trap vector was designed to trap, identify and mutate genes relevant to certain signal transduction pathways. Different soluble factors (e.g. retinoic acid, growth factors) were added to the ES-cell cultures and cells selected for the expression of a given reporter gene. By inducing or repressing the expression of such a reporter gene, genes can be trapped that are under the control of the given factor. Furthermore, many secreted and/or receptor molecules represent interesting targets for pharmacological approaches and putative pharmaceutical studies. Since such targets seem to be underrepresented in screens employing classical vectors, the design of alternative vectors has been enforced (5, 6). A prominent example is the U3Ceo vector, a retroviral gene trap vector containing a human CD2 cell surface antigen/neomycin-phosphotransferase fusion gene in the U3 region of its LTR. U3Ceo was used to screen the mammalian genome for genes encoding secreted and/or transmembrane proteins (6). Molecular analysis of a random sample of neomycin-resistant clones revealed that the U3Ceo gene trap vector indeed preferentially disrupted genes coding for secreted and transmembrane proteins.

Large-Scale Gene Trap Approaches in Mice.

The German Gene Trap Consortium

In 1998 the German Gene Trap Consortium (GGTC) was established within the framework of the German Human Genome Project (DHGP) and carries out large-scale gene trap mutagenesis in ES cells. Its goal is to contribute to the saturation mutagenesis of the mouse

Large-Scale Gene Trap Approaches in Mice. Figure 3 The German Gene Trap Consortium's database (a) offers access to more than 18,000 mutated and characterized ES-cell clones. In addition, it enables searching of the data using keywords (b), DNA sequences and accession numbers.

genome and to generate a mouse model for each gene in cooperation with the International Mouse Mutant Consortium (IMMC). Towards this goal, the GGTC has generated 16,000 mutant ES cell lines and has identified the gene trap integration sites. Of the generated gene trap sequence tags (GTSTs), 8,689 informative sequences were obtained of which 6,077 corresponded to known mouse genes, 1,288 to known homologous genes, 483 to ESTs and 295 to putative novel genes (7). Data obtained from individual clones, such as GTSTs, expression patterns and phenotypes, are deposited in the GGTC's database, which is publicly accessible via <http://genetrap.de> (Fig. 3). For the first time, the insertion performance of four different gene trap vectors, pT1 β geo, pT1ATG β geo, U3 β geo and Rosa β geo was compared (7). The integration sites of all vectors were found randomly and evenly distributed over the entire mouse genome, although several hot spots were identified for the different vectors. These turned out to be common to all the different vectors as well as vector-specific, although gene size independent. In addition integrations into all the different classes of gene products were identified. Signal-sequence containing proteins were underrepresented.

Clinical Relevance

In attempting to engineer a mouse model for a human disease, it is important to know what kind of mutation causes the disease and if possible introduce the same kind of mutation into the mouse gene. Mutants corresponding to genes associated with human diseases are of particular value and interest. An ideal mutant collection would therefore contain mutants for every human gene

and for every phenotype or disease, to the limit of species differences between humans and the mouse.

According to the Online Mendelian Inheritance in Man database (OMIM), out of all the gene trap integrations into previously characterized genes 159 insertions characterized by the German Gene Trap Consortium occurred in genes involved in human disease (e.g. Emery-Dreyfuss muscular dystrophy, epidermolysis bullosa dystrophica, Huntington disease, xeroderma pigmentosum). Furthermore, over 100 germline chimeras were generated by this consortium and 60% of the resulting homozygous mutants exhibited an obvious phenotype either at embryonic stages or during adulthood. Indeed, the suitability of these mouse mutants as models for human disease was also shown; gene trap mouse mutants with an insertion into the *Nephrin* gene perfectly mimic the human congenital nephrotic syndrome CNF (8). However, to circumvent embryonic lethality and enable the analysis of gene function in the adult mouse, novel gene trap vectors that induce conditional mutations in ES cells are currently being developed and implemented (9).

One can conclude that gene trap mutagenesis is an efficient approach for annotating and dissecting the function of mammalian genes. Its large-scale implementation has already enabled the worldwide establishment of several databases containing GTSTs from thousands of mouse genes (e.g. <http://genetrap.de>, <http://baygenomics.ucsf.edu>). Collectively, these databases provide an unprecedented resource for the scientific community in the postgenomic era, as clones from the corresponding ES cell libraries can be used immediately to cost-effectively generate mouse models

of human disease. Clearly, the goal of understanding the function of every gene in the genome could be attained more quickly with the establishment of ES cell libraries with mutations in every single gene. Since each gene trap vector appears to have its own set of genomic integration targets, the most effective generation of an ES cell library saturated with mutations must involve a collection of different gene trap vectors. The ongoing collaboration within the International Mouse Mutagenesis Consortium can be expected to achieve the complete saturation of the mouse genome within the next few years.

Definition

Homologous recombination (HR) is the precise strand exchange of a section of host DNA sequence for an externally derived sequence. Homologous recombination is dependent upon shared sequence homology between the host target DNA (e.g. the embryonic stem cell genome) and the externally derived sequence (i.e. a targeting construct or vector) and aims to genetically modify the host target region permanently (1, 2, 3).

Mouse embryonic stem (ES) cells are immortal, non-transformed cell lines derived from the inner cell mass of a ►blastocyst (~3.5 days post fertilization). Mouse ES cell lines have been derived from multiple inbred mouse strains, including 129/Sv, C57BL/6, BALB/c, etc and from F1 hybrids (4, 5, 6). When reintroduced into the embryo, ES cells can colonize the developing embryo, giving rise to chimeras containing ES cell contributions to all cell lineages including the germline. HR in mouse ES cells is the principal tool for creating specifically genetically modified mice. The process is known as a targeted mutation or gene ►knockout (KO) and produces “knockout mice” (generally designed to generate a ►null phenotype, although other modifications are possible), ►knock-in mice, where the modification is a functional replacement with an alternative sequence and knockdown mice, where the gene expression level is reduced.

Large scale HR in ES cells represents a shift from the research scale, where a few genes or host sequences are modified per year per lab, to a scale where many hundreds of genes per year are modified at a single facility. This shift involves a fundamental change in laboratory philosophy from a single gene being the principal driving parameter to the overall robustness and final efficiency of hundreds of gene modifications.

Characteristics

It is estimated using comparative data from the mouse and the human genome that there are ~35,000 genes in the mammalian genome. These genes operate interactively with the environment defining the organism, be it woman, man or mouse.

HR in ES cells with subsequent germ line transmission is a methodology to help us understand how a gene or other DNA sequence functions, by modifying it and observing the effect (the phenotype) in the resulting organism. In its crudest form, this involves destroying the gene under study by the precise removal or interruption of part or all of the genomic sequence under study (null mutation) with the resulting (homozygous) animals having a null phenotype, although varying degrees of partial loss or modified function (►hypomorph, ►hypermorph, etc) can occur at times serendipitously.

In more advanced incarnations, HR is used to create more subtle modifications of a gene or other region of

the genome. These modifications can range from a single base change mimicking, for example a sequence polymorphism, to major changes reconstructing a human disease ►[phenotype](#) in the mouse. Such modifications, called “humanization” are being used to assist pharmacogenetic research, including disease control and toxicology studies e.g., allowing the monitoring of a drug-substrate interaction with a human protein in a non-human animal test system (7). HR gene modification is also used to engineer changes that are under spatial and/or temporal control. Such genetically engineered mutations are referred to as conditional KO’s as the gene modification effect only occurs in cells upon the fulfilling of defined preset conditions. There are many rapidly evolving methods to achieve conditional gene modifications. One approach, for example, uses a vector containing ►[LoxP](#) sites flanking the region to be modified. This leaves the region unchanged until a recombination event is initiated using the LoxP sites. These sites act as a recombination substrate for ►[Cre recombinase](#). When the recombinase is present in the cell, sequences between the two LoxP sites are deleted. This genetically modifies the targeted locus irreversibly, but only in cells where Cre recombinase is expressed (8, 9). Using animals that contain the Cre recombinase under specific (i.e. temporal and/or spatial) control allows target loci to be genetically modified upon command, giving exquisite control of when and where the targeted gene/region is modified. Cre recombinase expression can be made inducible (e.g. by tetracycline), again allowing exact control of a genetic modification event.

Large-Scale Processes – Outline of Operating Concepts

When planning a production line it is essential to view the process as a whole. This global view of a process is one of the principal philosophy shifts when a research tool or process is industrialized. This viewpoint allows the definition of operational principals and current working methodologies and begins to help develop policies. Below is a non-exhaustive listing of considerations to help to visualize such a pipeline.

Detailed laboratory protocols for various steps of a HR pipeline are available in publications such as (10, 11, 12, 13).

Operating considerations include the following:

- a) Definition of the desired outcome, including expected output animals, goals, including costs and timelines, i.e. what is the goal of this pipeline.
- b) Which genes – i.e. selection criteria for targeted gene families and/or gene types.
- c) Desired gene modifications, e.g. KO, knock-in, conditional KO, ►[knockdown](#), etc.
- d) Derivation, number and method of construction of DNA vectors, e.g. isogenic DNA, use of

- [bacterial artificial chromosome](#) (BAC) with recombinogenic engineering (14), use of lambda phage DNA or DNA generated by ►[long range PCR](#) (LR-PCR) using available sequence information followed by ligation construction (15), etc.
- e) Vector verification ►[quality control](#) (QC) methods and depth, e.g. ►[PCR](#), restriction digests, sequencing etc.
- f) Use of cell expression lineage markers incorporated into the vector design, e.g. ►[LacZ](#), green fluorescent protein (GFP), ►[alkaline phosphatase](#) reporter (16) etc and reporter localization signals, e.g. nuclear, membrane etc.
- g) System/s for the selection for HR events in ES cells during culture, e.g. G418, positive-negative selection etc.
- h) ES cell line germline competence and ►[genetic background](#), e.g. inbred strains such as 129S1/SvImJ, C57BL/6J or hybrid F1 strains etc. This also influences the need for feeders and the overall robustness of the cell culture stage.
- i) Selection and isolation methods after ES cell ►[electroporation](#), as well as the number of ES cell clones to be screened for HR events and the screening method used, e.g. ►[Southern blot](#), LR-PCR, ►[FISH](#), ►[quantitative PCR](#) etc, including independent verification of HR events.
- j) Number of independent ES cell clones required for each construct and each gene.
- k) Chimera production, e.g. *via* ►[aggregation](#) or ►[blastocyst injection](#), definition of host embryo strain, details to include the acceptable chimera level and subsequent breeding strategies.
- l) Number and quality of chimeras produced per ES cell clone.
- m) Methods for mouse genotyping and verification of HR transmission of chimera offspring, e.g. coat color followed by PCR analysis or Southern blot.
- n) Establishing goals for each stage of the output as well as reiteration limits, i.e. when to give up on a particular gene, construct, electroporation, ES cell screening, number of chimeras, number of breeding rounds for ►[germline transmission](#) etc (i.e. define step reiterations for each stage). This should also include what actions needs to be taken to deal with recalcitrant genes, e.g. repeat, change construct, drop etc.
- o) An effective pipeline communication and information storage/control system is an absolute requirement, i.e. a controlling database allowing efficient pipeline process control and interrogation.

The first step in designing a large-scale process is to obtain a functional pilot pipeline. This is used to define feasibility and limits for each part of the process, allowing adaptation etc where needed. It is crucial to

Large-Scale Homologous Recombination Approaches in Mouse Embryonic Stem Cells. Table 1 For the process of Large Scale HR in ES cells suggested operational units could be as follows

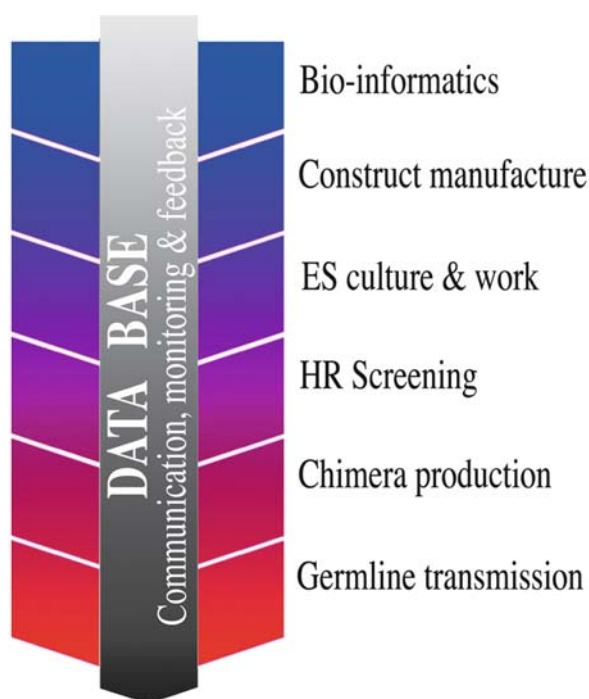

Units		Responsibilities
1	Bio-informatics	Target identification, theoretical construct design, ►QC for pseudogenes and published data
2	Construct manufacture	Vector building and QC, plus designing analytical probes for screening HR events and subsequent genotyping of animals
3	ES culture	General ES cell maintenance and QC, vector introduction, clone isolation, cryopreservation and clone DNA for screening
4	HR Screening	Screening for HR events and QC of HR events
5	►Chimera production	Supply of host embryos, ►pseudopregnant females and production of chimeras
6	►Germline transmission	Initial screening for germline transmission, breeding/maintenance of genetically modified animals

define each operational methodology before charging ahead. Essentially, if a process does not work (well) on a small scale, it won't work when scaled up. On the other hand, no matter how exhaustive the pilot studies are, they can never be perfect in predicting how the scale up will perform. It is a balance between seeking perfection in the pilot study and the desire to move on and scale up rapidly. As each of the processes is defined, scale up can begin – carefully. These ideas are obvious but they are too often ignored, possibly leading to the scale up becoming an expensive quagmire of technical problems and delays.

As the pipeline scales up, communication between the various units becomes the essential tool in maintaining process control. The best communication tool is a user-friendly, flexible database allowing complete access and interchange of information between the various units over the whole process. The control database should be designed to provide complete process tracking information and, importantly, serve as an early warning system. If designed well, it will assist in spotting problems *before* they impact the entire process.

Outline Units

It is readily apparent that a process pipeline for homologous recombination in ES cells is a complex operation involving many quite different technologies. It is therefore convenient that the process be broken down into operational units or teams (Table 1), each unit having defined goals, process QC methods and trouble shooting routines. This facilitates control and continual optimization as each unit's input and output can be isolated and monitored. Further, by placing people in teams responsible for a unit, the management of the whole process is simplified (Fig. 1).

Large-Scale Homologous Recombination Approaches in Mouse Embryonic Stem Cells.

Figure 1 Process flow pilot studies will help define a series of units. Although the subdivisions may appear artificial in some cases, the idea is that they be viewed as "gates" allowing the isolation of stages, each with defined limits, inputs, outputs, QC and specific trouble shooting routines. If a unit's goals are not reached, this can be easily seen and the situation analyzed in isolation.

It is essential for any industrial process that ►**standardized operating procedures** (SOPs) and relevant QC protocols be established for each procedure and a unit's output. Further, it must be stressed that these SOPs and QC protocols be followed, updated when necessary and not allowed to fall into disuse. Abandonment of SOPs is a recurring problem giving rise to "►**protocol mutagenesis**", i.e. loss of control of the methodologies used. If unchecked this will lead to degradation of the pipeline and a loss of the ability to trouble shoot individual steps efficiently. At the same time, innovation must be allowed to enter the process. New ideas, methods or technologies are continually arising; these should be looked at and if worthwhile implemented with care, together with the updating of all SOPs and QC protocols.

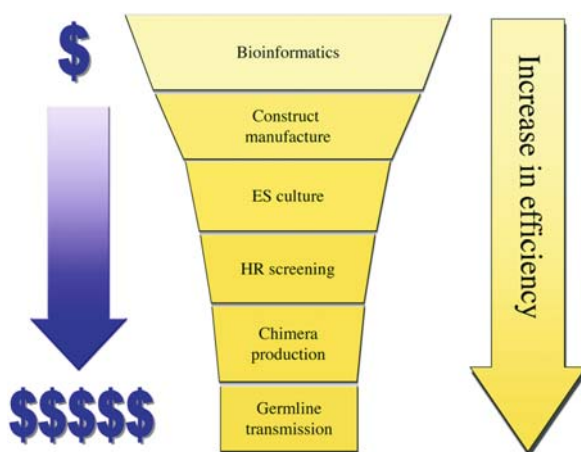

In establishing large scale HR in ES cells, it is the final speed and efficiency that are the key measures of success. For any multiple stage process the final efficiency is 100% minus the cumulative failure of each of the process units (Fig. 2). For example, in a pipeline consisting of ten units, if each unit has an internal failure rate of 5% the pipeline will produce ~60% of its original input (e.g. if 1000 genes are selected as genetic targets, ~600 will make it though the complete process). Accordingly input has to be adjusted. The use of units allows the allocation of resources in the most efficient manner. However, when dealing with limited resources, not all units are equal. In general it is acceptable that units at the initial stages

can have a higher failure rate than later ones. This is due to cumulative costs – i.e. as an individual project travels through the process pipeline its actual value, as calculated by the resources spent on it, increases. Hence errors need to be removed before they have traveled far in the pipeline, otherwise they will have a higher negative financial impact. A QC process should be established which reflect this, for example, it is better to stop a 'dubious' DNA vector construct when the investment is still low, before the whole process of making chimeras is reached.

General Discussion

The process described, especially if it is to be developed on a truly large scale, is complex and expensive. It is therefore worth investing effort in the forward planning, as once errors are built into a process they are costly financially and in time lost. Pilot studies will help in building the system and will assist in developing a whole series of QC measures to prevent expensive errors. However, the main elements in such a labor-intensive endeavor are the people involved. It is vital that the teams and especially the team leaders fully understand not only the processes involved in their section but also how their work is an integral part of the whole process. Personnel are also one of the most expensive elements. The use of robotic systems can increase efficiency and reduce human errors in what can be boring, but high precision, work. As a pipeline is piloted, some steps will obviously be open to using robotic approaches. Robots can also reduce repetitive strain injuries, an intrinsic problem with this type of work. If used imaginatively, robots can bring in completely novel methods that, for example, would not be practical for people. However, such machines must be viewed with caution. For example, will a robot actually do the work more efficiently than a person equipped with electro-mechanical pipette aids? Further, robotic systems generally involve a large capital investment. Once installed, they can inhibit subsequent innovative process enhancements, i.e. they lack adaptability. However, in general, once a process has matured and the methodology is stable, robotics brings considerable increases in efficiency and accuracy in processing, when applied to labor-intensive sections and process bottlenecks.

In any industrial process and especially in the rapidly developing field of molecular biology, it is important to avoid ossification. Whatever pipeline is constructed, it will be a combination of innovative ideas and expedient compromises. As such, the process pipeline should be under constant review for efficiency improvement, ranging from the individual units to reassessing the reasoning and method of the entire process, i.e. keep asking, "Why are we doing this" and "Is this the best way to do it?" In the case of HR in ES cells, the general need is to produce animals that have specific permanent

Large-Scale Homologous Recombination Approaches in Mouse Embryonic Stem Cells.

Figure 2 For a multistage process the final efficiency is 100% minus the cumulative failure of each process step. When setting up large-scale HR screens with the aim of generating genetically modified mice, one has to keep in mind that there is an increase in the money invested in the later stages of the process. The QC processes should reflect this.

genetic modifications. In this field new technologies are continually arising, eventually they will have an impact on any current approach used. For example, possible new methods that may give us similar results include reverse genetic methods, transgenics expressing RNAi or perhaps even HR directly in oocytes (17). Such novel methodologies are the substance of opportunity, not threats. The final goal must be kept in mind, not the protection of antiquated processes.

Clinical Relevance

The use of homologous recombination in ES cells allows the development of genetically modified animals that offer almost unlimited possibilities for developing models that advance the understanding of gene function. Gene targeting allows the design of tractable model systems, assisting target discovery and validation. The data obtained allow the dissection of disease pathways and establish new disease models for drug development including safety assessment (18, 19, 20). Additionally, knock-ins using human genes have the potential to revolutionize drug development.

Gene targeting technology is now at the level where it can be performed on a scale similar to the human genome-sequencing project (21). The data obtained are already building a bridge between ►genomics and ►proteomics – from sequence to function.

Laryngospasm

Definition

Laryngospasm describes a spasmodic closure of the glottic aperture.

►Hyper-and Hypoparathyroidism

Laser Capture Microdissection

Definition

Laser capture microdissection (LCM) refers to a method for isolating a homogeneous population of a

single cell type from any tissue section. LCM uses infrared laser to adhere a single cell or region of cells to a specially coated cap, which can then be lifted from the tissue.

► [Genomic Information and Cancer](#)

LCA

► [Leber's Congenital Amaurosis](#)

Laser Interferometer

Definition

Laser interferometer is an optical system that uses the interference from two coherent beams to assess the optical path length differences, resulting from differential refractive index or distance changes along the light paths.

► [Analytical Ultracentrifugation](#)

LCM

► [Laser Capture Microdissection](#)

Lateral Inhibition

Definition

Lateral inhibition is a well studied mechanism in *Drosophila*, and describes how Notch signalling leads to the selection of a single neural precursor cell from a cluster of equivalent cells that are marked by the expression of proneural genes.

The term is also used to describe how activity in one area of the visual processing system will tend to produce a dampening effect on other areas of the same system. For example, activity in a given photoreceptor of the retina will inhibit activation in nearby photoreceptors via inhibitory synapses.

LD

► [Linkage Disequilibrium](#)

LDL

► [Low Density Lipoprotein](#)

LDL Receptor

Definition

LDL (low density lipoprotein) receptor is a membrane protein of 839 amino acids, which is responsible for cholesterol uptake into cells via receptor-mediated endocytosis of cholesterol-rich particles secreted by the liver. LDL receptors are receptors on the cell surface that remove LDL and some other forms of lipoproteins from the plasma into the cell.

The LDL receptor gene is located on chromosome 19 (p13.1-p13.3). It spans 45 kb and comprises of 18 exons and 17 introns.

Leader Signal

Definition

Leader signal denotes a specific amino acid sequence at the N-terminus of a protein targeting it to specific cell

Leber's Congenital Amaurosis

Definition

Leber's congenital amaurosis (LCA) denotes a heterogeneous group of inherited retinal dystrophies, causing severe visual loss with nonrecordable or a largely reduced ERG response, either congenitally or in very early childhood. The fundus of the eye is marked by an usually flecked appearance with loss of retinal pigment epithelium and/or pigment deposit. Many cases of Leber's congenital amaurosis are caused by dysfunction of an isomerase important for the retinoid cycle induced by a mutation in the ► [RPE 65 gene](#).

► [Retinitis Pigmentosa](#)

Leber's Hereditary Optic Neuropathy

Definition

Leber's hereditary optic neuropathy comprises of a group of disorders most commonly affecting males, and is inherited through the maternal line affecting vision and resulting from pathological mutations of mitochondrial DNA.

► [Genetic Predisposition to Multiple Sclerosis](#)

LEF/TCF Family

Definition

LEF-1 (lymphoid enhancer factor-1) and TCF (T cell factor) are members of a family of DNA binding proteins (HMG box transcription factors) that affect the expression of specific genes, and are downstream components of the Wnt signaling pathway. All proteins interact with β -catenin at an N-terminal domain, and with DNA via the HMG (high mobility group) box.

Leptin

Definition

Leptin is a hormone of ~16 kDa which is encoded by the obese (ob) gene. Leptin is an important regulator of food intake, body weight and energy metabolism. Leptin is mainly produced and secreted from adipocytes (fat cells). It appears that as adipocytes increase in size due to accumulation of triglyceride, they increase their rate of leptin secretion. Thus, there is a strong positive correlation of serum leptin concentrations with percentage of body fat. Via leptin receptors in areas of the hypothalamus the hormone signals to the brain the size of the peripheral adipose tissue deposits. Leptin levels are considerably decreased in narcolepsy.

► [Narcolepsy](#)

► [Obesity](#)

Leptomycin B

Definition

Leptomycin B is a secondary metabolite (an unsaturated branched fatty acid chain) produced by *Streptomyces sp.* with known antifungal and antitumor effects. It is a potent inhibitor of nucleocytoplasmic export and exhibits significant antiproliferative activity.

► [Actin Cytoskeleton](#)

Leptotene

Definition

Leptotene describes the earliest stage of prophase 1 of the meiosis, when the despiralized chromosomes first

become visible as fine threads and have not yet associated in pairs. (Gk. leptos, thin; taenia, ribbon.)

► [Meiosis and Mitotic Recombination](#)

Lethal Mutations

Definition

Lethal mutations are mutations in genes that result in the death of the organism. Such mutations can be genetically visualised using genetic balancers covering the region of the mutation.

Leucine Zipper

Definition

The leucine zip or zipper is a motif that mediates protein-protein interaction. It describes the coiled-coil dimerization of two α -helical-like polypeptides, by interdigitation of periodic leucines or other hydrophobic or bulky amino acids, which lie along the cylinder of the monomeric α -helix. This has the effect of sequestering the hydrophobic residues away from the aqueous environment of the cytoplasm and so forms a very stable dimer. It is an association seen in a large number of protein dimers from transcription factors (usually short stretches) to intermediate filaments (where they can be very long).

Leucine Zipper Transcription Factors: bZIP Proteins

ANDREAS G. BADER, PETER K. VOGT

The Scripps Research Institute, La Jolla, CA, USA
pkvogt@scripps.edu

Definition

bZIP proteins are ► [transcription factors](#) that consist of three modular functional regions mediating dimerization, DNA binding and transcriptional regulation. The hallmark of these proteins is the bZIP (basic region, leucine zipper) domain, a well-defined motif in eukaryotic proteins (1, 2). The basic region of the bZIP domain, rich in lysines and arginines, represents the DNA contact surface, interacting with the major groove of the DNA double helix. The zipper region is an ► [amphipathic](#) helix of 30–40 residues with every seventh residue a leucine. These leucines, together with the intervening residues, form a zipper-like structure that dimerizes with the corresponding region of a partner bZIP protein.

Characteristics

Proteins with a bZIP domain are grouped into one super-family. They are distinct from other proteins that contain similar structural elements like the numerous proteins with only leucine zippers or the basic helix-loop-helix leucine zipper proteins in which basic region and leucine zipper are functionally equivalent to those of bZIP proteins but are separated by an intervening helix-loop-helix region (2, 3). There are seven bZIP protein families, Jun, Fos, ATF, CREB, C/EBP, Maf and PAR (Table 1). This classification is based on ► [protein homology](#) and DNA-binding specificity (4, 5). To become biologically functional, a bZIP protein must dimerize with another bZIP protein. Dimers can form between members of the same bZIP family or between members of different families. Some bZIP proteins form exclusively homodimers; others are only capable of heterodimerization. A third category can homo- as well as hetero-dimerize, with one combination energetically favored over all other possible unions. Dimerization specificity is determined by the non-leucine residues in the zipper region (5, 6).

Cellular and Molecular Regulation

One of the best-characterized bZIP proteins is Jun. Jun was originally recognized as the ► [oncoprotein](#) of the avian ► [retrovirus](#) ASV17. Sequence homology and DNA binding properties led to the identification of the cellular Jun as a component of the ► [AP-1](#) transcription

Leucine Zipper Transcription Factors: bZIP Proteins. Table 1 Human bZip protein families and their members

Protein family	Name	Protein members
Jun	v-jun avian sarcoma virus 17 oncogene homolog	c-Jun, JunD, JunB,
Fos	FBJ murine osteosarcoma viral oncogene homolog	c-Fos, FosB, Fra-1, Fra-2, JDP1, JDP2
ATF	activating transcription factor	ATF 1-7
CREB	cAMP responsive element binding protein	CREB1, CREB3, CREM, CREB-H, CREB-L1
C/EBP	CCAAT/enhancer binding protein	CEBPa, CEBPb, CEBPd, CEBPe, CEPBg
Maf	avian musculoaponeurotic fibrosarcoma virus homolog	c-Maf, MafB, MafG, MafF, MafK, NRL
PAR	proline and acidic rich	DBP, TEF, HLF

factor complex (7, 8). The classic AP-1 dimer consists of Jun and Fos. Other combinations include the Jun relatives JunB and JunD; Fos-related proteins or ATFs are also found as components of AP-1. Jun can form weak homodimers; heterodimers with Fos are significantly more stable. Fos family proteins cannot homodimerize. *In vivo*, the composition of bZIP dimers is determined by partner concentrations and subcellular distribution (9).

The three-dimensional structure of the bZIP domain has been determined by X-ray crystallography of the Jun homolog GCN4 from yeast and of the Jun-Fos heterodimer (10, 11, 12). The bZIP dimer consists of a pair of continuous α helices with the zipper region forming a parallel **coiled coil** that diverges in the amino terminally located basic region. This creates a Y-shaped structure in which the α helices of the basic region reach into the major groove of the DNA double helix. The coiled coil of the leucine zipper extends away from the longitudinal axis of the DNA at almost 90° (Fig. 1).

In the absence of DNA binding, the basic region is disordered; it assumes helical structure only upon contact with DNA. There is a limited degree of flexibility in the joint region that connects the zipper and basic domains. Basic residues close to the zipper domain interact with the DNA backbone; more amino terminally positioned alanines and one asparagine as well as other residues make specific contacts with DNA base pairs (Fig. 2). The sequence of the basic region and the composition of the dimer specify the recognition site on the double helix. Because of the dimer structure of bZIP proteins the corresponding DNA target sequences usually have dyad symmetry. Upon binding to DNA, bZIP proteins may introduce a bend in the target molecule. The degree of bending is specified by dimer composition and DNA sequence. The coiled coil of leucine zippers determines the stability of the bZIP dimer. The α helices in these coiled

Leucine Zipper Transcription Factors: bZIP Proteins. Figure 1 Illustration of the Jun-Fos heterodimer bound to DNA (redrawn from Ref. 11). The leucine zippers of Jun and Fos facilitate dimerization; the basic regions of the protein dimer reach into the major groove of the DNA double helix.

coils have a periodicity of 3.5 residues per helical turn and hence every seventh amino acid is in the same structural environment. The hallmark of the zipper structure is the seven-residue periodicity of leucines or alternative hydrophobic residues. The leucine zipper consists of a series of heptads where the position of each residue is designated by a lower case letter *gabcdef* (helix 1) and *g'a'b'c'd'e'f'* (helix 2). Leucines occur in the *d* and *d'* positions; additional hydrophobic residues are found in the *a* and *a'* positions. Residues in

Leucine Zipper Transcription Factors: bZIP Proteins. Figure 2 Alignment of the basic regions and the leucine zipper domains of various human bZip-proteins and yeast GCN4. Conserved leucines within the zipper region are shadowed black, conserved charged residues are shadowed gray. The consensus sequence is shown at the bottom of the figure. The sequences were taken from Pubmed according to their accession numbers as follows: GCN4, NP_0109107; c-Jun, NP_002219; CREB1, NP_004370; CEBPa, NP_004355; ATF2, P15336; c-Fos, NP_005243; c-Maf, AAC27038. aa, amino acid; B, basic residue arginine or lysine.

the *a* and *d* positions form the hydrophobic core of the coiled coil (Figs. 2, 3). The side chains of the leucines and of hydrophobic residues in the *a* positions form “knobs” that fit into “holes” generated by the spaces between the side chains of the partner helix. The hydrophobic residues of the dimerizing helices are not in exactly opposite positions but interact from side to side as in a handshake (Fig. 3). In homodimerizing bZIP proteins, the *a* position of the second heptad is occupied by an asparagine which favors interaction with another asparagine in the same position of the partner helix and appears to be critical for homodimerization. The *g* and *e* positions typically contain charged amino acids that affect partner selection and dimer stability. They undergo electrostatic *g-e'* and *g'-e* interactions where the *e* position belongs to the adjacent heptad, five residues C-terminal. The electrostatic interactions can be attractive or repulsive and regulate homo- and hetero-dimerization. A leucine zipper can have up to five heptad repeats, allowing for a great diversity of electrostatic *g-e'* and *g'-e* interactions. The distinct dimerization patterns determined by the leucine zippers of bZIP proteins can be used to define protein families (5).

Clinical Relevance

Several bZIP proteins have been identified as oncogenic components of retroviruses establishing a fundamental role in transcription in cancer. Transcriptional regulation has an inherent oncogenic potential, and deregulated transcription is a principal mechanism of oncogenic transformation (7). *maf* and *mafB* gene rearrangements are found in about 5–10% of multiple myelomas presumably resulting in a gain of function; c-Maf is over-expressed in 50% of multiple myelomas

Definition

Acute Leukemias

Acute leukemias represent highly heterogeneous groups of malignancies that, nowadays, require an extensive routine diagnostic workup of their phenotypic

and genetic characteristics for the most appropriate classification and tailoring of therapy. The recently introduced World Health Organization (WHO) classification takes into account morphologic, immunophenotypic, genetic and clinical features of acute leukemias to define entities that are biologically homogeneous and that have clinical relevance (1).

Through the use of conventional and molecular cytogenetic analyses, acute leukemias have been recognized as genetic diseases reflecting deranged and disordered haematopoiesis, that results from a series of acquired or, rarely, inherited mutations in the structure of certain genes. These mutations are passed from the original transformed stem cell or progenitor cell to its clonal descendants. The diversity of molecular abnormalities in acute leukemias is, to a large extent, explained by the complexity of the genetic circuits that regulate the cell cycle, proliferation, differentiation, survival and cell death (►apoptosis) of the different haematopoietic progenitor cells that provide the biological targets for leukemogenesis. Although general mechanisms underlying the induction of acute myeloid (►AML) and acute lymphoblastic leukemias (►ALL) are often similar (e.g. the conversion of a transcription factor from an activator to a repressor of genes), there are significant differences in the genetic alterations implicated in AML and ALL pathogenesis.

Acute Myeloid Leukemia

The term AML collectively refers to a mixture of distinct disorders that differ with regard to their pathogenetic evolution, genetic abnormalities, clinical features, response to therapy and prognosis. AML arise in primitive, myeloid-lymphoid stem cells or from the accumulation of lineage-restricted myeloid progenitor cells arrested at early stages of differentiation. The different subtypes correspond roughly to maturation stages of granulocytic, monocytic, erythroid and megakaryocytic development (1). Age-specific incidence of AML, the most common acute leukemia in adults, rises linearly after age 40 with a median age of approximately 65 years. Most cases are sporadic, but congenital disorders (e.g. Fanconi's, ►Down's syndrome and Diamond-Blackfan syndromes) can increase the relative risk of developing AML. According to karyotypic analysis, three different prognostic groups with favourable, intermediate and unfavourable cytogenetic features have been defined. As treatment outcome differs substantially between these groups, with survival rates at five years ranging from 60–70% in the favourable to less than 20% in the unfavourable prognostic subgroup, the presence or absence of recurrent cytogenetic aberrations is currently used to identify the appropriate therapy.

Acute Lymphoblastic Leukemia

The distinct subtypes of ALL are characterized by leukemic lymphoblasts that are arrested in their differentiation at a precursor stage of B- or T-cell development. Although the general mechanisms underlying the induction of ALL are similar, the level of leukemic transformation, the frequency of particular genetic subtypes and cure rates differ markedly in children and adults. Lineage-committed stem cells are active in early development and provide potential targets for transformation in childhood ALL, whereas in adult ALL stem cells predominantly reside at the multipotential, lymphoid-myeloid cell level (e.g. B-cell precursor ALL with *BCR-ABL* fusion gene), and hence are preferentially at risk (4). ALL is the most common malignancy in children and has a bimodal age distribution with an early peak between 2 and 6 years of age and a second peak in the fifth decade. With the use of modern treatment strategies, about 80% of children and 35–40% of adults can be cured (5).

Chronic Leukemias

In contrast to acute leukemias, which show an aggressive clinical course, chronic leukemias have a more indolent clinical course often requiring less aggressive therapy. Chronic leukemias represent a heterogeneous group of different clonal disorders and belong, according to the WHO classification of tumours of the haematopoietic and lymphoid tissues, either to the mature B- or T-cell neoplasms or to the chronic myeloproliferative disorders. The most common chronic leukemias are chronic B-cell lymphocytic leukemia (B-CLL) and chronic myelogenous leukemia (CML). Whereas ▶B-cell is characterized by a marked genetic heterogeneity, which allows division of this malignant disorder into different prognostic subgroups, ▶CML is typically characterized by one specific genetic abnormality, which is the central event in the pathogenesis of this disease.

Chronic Lymphocytic Leukemia

B-CLL is the most common leukemia of adults in western countries and might originate either from immature pregerminal B-cells or from mature post-germinal centre B-cells. Although objective remissions can be achieved by various chemotherapy regimens, patients will relapse and ultimately succumb to their disease. Thus, CLL cannot be cured by currently available treatment options.

Chronic Myelogenous Leukemia

CML is a chronic myeloproliferative disease that originates in an abnormal pluripotent haematopoietic stem cell and is consistently associated with the Philadelphia chromosome (Ph) or its molecular equivalent, the *BCR-ABL* fusion gene.

Characteristics

Acute Myeloid Leukemia

AML involves a large variety of genetic alterations, including mainly chromosomal translocations that are selectively associated with distinct subtypes of the disease, point mutations and deletions (2). The chromosomal translocations can be clustered into groups based on similar structure and function of the expressed genes (Table 1). Some of the chromosomal translocations that occur in disparate loci in the human genome are associated with clinically indistinguishable phenotypes. Chromosomal translocations in AML most often result in loss of function of transcription factors or transcriptional coactivators that impair normal haematopoietic differentiation. There is now abundant evidence, however, that many of the fusion oncogenes resulting from balanced chromosomal translocations are not sufficient by themselves to cause AML. The observation that chimeric fusion genes generated by chromosomal translocations commonly coexist with a defined spectrum of mutations affecting tyrosine kinases has led to the notion of cooperating gene lesions, which couple a block in differentiation with enhanced cellular proliferation (Fig. 1). Such cooperating mutations have been divided into Class I and Class II mutations. Class I mutations (e.g. constitutively activated tyrosine kinases or their downstream effectors) confer a proliferative and/or survival advantage to haematopoietic progenitors, but do not have any effect on haematopoietic differentiation. Class II mutations (e.g. chromosomal translocations targeting core binding factor, ▶CBF, and the PML/RAR α oncogene) impair haematopoietic differentiation and might provide a survival advantage by interfering with terminal differentiation and apoptosis. Together, Class I and Class II mutations result in the AML phenotype characterized by proliferation and impaired haematopoietic differentiation of haematopoietic progenitor cells. While this model for a multistep pathogenesis, also referred to as the “two-hit” model of oncogenes in AML, might be an oversimplification, there is convincing experimental support for this model in mouse models of leukemia and it has a number of therapeutic implications (Fig. 1).

Acute Lymphoblastic Leukemia

Molecular analysis of the common genetic alterations in ALL has contributed greatly to the understanding of the pathogenesis of ALL and has been used successfully as a diagnostic and prognostic tool that gives important clues to risk-adapted therapeutic interventions. These genetic alterations contribute to the leukaemic transformation of haematopoietic stem cells or their committed progenitors by altering key regulatory processes that maintain or enhance an unlimited capacity for self-renewal, subvert the

Leukemia. Table 1 Main biological subtypes, recurrent chromosomal changes, and genes affected by chromosomal breakpoints in acute myeloid leukemias and acute lymphoblastic leukemias

Subtype	Cell type involved (Immunophenotype)	Chromosome abnormality	Molecular lesion	Function
AML	Acute myeloid leukemia with maturation	t(8;21)(q22;q22)	AML1-ETO fusion	Chimeric TF
AML	Acute myeloid leukemia with abnormal bone marrow eosinophils	inv(16)(p13q22) t(16;16)(p13;q22)	CBF β -SMMHC fusion	Chimeric TF
AML	Acute promyelocytic leukemia	t(15;17)(q22;q12-21)	PML-RAR α fusion	Chimeric TF
AML	Acute myeloid leukemia	t(9;11)(p22;q23)	MLL-AF9 fusion	Modified TF, dysregulated expression of HOX genes
AML	B-cell precursor (pro-B)	t(4;11)(q21;23)	MLL-AF4 fusion	Modified TF, dysregulated expression of HOX genes
ALL	B-cell precursor (common, pre-B)	t(12;21)(p13;q22)	TEL-AML1 fusion	Chimeric TF
ALL	B-cell precursor (pre-B)	t(1;19)(q23;p13)	E2A-PBX1 fusion	Chimeric TF
ALL	B-cell precursor (common, pre-B)	t(9;22)(q34;q11)	BCR-ABL fusion	Activated kinase
ALL	T-cell precursor	1p33 deletion (CD3- or + $\alpha\beta$)	TAL1-SCL fusion	dysregulated TF
ALL	T-cell precursor	t(5;14)(q35;q32)	HOX11L2 rearrangement	HOX11L2 over-expression
ALL	T-cell precursor	t(10;14)(q24;q11)	HOX11 rearrangement	HOX11 over-expression

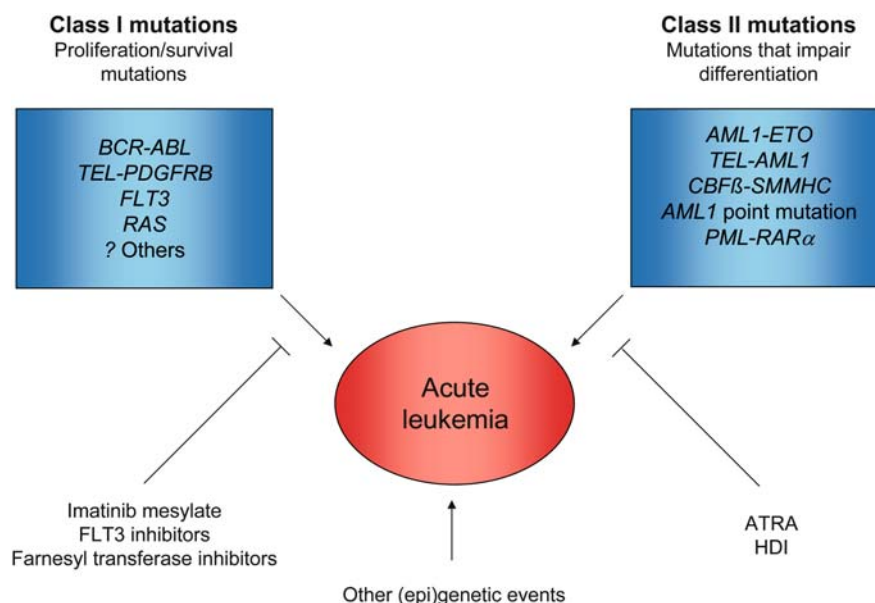

AML, acute myeloid leukemia; ALL, acute lymphoblastic leukemia; TF, transcription factor

controls of normal proliferation, block differentiation and promote resistance to apoptosis. Like AML, the conversion by chromosomal translocation of a transcription factor from an activator to a repressor of genes (e.g. the t(12;21) translocation and translocations involving the *MLL* gene, see below) or the generation of fusion genes leading to constitutive activation of a tyrosine kinase (e.g. the t(9;22) translocation, also referred to as the Philadelphia (Ph) chromosome) are recurrent pathogenetic mechanisms in ALL (Table 1). These oncogenic events triggered by chromosomal rearrangements probably cooperate with a second class of mutations that alter the proliferation and survival of haematopoietic progenitors, including over-expression of **▶FLT3** or alterations in the retinoblastoma protein (RB) and **▶p53** pathways that have a central role in both tumour suppression and the response of tumour cells to chemotherapy. Alternatively, transcription factor genes in ALL are dysregulated by their

juxtaposition with transcriptionally active T-cell receptor (*TCR*) or immunoglobulin (*Ig*) genes. In addition, numerical chromosomal changes, especially hyperdiploidy involving more than 50 chromosomes, occur frequently in childhood ALL and are associated with more favourable presenting features and higher cure rates than other major prognostic subgroups.

Chronic Lymphocytic Leukemia

Although many patients with B-CLL have an indolent course with a median survival of 7–10 years, the disease is characterized by a marked clinical heterogeneity; some patients are refractory to initial chemotherapy and die from the disease within a few months, whereas others live for 20 years or longer. The clinical heterogeneity is reflected in a considerable genetic heterogeneity and certain genomic aberrations and mutations have turned out to be associated with either a more aggressive or a more indolent clinical course (6).

Leukemia. Figure 1 Multistep pathogenesis of AML and targeted treatment strategies. Model for cooperation between gene rearrangements and mutations that confer a proliferative and/or survival advantage to leukaemic blasts and those that impair differentiation (modified from reference 2). Targeted therapies have been developed and have proven to be effective (e.g., small molecule inhibitors, such as imatinib mesylate for BCR-ABL or TEL/PDGFR β , and all-trans-retinoic acid (ATRA) or arsenic trioxide for the treatment of APL). Other molecularly targeted drugs, including histone deacetylase, farnesyl transferase, and FLT3 inhibitors, are being tested in AML. There may be therapeutic synergy achieved by targeting each class of mutation, such as a combination of FLT3 inhibitors and ATRA in treatment of APL.

Chronic Myelogenous Leukemia

CML is characterized by the expansion of all maturation stages of the myeloid lineage, but other haematopoietic lineages may regularly be affected as well. The clinical course of the disease is triphasic: 1) an initial chronic phase with an indolent clinical course (median duration 5–6 years), 2) an accelerated phase (median duration 6–9 months) and 3) a blast crisis which resembles acute leukemia with a poor prognosis (median survival 3–6 months). Treatment of patients in chronic phase with interferon- α and/or cytotoxic drugs induces stable remissions and can lead to disease control for several years. However, despite treatment the disease is progressive and ultimately fatal. Currently, the only curative therapy is allogeneic bone marrow or peripheral blood stem cell transplantation.

Molecular Interactions Acute Myeloid Leukemia

Transcription factors that are targeted by multiple chromosomal translocations in AML include CBF, retinoic acid receptor alpha (RAR α), and members of the \blacktriangleright *HOX* family of transcription factors (Table 1). As chromosomal translocations involving CBFs are a frequent target of gene rearrangements and mutations in acute leukemias, molecular interactions impairing

haematopoietic differentiation will be exemplified by CBF gene rearrangements (2). CBF is a heterodimeric transcription factor composed of a DNA-binding component, *AML1* (also known as *PEBPA2B* and *CBFA2*; recently renamed by the HUGO as Runt-related transcription factor 1 – *RUNX1*) and the CBF β subunit that does not contact DNA but increases transcriptional activity of *AML1*. CBF transactivates expression of a broad spectrum of genes that are critical for normal haematopoietic differentiation. The three most common translocations involving CBF are t(8;21) and inv(16), accounting for approximately 25% of adult AML, and t(12;21), occurring in 20–25% of childhood ALL. The molecular consequence of these chromosomal translocations is the production of AML1-ETO (acute myeloid leukemia 1/eight twenty one), CBF β -SMMHC (smooth muscle myosin heavy chain), and TEL (translocation ETS leukemia)-AML1 fusion proteins, respectively. *In vitro* data and experiments with knock-in mice have provided convincing evidence that the main physiological function of these fusion proteins is dominant inhibition of CBF-mediated transcription, resulting in severely impaired haematopoietic differentiation, a phenotypic hallmark of AML. Transcriptional repression of CBF target genes by CBF-related fusion proteins is mediated in part through

aberrant recruitment of the nuclear corepressor/histone deacetylase complex. Some of these mechanisms of transcription repression are similar to those reported for the PML (promyelocytic leukemia)-RAR α and PLZF-RAR α fusion proteins that are associated with acute promyelocytic leukemias (APL), and that also recruit the nuclear corepressor complex.

Genetic alterations involving CBFs probably cooperate with a second class of mutations that alter the proliferation and survival of haematopoietic progenitors. Recently, several such mutations have been identified in AML patients with CBF leukemias, including internal tandem duplications in the juxta-membrane domain of FLT3 as well as activating loop mutations of FLT3 or \blacktriangleright c-KIT, resulting in constitutive activation of the Class III receptor tyrosine kinases, FLT3 or c-KIT and activation of growth-related signalling pathways (3). In addition, activating mutations in *RAS* (rat sarcoma) family members, primarily *N-Ras* and *Ki-Ras*, have been identified in a subset of AML patients.

Acute Lymphoblastic Leukemia

ALL-specific translocations can oncogenically activate transcription factors by at least two mechanisms (4, 5). First, especially in B-cell precursor ALL, translocations fuse discrete portions of two different genes to create chimeric transcription factors with oncogenic properties. This mechanism can be exemplified by translocations involving the mixed-lineage leukemia (*MLL*) gene, also called myeloid lymphoid leukemia gene. Structural genetic alterations of the *MLL* locus (11q23) occur in more than 80% of infants with ALL, 5% of AML cases and in most therapy-induced leukemias caused by topoisomerase II inhibitors. Translocations involving *MLL* result in chimeric proteins consisting of the N-terminal portion of *MLL* fused to the C-terminal portion of one of more than 40 partners. The most common translocations represent the t(4;11), t(9;11) and t(11;19) which fuse *MLL* to a family of genes (*AF-4*, *AF-9* and *ENL*) that may contribute similar functional domains to the chimeric proteins. The *MLL* fusion proteins have a dominant gain-of-function effect than enhances their transcriptional activity. These alterations disrupt the normal pattern of expression of *HOX* genes, resulting in a change in the self-renewal and growth of haematopoietic stem cells and progenitor cells.

Alternatively, B- and T-cell precursor ALL are characterized by the juxtaposition of strong enhancer elements from *TCR* or *Ig* genes with various transcription factors leading to protein over-expression and ultimately to leukaemic transformation. For example, recurring translocations in T-cell precursor ALL often involve transcriptionally active sites of the

beta (7q34) or the delta locus (14q11) of the TCR, leading to dysregulated expression of transcription factors. These rearrangements may result from mistakes in the normal recombination process involved in the generation of functional antigen receptors. Developmentally important transcription factor genes altered in T-cell precursor ALL include members of the basic helix-loop-helix (bHLH), LIM and homeodomain families.

Chronic Lymphocytic Leukemia

Genetic analysis of the variable region of the immunoglobulin heavy chain gene (\blacktriangleright IgV_H) revealed that CLL can be divided into two subgroups, tumours with unmutated IgV_H genes are associated with rapid clinical progression and unfavourable clinical course, whereas tumours with hypermutated IgV_H genes have a better prognosis requiring late or no treatment. Physiologically, an unmutated IgV_H locus reflects an immature pregerminal B-cell maturation stage, whereas B-cells with hypermutated IgV_H have passed through the germinal centre and represent a positively selected mature differentiation stage (postgerminal centre B-cells). Therefore, it has been proposed that B-CLL may originate from two different B-cell stages, immature (unmutated) pregerminal B-cells or mature (hypermutated) postgerminal B-cells.

Although the link between IgV_H mutations and clinical outcome is still unclear, one crucial factor probably relates to the different chromosomal abnormalities associated with each of the two subgroups. The malignant cells from patients with unmutated IgV_H genes frequently have cytogenetic changes that are associated with a poor clinical outcome such as an 11q or a 17p deletion, whereas cells from patients with hypermutated IgV_H more frequently have chromosomal aberrations with a benign clinical course (e.g. 13q deletions). Although certain chromosomal aberrations allow division of B-CLL into different prognostic subgroups, relatively little is known about the molecular correlates and consequently about the molecular mechanisms underlying the pathogenesis of this disorder (Table 2).

The deleted regions of the affected chromosomes 17 and 11 are known to contain tumour suppressor genes that regulate proliferation, apoptosis and cellular response to DNA damage. Deletions of the short arm of chromosome 17 (17p) affect the tumour suppressor gene *p53* and deletions of the long arm of chromosome 11 (11q) can affect the \blacktriangleright *ATM* (ataxia telangiectasia mutated) gene (Table 2). Accordingly, it could be demonstrated that B-CLL tumours that have inactive ATM or p53 proteins show defects in p53 DNA damage response and in ionizing radiation (IR)-induced apoptosis.

Leukemia. Table 2 The most common chromosomal abnormalities found in patients with CLL. Little is known about the molecular correlates of these chromosomal abnormalities. The tumour suppressor gene *p53* is affected by 17p deletions, the *ATM* gene is affected by 11q deletions

Aberration	Affected Genes
13q deletion	unknown
11q deletion	<i>ATM</i>
12q trisomy	unknown
17p deletion	<i>p53</i>
6q deletion	unknown
8q trisomy	unknown

Chronic Myelogenous Leukemia

At diagnosis, 90–95% of CML cases have a reciprocal chromosomal translocation involving the long arm of chromosomes 9 and 22, resulting in the Ph chromosome. This translocation fuses the *BCR* gene (break-point cluster region) on chromosome 22 with regions within the *ABL* gene (Abelson mouse leukemia proto-oncogene) on chromosome 9. Physiologically, ABL is a non-receptor tyrosine kinase that activates growth regulating signalling pathways upon growth factor stimulation. The *BCR-ABL* fusion gene leads to the expression of a kinase with constitutive activity. The reason for the constitutive activity of the **BCR-ABL** fusion kinase is still unclear. The aberrant BCR-ABL fusion kinase leads to the constitutive activation of signalling pathways which mediate cell survival, cell-cycle progression, and cell adhesion (Fig. 2). Thus, BCR-ABL has been described to activate the RAS/MAPK, STAT 1 + 5 and PI3K/AKT signalling pathways, which are known to be involved in the regulation of proliferation, differentiation and apoptosis. The *BCR-ABL* fusion gene is the hallmark of CML, defines the disease and is most likely the major causative event in disease development (7).

Thus, at least in the chronic phase, the expansion of the malignant clone is largely dependent on this specific genetic defect. During disease progression to accelerated phase and blast crisis, the malignant clone acquires additional genetic defects.

Regulatory Mechanisms

Acute Myeloid Leukemia

The better understanding of the molecular pathogenesis of AML, especially CBF leukemias, and the growing number of tyrosine kinases now known to be activated by mutations in leukemic blasts from AML patients,

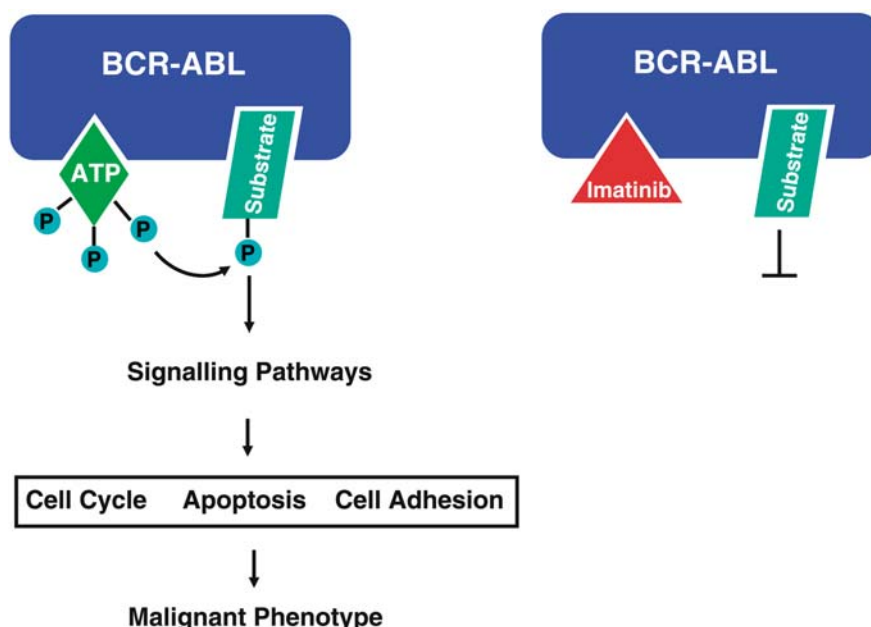

Leukemia. Figure 2 BCR-ABL triggered signalling pathways in CML. The Philadelphia chromosome produces a constitutively activated BCR-ABL tyrosine kinase, which leads to the constitutive activation of different signalling pathways (e.g., RAS/RAF/MEK/MAPK, STAT 1 + 5, PI3K/AKT, FAK) and oncogenes (e.g., MYC). The activation of these pathways protects the cell from apoptosis, promotes cell-cycle progression and alters proteins of the cytoskeleton and cell adhesion properties, thereby critically contributing to the process of malignant transformation. The activation of RAS, PI3K, STAT and FAK is mediated by a series of adapter proteins (SHC, SOS, GRB2, CRKL, CBL).

provide a foundation for the development of new molecularly targeted therapies. These include histone deacetylase inhibitors (HDI), specific inhibitors of tyrosine kinases such as FLT3 and c-KIT, farnesyl transferase inhibitors and the identification of small molecules that specifically inhibit fusion proteins without affecting the function of native CBF components or specifically disrupt association of the nuclear corepressor complex with leukaemogenic fusion proteins. Several of these new molecularly targeted therapies, including HDI and FLT3 inhibitors, have entered clinical trials. A combination of basic, clinical and translational studies will ultimately determine the clinical utility of these agents and their mechanism of action.

Acute Lymphoblastic Leukemia

The different clinical outcomes associated with the various subtypes of B- and T-cell precursor ALL can be

Leukemia. Figure 3 Mechanism of action of imatinib mesylate. The BCR-ABL fusion protein is a constitutively activated non-receptor tyrosine kinase that is causally linked to malignant transformation in CML. Imatinib mesylate selectively blocks the binding site for ATP in the ABL kinase, thereby preventing phosphorylation of tyrosine residues on substrate proteins. This leads to the disruption of the downstream signalling cascades and might revert the malignant phenotype.

attributed mainly to drug sensitivity or resistance of leukaemic lymphoblasts harbouring specific genetic abnormalities. The unusual sensitivity of leukaemic lymphoblasts with a hyperdiploid karyotype to chemotherapy, especially in childhood ALL, is an example. Although the precise mechanism of leukaemic transformation in hyperdiploid ALL is unknown, leukaemic cells from patients with this numerical abnormality have an exquisite sensitivity to chemotherapy. This *in vivo* response correlates with the propensity of leukaemic cells to undergo spontaneous apoptosis *in vitro* and to have higher than average intracellular concentrations of methotrexate and its active polyglutamate metabolites. The latter probably results from three or four copies of chromosome 21, which harbours a gene encoding the transporter of methotrexate into cells, in more than 97% of hyperdiploid blasts. Recent emphasis has been placed on the study of genetic polymorphisms in drug-metabolizing enzymes, drug transporters and targets of drug action. The information should be useful for optimising drug doses and drug combinations. As with AML, identification of specific oncoproteins and better understanding of the molecular processes regulating treatment response have paved the way for therapy directed to pivotal molecular targets (e.g. ►[imatinib](#)

[mesylate](#) for the treatment of *BCR-ABL*-positive ALL). Progress in the molecular classification of ALL, e.g. by using DNA microarrays, coupled with methods to assess the functional significance of newly discovered genes or through proteomic techniques will hopefully lead to identification of new targets for specific treatments.

Chronic Lymphocytic Leukemia

ATM functionally interacts with the p53 protein. The p53 protein preserves genome integrity by regulating cell-cycle arrest and apoptosis. In response to DNA damage (e.g. DNA double strand breaks induced by IR), ATM stabilizes and activates p53 through phosphorylation. As a transcription factor, activated p53 represses or induces genes that are involved in the regulation of cell-cycle arrest, apoptosis and DNA repair. Thus, mutations or chromosomal deletions of the *ATM* or the *p53* gene might provide some explanation as to why patients with these genetic aberrations often respond poorly to cytotoxic chemotherapy and have an unfavourable clinical course. Activated p53 acts as a transcription factor and drives the expression of proapoptotic genes such as *Bax*, cell-cycle inhibitors such as *p21* and DNA-repair genes. Therefore, besides their role in DNA repair, mutations

in *p53* and *ATM* may contribute to the pathogenesis of a certain unfavourable subgroup of B-CLL.

Chronic Myelogenous Leukemia

Since the BCR-ABL fusion protein has been thought to be causative for the expansion of the malignant clone, attempts have been made to develop selective inhibitors. Recently, an inhibitor specific for a small family of tyrosine kinases, including PDGF-R, c-KIT and BCR-ABL, was generated. This small compound, designated imatinib mesylate, binds as a competitive inhibitor to the ATP binding site of these kinases, thereby blocking their enzymatic activity (8). Consequently, the activation of apoptosis and proliferation regulation signalling pathways is blocked as well (Fig. 3). In first clinical trials, imatinib mesylate has induced complete haematological and cytogenetic remissions in patients with CML. In particular in the chronic phase, high remission rates could be achieved and in a phase III trial imatinib mesylate appeared to be superior to the conventional standard therapy consisting of interferon- α and cytosine arabinoside. However, despite these promising clinical results, resistance against this novel drug might develop preferentially by the selection of malignant clones which have point mutations affecting the imatinib mesylate binding site of *BCR-ABL*. Furthermore, despite the induction of high remission rates, imatinib mesylate alone probably cannot cure the disease and how long this selective tyrosine kinase inhibitor can keep CML patients in stable clinical remission is still unclear. Nevertheless, treatment of CML with imatinib mesylate is a *par excellence* example of molecularly targeted therapy that has been developed based on the understanding of the molecular mechanisms of malignant transformation.

Leukocytes

Definition

Leukocytes (or white blood cells) are differentiated hematopoietic cells expressing the surface marker CD45. They include cells of the myeloid and lymphoid lineage (i.e. monocytes, macrophages and lymphocytes), but exclude the erythroid lineage. Leukocytes help the body fight infections and other diseases.

LIM Gene

Definition

LIM genes constitute a large gene family of homeobox genes, whose gene products carry the LIM domain, a unique cysteine-rich zinc-binding domain. The acronym stands for *lin-11*, *islet-1* (*isl-1*) and *mec-3*. At least 40 members of this family have been identified in vertebrates and invertebrates, and are distributed into 4 groups according to the number of LIM domains and to the presence of domains such as homeodomains and kinase domains.

Limb Development

NATALIA SOSHNIKOVA, WALTER BIRCHMEIER
Max-Delbrueck-Center for Molecular Medicine,
Berlin, Germany
wbirch@mdc-berlin.de

Definition

The developing limb is a classical model system for studying cytological and genetic aspects of pattern formation and signal transduction. The vertebrate limb is an outgrowth of the embryonic body wall at a specific position along the anterior-posterior axis of the embryo. The forelimbs always arise at the cervical to thoracic transition and the hind limbs at the lumbosacral transition. The limb consists of mesenchymal tissues covered by a layer of ectoderm. Cartilage and bone elements develop from the limb ► [mesenchyme](#). Other tissues such as muscles, nerves and blood vessels evolve from cells that migrate into the limb bud. Three discrete compartments form in vertebrate limbs, proximal (stylopod), middle (zeugopod) and distal (autopod) (Fig. 1).

Limb Development. Figure 1 Skeletal pattern of a newborn mouse forelimb (a) and hindlimb (b). The stylopod contains humerus (hu) in the forelimb and femur (fe) in the hindlimb. The zeugopod consists of radius (ra) and ulna (ul) in the forelimb, and tibia (ti) and fibula (fi) in the hindlimb, whereas the autopod comprises wrist and five fingers in the forelimb, and ankle and five toes in the hindlimb. Alcian blue and alizarin red staining produces coloration of cartilage elements in blue and bone elements in red. Bar: 2 mm.

Characteristics

The outgrowth and patterning of the limb depends on the establishment and maintenance of three distinct signaling centers, the ►**apical ectodermal ridge** (AER), the ►**zone of polarizing activity** (ZPA) and the non-ridge ectoderm of the limb bud (1, 2).

- The AER is a specialized epithelial structure positioned at the border between dorsal and ventral

Limb Development. Figure 2 Signaling centers in the limb bud. A posterior view of mouse limb buds at the 11th day of embryonic development. (a) The AER is positioned at the border between dorsal and ventral ectoderm as specified by the expression of *Fgf8*. (b) The ZPA is located in the posterior mesenchyme as marked by the expression of *Shh*. The expression of genes is visualized by whole-mount RNA *in situ* hybridization. Pr, proximal; Di, distal; A, anterior; P, posterior; D, dorsal; V, ventral. Bar: 150 µm.

ectoderm (Fig. 2a). It is responsible for the continuous proliferation of the underlying mesenchymal cells that leads to the outgrowth of the limbs along the proximal-distal axis (shoulder to finger tip). When the AER is surgically excised, proliferation of mesenchymal cells is affected and the limb is truncated. Truncations are more severe when the AER is removed early in development, indicating that there is a differential temporal necessity for the AER. The AER produces fibroblast ►**growth factors** (FGFs) that are the key signals for stimulation of cell division in the subjacent mesenchyme.

- The ZPA, a group of mesenchymal cells, is located directly below the posterior margin of the AER (Fig. 2b). Transplantation of posterior mesenchymal cells into the anterior side of the limb results in mirror duplication of digits, indicating that the ZPA organizes structures within the limb along the anterior-posterior axis (thumb to little finger). The ZPA cells secrete a ►**morphogen**, Sonic Hedgehog (Shh). Cells near to the ZPA receive a high concentration of Shh and adopt posterior fates, while cells further from the ZPA receive a lower Shh concentration and adopt anterior fates.
- The non-ridge limb ectoderm regulates the patterning of the limb along the dorsal-ventral axis (back of the hand to palm). Inversion of limb ectoderm along the dorsal-ventral axis leads to inversion of muscle, skeleton and skin appendages. The earlier rotation is performed, the more complete is the reversal of the dorsal-ventral limb pattern. Ventral identity of the limb is specified by ►**bone morphogenetic protein** (BMP) signals. Wnt-7a signals from dorsal ectoderm are required for limb cells to adopt a dorsal character.

Importantly, there are regulatory interactions among the different signaling centers that coordinate limb development along the three axes. For example, signals from the AER and the dorsal ectoderm cooperate to maintain ZPA activity. In a reciprocal manner, signals from the ZPA are necessary for the maintenance of the AER. Moreover, dorsal-ventral polarity and AER formation are processes initiated by a common mechanism.

Molecular Interactions

Significant progress has been achieved in defining signals that control patterning of each of the cardinal axes of the developing limb (1, 2, 3). These signals do not act in isolation but rather interactions between them direct the formation of various limb elements.

The Wnt/ β -catenin-FGF Regulatory Loop (Fig. 3a)

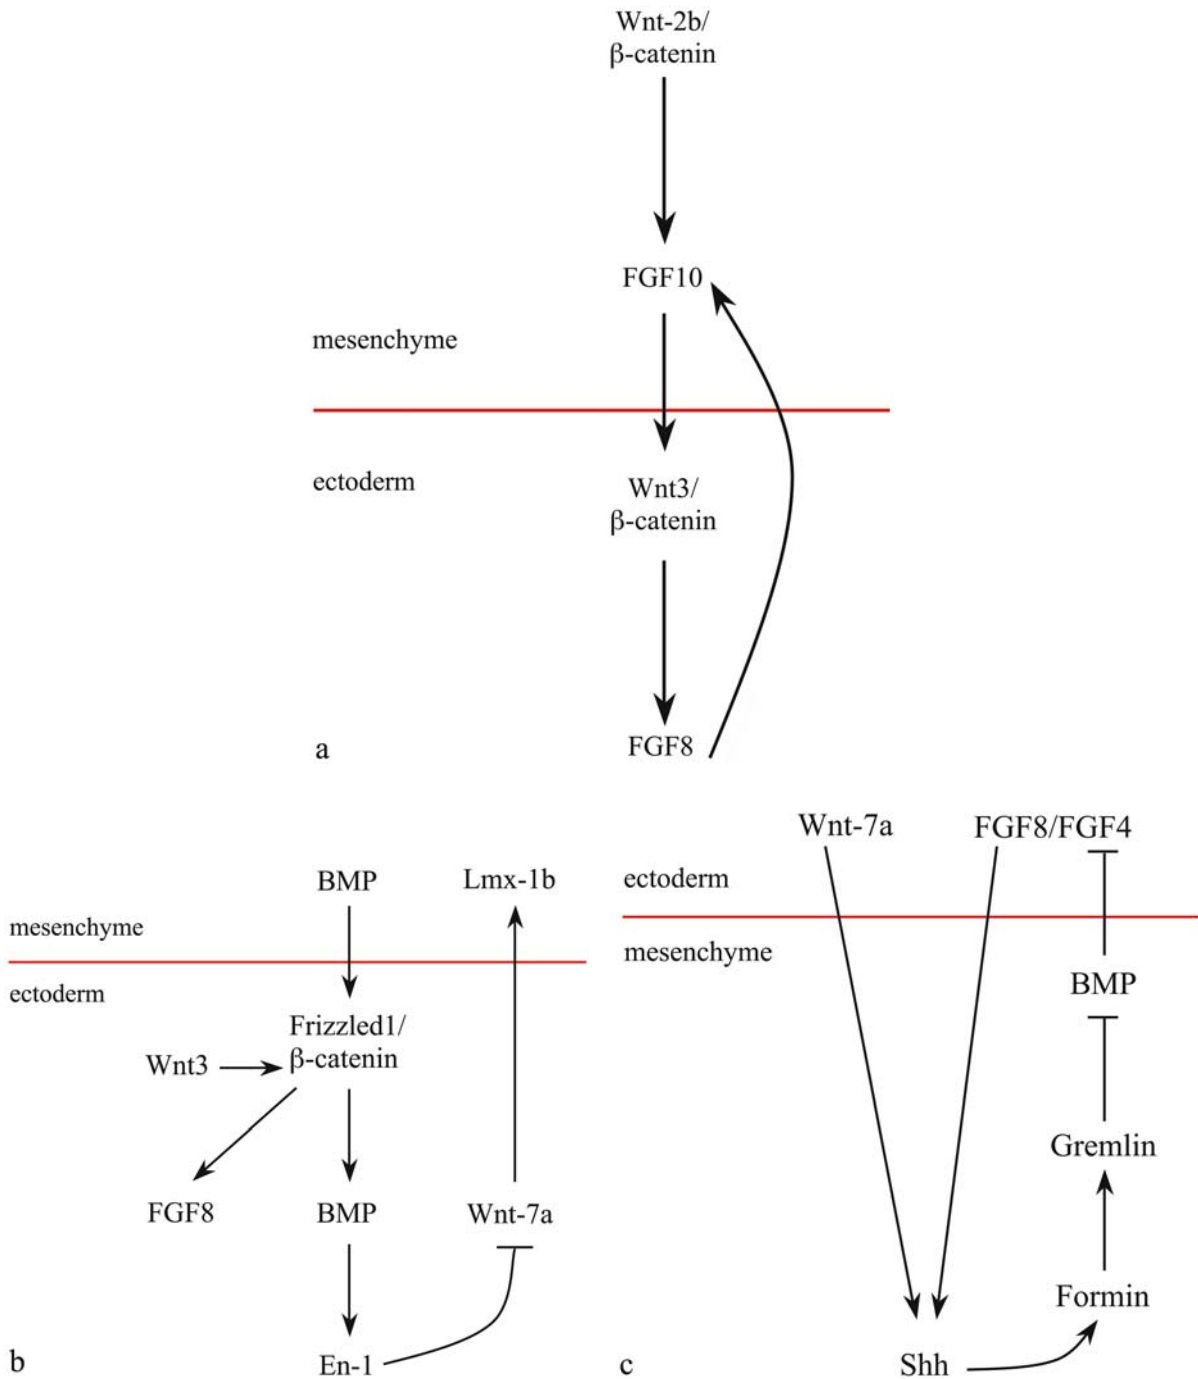

The crucial event in vertebrate limb development is the interaction of the presumptive limb mesenchyme with the surface ectoderm that results in the formation of the AER. Among the earliest genes expressed in the presumptive fore- and hind-limb mesenchyme are *Wnt-2b* and *Wnt-8c*, respectively. Wnt signals are mediated by the Frizzled receptors, which act to stabilize β -catenin in the cytoplasm (4). Upon nuclear translocation, β -catenin interacts with LEF/TCF transcription factors to regulate expression of target genes. Mutations in β -catenin, which increase stability of the protein, cause constitutive transduction of the signal to the nucleus, even in the absence of Wnt ligands. Ectopic expression of *Wnt-2b*, *Wnt-8c* or β -catenin results in induction of ectopic limbs in the chick embryonic flank (3). It has been shown that both *Wnt-2b* and *Wnt-8c*, via β -catenin, activate *Fgf10* expression in the limb mesenchyme. Genetic experiments in mouse and embryological manipulations in chick have demonstrated that FGF10 is a key factor for limb outgrowth. FGF10 acts specifically on the epithelium and induces the expression of *Wnt-3a* (in chick) or *Wnt3* (in mouse) in the limb ectoderm. Recently, it has been shown that *Wnt3*/ β -catenin signaling plays a crucial role in AER formation. Ablation of β -catenin in the limb ectoderm using the Cre/loxP system results in a block in AER induction and a loss of *Fgf8* and *Fgf4* expression in the presumptive AER cells (5). In contrast, activation of β -catenin-mediated signaling leads to ectopic AER formation and *Fgf8* expression in the limb ectoderm of both mouse and chick embryos. The expression of *Fgf8* and *Fgf4* in the limb ectoderm is required for the maintenance of *Fgf10* expression and for the proliferation of the underlying mesenchymal cells. Thus, three Wnts signaling through β -catenin mediate the FGF10/FGF8 loop during formation of the AER. Inactivation of any gene that encodes

components of this regulatory loop results in deficits of limb outgrowth along the proximal-distal axis.

The BMP-Wnt/ β -catenin Regulatory Network (Fig. 3b)

Conditional *Wnt3* and β -catenin mutant mice display a complete absence of *Bmp2* and *Bmp4* expression in the limb ectoderm (5). It has been demonstrated that BMP signaling plays an essential role in AER induction and proximal-distal outgrowth of the limbs (2). Mice carrying a *Bmp receptor IA* loss-of-function mutation in the limb ectoderm fail to form the AER and express *Fgf8*, whereas ectopic expression of constitutively active *BMP receptor IA* results in induction of *Fgf8* expression in the limb ectoderm of chick embryos. Moreover, inactivation of the *p63* gene, which is regulated by both Wnt/ β -catenin and BMP signals, also results in a loss of AER formation and in severe truncation of the limbs. To verify the epistatic relationship between Wnt/ β -catenin and BMP signaling pathways, compound mutant mice that carry β -catenin gain-of-function and *Bmp receptor IA* loss-of-function mutations in the limb ectoderm have been generated (5). Analysis has revealed that β -catenin-mediated signaling acts downstream of the BMP receptor IA during AER formation. Specifically, BMP signals from the ventral mesenchyme are required for expression in the ventral limb ectoderm of the *Frizzled1* gene, which acts as a permissive signal to establish competence of the limb ectoderm to respond to *Wnt3* signals. β -Catenin does, however, control *Bmp2* and *Bmp4* expression in the ectoderm and is responsible for the initiation of a positive feedback loop.

The formation of the AER and of the dorsal-ventral axis is tightly linked during early limb development (1, 2, 5). For example, conditional β -catenin or *Bmp receptor IA* loss-of-function mutants demonstrate absence of ventral structures of the limb such as dermal pads and duplication of dorsal structures such as nails. These findings indicate that both β -catenin and BMP receptor IA-mediated signaling are required not only for AER formation but also for the correct dorsal-ventral patterning of limbs. Interestingly, analysis of the compound mutant mice that carry β -catenin gain-of-function and *Bmp receptor IA* loss-of-function mutations in the limb ectoderm has demonstrated that β -catenin acts upstream of or in parallel to the BMP receptor IA for the establishment of the dorsal-ventral polarity of the limb. Gain-of-function experiments in the chick have shown that BMP signaling can induce the expression of *En-1* in the ventral limb ectoderm. *En-1*, a homeobox-containing transcription factor, is essential for the acquisition of the ventral pattern in limbs. In *En-1* mutant mice, dorsal structures such as nails and hair follicles also develop on the ventral side

Limb Development. Figure 3 Signaling pathways regulating limb morphogenesis. (a) The Wnt/β-catenin-FGF regulatory loop. (b) The BMP-Wnt/β-catenin regulatory network. (c) The FGF-Shh regulatory loop.

of the limb. Remarkably, *Wnt-7a* is ectopically expressed in the ventral limb ectoderm of *En-1* mutants. It has been suggested that *En-1* functions to restrict *Wnt-7a* expression to dorsal limb ectoderm. *Wnt-7a* activates the *Lmx-1b* expression in the dorsal

mesenchyme that is required for dorsal fate specification in limbs. Ectopic expression of *Wnt-7a* or *Lmx-1b* causes dorsalization of ventral mesenchyme, leading to the loss of dermal pads and to the formation of nails and hair follicles on the ventral side of limbs. In contrast,

loss of *Wnt-7a* or *Lmx-1b* results in formation of dermal pads on the dorsal side of the limb and in ventralization of dorsal muscles and tendons. Taken together, the intricate interplay between BMP and Wnt signaling pathways provides the molecular basis for the coordination of the development of the proximal-distal and dorsal-ventral axes in the limb.

The FGF-Shh Regulatory Loop (Fig. 3c)

Specific interactions between the AER and the ZPA establish growth and patterning of the limb along the proximal-distal and the anterior-posterior axes (1, 2, 3). It has been demonstrated that removal of the AER or the dorsal ectoderm results in rapid loss of *Shh* expression in the posterior mesenchyme of chick limbs. *Shh* plays a crucial role in specifying the identity of the limb along the anterior-posterior axis. Genetic studies in mice have shown that FGF8 and FGF4 from the AER and *Wnt-7a* from dorsal ectoderm are required for the induction of *Shh* expression in posterior mesenchyme. Moreover, regulatory interactions between *Shh* and FGF4 are reciprocal. Application of *Shh* to the anterior side of the chick limb causes ectopic expression of *Fgf4* in the overlying anterior ectoderm. Consistently, *Shh* mutant mice display a loss of *Fgf8* and *Fgf4* expression, the precocious regression of the AER and absence of digits 2–5. Recently, the molecular mechanism for *Shh*-dependent limb outgrowth has been revealed. *Shh* acts *via* formin to maintain the expression of *Gremlin*, an antagonist of BMP signaling, in limb mesenchyme. The inhibition of BMP signaling is required for the maintenance of *Fgf4* expression in the posterior AER. Loss of *formin* leads to a failure of *Fgf4* expression in the AER and subsequently to a decrease in the expression of *Shh* in limb mesenchyme. Thus, a positive feedback loop between FGFs and *Shh* controls outgrowth and patterning of the limb along the proximal-distal and anterior-posterior axes.

Limb Defects in Humans

Mechanisms controlling limb outgrowth and patterning in chick and mouse also function in a similar manner during human limb development. Identification of mutations in human genes that cause limb malformations has confirmed this (3, 6).

Mutations in genes that are responsible for early steps in limb development such as AER formation result in a complete loss of limbs (amelia) or in severe truncations of limbs. Tetra-amelia is a rare genetic disorder characterized by complete absence of all four limbs. Recently, it has been demonstrated that a [▶nonsense mutation](#) in the *Wnt3* gene causes the disorder. The Q83X mutation in the NH2-terminus of *Wnt3* creates a stop codon resulting in a truncated protein. Hence, the

loss-of-function in both copies of *Wnt3* is the mechanism for the disease.

The Holt-Oram syndrome is an autosomal dominant disorder characterized by forelimb abnormalities and congenital heart defects. Mutations in the *Tbx5* gene have been shown to be responsible for this syndrome. *Tbx5* encodes a T-box containing transcription factor that is expressed in embryonic forelimbs prior to induction of the AER. Frameshift, splicing and nonsense mutations that produce truncated TBX5, or an in-frame deletion of 27 nucleotides in the T-box that reduces the DNA binding ability of TBX5 have been reported in humans. Moreover, mutated TBX5 protein has been observed predominantly in the cytoplasm, indicating that impaired nuclear localization and dysfunction in DNA binding and transcriptional activity are the mechanisms for the loss-of-function mutation in these patients. Consistently, genetic studies in mice have demonstrated that a deletion of *Tbx5* results in a complete absence of limb bud outgrowth. It has been shown that TBX5 initiates limb bud outgrowth by activation of *Fgf10* in the early forelimb mesenchyme.

Nail patella syndrome (NPS) is an autosomal dominant disorder, characterized by a small or absent patella, malformations of the radial head, iliac horns and an absence or hypoplasia of nails on the fingers and toes. Many [▶missense mutations](#) in the homeodomain of LMX1b that abolish DNA-binding activity of the protein or in the LIM-domain of the protein that affect essential co-factor interactions have been identified in individuals with NPS.

Mutations in genes, which are responsible for patterning of the autopod cause abnormal development of digits, polydactyly (extra digits), syndactyly (fusion of digits) and brachydactyly (shortening of digits). Mutations in *Fgfr2* are associated with human disorders of limb patterning, such as Pfeiffer syndrome and Apert syndrome. Mutations of the splice sites surrounding the alternatively spliced exon IIIc of *Fgfr2* cause Pfeiffer syndrome, which is characterized by the broadening of thumbs and halluces, and radio-humeral or -ulnar synostosis. FGFR2c functions to transmit FGF8 signals from the AER to limb mesenchyme. Exon IIIc splicing mutations lead to ectopic expression of FGFR2b, a receptor isoform for FGF10, in limb mesenchyme. Moreover, mutations in the IgIIIa or IgIIIc domains of FGFR2c either substitute one of the paired cysteine residues (at C278 and C342) or create extra cysteines (W290C and S351C). The production of an odd number of cysteine residues enables mutant FGFR2 molecules to form covalently cross-linked dimers, resulting in constitutive activation. In Apert syndrome, there is a complex bony syndactyly involving the central three digits, radio-humeral or

-ulnar synoptosis. Mutation P253R in the extracellular domain of the FGFR2c leads to loss of ligand selectivity. The P253R mutant aberrantly binds FGF10 resulting in ectopic FGF10 signaling in limb mesenchyme.

Missense mutations in the p63 gene account for most cases of ectrodactyly-ectodermal dysplasia-clefting (EEC) syndrome. Arginine codons were frequently found to be mutated in the DNA binding domain of p63. Since the deletion of p63 is not associated with any of the signs of EEC syndrome, it has been suggested that a gain-of-function in p63 causes the limb defects.

Greig cephalopolysyndactyly (GCPS) is a rare autosomal dominant disorder that affects limb and craniofacial development. In the hands both preaxial and postaxial polydactyly and in the feet duplication of the hallux combined with syndactyly of toes 1–3 can occur. Haploinsufficiency of the Gli3 gene is the molecular mechanism that underlies GCPS. GLI3 is a dual-function transcription factor, which is crucial for the formation of the anterior-posterior axis of the limb.

Synpolydactyly (SPD) is a dominantly inherited disorder characterized by 3/4 finger and 4/5 toe syndactyly and urogenital tract abnormalities. The disease is caused by an expansion of CGC trinucleotide repeats (greater than 15 repeats) in the first exon of the Hoxa13 or Hoxd13 genes. The CGC repeats are translated into polyalanine sequence in the NH2-terminus of HOX proteins. The functions of the domain containing the polyalanine tract are unclear, although it may be involved in interactions with other proteins. Target inactivation of Hoxd13 in mice results in the loss of several skeletal elements of autopods. However, Hoxd13 loss-of-function mutation produces milder phenotypes than does synpolydactyly homolog (Hoxd13spdh) mutation, suggesting that mutant HOXD13 interferes with the activity of other proteins.

Limb Girdle Muscular Dystrophies

ISABELLE RICHARD

Généthon CNRS, Evry, France

richard@genethon.fr

Definition

Limb girdle muscular dystrophies (LGMD) are inherited degenerative disorders of the skeletal muscle (1, 2, 3, 4). As their name indicates, they are characterized by progressive atrophy and weakness of pelvic and scapular girdle muscles. Other clinical features include an elevation of the serum creatine kinase level and a dystrophic pattern on muscle biopsies. At the histological level, this pattern typically includes heterogeneity in fiber size, areas of muscle necrosis and regeneration, fiber splitting and ultimately increased amounts of fat and connective tissue.

Despite their common name, there is a marked clinical and genetic heterogeneity within this group of muscle diseases. Following the genetic definitions generated by the application of molecular strategies, a classification was established in which dominant and recessive forms are designated LGMD1 and LGMD2, respectively. The different subtypes are distinguished by addition of capital letters in the order of identification. To date, 7 different subtypes have been recognized for the dominant forms (LGMD1A to 1G) and ten for the recessive forms (LGMD2A to 2J). The genes responsible for 3 dominant and all recessive forms have been identified. The corresponding proteins belong to different groups of proteins with respect to their subcellular localization (nucleus, ►cytoplasm, ►cytoskeleton and ►sarcolemma) and to their functions (structural, enzymatic, etc.).

Characteristics

►Autosomal Dominant (Inherited Disorder) LGMD

The dominant forms usually show a mild course and are often associated with other clinical features. Only a few families have been described for each form.

LGMD1A: Genetic Localization: 5q31; Causative Protein: Myotilin (TTID)

LGMD1A is characterized by an adult-onset proximal weakness, later progressing to distal extremities and is often associated with a dysarthric pattern of speech. Myotilin is a structural protein located in the ►Z-disc of the ►sarcomere in cardiac and skeletal muscles. By its association with other proteins that include α -actinin, γ -filamin and F-actin, it may participate in Z-disc organization. Histologically, the mutations

Limb Girdle Muscular Dystrophies. Figure 1 Schematic representation of the muscle cell and localization of the proteins involved in LGMDs. The proteins involved in dominant and recessive LGMD are in red and purple, respectively. The main proteins of the muscle are depicted in blue.

induce a large number of autophagic vesicles and disruption of the Z-disc.

**LGMD1B: Genetic Localization: 1q11-21;
Causative Protein: Lamin A/C (LMNA)**

LGMD1B is characterized by muscle weakness starting in the proximal lower-limb muscles and preceding the appearance of life threatening cardiac dysrhythmias. Lamins A/C are components of the nuclear lamina, a network of fibrous proteins located in the internal face of the internal nuclear membrane. A role for lamin has been suggested in DNA replication, chromatin organization, spatial organization of nuclear pore complexes and anchorage of nuclear envelope proteins. It is interesting to note that mutations in LMNA can lead to a number of other tissue-specific disease phenotypes.

LGMD1C: Genetic Localization: 3p25; Causative Protein: Caveolin 3 (CAV3)

LGMD1C presents as a mild to moderate proximal muscle weakness and calf hypertrophy, starting in childhood around 5 years of age. Caveolin 3 is a muscle-specific member of the caveolin family and is

the principal structural protein of caveolae in striated muscles. Caveolae are vesicular invaginations of the plasma membrane participating in vesicular trafficking events and signal transduction processes. It has been shown that LGMD1C mutants of caveolin 3 form unstable high molecular aggregates that are retained within the ►Golgi complex instead of being targeted to the plasma membrane.

Other LGMD1:

Four other genetic loci have been identified for dominant LGMD although the genes involved have not yet been identified. LGMD1D was mapped to chromosome 7q in two families. It is characterized by proximal weakness starting in adulthood in the lower limbs. LGMD1E was mapped to chromosome 6q23 and is associated with dilated cardiomyopathy with conduction defect (CMD1F, OMIM602067). LGMD2F was mapped to chromosome 7q32.1-q32.2 in a Spanish pedigree. Occurrence of genetic anticipation was proposed by the authors as severity appears to worsen between successive generations. LGMD1G was mapped to chromosome 4p21 in a Brazilian family.

It has a late-onset and is associated with progressive fingers and toe flexion limitation.

►Autosomal recessive LGMDS

Autosomal recessive limb-girdle muscular dystrophies have a wide spectrum of clinical severity. In the milder forms of LGMD, onset may be in the first, second or even third decade; loss of ambulation usually occurs after the third decade. In the most severe forms, onset usually occurs between 3 and 5 years and progression is very rapid with loss of ambulation usually before the third decade. There is significant variability of clinical features in unrelated patients and within families

LGMD2A: Genetic Localization: 15q15.1-15.3; Causative Protein: Calpain 3 (CAPN3)

LGMD2A is also referred as calpainopathy. It is characterized by a symmetric involvement of the proximal muscles, especially those of the posterior compartment of the lower limbs. LGMD2A has a worldwide distribution and represents a large proportion of the LGMD2s. Calpain 3 is the muscle specific member of the family of calpains, ►cysteine proteases whose activities are calcium-dependent. In humans, the calpain 3 protein can be localized either in the cytoplasm where it binds to titin, a giant elastic protein of the sarcomere, or in the nucleus. The presence of mutations seems to impair mainly the proteolytic activity and is associated with a perturbation of the apoptotic-regulating pathway of NF- κ B/I κ B α .

LGMD2B: Genetic Localization: 2p13; Causative Protein: Dysferlin (DYSF)

LGMD2B is also referred as dysferlinopathy. It is characterized by a very high serum creatine kinase level and prominent inflammatory changes. It is allelic to a distal phenotype, Miyoshi myopathy, and, like LGMD2A, is a frequent LGMD2. Dysferlin is a 230 kD protein localizing to the muscle fiber membrane and belonging to the ferlin family. The dysferlin mutations induce its intracellular accumulation, in the form of nuclear staining or abundant cytoplasmic vesicles, associated with a reduction in its sarcolemmal expression. It was shown that dysferlin is involved in membrane repair.

LGMD2C, D, E, F: Genetic Localization: 3q12, 17q21-q21.33, 4q12, 5q33-34; Causative Proteins: γ -, α -, β -, δ -Sarcoglycans (SGCG, SGCA, SGCB and SGCD)

This group of diseases is referred as sarcoglycanopathies and includes the most severe forms of LGMD2s. Alpha-sarcoglycanopathy is the only sarcoglycanopathy with a universal distribution. The sarcoglycans form a subcomplex in the ►dystrophin glycoprotein complex (DGC) linking the subsarcolemmal cytoskeletal proteins to the

extracellular matrix (ECM) via β -dystroglycan and dystrophin. In each of the sarcoglycanopathies, most of the mutations destabilize the whole sarcoglycan complex at the plasma membrane.

LGMD2G: Genetic Localization: 17q11-q12; Causative Protein: Telethonin (T-CAP)

LGMD2G is a mild myopathy with some involvement of the distal muscles. Rimmed vacuoles were observed in the muscle biopsies. Telethonin is a sarcomeric protein of 19 kD found exclusively in striated and cardiac muscle and localized to the Z-disk. Telethonin is phosphorylated by the serine kinase domain of titin in early differentiating myocytes. This event seems to be involved in the reorganization of the cytoskeleton during ►myofibrillogenesis. Through binding, telethonin inhibits the secretion of myostatin, an inhibitor of skeletal muscle growth.

LGMD2H: Genetic Localization: 9q31-33; Causative Protein: Tripartite-motif-containing Gene-32 (TRIM32)

This mild muscular dystrophy was only found in Hutterite population in North America. TRIM32 is a member of the growing family of tripartite motif proteins. Members of this family may form, through homodimerization, high molecular weight complexes that define subcellular compartments. The tripartite motif includes a RING-finger domain that mediates transfer of ►ubiquitin to substrates, suggesting that TRIM 32 is a ►E3 ubiquitin ligase.

LGMD2I: Genetic Localization: 19q13.3; Causative Protein: Fukutin-related protein (FKRP)

LGMD2I is a mild to severe LGMD2 presenting with calf hypertrophy. FKRP is ubiquitously expressed with the highest level in skeletal muscle and heart. It was identified through a homology search to fukutin, the protein involved in ►Fukuyama myopathy. These two proteins are Golgi-resident ►glycosyl transferases that seem to cooperate in the transfer of sugars to α -dystroglycan. Alteration of ►glycosylation of α -dystroglycan reduces its ability to bind to ECM ligands such as laminin- α 2 and agrin, disrupting linkage of the internal cytoskeleton to the ECM.

LGMD2J: Genetic Localization: 2q24.3; Causative Protein: Titin (TTN)

Homozygous mutations in Mex6, the last exon of titin, are responsible for LGMD2J. The same mutation in a heterozygous state causes tibial muscular dystrophy, a late-onset autosomal myopathy affecting mostly the anterior compartment of the lower limb. Titin is a giant elastic protein spanning half a sarcomere. LGMD2J is associated with a secondary deficiency in calpain 3 that has a binding site in the vicinity of the mutation.

Limb Girdle Muscular Dystrophies. Table 1 Chromosomal localization and causative genes of the different LGMDs

	Chromosomal localization	Causative gene	Locus	Size protein (kD)	Site of main expression	Subcellular localization
LGMD1A	5q22.3-q31.3	Myotilin	TTID	57	Sk. and cardiac muscles	Z-disc
LGMD1B	1q11-q21	Lamin A/C	LMNA	80 and 65	Ubiquitous	Nuclear lamina

LGMD2J	2q24.3	Titin	TTN	3 000	Sk. and cardiac muscles	Sarcomere

Sk: skeletal

Cellular and Molecular Regulation

Muscular dystrophies could be seen as a consequence of an imbalance between muscle cell death and survival. Considering the nature of the LGMD proteins, it is clear that such an imbalance can be the consequence of a diversity of pathological mechanisms, highlighting some aspects that are of utmost importance for skeletal muscle ►[homeostasis](#).

Skeletal muscle endures important mechanical constraints during muscular contractions. The structural characteristics of its complex cytoskeleton and the linkage of the DGC with the ECM confer on the muscle the necessary load-bearing properties to support these stresses. In addition to providing structural integrity,

there is increasing evidence that many of the cytoskeletal proteins also support cellular signaling processes important for cell survival. The LGMDs, that can be put in the category where these functions are impaired, are: LGMD2I where dysglycosylation of α -dystroglycan disrupts the sarcolemma-ECM linkage, the sarcoglycanopathies where the absence of sarcoglycans lead to alterations in membrane permeability and possibly of ►[signal transduction](#), LGMD1A where myotilin mutations induce a disruption of the Z-disc and LGMD1B in which deficiency in laminA/C makes the nuclear envelope fragile. Another mechanism of protection, in which dysferlin plays a role and that is therefore impaired in LGMD2B, is the capacity to

reseal membrane disruptions generated during mechanical injury.

Another characteristic of the skeletal muscle is its important plasticity. By constant alterations in synthesis, degradation and assembly of metabolic, structural and regulatory proteins, it is capable of responding to changes in cellular physiology such as modification of contractile activity, nutrient supply or environmental factors. Many of the LGMDs may be linked to defects in those processes, especially for those that are supported by cytoskeletal networks. In LGMD1C, it can be hypothesized that signaling pathways supported by the caveolae are impaired. There is also a possible perturbation in the regulation of ►glycolysis, as phosphofructokinase, an important enzyme of this pathway, is one of the major caveolin binding proteins. Calpain 3 may participate in linking sarcomeric to nuclear function and may prevent cell death by controlling the ►apoptosis regulatory pathway of NF- κ B/I κ B α in response to mechanical stress. Telethonin deficiency may be related to an impairment of muscle growth with respect to its inhibitory role in myostatin secretion. Mutations in TRIM 32 may result in defects in protein turnover by preventing the targeting of one or a group of proteins to the ►proteasome. Titin mutations in LGMD2J are not associated with disruption of the sarcomere and may more probably be associated with a signaling pathway perturbation, possibly in relationship with calpain 3.

Independently of the pathological mechanism, mutations in the increasingly diverse group of the LGMD proteins lead to an overall similar outcome, which is the predominance of proximal muscle weakness. Much work remains to be done to fully understand the biochemical basis of susceptibility to cell death, especially with respect to the unsolved issue of the muscle specificity of these disorders.

Clinical Relevance

Even though the molecular discoveries led to a better definition of each disorder, each genetically distinct entity may present heterogeneity of clinical signs resulting in an overlap in presentation and making them often difficult to distinguish clinically. Therefore, differential diagnosis should rely on molecular tools and especially on protein analysis by western blotting or immunohistochemistry with specific antibodies (5). However, it is complicated by the fact that a genetic alteration could lead to a secondary defect in another protein.

None of the LGMDs are effectively treatable to date. However, there is hope that advances in knowledge of disease mechanisms and in solving the issues involved by ►gene-based therapies will lead to applications in treating these muscular dystrophies. A number of viral and non-viral vector systems have been evaluated for

muscle-directed gene transfer in several dystrophic mouse models bringing proof-of-principle for feasibility and efficacy (6). Currently, ►adeno-associated virus vectors may be the best choice with regard to efficiency and longevity of gene transfer in muscle tissues. However, the gene transfer approach for muscular dystrophy presents significant challenges, especially regarding gene delivery into such large amounts of tissue as muscles, which represent 40 % of the body mass. In parallel to gene-based therapy, a better understanding of causative protein functions and of downstream pathological consequences of the genetic defect could facilitate the identification of novel drug targets. In addition, systematic drug screening could help to identify compounds that would improve the condition of the patients.

Limbic System

Definition

The limbic system is a heterogeneous neuronal system that is involved in the generation of feelings, emotions and motivations, and is intimately involved in learning and memory consolidation related to drug effects. Functional imaging techniques in humans demonstrate that craving for drugs of abuse involves areas (e.g. limbic system) predicted from animal experiments.

►Addiction, Molecular Biology

LIMS

Definition

LIMS (Laboratory Information Management System) refer to the output from high throughput analyses of the proteome with clinical information, protein structure,

sample storage and stock, and the status of various items for data production.

Lineage determination designates the restriction of developmental options of cells to one or few differentiation pathways.

► [Muscle Development](#)

Linear Unmixing

Definition

If several fluorochromes are used simultaneously to record images in fluorescence microscopy, the resulting image is the sum of the contributions of the single fluorochromes and a separation of those contributions is desirable. Linear unmixing refers to a mathematical algorithm used to separate the signals from different fluorochromes at each pixel within an image. It is based on a matrix where the relative contributions of each of the fluorochromes into each detection channel are first recorded as reference spectra, and subsequently applied to the spectral image. This operation deconvolves the weighting coefficients of the component spectra from the measured sum spectra, and thus reveals each individual contribution.

► [Fluorescence Microscopy: Spectral Imaging vs. Filter-Based Imaging](#)

Linkage

Definition

Linkage means the tendency of (series of) polymorphisms at specific loci to be inherited together. If two genes (genetic loci) are in close proximity on the same chromosome they are said to be linked. Genetic linkage between a marker and a disease gene implies that alleles at the marker locus co-segregate with the disease allele within families, but that different marker alleles may co-segregate with the disease allele in different families. Under linkage, the overall frequencies of the marker alleles calculated from population-based samples need not vary between affected and control groups.

► [Common \(Multifactorial\) Diseases](#)

► [COPD and Asthma Genetics](#)

Linkage Disequilibrium

Definition

Linkage disequilibrium (LD) is the result of non-random association of alleles at the population level of variants at the marker and disease genes. This usually implies close physical linkage of the marker and disease gene, reflecting the historical origin of a mutation on a specific chromosome with a characteristic set of variations. Evidence for linkage disequilibrium can be

helpful in mapping disease genes, since it suggests that the two may be very close to one another.

Linker DNA

Definition

Linker DNA denotes the DNA tract that connects adjacent nucleosomes in the chromatin fiber.

- ▶ Nucleosomes

Lipid Asymmetry

Definition

Lipid asymmetry defines the asymmetric distribution of lipids between the two layers of a biological membrane, which causes differences in the physicochemical and functional properties between both layers.

- ▶ Biological Membranes

Lipid Peroxidation

Definition

Lipid peroxidation is a term commonly used for free radical-driven oxidative destruction of unsaturated fatty acid residues in complex lipids that ultimately leads to biomembrane disruption. Lipid peroxidation can also be initiated by lipoxygenases. Such enzymatic lipid peroxidation by 15-lipoxygenase, has been implicated in, e.g. the elimination of mitochondria during erythrocyte maturation. If catalyzed by 5-lipoxygenase it represents the initial step of leukotriene biosynthesis.

- ▶ Free Radicals

Lipid Rafts

Definition

Lipid rafts are membrane microdomains enriched in lipids such as sphingolipids and cholesterol. These “rafts” or microdomains have been implicated in cell signaling and in apical transport of plasma membrane proteins in polarized cells.

- ▶ Cell Polarity
- ▶ Epithelial Cells

Lipidophilicity

Definition

Lipidophilicity describes the affinity of a molecule or a moiety for a lipophilic environment, commonly measured by its distribution behaviour in a biphasic system.

- ▶ Hydrophobicity
- ▶ QSAR

Lipopolysaccharide

- ▶ LPS

Lipoprotein

Definition

Lipoprotein refers to a complex of lipid and protein. It is the way lipids travel in the blood.

► [Familial Hypercholesterolemia](#)

Liposomes

Definition

Liposomes are spherical particles that consist of an aqueous compartment enclosed by a lipid bilayer.

► [Surface Plasmon Resonance](#)

Liquid Chromatography

Definition

Chromatography basically involves the separation due to differences in the equilibrium distribution of sample components between two different phases. One of these phases is a mobile phase and the other is a stationary phase. In *liquid chromatography* a sample mixture is passed through a column packed with solid particles which may or may not be coated with another liquid. With the proper solvents, packing conditions, some components in the sample will travel the column more slowly than others resulting in the desired separation.

Locus Control Region

Definition

The Locus Control Region (LCR) is a regulatory DNA segment, originally identified as an extended cluster of DNase I hypersensitive (HS) regions in the beta globin locus. An LCR is typically extended over several kilobases and contains several enhancer-active subsegments of 100-300 bp each. The LCR may be considered an umbrella term that encompasses all enhancers required for the correct developmental expression pattern of one or more genes under its influence. It also may direct the position-independent and copy number-dependent expression of transgenes.

- ▶ [Enhancer](#)
- ▶ [Transgene Silencing](#)

Locus Heterogeneity

Definition

Locus heterogeneity refers to mutations in different genes at different chromosomal loci that cause an identical phenotype.

- ▶ [Chromosomal Instability Syndromes](#)

Lod Score

Definition

Lod score stands for (decadic) logarithm of the odds ratio. In genetic linkage analysis, the lod score quantifies the empirical evidence in favour of linkage between two loci of interest.

Long Term Depression

Definition

Long term depression (LTD) is a synaptic plasticity phenomenon that corresponds to the decrease in the synaptic strength (decrease in the post-synaptic response observed for the same stimulation of the presynaptic terminals) observed after a specific stimulation of the afferent (input) pathway. This decrease is still observed hours after its induction.

Long Term Potentiation

Definition

Long term potentiation (LTP) is a synaptic plasticity phenomenon that corresponds to the increase of synaptic strength (increase in the post-synaptic response observed for the same stimulation of the presynaptic terminals), observed after a high-frequency stimulation (tetanus) of nerve fibers. The increased response in synaptic sensitivity is long lasting, and is still observed hours or even days after the tetanus. The phenomenon is often observed at glutamatergic synapses and involves, in most cases, the activation of the N-methyl-D-aspartate (NMDA) subtype of ionotropic glutamate receptors.

LTRs

Definition

LTRs are long sequences of double stranded DNA, a sequence directly repeated at both ends of retroviral DNA. LTRs originate from reverse transcription of retroviruses and contain strong promoters as well as transcription termination signals.

L-Type Calcium Channel

Definition

L-type calcium channels are voltage-operated calcium channels with high electrical thresholds found in both excitable and nonexcitable tissue. It is essential for most of the early plateau current of the action potential, and thus for normal myocardial and vascular smooth muscle contractility. The channels are formed by five subunits (alpha-1, alpha-2, beta, gamma, and delta).

Definition

The mouse embryonic lung is an excellent example of a branched organ. The branching pattern in the lung is extremely reproducible from one embryo to another suggesting a tight temporal-spatial genetic control of the branching process. It is only during the last decade that the molecular interactions at the base of the branching process in this organ have begun to become elucidated. This review will focus on the current knowledge of the ►growth factors, produced either by the ►epithelium or the ►mesenchyme, playing a key role in controlling branch formation. For more information about lung development, we will address the reader to excellent reviews published recently (1, 2) and some key papers.

Early Lung Development and Branching

►Morphogenesis

The mouse lung arises at E9.5 (Fig. 1), from the ventral foregut, just anterior of the developing stomach. The primordia of the trachea and the two lung buds consist of an epithelial layer of ►endoderm surrounded by ►splanchnic (lateral plate) ►mesoderm. The trachea is separated from the esophagus by means of a longitudinal septation of the foregut, while the rest of the lung develops from two ventral buds that form at the posterior end of the trachea. Initially the primary buds

Lung. Figure 1 Lung branching morphogenesis illustrated by *Hnf3 β* expression. Embryonic lung development in mouse. Lung development starts at E9.5 with the emergence of two primary buds from the ventral foregut (only one is shown in the picture). At E10.5, the lung is composed of a trachea (tr) and two bronchi (br).

undergo repetitive outgrowth and branch laterally at invariant positions. They develop asymmetrically, so that in the mouse the right bud gives rise to four lobes, whereas the left bud gives rise to only one. The number of secondary buds on the left and right sides varies amongst species and is regulated by the pathways that control left-right asymmetry. As lung morphogenesis continues, dichotomous branching is observed at the tip of each duct, driven by reciprocal interactions between the distal mesenchyme and endoderm. The early lung branching pattern is stereotypic and invariant, indicating that it is probably genetically programmed.

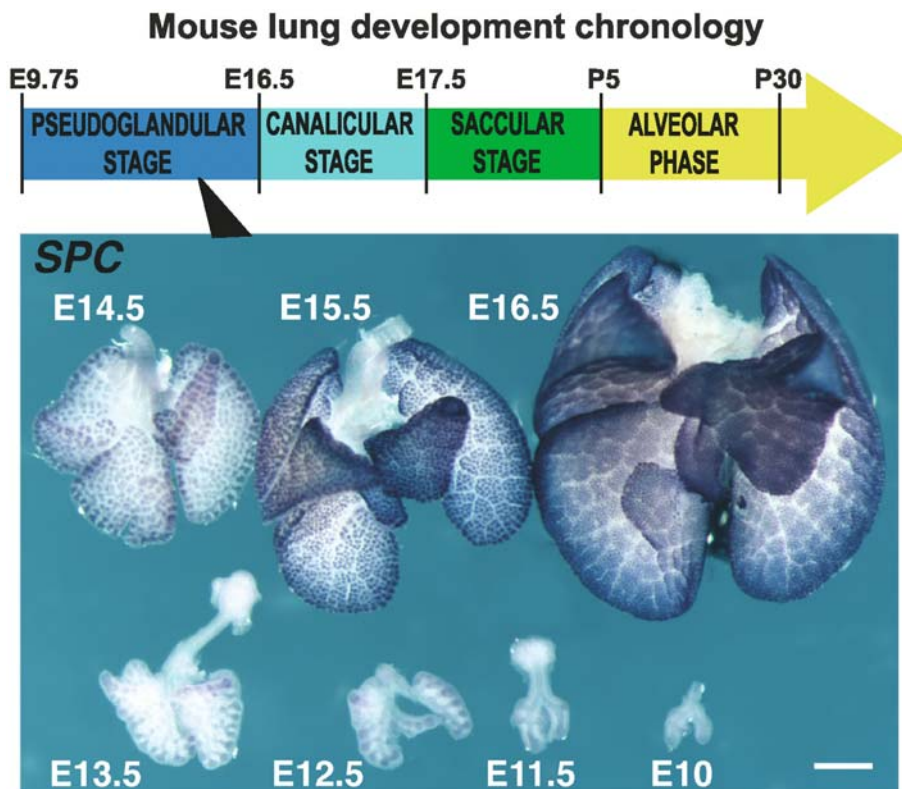

Characteristics

Histologically, lung development has been divided into four stages in mouse (Fig. 2): 1) pseudoglandular stage (E9.5–16.5), characterized by the development of the bronchial and respiratory tree and a relatively undifferentiated distal endoderm; 2) canalicular stage (E16.5–17.5), when the distal endoderm begins to form terminal sacs and vascularization begins; 3) sacular stage (E17.5–P5), characterized by thinning of the mesenchyme, an increase in the number of terminal sacs, vascularization and ►differentiation of the endoderm into type I and type II cells; 4) alveolar stage (P5–P30), when the terminal sacs develop into mature alveolar ducts and alveoli. Unlike in the mouse, the alveolarization of the human lung begins before birth. This review will focus mostly on the pseudoglandular stage.

Molecular Interactions

Fibroblast Growth Factor 10 (*Fgf10*) Expression is Associated with Directional Growth of the Epithelial Buds

Fgf10 (Fig. 3a), which is expressed focally in the embryonic lung distal mesoderm adjacent to stereotypically determined branching sites, has been shown to trigger chemotaxis and proliferation on the adjacent epithelium. This results in directional growth of the primary lung buds. Mutant embryos defective in signaling for either *Fgf10* or *Fgfr2IIIB* (encoding the principal and highest affinity FGF10 receptor) die at birth as a consequence of lung defects; they develop a trachea and primary bronchi, but no respiratory tree. *FGFR2IIIB* is expressed in the lung epithelium with a higher expression distally. *Fgf10*, a key mesenchymal signal in inducing epithelial branching during lung development translates the positional information in the mesenchyme into the early branching pattern. High levels of *Fgf10* expression are detected in the mesenchymal cells some distance from the epithelium at the focal sites adjacent to where secondary branches later emerge (3). Regulated expression of heparan sulfate (HS) at sites of budding, with distinct patterns of HS sulfation in the epithelial-associated ►basement

Lung. Figure 2 Different stages of lung development. Histologically, lung development is divided into four stages; pseudoglandular (E9.5–16.5), canalicular (E16.5–17.5), saccular (E17.5–P5) and alveolar stages (P5–P30). The development of the mouse bronchial and respiratory tree during the pseudoglandular stage is illustrated by *SP-C* expression.

membrane and mesenchyme, influence lung pattern formation by mechanisms that include regulation of FGF10 protein distribution and binding to its epithelial receptor. FGF10 also controls the differentiation of the epithelium by inducing ► *Surfactant protein C* (*SP-C*) expression and by up-regulating the expression of *Bmp4*, a known regulator of lung epithelial differentiation (4). FGF10 induces the expression of its own antagonist, *Sprouty2* (*Spry2*), in the distal epithelium. Reduction of *Spry2* expression in cultured lungs using ► antisense oligonucleotides resulted in an increase in lung branching and up-regulated expression of specific lung epithelial maturation/differentiation markers. Conversely, targeted over-expression of *Spry2* in peripheral lung epithelium results in a lower level of branching, smaller lungs with a particular “moth-eaten” dysplastic appearance along the edges of the lobes and a decrease in epithelial cell proliferation.

The lung is enveloped by a thin serous membrane, the mesothelium, composed of a monolayer of flat cells of mesodermal origin. The mesothelium expresses *Fgf9*, which acts as a proliferative growth factor on the underlying mesenchyme, mostly through the receptor FGFR2-IIIc.

Sonic Hedgehog (SHH) Induces Mesenchymal Cell Proliferation

Sonic hedgehog (*Shh*) (Fig. 3b) is expressed throughout the endoderm with the highest levels at the most distal tips. By contrast, the gene encoding the SHH receptor (called *Patched* or *Ptc*), is expressed mostly in the adjacent mesoderm. In *Shh*^{-/-} embryos, the trachea and primary buds fail to separate from the esophagus. The primary buds also remain as small sacs and do not grow out or branch. *Fgf10* expression, which is highly spatially restricted in wild type, is up-regulated and widespread in the mesenchyme in contact with the epithelium of the *Shh* null mutant mouse lung. In addition, over-expression of *Shh* in the mouse lung using a transgenic approach leads to reduced *Fgf10* expression. Thus, *Shh* signaling to the mesenchyme negatively regulates *Fgf10* expression, and the resulting misregulation of *Fgf10* in *Shh* mutant lungs most probably accounts for the observed failure of secondary branching. Local suppression of *Shh* signaling by the induction of Hh-binding proteins such as *Patched* (*Ptc*) and *Hedgehog interacting protein* (*Hip*) in the mesenchyme at branch tips, may serve to facilitate FGF signaling locally (1).

Bone Morphogenetic Protein 4 (BMP4) Controls Proliferation and Proximal-distal Differentiation of the Lung Epithelium

Bmp4 (Fig. 3c) expression is first detected in the ventral mesenchyme of the developing lung when the primordial lung buds are merging from the foregut. This mesenchymal expression is maintained until E13.5. Expression of *Bmp4* is also detected in the distal endoderm of the developing lung bud. Over-expression of *Bmp4*, driven by the *Surfactant Protein-C* (*SP-C*) promoter in the distal endoderm of transgenic mice, causes abnormal lung morphogenesis, with cystic terminal sacs and inhibition of epithelial

proliferation. In contrast, *SP-C* promoter-driven over-expression of either the BMP antagonist *Xnoggin* or a dominant negative *Alk6* BMP receptor to block BMP signaling, results in severely reduced distal epithelial cell phenotypes and increased proximal cell phenotypes in the lungs of transgenic mice (4). However, the exact roles of BMP4 in early mouse lung development remain controversial. *Bmp4* is induced at the tip of the growing lung buds in response to mesenchymal *Fgf10*. In isolated E11.5 mouse lung endoderm cultured in ▶Matrigel™, addition of exogenous BMP4 prevents further budding in response to FGF10, therefore ensuring a single extending bud, rather than a cluster of buds (4). However, addition of BMP4 to intact embryonic lung explant cultures stimulates lung branching morphogenesis.

Lung. Figure 3 Gene expression in early mouse lung between E11.5 and E12. (a) *Fgf10* is expressed in the distal mesenchyme at sites of budding (arrows). (b) *Shh* is expressed throughout the epithelium. Note that its expression is up-regulated at sites of budding. (c) *Bmp4* is expressed at high levels in the distal epithelium. (d) Lung at E12, *Wnt7b* is expressed throughout the epithelium.

Wnt Signaling Controls Epithelial and Mesenchymal Differentiation

Wnt signaling plays also an important role in lung development. Between E10.5 and 17.5, β -catenin is localized in the cytoplasm and often also in the nucleus of the undifferentiated primordial epithelium (PE), differentiating alveolar epithelium (AE) and adjacent mesenchyme. *Tcf1* (*T-cell factor 1*), *Lef1* (*Lymphoid enhancer factor 1*), *sFrp1* (*secreted Frizzled-related protein 1*) and *sFRP2* are highly expressed in the mesenchyme adjacent to the PE and AE. *Tcf3* is highly expressed at the apical side of the PE and AE while *Tcf4* and *sFrp4* are detected in both the PE and adjacent mesenchyme. *Fz8* is highly expressed throughout the epithelium while *Fz2*, 3, 6 and 7 are expressed both in the epithelium and mesenchyme (5). These expression patterns suggest that Wnt signaling can originate from the epithelium and mesenchyme and can target both tissues in an autocrine and/or paracrine fashion. TOPGAL or BATGAL mice, which harbor a β -galactosidase gene under the control of a LEF/TCF and β -catenin inducible promoter, reveal that from E10.5 until E12.5, canonical Wnt signaling occurs throughout the epithelium and in the mesenchyme adjacent to the proximal airways where the bronchial smooth muscle cells (SMC) arise (5). From E13.5, TOPGAL activity is no longer present in the mesenchyme and the activity in the epithelium is reduced distally concomitant with the onset of expression of *Dkk1* in the distal epithelium (5). Conditional inactivation of the β -catenin gene in the epithelium of the developing mouse lung leads to neonatal death resulting from severe lung defects (6); branching of secondary bronchi is altered and the number of small peripheral alveolar ducts and terminal saccules is markedly reduced. In addition, the epithelium fails to undergo proper distal differentiation, lacking the expression of pro-*SP-C* protein and *Vascular endothelial growth factor a*, the latter correlating with a

reduction in alveolar capillaries. So far, inactivation of only two Wnt ligands has resulted in lung defects. *Wnt7b* (Fig. 3d) is normally expressed in epithelial cells of the lung periphery. *Wnt7b*^{-/-} mice exhibit perinatal death due to respiratory failure. Defects were observed in proliferation of the lung mesenchyme resulting in lung hypoplasia. In addition, *Wnt7b*^{-/-} embryos and newborn mice exhibit severe defects in the smooth muscle component of the major pulmonary vessels, with increased apoptosis of the vascular smooth muscle cells (VSMCs), resulting in rupture of the major blood vessels and hemorrhages in the lungs after birth. *Wnt5a* is expressed at high levels in the distal lung mesenchyme. *Wnt5a*^{-/-} mice die perinatally from lung defects including truncation of the trachea, overexpansion of the peripheral airways and delayed lung maturation. Absence of WNT5a activity in the mutant lungs leads to increased cell proliferation and up-regulation of the expression of *Fgf10*, *Bmp4*, *Shh* and *Ptc*.

On the other hand, hyperactive Wnt signaling changes the developmental potential of embryonic lung endoderm to express markers of gut endoderm differentiation. Inhibition of Wnt signaling throughout the lung by treatment of lung explants with exogenous DKK1, a potent and specific diffusible inhibitor of Wnt action, results in impaired branching and defects in smooth muscle differentiation and in the formation of the pulmonary vascular network as a result of decreased Fibronectin (FN) deposition (5). This points out the importance of correct deposition of the extracellular matrix in response to growth factor signaling and suggest that for branching/epithelial tip splitting, a solid bar of Fibronectin in the mesenchyme can act like a “rock in the stream” to divide the flowing stream of epithelium into two as it chemotaxes towards FGF10.

Regulatory Mechanisms

Proximal Distal Differentiation of the Lung Endoderm

Epithelial cell lineages are arranged in a distinct proximal-distal pattern in the airways. The larynx is lined with squamous epithelium and the upper airways are lined with ciliated columnar cells that express the forkhead gene *Hfh4* and mucus secreting cells. The lower airways are lined with Clara cells, which secrete a protein called Clara cell 10 kD protein or CC10. The alveoli are lined with alveolar type 1 and 2 epithelial cells (AEC 1 and 2). In the adult lung, the type 1 cells lie in close apposition to the capillaries of the alveoli, whereas the type 2 cells tend to be clustered at the junction between the alveolar ducts and the alveoli. Type 2 cells have the potential to transdifferentiate into type 1 cells. AEC 2 cells are characterized by their expression of the gene for surfactant protein C (SP-C). Pulmonary endocrine (PNE) cells are situated in small

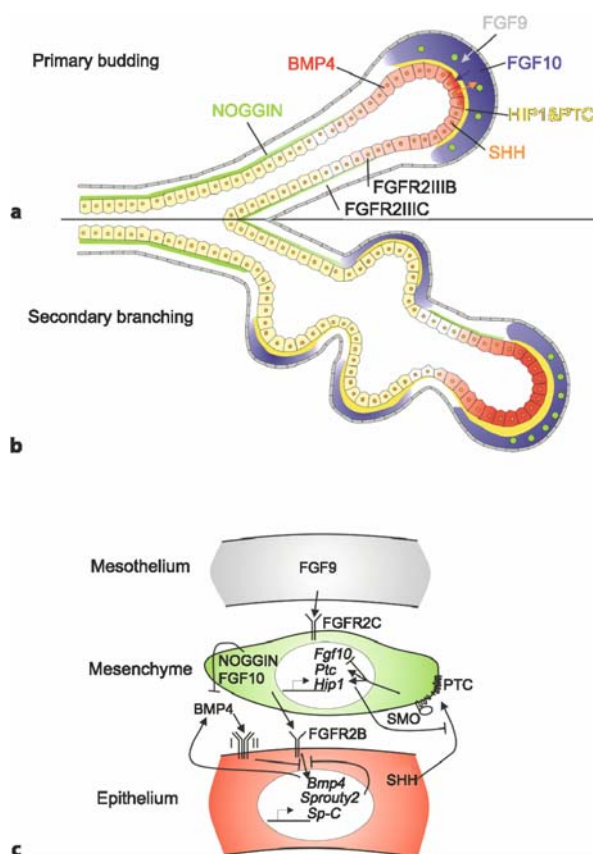

foci and are surrounded by other epithelial cells in the upper airways. PNE cells secrete peptides such as bombesin and calcitonin gene-related peptide, but their precise function is unknown. They also express high levels of *Delta1* (Dll1), encoding a surface ligand for Notch that may function in determining cell fate. The epithelial cells also express uniformly *Fgfr2* and *Hnf3* (*Foxa1*) and (*Foxa2*). The epithelial and mesenchymal cells at the very tips of the extending branches and buds have a specific pattern of gene transcription, related to intercellular signaling pathways (see molecular interactions). Genes expressed at high levels in the epithelium at the tips include *Shh*, *Bmp4*, *Wnt7b*, *Fgfr4* and *c-Fos*. By contrast, the mesenchyme around the tips expresses high levels of *Fgf10*, *Ptc* and *Pod1*. The distal tips are thus thought to be organizing centers that play key roles in regulating both the epithelial-mesenchymal interactions that drive branching morphogenesis and the proximal distal patterning of the lung epithelium.

Formation of a Functional Respiratory Unit (Alveolus)

The alveolar stage involves the formation and maturation of the alveoli. It involves the formation of primary and secondary septa that subdivide the saccules into multiple alveoli. The interstitial mesenchyme layer of each septum is initially quite substantial and contains a capillary network, which is not in very tight contact with the endodermal cells. As postnatal development in the mouse continues, the number of interstitial cells declines and the AEC 1 cells become very closely apposed to the capillary endothelial cells. In the mature lung, the tips of the septa contain smooth muscle cells that produce bundles of elastin fibers, which are important for alveogenesis. Knock out of several genes has resulted in failure of alveogenesis. In *Elastin*^{-/-} mice, perinatal development of airway branches is arrested and is accompanied by fewer distal air sacs that are dilated with attenuated tissue septa resulting in an emphysematous phenotype. In *Pdgfra*^{-/-} (*Platelet derived growth factor a*) mice, the smooth muscle cells and elastin fibers are absent and septae fail to form, leading to postnatal death (7). During the pseudoglandular stage, the growth factor PDGF-A is expressed by the distal epithelial cells and the receptor, PDGFR-A, by the surrounding mesenchyme cells from which the smooth muscle cells derive. Finally, inactivation of both *Fgfr3* and *Fgfr4* results in a postnatal lethal pulmonary phenotype in which excess elastin is laid down and alveoli fail to form.

Toward an Integrated Model of Branching Morphogenesis

As outlined earlier, different growth factors expressed either in the epithelium or mesenchyme are regulating

Lung. Figure 4 Integrated model of Budding. (a) The two primary buds initially elongate. FGF10 (blue), expressed in the distal mesenchyme, acts on the endoderm, through the FGFR2IIIB receptor isoform, to promote its proliferation (blue arrow). SHH (orange dots) is expressed in the epithelium and is up-regulated at the distal tips of the primary buds (darker orange dots). In response to FGF10 signaling, *Bmp4* (red) and *Sprouty2* expression are building up in the endoderm. Because *Fgf10* expression at the sites of future bud formation precedes *Bmp4* up-regulation and *Sprouty2* induction, lung bud outgrowth will occur before BMP4 and SPROUTY2 reach a critical concentration sufficient to inhibit FGF10. NOGGIN (a BMP4 inhibitor; green dots) is expressed in the distal mesenchyme in response to BMP4 signaling and at higher levels in the proximal mesenchyme near the proximal epithelium. The mesothelial layer expresses FGF9 and acts as a proliferative factor on the mesenchyme through receptor FGFR2IIIC (gray arrow). (b) Secondary bud formation is also induced by localized FGF10 (blue) expression in the mesenchyme corresponding to the future sites of secondary bud formation. Epithelial expression of SHH might be instrumental in restricting *Fgf10* expression to the sites of secondary bud formation by inhibiting *Fgf10* expression. SHH (orange dots) is up-regulated in the epithelium of the secondary buds after the activation of *Fgf10*. However, SHH signaling to the mesenchyme transcriptionally activates *Hedgehog-interacting protein 1* (*Hip1*) and *Patched 1* (*Ptc1*) (yellow), repressors of

the branching process. These factors are inducing cell proliferation, apoptosis and cell differentiation. The goal of this section is to integrate seemingly disparate data concerning the regulation of the branching process into a coherent overview. The complete cycle of budding consists of three phases, bud initiation, bud outgrowth and growth arrest. The molecular mechanisms controlling the initiation phase are still unclear and will certainly be the focus of future studies. In particular it will be extremely important to identify the first genes expressed in the region where the bud will form. These early genes are likely to regulate the expression of the genes that we have already identified. During the growth phase, FGF10 is so far the key molecule, and is expressed specifically in the mesenchyme adjacent to the forming epithelial buds. In the future it will be of vital importance to identify the positive regulators which allow such precise temporal-spatial expression. FGF10 expressed in the distal mesenchyme acts on the epithelium mostly through FGFR2-IIIb to promote cell proliferation. FGF10 also triggers chemotaxis on the epithelium (*via* a receptor which is not yet characterized) by modulating cell-cell and cell-extracellular matrix interactions to facilitate or promote cell migration. On the other hand, SHH secreted by the distal epithelium induces cell proliferation in the mesenchyme through PTC and GLI. This process would allow directional growth of the buds toward the localized domain of *Fgf10* expression until a negative feedback loop blocks bud outgrowth. Interestingly, the positive regulators of *Shh* and *Fgf10* expression are still unknown. For example, factors like the WNTs *Wnt7b* is expressed in the epithelium, could regulate *Fgf10* expression. During the growth arrest phase, sonic hedgehog in the epithelium negatively regulates *Fgf10* expression in the mesenchyme. The precise nature of this inhibition is unclear, and more experiments will have to be done to determine if the inhibition is directly promoted by SHH and at what threshold level the effect is elicited.

SHH signaling, to down-regulate the SHH pathway at sites of bud formation. As a result, *Fgf10* expression gets effectively inhibited only at the inter-bud regions. As outgrowth proceeds, the expression of *Bmp4* (red) increases in the distal endoderm, which prevents FGF10 inducing further budding from the growing lung bud. As a result, a single extending bud, rather than a cluster of buds, is generated. In response to lateral *Fgf10* expression, a new lateral, secondary bud is initiated, but only where the level of *Bmp4* expression falls below a threshold in the endoderm. The mechanism by which a new *Fgf10* expression domain is initiated is unknown. (c) Molecular interactions during lung development. The interactions described above are shown in more detail.

In parallel, FGF10 up-regulates *Bmp4* and *Sprouty2* expression in the epithelium, which in turn inhibit epithelial cell proliferation. This model, built essentially on signaling molecules, is obviously incomplete. Other molecules such as the extracellular matrix proteins, integrins and metalloproteases certainly play important roles in the bud outgrowth and growth arrest phases. In the future, we will take into consideration discoveries concerning signaling pathways, cell-cell and cell-extracellular matrix interactions to propose an integrated model of branching morphogenesis.

Definition

► **Multi-wavelength anomalous diffraction (MAD)** is a method for phase determination in crystal structure analysis with X-rays. Tunable synchrotron beam lines permit measurement of X-ray diffraction data from crystals at two or more energies near the K- or L-► **absorption edges** of ► **anomalous scatterers** present in biological macromolecules with optimal signal-to-noise ratios. Anomalous scatterers may be naturally present in the crystalline molecule or introduced in various ways. Cryo-cooling extends the lifetime of the crystals and newly developed CCD or other X-ray detectors shorten the measuring time to ensure highly precise measurements with low radiation damage to the molecules. Highly redundant measurements at low noise level permit phase determination at one wavelength at or distant from the absorption edge (► **single-wavelength anomalous diffraction, SAD**).

Description

Diffraction experiments with crystals yield intensities of reflections at coordinates h, k, l in reciprocal space. To determine the crystal structure, i.e. the arrangement of atoms or molecules in the crystal lattice, the amplitudes and phases of the reflections are needed. Amplitudes are proportional to the square root of the measured intensities, but the phases are not revealed by the experiment. Crystal structures of small molecules or inorganic compounds are routinely determined by employing statistical, “direct” methods for solving the phase problem. These methods are suitable for the structure analysis of biological macromolecules only in exceptional cases, when the diffracting power of the protein or nucleic acid crystal is unusually high. To permit the crystal structure analysis of other biological macromolecules, several methods have been introduced that require either the presence of heavy atoms in the crystal (atomic number ≥ 15) or the availability of a model with similarity to the structure being determined. Heavy atoms are used for phasing the diffraction pattern through isomorphous replacement, by exploiting the anomalous effect or by a combination of both. Similar structures that can be used as search models

are a prerequisite for phasing through molecular replacement (for reviews see 1, 2). Here we will focus on modern phasing methods that rely exclusively on anomalous scattering.

MAD (multi-wavelength anomalous diffraction) phasing became the method of choice in macromolecular crystallography with the introduction of new techniques for (i) incorporating anomalous scatterers into biomolecules, (ii) cryo-crystallography, (iii) new fast X-ray detectors and (iv) the availability of tunable, highly brilliant synchrotron beam lines. Since 1990, more than 1800 new crystal structures have been determined using this method. The anomalous scattering is highly dependent on the energy of the X-rays interacting with the anomalous scatterer present in the biomolecule. Although anomalous scattering is not an absorption effect, the signal size is largest near the absorption edge of the scatterer and varies strongly with the X-ray energy at which the diffraction experiment is done. Some of the photons are absorbed and re-emitted by the sample electrons at the same energy (strong coupling to absorption edge energy), but retarded compared to a normally scattered photon. This retardation (phase shift) of the scattered photon causes the atomic form factor f to acquire an imaginary component.

The total scattering factor of an atom is the sum of the ‘normal’ f^0 (scattering angle-dependent) and the ‘anomalous’ (wavelength/energy-dependent) component

$$f_{\text{total}}(\theta, \lambda) = f^0(\theta) + \{f'(\lambda) + if''(\lambda)\} \quad [1]$$

where θ is the scattering (Bragg) angle and λ is the X-ray wavelength.

In anomalous scattering, Friedel’s law is no longer valid, and this can be exploited to determine the phases of X-ray reflections and, furthermore, the absolute configuration of molecules. Reflections which follow Friedel’s law have equal amplitudes F_{hkl} and opposite phases φ (Fig. 1a). If all atoms scatter equally but anomalously, the amplitudes remain the same but the phase relationship no longer holds (Fig. 1b). This is because the f'' term is always positive. If normal and anomalously scattering atoms co-exist, the amplitude as well as the phase relationships are broken.

The imaginary component of the anomalous scattering, f'' , is approximately proportional to the atomic absorption coefficient and to the fluorescence at a chosen X-ray energy, and has its maximum near the absorption edge of an atom (Fig. 2, λ_1). The real component of the anomalous scattering, f' , has a minimum at the inflection point (λ_2) of the absorption curve. Reduction/oxidation and the local chemical environment of an anomalous scatterer modulate the

MAD Phasing. Figure 1 Vector diagrams illustrating anomalous scattering for the reflections (h, k, l) and $(-h, -k, -l)$. A reflection is presented as a vector with length equal to the scattering amplitude F and angle from the positive horizontal equal to the phase ϕ . (a) Friedel pairs of structure factors of normal atoms with equal amplitudes $|F(h, k, l)| = |F(-h, -k, -l)|$ and opposite phases $\phi(h, k, l) = -\phi(-h, -k, -l)$. (b) of anomalous scatterers where the amplitude law holds but the phase relationship is broken. (c) Normal and anomalously scattering atoms are mixed; the amplitude as well as the phase relationships are broken.

MAD Phasing. Figure 2 Anomalous scattering factors f' and f'' for Fe. The spectra are derived from fluorescence measurements near the Fe K-absorption edge at 7.111 keV (1.74346 Å). The wavelengths λ_1 (1.737 Å), λ_2 (1.744 Å), λ_3 (1.797 Å), λ_4 (0.92 Å) correspond to the wavelengths λ_{peak} , λ_{edge} , λ_{remote} , and λ_{native} in a MAD experiment because of maximal anomalous signals for those energies. The dotted lines are theoretical curves calculated using the server at http://www.bmsc.washington.edu/scatter/AS_periodic.html.

absorption compared with the free atom. The X-ray energy ($E_{\text{X-ray}} = 12.398 [\text{keV}]/\lambda [\text{\AA}]$) for an optimal anomalous signal is determined for each crystal by a fluorescence scan before a diffraction experiment is carried out at the synchrotron.

For a single type of anomalous scatterer, i.e. a MAD experiment at a single absorption edge, a minimum of two wavelengths are required to generate phases. MAD phasing is over-determined if one measures diffraction data at three or four wavelengths. Optimal anomalous

signals f'' and f' require great precision in setting up and controlling the wavelength during the diffraction experiment. Additional wavelengths (λ_3 and λ_4) may be chosen at points typically between 100 eV and 1000 eV distant from the absorption edge.

Estimation of the Size of the Anomalous Signal in Diffraction Data

Numerous elements have been used as anomalous scatterers in crystal structure analysis of biological macromolecules over the past fifteen years (3, 4; Table 1). Mn, Fe, Co, Ni, Cu and Zn ions are often natural components of metalloproteins. Selenomethionine as a substitute for methionine has been widely used as an anomalous-scattering label for proteins and brominated bases (5-bromouracil, 5-bromocytosine) may serve as labels for nucleic acids. Furthermore, elements used conventionally for [▶isomorphic replacement](#) like Pt, Au, Hg, Tl, Pb, Bi, As, Ga, Sr, Os, Ir, Th, Pa, U, Y, Sm possess K- or L-absorption edges within the energy region suitable for diffraction experiments (Table 1). Quick soaking with Br^- or K^+ , as well as high-pressure labeling with noble gases (basics, see (6)) have also been successfully used to incorporate anomalous scatterers into protein crystals. Although their absorption edges are outside the wavelength range of convenient X-ray diffraction experiments, the anomalous signal of sulfur and phosphorus can also be used for structure determination. Recently, an increasing number of macromolecular crystal structures have been determined by collecting very precise diffraction data at only one wavelength, establishing the single-wavelength anomalous diffraction method, SAD (4). Just as MAD, SAD, coupled with powerful phase improvement methods, may be based upon almost all atoms contained in Table 1 for phase determination, even if the diffraction experiments are performed in the home laboratory using X-ray generators with rotating copper anodes (f'' at $\text{CuK}\alpha$ wavelength, see column 7 in Table 1). The largest anomalous signals are available from lanthanides (good substitutes in Ca^{2+} binding sites) and actinides.

Because the anomalous signal is weak, special experimental efforts have to be made to obtain a high anomalous signal-to-noise ratio. The magnitude of the signal is estimated as the ratio of the dispersive, or the Bijvoet difference to the expected root-mean-square structure amplitude at zero scattering angle of N_m identical atoms within the macromolecule

$$\text{rms}|^0F|_{\text{macromolecule}} = \sqrt{N_m} \cdot f \quad [2]$$

The scattering factor f of an average non-hydrogen atom in a protein is usually taken as $6.7 e^-$, $7.2 e^-$ in

DNA and $7.26 e^-$ in RNA. The diffraction ratios for estimating the significance of the signal originating from N_a anomalous scatterers of a single type included in the macromolecule are

$$\frac{\sqrt{N_a/2} \cdot |f'_{\lambda 1} - f'_{\lambda 2}|}{\text{rms}|^0F|_{\text{macromolecule}}} \quad [3]$$

for the dispersive signal, and

$$\frac{\sqrt{N_a/2} \cdot 2f''_{\lambda}}{\text{rms}|^0F|_{\text{macromolecule}}} \quad [4]$$

for the Bijvoet signal. $|f'_{\lambda 1} - f'_{\lambda 2}|$ and f''_{λ} are listed in Table 1 for the most frequently used anomalous scatterers at their absorption edges or at $\text{CuK}\alpha$ wavelength.

Both expected relative changes in the diffraction intensities caused by the anomalous scattering can be compared directly with the R_{meas} (R_{sym} , R_{merge}) estimates of errors (2) in the raw data. If the expected anomalous signal is about 3%, the error estimates should be below this value.

As a rule of thumb, one ordered Se atom per 100 amino acid residues (with 7.7 atoms per residue on average) is usually assumed to permit the phasing of the corresponding X-ray diffraction data.

Algebraic Background of the Phase Determination

The structure factor equation for any reflection hkl derived from a crystalline macromolecule with N non-hydrogen atoms and N_{ano} anomalous scatterers can be written as

$$F_{\text{obs}}(\lambda, hkl) = \sum_{j=1, N} [f^0 + f'(\lambda) + if''(\lambda)]_j \exp[-B_j s^2(hkl)] \exp[2\pi i(hx_j + ky_j + lz_j)] \quad [5]$$

or as

$$\begin{aligned} F_{\text{obs}}(\lambda, hkl) = & \sum_{j=1, N} f_j^0 \exp[-B_j s^2(hkl)] \\ & \exp[2\pi i(hx_j + ky_j + lz_j)] \\ & + \sum_{m=1, N_{\text{ano}}} f'_m(\lambda) \exp[-B_m s^2(hkl)] \\ & \exp[2\pi i(hx_m + ky_m + lz_m)] \\ & + i \sum_{m=1, N_{\text{ano}}} f''_m(\lambda) \exp[-B_m s^2(hkl)] \\ & \exp[2\pi i(hx_m + ky_m + lz_m)] \end{aligned} \quad [6]$$

Eqs. [1] and [5] hold for all atoms, however, the magnitudes of f' and f'' are negligible for the light atoms H, C, N, O of biological macromolecules. This allows separation of the wavelength-independent and

MAD Phasing. Table 1 Selection of anomalous scatterers with absorption edges accessible by most synchrotrons. Atoms which occur naturally in some proteins, or belong to the lanthanides or actinides are colored in column 2. Roughly, the anomalous scattering factors f'' are 4 e⁻ near the K-edge and 10 e⁻ near L_{III}-edges. In reality, they may be higher because of resonance effects (white line = h{igh}, else l{ow}). For wavelengths far from the absorption edge, anomalous scattering may also be significant and anomalous effects are sometimes measurable at home X-ray sources using CuK α radiation (column 7). The [Protein Data Bank](http://www.bmrc.washington.edu/scatter/AS_periodic.html) entry (5) of a sample structure determined using the corresponding anomalous scatterer is provided in column 8. The calculated values are taken from http://www.bmrc.washington.edu/scatter/AS_periodic.html

wavelength-dependent terms in eq. [6]. The anomalous contributions for each type of scatterer can be expressed in terms of their normal structure factor components

$$F_{\text{obs}}(\lambda, hkl) = {}^0F_{\text{total}}(hkl) + \left\{ f'(\lambda)/f_0 + i f''(\lambda)/f_0 \right\} {}^0F_{\text{anops}}(hkl) \quad [7]$$

${}^0F_{\text{anops}}(hkl)$ is the normal structure factor of the partial structure representing the anomalous scatterers. Hendrickson (7) reformulated the magnitude of the measured intensity

$$|F_{\text{obs}}(\lambda, \pm hkl)|^2 = |{}^0F_{\text{total}}(hkl)|^2 + a(\lambda) |{}^0F_{\text{anops}}(hkl)|^2 + b(\lambda) |{}^0F_{\text{total}}(hkl)| |{}^0F_{\text{anops}}(hkl)| \cos(\varphi_{\text{total}} - \varphi_{\text{anops}}) \pm c(\lambda) |{}^0F_{\text{total}}(hkl)| |{}^0F_{\text{anops}}(hkl)| \sin(\varphi_{\text{total}} - \varphi_{\text{anops}}) \quad [8]$$

where the wavelength dependence is confined to the experimentally measurable coefficients

$$a(\lambda) = \frac{f'(\lambda)^2 + f''(\lambda)^2}{f_0^2} \quad b(\lambda) = \frac{2f'(\lambda)}{f_0} \quad c(\lambda) = \frac{2f''(\lambda)}{f_0}$$

For each reflection hkl and wavelength λ , one obtains two equations for the three unknowns F_{total} , F_{anops} , and $\delta\varphi = \varphi_{\text{total}} - \varphi_{\text{anops}}$. Measurement at two or more wavelengths results in over-determination of the

MAD Phasing. Figure 3 Harker section for the native anomalous difference Patterson map from the ferredoxin from *Anabaena* 7120 at 1.7 Å resolution (with permission from (8)). The section at $w = 1/2$ was calculated with coefficients $\|F(hkl) - F(-hkl)\|^2$. The map was contoured at 2σ and increasing in increments of 1σ . An entire unit cell in the u and v direction has been plotted. The positions of the iron atoms in the cluster were determined in the space group $P6_5$. Shown here are the positions of the Harker peaks arising at $u = 2x$, $v = 2y$, and $w = 0.5$. The corresponding positions of Fe I are $x = 0.365$, $y = 0.573$, $z = 0.018$ and of Fe II $x = 0.327$, $y = 0.593$, $z = 0.0$. The distance between the Fe in the [2Fe-2S] cluster is 2.68 Å as in the refined structure.

unknowns and renders possible least squares fitting procedures.

The maximal pure anomalous signal components can be experimentally determined from the so-called Bijvoet pairs of reflections $|F_{\text{obs}}(\lambda, 'hkl)|$, the space group symmetry equivalents to the two members of a Friedel pair (see above).

'Dispersive' phase information can be derived from differences between $|F_{\text{obs}}|$ at wavelengths having different f'

$$\Delta F_{\text{disp}} = |F_{\text{obs}}(\lambda_i, hkl)| - |F_{\text{obs}}(\lambda_j, hkl)| \quad [9]$$

the difference of amplitudes from Friedel pairs of reflections at wavelengths with significant f'' contributes to the 'Bijvoet' phase information

$$\Delta F_{\text{Bijvoet}} = |F_{\text{obs}}(\lambda_i, hkl)| - |F_{\text{obs}}(\lambda_j, -hkl)| \quad [10]$$

Taking equations [8, 9] and following (7)

$$\Delta F_{\text{Bijvoet}} = \frac{2f''(\lambda)}{f_0} |^0 F_{\text{anops}}(hkl)| \sin(\varphi_{\text{total}} - \varphi_{\text{anops}}) \quad [11]$$

the Bijvoet difference contributes to $\sin(\varphi_{\text{total}} - \varphi_{\text{anops}})$. The **▶ dispersive difference** contributes to the $\cos(\varphi_{\text{total}} - \varphi_{\text{anops}})$.

After calculation of initial estimates for F_{total} , F_{anops} , and $\delta\varphi$ using a phasing program, a phase estimate for the protein φ_{total} at each h, k, l

$$\varphi_{\text{total}} = \Delta\varphi + \varphi_{\text{anops}} \quad [12]$$

MAD Phasing. Figure 4 Structure determination of truncated adrenodoxin Adx(4-108) (Protein Databank entry 1AYF) by MAD phasing using the intrinsic Fe atoms as anomalous scatterers. (a) Vicinity of the C-terminal Pro108 of Adx(4-108) with the experimental electron density determined from the anomalous signal of the [2Fe-2S] cluster and contoured at 1σ (a), and (b), the final $2F_o - F_c$ electron density map at 1.85-Å resolution contoured at 1.5σ . (c) Secondary structure diagram of Adx(4-108) (9), the [2Fe-2S] cluster is shown in ball-and-stick representation with the anomalous scatterer Fe colored magenta (S in yellow). Water molecules are shown as green spheres.

can be calculated if the phase φ_{anops} of the anomalous scatterers' partial structure is known. One possible way to determine the partial structure is the use of the [▶Bijvoet-difference](#) [▶Patterson map](#) with coefficients $|\delta F_{\text{Bijvoet}}|^2$ when the number of sites is small (Fig. 3). In principle, the sub-structure can be determined using only the Bijvoet differences for single-wavelength data (4). For a larger number of sites direct methods are recommended (OASIS, SHELXS, SHELXD, SnB, (2, 10)). Several methods to overcome the phase ambiguity caused by the identity

$$\sin(\varphi_{\text{total}} - \varphi_{\text{anops}}) = \sin(180^\circ - \varphi_{\text{total}} + \varphi_{\text{anops}}) \quad [13]$$

when solving eq. [11] have been summarized in (2).

From the Anomalous-Scatterer Partial Structure to the Macromolecular Structure

After the determination of the heavy atom position, a phase refinement (e.g. MLPHARE, (10)) will follow, and after density modification (e.g. DM, (10)), the experimental electron density map is obtained (Fig. 4a). This process is widely automated in the programs SHARP and SOLVE (2). The main chain and side chains of the macromolecule can be traced interactively by hand (program O) or automatically (e.g. ARP/WARP, SOLVE/RESOLVE, for overview see (2)) depending on the quality of the phases and, thus, the electron density map. After several rounds of computer-assisted manual model correction, addition of water molecules, ions and other low-molecular-weight components and automatic refinement (e.g. REFMAC, (10)), the crystal structure (e.g. Figs. 4b, 4c) will be validated according to a set of quality criteria (2) including a reasonable stereochemistry, and the final atomic coordinates along with the experimental data will be deposited with the [▶Protein Data Bank](#) (5).

Madin-Darby Canine Kidney Cells

Definition

Madin-Darby Canine Kidney (MDCK) cells are a model system of simple epithelia that, when cultured on a permeable support, form an electrically tight monolayer of polarized cells. MDCK cells have been extensively used since the 1970s to study the establishment of intercellular junctions, polarized sorting and trafficking of membrane proteins.

Definition

Fertilization in Mammals

The essence of life is the ability to reproduce and perpetuate the species. ► **Fertilization** or sexual reproduction is defined as the union of two germ cells, ► **egg** (female) and ► **sperm** (male), whereby the somatic chromosome number is restored and the resulting offspring exhibit characteristics of their parents (1). Male and female gametes fuse and recombine inherited traits of the two parents to produce individuals with novel assortments of genes. Sexual reproduction, as opposed to asexual reproduction, a process that gives rise to offspring genetically identical to the parent organism, has great advantages. Consequently, a vast majority of plants and animals have adopted it.

Fertilization refers specifically to fusion of male and female gametes to form a zygote. However, the overall pathway to fertilization encompasses a host of events that precede gamete fusion. Among these, extensive transcription and translation, architectural rearrangements and modification of existing organelles, production of new organelles, meiotic maturation and capacitation and other events must occur in sperm and eggs prior to fertilization. In mammals, fertilization takes place internally in the protected environment of the ampulla of the oviduct, as opposed to external fertilization where sperm and egg meet outside the parent's body (e.g., as in fish, reptiles, amphibians and invertebrates).

Characteristics

Oogenesis in Mammals

► **Oogenesis** is initiated during fetal development and continues throughout the reproductive lifetime of females (3, 6). Primordial germ cells become the oogonia that populate fetal ovaries and proliferate to become non-growing oocytes. The transition from oogonia to oocytes involves a change from ► **mitosis** to ► **meiosis**. Shortly after birth, non-growing oocytes are arrested in prophase I of meiosis until stimulated to grow and resume meiotic progression at about the time of ovulation. The pool of small, non-growing oocytes is the sole source of unfertilized eggs in sexually mature females. At least fifty percent of oocytes present in the ovary at birth are lost during the first week following birth. In this context, it has recently been proposed that there is a pool of proliferative germ cells that sustains oocyte and follicle production in the postnatal mammalian ovary (Johnson J et al (2004) *Nature* 428:145–150).

Human oogonia undergo numerous rounds of mitotic divisions over a period of several months until shortly before birth (mice ~4 mitotic cycles). For example, 7 million oogonia are present at ~20 weeks gestation, but only 0.5–1 million oocytes, more or less evenly divided between each of two ovaries, remain at birth (mice

~10,000–15,000 oocytes/ovary). Following birth, the number of oocytes continues to decline even before the onset of puberty. After puberty, many oocytes are lost each month, with typically one oocyte undergoing ovulation out of the population recruited. During the reproductive lifespan of a woman, only 400–500 oocytes will be ovulated, while remaining oocytes slowly undergo atresia and are lost.

The non-growing human oocyte, ~35 µm in diameter (mice ~15 µm), is contained within a cellular follicle that grows concomitantly with the oocyte from a single layer of a few epithelial-like cells to three layers of cuboidal granulosa cells by the time the oocyte has completed growth (≥6 months; mice ~2 weeks). Non-growing oocytes progress through the pachytene stage of prophase I of meiosis during which time homologous chromosomes pair and crossing-over and recombination occur between paired chromosomes (mice ~60 h). During their growth phase characterized by high rates of transcription and translation, modification of existing organelles (e.g., Golgi and mitochondria) and production of new organelles (e.g., zona pellucida and cortical granules), oocytes are arrested at the diplotene stage of the first meiotic prophase. Oocytes then enter a prolonged resting phase, which is terminated before ovulation, which occurs for the first time at puberty. Oocytes progressively acquire meiotic competence (i.e., the ability to undergo ► **meiotic maturation**) and fertility potential during the final days (► **Graafian follicle** stage) before ovulation. Fully-grown human oocytes, ~120 µm in diameter (mice ~80 µm), in Graafian follicles resume meiosis and complete the first meiotic reductive division (meiotic maturation, separation of homologous chromosomes) just prior to ovulation. Meiotic maturation (~36 h, mice 12–14 h) is characterized by germinal vesicle (nuclear) breakdown, formation of the first meiotic spindle (metaphase I), expulsion of the first polar body and arrest at metaphase of the second meiotic division (metaphase II). It occurs in preovulatory Graafian follicles in response to a surge of gonadotropins and leads to a mature, ovulated oocyte or unfertilized egg. Unfertilized human eggs possess 22 somatic chromosomes or autosomes (mice, 19 autosomes) and 1 sex chromosome (total haploid content, 23 chromosomes), each composed of 2 chromatids aligned on the metaphase II spindle and a small polar body containing 22 autosomes and 1 sex chromosome. Ovulated eggs are released from Graafian follicles, enter the opening of the oviduct (Fallopian tube) and move to the lower ampulla region of the oviduct where fertilization can take place. Ovulated eggs complete meiosis (i.e. become haploid cells) with separation of chromatids and emission of a second polar body only upon fertilization by sperm (i.e. restoring the diploid state). Human eggs remain capable of being fertilized

and giving rise to offspring for ~24 h (mouse 8–12 h) following ovulation.

Spermatogenesis in Mammals

► **Spermatogenesis** is the process by which spermatogonial cells divide and differentiate into mature spermatozoa (2, 4). Spermatogonial cells, which are diploid, multiply mitotically and can differentiate to produce primary spermatocytes (meiotic cells). These do not divide until after puberty and are then produced continuously within the testis throughout the lifetime of sexually mature males, providing a steady-state turnover of male gametes. Pituitary gonadotropins, such as LH and FSH, are the major regulators of spermatogenesis and are required to initiate it at the time of puberty. Spermatogenesis is divided into three functionally distinct phases, (1) the proliferative phase, during which some spermatogonia divide to replenish the stem cell pool and others undergo mitotic divisions and become committed to further differentiation and produce primary spermatocytes, (2) the meiotic phase, in which each spermatocyte undergoes meiotic divisions to give rise to 4 haploid spermatids and (3) spermiogenesis, during which round spermatids differentiate into mature spermatozoa that are motile and become capable of fertilizing eggs.

Spermatocytes do not separate completely during meiosis and, as a result, a group of germ cells remain connected to one another *via* cytoplasmic bridges and undergo further development within this syncytium in a synchronous manner throughout the remainder of the spermatogenic process. Spermatocytes enter a prolonged meiotic phase of spermatogenesis, which in humans takes 22–24 days to complete. Primary spermatocytes enter prophase I of the first meiotic division (meiosis I) and homologous chromosomes pair and exchange genetic material by crossing-over and recombination during the pachytene stage of prophase I (~14 days). They divide to form two secondary spermatocytes, each containing a haploid complement of chromosomes. After a brief interphase, secondary spermatocytes enter the second meiotic division (meiosis II) and each divides to form two haploid spermatids. There is no period of arrested development during meiosis for spermatocytes as is the case for oocytes. RNA and protein synthesis is maximal during meiosis and decreases abruptly during early spermiogenesis and differentiation. Spermatids differentiate into mature spermatozoa that are motile and capable of fertilizing eggs, a process that involves morphological and functional changes. The major changes that occur are formation of the flagellum for motility, development of the ► **acrosome**, which contains proteolytic enzymes needed for sperm penetration through egg investments, condensation of chromosomes and nucleoproteins of the nucleus and removal of excessive cytoplasm.

Spermatozoa undergo minor morphological but significant functional modifications during transport in the male genital tract, especially in the epididymis where the ability of sperm to fertilize eggs is acquired. The final stage of maturation, called ► **capacitation**, occurs in the female genital tract following ejaculation. Ejaculated sperm have an oval head, which is composed of a nucleus and acrosomal cap (vesicle), which covers the anterior portion of the head. The neck is the region of connection of the sperm tail (flagellum) to the head. The flagellum, composed of microtubules, is the mobile part of the sperm and consists of a middle-piece and tail. The middle-piece is surrounded by a mitochondrial sheath and the tail is divided into two regions, the principal- and end-pieces. The sperm length of different mammals varies considerably, ranging from 50–250 μm (humans, 60–65 μm).

► **Sertoli cells** play a crucial role in spermatogenesis, providing a favorable environment for male germ cell differentiation. They are in direct contact with developing spermatogonia, spermatocytes and spermatids during an active period of macromolecular biosynthesis. When spermatogenesis is complete, cytoplasmic extensions with the Sertoli cells are broken and spermatozoa are released. The major regulators of Sertoli cell function are FSH produced by the pituitary and testosterone produced by ► **Leydig cells** of the testis in response to LH from the pituitary.

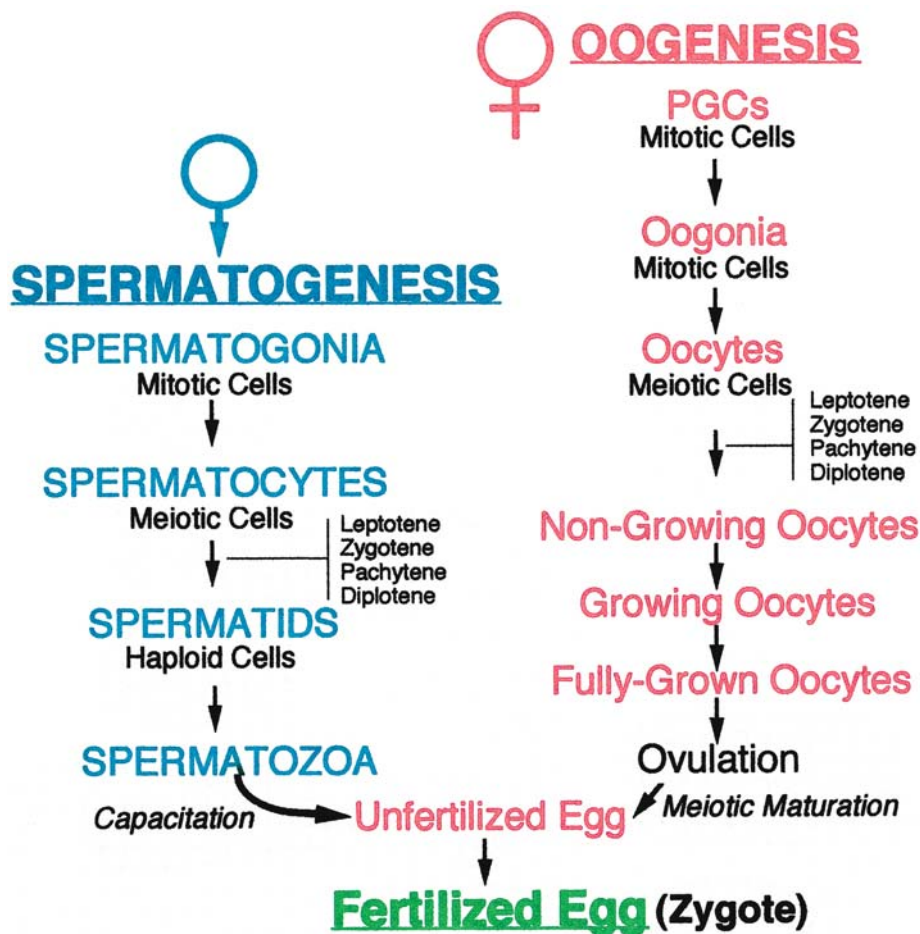

A common feature of spermatogenesis is that the majority of spermatocytes and spermatids fail to complete development. Degeneration of developing germ cells is a physiological phenomenon, with critical phases of extensive cell loss during spermatogonial development, meiotic divisions and spermiogenesis.

Molecular Interactions

Sperm-Egg Interactions

Eggs released from Graafian follicles enter the opening of the oviduct and move to the lower ampulla region where fertilization takes place (5, 7). Very few (~10) ovulated eggs are found in oviducts of mice (humans ~1) and, similarly, very few sperm are found at the site of fertilization (~100–150) as compared to the number of sperm deposited into the female reproductive tract (~10,000,000). It takes ~15 min for ejaculated mouse sperm (human ~30 min) to traverse the reproductive tract and reach the oviduct, possibly guided by chemotaxis regulated by follicular factors. Like eggs, spermatozoa have quite a short lifespan (~24 h) in the female reproductive tract.

Ovulated eggs are surrounded by a ► **zona pellucida** (ZP), an extracellular coat made up of three glycoproteins, called ZP1, ZP2 and ZP3. Follicle cells, interspersed in a matrix of hyaluronic acid, are coupled *via* gap junctions to fully-grown oocytes, with processes that traverse the ZP and contact and connect

Mammalian Fertilization. Figure 1 Top: Outline of mammalian oogenesis and spermatogenesis leading to production of mature eggs and sperm and to fertilization (see text for details). PGCs, primordial germ cells. Bottom: Photomicrograph of mouse sperm bound to the unfertilized mouse egg zona pellucida. Magnification approximately 775x.

with oocyte plasma membrane. The ZP is an oocyte/egg-specific organelle whose glycoprotein components are synthesized and secreted by growing oocytes. The ZP is a relatively thick and homogeneous meshwork of interconnected filaments that increases in thickness to $\sim 6.5 \mu\text{m}$ in mouse (human $\sim 13 \mu\text{m}$) as the oocyte grows and increases in diameter. The ZP of eggs from all mammalian species (including marsupials) consists of ZP1–3 and even egg coats from non-mammalian species (e.g., fish, amphibia, and birds) contain glycoproteins structurally related to ZP1–3.

Much of our knowledge about sperm-egg interactions comes from studies with mice. The ZP is responsible for species-specific sperm binding and induces bound sperm to undergo the acrosome reaction (i.e. cellular exocytosis). Removal of the ZP exposes egg plasma membrane directly to sperm and, as a result, virtually eliminates any barriers to *in vitro* fertilization between mammalian species. In response to fertilization, the ZP hardens and becomes impenetrable to sperm, a reaction referred to as the “slow block” to polyspermy. In addition, the ZP protects unfertilized eggs during ovulation as they are extruded from Graafian follicles and released into the oviduct. The ZP also protects growing embryos as they are transported along the oviduct and into the uterus. Just prior to implantation in the uterus, expanded blastocysts hatch from the ZP.

ZP2 and ZP3 are assembled into long filaments using non-covalent bonds and the filaments are interconnected by ZP1. ZP2 and ZP3 are monomers and are present in about equimolar amounts, whereas ZP1, a dimer composed of identical polypeptides held together by intermolecular disulfides, is present in minor amounts. The three glycoproteins, ZP1–3, are encoded by single copy genes located on different chromosomes (mouse, chromosomes 19, 7 and 5; human, chromosomes 11, 16 and 7). The primary structures of ZP polypeptides from different mammals are closely related to one another; for example, the polypeptide sequences of mouse and human ZP1, ZP2 and ZP3 are $\sim 40\%$, 56% and 67% identical, respectively. Since all three glycoproteins play structural roles in the egg ZP, they probably interact with one another in a similar manner regardless of species.

At fertilization, sperm must recognize and bind to the ZP, undergo the **acrosome reaction** and traverse the ZP in order to reach and fuse with egg plasma membrane. These events are mediated by ZP3 and ZP2 respectively. ZP3 serves as the primary receptor for sperm and initiates the acrosome reaction upon binding of acrosome-intact sperm to the ZP. Acrosome-intact sperm bind to specific O-linked oligosaccharides present on ZP3 in a region of ZP3 polypeptide near the carboxy-terminus (“sperm combining-site”) and, since sperm are highly motile cells, each must bind to tens of thousands of ZP3 molecules located at the surface of

the ZP. Acrosome-intact sperm bind to the ZP using one or more proteins associated with plasma membrane overlying the sperm head. These proteins recognize and bind to ZP3 and are often called “egg binding-proteins”. Although several candidates have been proposed, for example β -galactosyltransferase, sperm protein-56, zonadhesin and mannose- and galactose-binding proteins, the nature of the egg binding-protein remains problematic. In this context, it has recently been proposed that the mammalian sperm protein “Izumo” (named after a Japanese shrine dedicated to marriage) is necessary for fusion of sperm and egg plasma membrane (Inoue N et al (2005) *Nature* 434:234-238).

As a consequence of binding to ZP3, sperm acrosome-react and release their acrosomal contents into the ZP. In this context, the ZP is a highly porous structure that is penetrated by large macromolecules and even by small viruses. The acrosome is a large secretory vesicle that appears in spermatids as a product of the Golgi and is biochemically similar to a lysosome. During the acrosome reaction, multiple fusions occur between plasma membrane and outer acrosomal membrane at the anterior region of the sperm head and hybrid membrane vesicles are formed. As a result, the egg ZP is exposed to the acrosomal contents of bound sperm. ZP3 is the natural agonist that initiates the acrosome reaction following binding of sperm to the ZP. Apparently, multivalent interactions between ZP3 and egg binding-protein(s) on the surface of the sperm head trigger this Ca^{2+} -dependent reaction. ZP2 serves as the secondary sperm receptor to which ZP-associated, acrosome-reacted sperm bind, possibly by using a sperm proteinase called acrosin and/or its zymogen form, proacrosin.

Penetration of the ZP by sperm is achieved by a combination of sperm motility and enzymatic hydrolysis, the latter being catalyzed by acrosin and possibly other acrosomal proteases. Only acrosome-reacted sperm can penetrate the ZP and fuse with egg plasma membrane. The course taken by sperm is indicated by a narrow slit left behind in the ZP of the fertilized egg. In mice, it takes ~ 15 – 20 min for acrosome-reacted sperm to penetrate the ZP and reach the egg plasma membrane. The post-acrosomal plasma membrane of acrosome-reacted sperm fuses with egg plasma membrane. Fusion of the sperm head with the egg is followed by entry of the sperm tail into egg cytoplasm. Several sperm proteins have been implicated in binding and fusion of sperm with egg plasma membrane. One of these, called fertilin, is a member of the ADAM (a disintegrin and metalloprotease domain) family of transmembrane proteins. Fertilin is a heterodimer of α and β subunits, with disintegrin and metalloprotease domains. In mice, but not in humans, binding of acrosome-reacted sperm to egg plasma membrane may be supported by the disintegrin domain of fertilin and

an integrin receptor (perhaps integrin $\alpha 6\beta 1$) on egg plasma membrane. In addition to integrins, CD9, a member of the tetraspanin family, is thought to facilitate sperm-egg membrane interactions in mice through lateral associations with integrins and other egg membrane proteins. Although sperm ADAMa and egg integrins and CD9 are the best characterized proteins involved in mammalian gamete interactions, recent evidence from knock-out mice models suggests that fertilin α/β and integrin $\alpha 6\beta 1$ may not be required for sperm-egg fusion and/or that other, as yet unidentified proteins, participate as well.

Once fertilized, the egg becomes a zygote. Soon after passage of a sperm into the egg cytoplasm, sperm and egg form distinct nuclei, the male and female pronuclei. The two haploid pronuclei approach each other, but remain distinct until after the membrane of each pronucleus has broken down and their chromosomes assemble on a metaphase spindle and progress toward the first cleavage division of the 1-cell embryo (zygote).

Regulatory Mechanisms

Prevention of Polyspermy

Eggs react very rapidly to sperm entry, undergoing both structural and functional changes (5, 7). Among these are fusion of cortical granules with egg plasma membrane accompanied by release of their contents, resumption of the second meiotic division and emission of a second polar body and formation of the egg nucleus. Some responses of the egg to fertilization by a single sperm occur in order to prevent polyspermic fertilization, a lethal event.

Prevention of polyspermy is achieved by immediate changes (within seconds) in electrical properties of egg plasma membrane (fast block) and by slower changes in the properties of the ZP; the latter represent the so-called “**▶zona reaction**” (slow block). The zona reaction occurs within a few minutes of fertilization and is induced by release of **▶cortical granule** contents into the ZP (**▶cortical reaction**). Cortical granules are small secretory vesicles in the egg cortex that fuse with egg plasma membrane upon activation, probably through release of Ca^{2+} from egg cytoplasmic stores. As a consequence of the cortical reaction and release of enzymes, the ZP hardens (i.e., becomes less soluble), bound acrosome-reacted sperm fall off the ZP and free-swimming acrosome-intact sperm are prevented from binding to the ZP.

Cortical granule enzymes, which include a variety of proteinases and glycosidases, modify ZP2 and ZP3. As a result, ZP3 no longer acts as a sperm receptor for acrosome-intact sperm and ZP2 cannot maintain binding of acrosome-reacted sperm. For example, a proteinase is released from activated mouse eggs that cleaves ZP2 by limited proteolysis, converting ZP2 to ZP2_f, a reaction that modulates ZP structure and

function. For ZP3, there is no evidence for proteolysis following fertilization, but it is likely that one or more glycosidases released from cortical granules are involved in inactivation of ZP3 sperm receptor activity. After fertilization in the ampulla region of the oviduct, the egg is transported down the oviduct and into the uterus (human ~80 h, mice ~72 h) by ciliary action and muscular peristalsis. The ZP is essential during transport, as it surrounds and protects the early embryo preventing it from disintegrating or sticking to the walls of the oviduct. Once the embryo approaches the uterus, it hatches from the ZP and implants in the uterine wall, a process probably aided by a “hatching” enzyme originating from the embryo itself. Localized proteolysis of the ZP is likely to account for the hole through which an expanded blastocyst finally emerges to implant in the uterus.

Mannose 6-Phosphate Receptor

Definition

Precursors of lysosomal enzymes are tagged with a luminal mannose 6-phosphate residue in the *cis*-Golgi. These residues are bound with high affinity by mannose 6-phosphate receptor (MPRs) which in turn mediate sorting from the *trans*-Golgi network (TGN) to the late endosome. Due to the low pH in the late endosomal lumen, the MPRs release their ligands and are recycled back to the TGN.

Map Distances

Definition

Maps of the human genome are generally of two types: genetic and physical. Genetic maps measure the amount of recombination between two loci and genetic map units, and are quantified as either % recombination (theta) or cM (centimorgan; Morgan unit(s)) between two loci. Physical maps aim to quantify the actual amount of DNA, usually in base pairs between two loci. One percent recombination is roughly equivalent to 1,000,000 base pairs of DNA.

Marfan Syndrome

PHILIP F. GIAMPIETRO

Department of Medical Genetic Services, Marshfield Clinic, Marshfield, WI, USA
giampietro.philip@marshfieldclinic.org

Synonyms

MFS

Definition

Marfan syndrome is an autosomal dominant ► [pleiotropic](#) disorder of ► [connective tissue](#) with an incidence in the general population of approximately two to three in 10,000. There is no particular ethnic predisposition. The major clinical findings associated with Marfan syndrome include aortic root dilatation that may lead to dissection, ► [ectopia lentis](#) and ► [dural ectasia](#) (4).

Characteristics

► [Mitral valve prolapse](#), aortic root dilatation, mitral regurgitation, aortic valve regurgitation and dissection and rupture of the ► [aorta](#) are the most common cardiovascular findings in patients with Marfan syndrome. Additional ocular signs include myopia, increased axial globe length that may lead to retinal detachment and corneal flatness. Skeletal features,

which may collectively represent a single major criteria and lead to earlier recognition of Marfan syndrome, include increased height and arm span, reduced ▶[upper to lower segment ratio](#), ▶[pectus excavatum](#) or ▶[pectus carinatum](#), joint laxity, scoliosis, ▶[acetabular protrusion](#), ▶[pes planus](#), ▶[arachnodactyly](#), high arched palate, dental crowding and hammer toes. Craniofacial features associated with Marfan syndrome include down-slanting palpebral fissures, ▶[malar hypoplasia](#), ▶[enophthalmos](#) and retrognathia. A diagnosis of Marfan syndrome should be considered in individuals who present with spontaneous ▶[pneumothorax](#). Minor features in individuals with Marfan syndrome include inguinal hernia and ▶[striae atrophicae](#).

Evaluation of individuals suspected of having Marfan syndrome is a multidisciplinary process. The evaluation should consist of clinical genetics, cardiology, ophthalmology and possibly orthopedics consultations. For a clinical diagnosis of Marfan syndrome, in the absence of family history, an affected person should display major criteria in at least two organ systems and involvement of a third organ system (1). In the presence of a positive family history, an affected person should display one major criterion in an organ system and involvement of a second organ system. Approximately 30% of cases of Marfan syndrome occur in the absence of a positive family history and represent new mutations in the fibrillin-1 (*FBN1*) gene.

Marfan syndrome has clinical overlap with other conditions including congenital contractural arachnodactyly, familial aortic aneurysm, familial aortic dissection, familial ectopia lentis, MASS phenotype (myopia, mitral valve prolapse, mild aortic dilatation and skeletal involvement) and homocystinuria (1). Ehlers Danlos syndromes Type I and II are associated with joint hypermobility, skin fragility, mitral valve prolapse and aortic root dilatation. Individuals with ▶[Klinefelter](#) and ▶[fragile X syndromes](#) may have a marfanoid body habitus. Fragile X syndrome is associated with pectus excavatum, pes planus, mitral valve prolapse and joint hypermobility. Chromosomal studies, fragile X DNA testing and serum amino acid quantitation demonstrating elevated homocysteine levels may be instrumental in ruling out these conditions that have phenotypic overlap with Marfan syndrome.

Dural ectasia may be associated with back pain, lower radicular pain, leg weakness and headaches, or may be asymptomatic. Evaluation by computerized tomography or magnetic resonance imaging evaluation to determine if dural ectasia is present may be helpful in the diagnostic process. Posterior laminectomy may be indicated if the back pain is severe. Acetabular protrusion may also be asymptomatic. Radiological evaluation by the crossing of the acetabular and iliopectineal lines may also be of help when there is

diagnostic uncertainty. Clinical evaluation, including echocardiography, of both parents of a child in whom the diagnosis of Marfan syndrome is being considered may be necessary as part of the evaluation process. Developmental dysplasia of the hip occurs with an incidence of 2%. Osteoporosis and osteopenia have been reported in Marfan syndrome. No reported association exists between decreased bone mineral density and fracture in Marfan syndrome.

Life expectancy has increased among females (50% probability of survival to age 72) and males (50% probability of survival to age 65), largely due to prophylactic cardiothoracic surgical intervention and improved survival after cardiothoracic surgery (6). Since these data were reported in the mid 1990s, the life expectancy for patients with Marfan syndrome is probably greater. Early recognition and diagnosis of Marfan syndrome is important in order to enable implementation of treatment for cardiovascular symptoms. ▶[Beta-adrenergic blockers](#), such as atenolol, and calcium channel blockers are used to decrease the rate of aortic root enlargement and cardiovascular events. Prophylactic repair of thoracic aneurysms is recommended when the diameter reaches between 5.0 and 5.5 cm. The “composite graft” technique involves suturing a prosthetic aortic valve to the end of a Dacron conduit and attaching it to the aortic annulus. Patients who undergo this procedure will need to be maintained on coumadin in order to prevent ▶[thromboembolism](#). ▶[Endocarditis](#) prophylaxis should be implemented for all patients with valvular heart disease, including a composite graft repair or placement of an artificial valve. A “valve sparing” procedure may be recommended in certain instances. Patients should avoid contact sports and isometric exercise in order to minimize shearing forces on the aorta. Cardiac arrhythmias may occur in patients with Marfan syndrome that can be related to underlying left ventricular dysfunction, mitral valve prolapse and mitral regurgitation.

Periodic ophthalmologic evaluation is necessary to assess amblyopia, lens subluxation, anterior chamber abnormalities, cataracts, glaucoma and retinal detachment. Orthopedic evaluation should be sought for concerns related to scoliosis, joint hypermobility, pes planus and acetabular protrusion. Surgical correction of scoliosis may be necessary if bracing has failed or if the curve is greater than 40°. Estradiol has been demonstrated to induce epiphyseal closure and decrease final adult height when administered to premenarchal females. Periodic assessment of pulmonary function should be performed in adults and children due to the association of restrictive lung disease, emphysema, asthma and obstructive sleep apnea. Cardiac assessment and echocardiography should be performed every 6–8 weeks during pregnancy because there is an

Marfan Syndrome. Figure 1 *FBN1* gene containing 65 exons and various epidermal growth factor-like and transforming growth factor β -like domains. A multitude of *FBN1* mutations are illustrated. increased risk of aortic dissection. As patients with Marfan syndrome survive longer, it is anticipated that degenerative arthritis of the hip, knees and other joints will represent new health concerns. The National Marfan Foundation provides a wealth of information and resources for patients and families (www.marfan.org).

Cellular and Molecular Recognition

Marfan syndrome is caused by mutations in the *FBN1* gene on chromosome 15q21.1 (2). Fibrillin-1, a glycoprotein with a molecular weight of 350 kD, represents the major component of the 10–12 nm diameter microfibrils, the scaffolding on which tropoelastin is deposited (5). With rotary shadowing electron microscopy, microfibrils appear as “beads on a string,” having a periodicity of 50–55 nm. Microfibrils form linkages to elastin fibers, other components of the extracellular matrix and neighboring cells. They also are the principal component of the ocular zonules and are responsible for anchoring the lens. Microfibrils are composed of a variety of proteins, including emilin, fibrillin-1, fibrillin-2, lysyl oxidase and microfibril-associated proteins (MAP)-1, MAP-2, MAP-3 and MAP-4. *FBN2* deficiency is associated with congenital contractural arachnodactyly. Using electron microscopy, distinctive differences in microfibrils studied in patients with Marfan syndrome, as compared to unaffected patients, have been identified.

The *FBN1* gene is composed of 65 exons encoding 2871 amino acids and 4 additional alternatively spliced exons at the 5' end of the gene (Fig. 1). Fibrillin-1 is composed of a series of 47 epidermal growth factor (EGF)-like domains, each containing six cysteine-repeats.

Latent transforming growth factor- β (TGF- β) binding protein-like domains are interspersed between the EGF-like domains. Calcium binding is mediated by the presence of the EGF domain structure, three intradomain disulfide linkages, and negatively charged amino acid residues, including aspartic acid and glutamic acid (Fig. 2). The restriction of interdomain flexibility, which may facilitate protein-protein interactions and provide protection against proteolytic cleavage, is due to calcium binding. A series of 12 calcium binding EGF domains in the central portion of the fibrillin-1 molecule are thought to form a rigid rod-like structure that may be necessary for microfibril assembly. At the present time there is no evidence for a second Marfan syndrome locus.

Recent studies have provided evidence for an interaction between fibrillin-1 and a large latent complex in the extracellular matrix, composed of TGF- β binding protein and a covalently bound small latent complex composed of TGF- β and latency associated peptide dimers. Haploinsufficiency of fibrillin results in destabilization of this interaction and a liberation of the TGF- β from the matrix, thus enabling cytokine activation. The end results of this process hypothetically include impediment of the septation of distal airspace septation in lung tissue, myxomatous valve changes and bone overgrowth (8).

More than 500 mutations in the *FBN1* gene have been identified. The mutations are distributed among the 65 exons and usually represent a unique occurrence within each family studied. The majority of mutations are missense mutations that alter one of the conserved cysteine residues of the EGF or TGF- β domains. Other types of mutations include frameshift, insertion,

Marfan Syndrome. Figure 2 Mutations in fibrillin-1 EGF motifs in patients with Marfan syndrome. Many mutations affect calcium binding. Reprinted with permission: Pyeritz RE (2002) Marfan syndrome and other disorders of fibrillin. In: Rimoin DL, Connor MJ, Pyeritz RE, Korf BR (eds) Emery and Rimoin's Principles and Practice of Medical Genetics. Fourth Edition. Churchill Livingstone, New York, p 3998 (Fig. 149.24).

deletion and splice site alterations. Approximately 70% of *FBN1* mutations are identifiable in individuals who satisfy the diagnostic criterion for Marfan syndrome. Missense mutations in *FBN1* that affect cysteine residues important for proper EGF structure or amino acids involved in calcium binding act in a dominant negative fashion, usually resulting in a moderately severe phenotype. Some *FBN1* mutations that impair folding of EGF domains may cause protein misfolding and result in retention of mutant fibrillin-1 within the endoplasmic reticulum, thereby altering intracellular trafficking (7). The severe neonatal form of the disease appears to be caused by missense mutations in exons 24 to 26 or skipping of exons 31 or 32.

The large number of exons in the *FBN1* gene makes direct DNA sequencing of the entire gene impractical. Various methods have been utilized for *FBN1* analysis, including single strand conformation polymorphism analysis, heteroduplex analysis and long reverse transcription-polymerase chain reaction (►RT-PCR). Denaturing high performance liquid chromatography for each *FBN1* exon followed by DNA sequencing of exons with abnormal chromatogram profiles has shown promise as a mutation detection method due to its high sensitivity, specificity and relatively low cost. Identification of a *FBN1* mutation in a patient with Marfan syndrome is necessary for prenatal diagnosis. Linkage analysis may be incorporated for prenatal diagnosis and identification of unaffected family members in situations where a causative *FBN1* mutation has not been identified.

Type-1 fibrillinopathies is a term that is used to refer to Marfan syndrome and a series of related connective

tissue disorders that are caused by mutations in *FBN1*. *FBN1* mutations have been identified in patients with the MASS phenotype and in several patients with Shprintzen-Goldberg syndrome. The identification of an in-frame *FBN1* deletion in affected family members with autosomal dominant Weill-Marchesani syndrome (3) and a mutation causing a single base substitution at codon 1796 in members of a three-generation kindred with kyphoscoliosis have widened the phenotypic spectrum associated with *FBN1* gene mutations.

Clinical Relevance

Marfan syndrome is a relatively common disorder of connective tissue. Early recognition of the clinical features of Marfan syndrome by health professionals and patients may help prolong life and provide optimal treatment for patients. Understanding of the molecular basis of Marfan syndrome and other type-1 fibrillinopathies have led to an improved understanding of the properties of microfibrils, the major constituents of connective tissue. Genetic heterogeneity of *FBN1* mutations has been associated with varying phenotypic differences among patients with Marfan syndrome and other distinct syndromes. There is evidence that inherited disorders involving other connective tissue proteins are associated with the development of aortic aneurysms. For example, a locus for familial aortic aneurysm that is distinct from the *FBN1* locus has been identified at 11q23.2-q24. Further studies are being performed to identify genes that are associated with familial aortic aneurysm. At the present time no causative gene has been identified. Because of the complexity of connective tissue and the heterogeneity of familial aortic aneurysm, it is anticipated that other loci will be identified.

Mass Action Law

The mass action law is the thermodynamic description relating the populations of unbound species and complex in interacting molecules; for example, if two molecules A and B form a reversible complex with the molar affinity constant K_A it takes the form $[AB] = K_A[A][B]$, with the molar concentrations $[A]$, $[B]$, and $[AB]$ of the unbound species A, B, and their complex, respectively.

Mass Spectrometer

Definition

A mass spectrometer is a device designed to produce a mass spectrum of a sample to find out its composition. This is normally achieved by ionizing the sample and separating ions of differing masses and recording their relative abundance by measuring intensities of ion flux. A typical mass spectrometer comprises three parts: an ion source, a mass analyzer, and a detector. Mass spectroscopy allows detection of compounds by separating ions by their unique mass.

Techniques for ionization have been key to determining what types of samples can be analyzed by mass spectrometry. Two techniques which are often used with biological samples include electrospray ionization (John Fenn, Nobel Prize in Chemistry in 2002) and Matrix-assisted Laser Desorption Ionization (► [MALDI](#)) (for which Koichi Tanaka, Nobel prize the same year). The produced ions can then enter the mass analyzer.

Mass analyzers of many varieties have been produced.

► [The Time-of-flight](#) (TOF) analyzer is typically integrated with MALDI ion sources. Ions are boosted to the same kinetic energy by passage through an electric field, and the times they take to reach the detector are measured. The smallest ions (or those most highly charged) move most rapidly. Quadrupoles and quadrupole ion traps use electrical fields to selectively stabilize or destabilize ions falling within a narrow window of m/z values. Sector instruments change the direction ions are flying through the mass analyzer. Fourier Transform Mass Spectrometry uses perturbations in magnetic fields to measure m/z values extremely accurately. The best mass analyzer for an experiment depends upon the type of information to be gleaned from the experiment.

The final element of the mass spectrometer is the detector. Typically, some type of electron multiplier is used. Because the number of ions leaving the mass analyzer at a particular instant is typically quite small, significant amplification is necessary to get a signal.

Definition

► [Electrospray ionization \(ESI\)](#) is a method of generating ions directly from a solution. Different types of mass analyzers and detectors can be combined

with an ESI source to build a mass spectrometer for the determination of the molecular weights of peptides and proteins and the mass spectrometric sequencing of peptides. Since the ionization process takes place at atmospheric pressure with little thermal input, ESI is a soft ionization technique and is therefore especially suitable for biological samples such as proteins, non-covalent interaction complexes, peptides, drugs and DNA segments.

Characteristics

The breakthrough for ESI of biological samples came in 1988 at a symposium in San Francisco with the presentation of molecular weight determinations of polypeptides and proteins by John Fenn. Fenn showed that a molecular weight accuracy of 0.01% could be obtained by applying a signal-averaging method to the multiple ions formed in the ESI process (1). These multiply charged ions with low mass/charge ratio could be easily analyzed by any mass analyzer.

In the electrospray ionization (ESI) process, a flow of sample solution is pumped through a narrow-bore metal capillary held at an electric potential of a few kilovolts relative to a counter electrode (Fig. 1A). Drops of the solution, emerging from the tip of the needle, spray as a mist of very fine, charged droplets. As these charged droplets evaporate in a flow of a warm drying gas, the increasing coulombic repulsive forces of the ions within the droplets finally exceed the surface tension, causing the droplets to undergo fission. Successive fissions ultimately give rise to droplets containing a single solute molecule that retains the droplet charge, left as the remaining solvent evaporates. Multiply charged ions are commonly observed. To produce negative ions, which are often formed by proton abstraction, similar voltages of opposite sign are applied.

Suitable solvents for the analysis of peptides and proteins include water, methanol and acetonitrile (e.g. methanol/water/formic acid, 50/49.9/0.1, v/v/v). Non-volatile agents like salts (e.g. NaCl, KH_2PO_4 , Tris), detergents (e.g. Tween, Triton, SDS), chaotropic agents (e.g. urea, guanidinium salts) and solvents (e.g. DMSO, glycerol) interfere with the ESI process and suppress the ionization of the analyte. In most cases a desalting step is necessary for biological samples to obtain expressive ESI spectra.

The sample solution flow rate in an electrospray ion source is most commonly in the range of 3–20 $\mu\text{l}/\text{min}$. Experimental evidence has shown that the optimal sensitivities of detection using electrospray can be achieved by delivering lower flow rates. The observed ion current correlates with the concentration of the analyte rather than with the flow rate. Micro-electrospray ion sources with flow rates in the range of 0.2–1 $\mu\text{l}/\text{min}$ were developed and often used with

Mass Spectrometry: ESI. Figure 1 (a) Scheme for a nano-electrospray mass spectrometer. Droplets of the analyte emerge from the capillary and pass through the sampling cone and skimmer toward the mass analyzer. The droplets shrink by losing solvent molecules, thereby desolvating the ions they contain. (b) Scheme for an ion source with an ESI chip. A disposable pipette tip containing sample presses and seals against the inlet-side of the chip with the nano-electrospray plume spraying towards the mass spectrometer's orifice. A scanning electron micrograph pointing down towards a single nozzle is shown in the inset. The ESI chip has a 10×10 array of nozzles. (By courtesy of Sheng Zhang).

continuous flow in connection with a capillary liquid chromatography (CapLC) system, comprising a low flow capillary pump and an autosampler. With such a configuration automated data acquisition can be implemented.

The nano-electrospray interface designed by Wilm and Mann (2) operates at low nl/min flow rates. The sample glass capillaries are metal coated and a backing gas pressure to aid flow stability but without pumping to impose a specific solvent flow is installed. ▶ **Tandem mass spectrometry MS/MS** characterization at the sub-femtomole level of samples present in 1–2 μl volumes can be accomplished with the nano-electrospray source. However, the low sample throughput is a disadvantage for ▶ **proteomics** and clinical approaches.

An automated nano-ESI-MS/MS method was described by Zhang et al. (3). It consists of a liquid handling robot (NanoMate) with a 96-well plate, a rack of 96 disposable, conductive pipette tips and a microchip containing a 10×10 array of nano-electrospray nozzles (ESI Chip). The nozzles are etched into the planar surface of a silicon microchip. Opposite to the surface containing the nozzles, a 10×10 array of through-chip channels is located. This is the inlet-side of the chip, where samples are introduced *via* a pipette tip (Fig. 1B). Typical flow rates are in the range of 100–200 nl/min. With the NanoMate, 100 relatively high sample throughput analyses can be performed without carryover.

ESI is compatible with many mass analyzers such as ion trap, quadrupole, hybrid quadrupole time of flight (TOF) and Fourier transform ion cyclotron resonance analyzers and is used for proteomics (4) and clinical analytics. Ion traps are robust, sensitive and relatively inexpensive and so have produced much of the proteomics data reported in the literature. More extensive and informative fragment ion (MS/MS) spectra are often generated in hybrid quadrupole TOF instruments. The combination of ESI and FTICR-MS is particularly powerful, because the trapping efficiency and resolving power increases with increasing charge (for a given mass) in the FTICR-MS and ESI generates multiply charged ions. The unsurpassed resolution and accuracy of the FTICR-MS technique facilitates the screening of complex biological samples without any extensive pre-purification (5).

As examples of protein and peptide molecular weight determination, mass spectra of horse heart apomyoglobin (Fig. 2a) and a peptide mixture of bovine adrenodoxin I peptides resulting from a digestion with the endoprotease GluC are shown. Myoglobin with the theoretical molecular weight of 16,951 D is analyzed with ESI. The process results in a typical charge pattern, an approximate Gaussian distribution of ion intensity. The resulting mass-to-charge ratio, from 700–2000 Th, can be easily measured in any mass analyzer. The charge pattern can be deconvoluted and the mass of the uncharged ion determined to a much higher accuracy than if the interpretation of data was based on a single ion. Averaging the results of multiply charged peaks leads to mass measurement with an accuracy of 0.01%.

The ability to retain fragile complexes during ESI enables the study of protein-protein and protein-drug complexes. In these cases special care must be taken in choosing the appropriate solvent for the analyses. Many proteins can be denatured and caused to unfold when subjected to extremes of pH, detergents or solutions containing high concentrations of organic solvents. An example of a noncovalent protein

Mass Spectrometry: ESI. Figure 2 (a) Positive ion electrospray mass spectrum of horse heart apo-myoglobin (myoglobin without the heme group). The insert shows the deconvoluted peak resulting from the transformation to the mass scale. The theoretical molecular weight is 16951.5Da. (b) Mass spectrum of a bovine adrenodoxin 1 peptide mixture resulting from a digestion with the endoprotease GluC. A triply charged peptide is shown in the inset with high resolution.

complex is myoglobin with a heme prosthetic group. The heme group is located in a hydrophobic crevice in the myoglobin molecules. Native myoglobin can be measured in water at a pH near physiological conditions. If acetonitrile is added to 50% by volume and at the same pH, the majority of the ion intensity converts to the apo-myoglobin form. If the pH of the water solution is dropped to pH 2.6, complete denaturation of the complex occurs. The automated nano-ESI system was used to investigate quantitative noncovalent interactions between ribonuclease A (RNase A) and cytidylic acid ligands, a well-characterized model protein-ligand complex and between an inactive endocellulase mutant and four oligosaccharide ligands (3).

The sensitivity and selectivity of analyte detection using electrospray MS and MS/MS are currently such that the limiting factors in trace detection frequently relate to sample preparation and presentation to the mass spectrometer.

Clinical Relevance

ESI with MS/MS is becoming an increasingly important analytical technology in the clinical laboratory environment (6). Immunoassays are very sensitive and can be very easily automated for clinical tests of one component. ESI-MS/MS is best suited for applications in which more than one compound must be measured simultaneously or tedious specimen preparation protocols or prohibitive interference problems occur.

This technology offers a new vision to newborn-screening programs that have the ability to screen for 30 or more metabolic disorders in a single analysis from one small disk of dried blood. It is evaluated as one of the most important advancements in neonatal screening since the introduction of a bacterial inhibition assay for phenylketonuria (7).

For patients at risk of inherited disorders of purine and pyridine metabolism, a rapid and specific method of diagnosis was developed based on ESI-MS/MS after chromatographic separation. This method proved to be effective in the detection of purine nucleoside phosphorylase deficiency, dihydropyrimidine dehydrogenase deficiency, ornithine transcarbamylase deficiency, molybdenum cofactor deficiency and adenylosuccinase deficiency.

In addition, ESI-MS/MS procedures to detect three immunosuppressant drugs (tacrolimus, sirolimus and cyclosporin) are used for the development of multiple-drug therapeutic regimens in specialized clinical laboratories.

Drug screening directly from urine, using HPLC ESI-MS/MS, without the need for prior sample extraction has been also demonstrated. Furthermore, the method is an essential technology for the laboratories that are charged with detecting drug doping among athletes and drug abuse.

Matrix-Assisted Laser Desorption/Ionization

Definition

Matrix-assisted laser [▶desorption/ionisation](#) (MALDI), an ionisation technique for mass spectrometric analysis of large biomolecules, was reported in 1988 by Franz Hillenkamp and Michael Karas of the University of Münster (1). Analytical samples are prepared for MALDI by embedding the analyte molecules in a condensed (most often solid) matrix of small molecules present at high molar excess ($>10^4$ – 10^7). The matrix has a very low vapour pressure and is highly absorbing at the wavelength of the desorption/ionisation laser. In a MALDI experiment a brief laser pulse irradiates a spot on the sample whereby the matrix molecules absorb the laser energy, resulting in ablation of a small volume of matrix and desorption of the embedded analyte molecules. In the expanding plume of desorbed material following the laser pulse, analyte molecules are ionised through processes that have not yet been fully elucidated (2), leading to the formation of predominantly singly charged positive and negative analyte ions.

Characteristics

MALDI – a Soft Ionisation Technique

Mass spectrometric analysis requires analytes in the form of gas phase molecular ions. These can be manipulated by magnetic and/or electric fields in a mass analyser and thus separated according to their mass-to-charge ratios (m/z), allowing one to determine their molecular mass. A long-time problem with mass spectrometry of large biomolecules was that the ionisation techniques known until the mid 80's were inefficient or led to decomposition of the analyte molecules, largely restricting mass spectrometry to molecules below 10 kilo-[▶Dalton](#) (kDa) and hampering the sensitivity of the technique. These limitations were overcome by the introduction of two new ionisation techniques, MALDI and electrospray ionisation (ESI), extending the accessible mass range to mega-Daltons. Due to the comparatively low degree of analyte decomposition observed with MALDI and ESI, these are known as soft ionisation techniques.

Desorption/Ionisation Lasers

The most commonly used lasers on commercial instruments are nitrogen lasers emitting in the ultra-violet (UV) at 337 nm. The beam is typically focused to a spot with a diameter of 10–500 μm , irradiating the surface with an effect of 10^6 – 10^7 W/cm^2 . The laser energy must be transferred to the sample in a very short time in order to avoid thermal decomposition of the analyte. Typically, pulse-widths of a few nanoseconds are used. The laser energy is an important parameter and is controlled by a laser beam attenuator. Best results are obtained with laser energies just above the threshold for desorption/ionisation. Excessive energy results in thermal decomposition of analyte molecules, increased chemical noise and saturation of the mass spectrometric detector. A current development is directed towards increasing the laser repetition rate in order to shorten the analysis time. For example, by using solid-state triple-wavelength Nd:[▶YAG](#) UV lasers emitting at 355 nm, kHz pulse rates can be achieved, thus making it possible to record over a thousand single-shot MALDI-TOF mass spectra per second. MALDI at different laser wavelengths is also being explored, for example using infrared (IR) lasers such as Nd:YAG emitting at 1065 nm and Er:YAG at 2940 nm.

MALDI Matrices

For successful MALDI MS analysis, the choice of the active matrix compound and selection of sample preparation technique are important parameters, both of which are dependent on the properties of the analyte. The MALDI matrix should fulfil the following requirements; be non-volatile in the high-vacuum of the [▶mass spectrometer](#), embed – or at least mix homogeneously with – the analyte molecules, have strong absorption at the desorption/ionisation laser wavelength and assist/enable ionisation of analyte molecules by proton transfer. Since the discovery of MALDI, several hundred compounds have been tested for their suitability as MALDI matrices but only about a dozen have proven efficient in fulfilling the above criteria. The most commonly used matrix compounds (for UV MALDI) and the analytes to which they are applicable are listed in Table 1. α -Cyano-4-hydroxycinnamic acid (CHCA) is arguably the most widely used matrix for peptide analysis. CHCA sample preparations can be used for samples containing a variety of contaminants such as buffer salts, chaotropic agents and detergents. Disadvantages of CHCA include strong background signals in the low-mass region (up to ca. 800 Da) and that it induces fragmentation of many large molecules. For proteins and fragile molecules, such as glycoconjugates, 2,5-dihydroxybenzoic acid (DHB) is the preferred matrix compound. Compared to CHCA, DHB yields fewer background

Mass Spectrometry: MALDI. Table 1 Some commonly used MALDI matrices, and examples of analytes to which they are applicable

matrix compound	analytes
α -cyano-4-hydroxycinnamic acid	peptides, small proteins
2,5-dihydroxybenzoic acid	peptides, proteins, glycoconjugates
sinapinic acid	peptides, proteins
2,4,6-trihydroxyacetophenone	glycoproteins, small oligonucleotides
3-hydroxypicolinic acid	oligonucleotides, small PCR products

signals and induces less analyte decomposition. A DHB sample preparation is, however, significantly more sensitive towards the above-mentioned contaminants, demanding efficient sample purification prior to the MALDI sample preparation. Compared to DHB, 2,4,6-trihydroxyacetophenone (THAP) and 3-hydroxypicolinic acid (HPA) result in even less analyte decomposition, at however, the cost of detection sensitivity. These matrices are the preferred choice for the analysis of nucleic acids, which are considerably more prone to undergo ion fragmentation reactions than peptides and proteins.

MALDI Sample Preparation

A variety of sample preparation techniques have been reported to date (3). The first and still much used, is the dried-droplet method (1). The aqueous sample is mixed with a matrix solution at a 10^4 – 10^7 molar excess of the matrix compound and a droplet of the analyte/sample mixture is placed on the MALDI sample plate, which is commonly made of stainless steel. After evaporation of the solvent, a crystalline mixture of analyte and matrix molecules is obtained. Another widely used sample preparation technique is the thin-layer method. First, a thin microcrystalline layer of matrix crystals is prepared on the sample plate. On top of this layer, an acidic aqueous droplet of the analyte solution ($\text{pH} < 2$) is placed and allowed to dry. As a result, the analyte molecules are exclusively incorporated into the outermost molecular layers of the matrix crystals. In this way, the analyte molecules are concentrated to a very small volume, thereby enhancing the detection sensitivity. In addition, the thin-layer preparation allows efficient washing of the sample, whereby salts, buffer components and chaotropic reagents such as urea can be removed. The resulting samples exhibit homogeneous morphology, resulting in good reproducibility for mass spectra acquired over the entire sample, thus facilitating automatic data acquisition. A disadvantage of the thin-layer method is that a sample spot is used up after only a few laser pulses, after which the sample plate has to be moved for the laser to irradiate a fresh spot. The thin-layer method relies on the analyte solution not dissolving the microcrystalline matrix layer, thus prohibiting the use of highly

Mass Spectrometry: MALDI. Figure 1 The MALDI process: Analyte molecules (white) are embedded in a condensed matrix of molecules (gray) exhibiting strong absorption at the desorption laser wavelength. A MALDI experiment is initiated by irradiating the sample with a brief laser pulse. The energy from the laser is efficiently absorbed by the matrix molecules resulting in ablation of a small sample volume, releasing analyte molecules into the gas-phase. In the rapidly expanding plume of desorbed analyte and matrix, analyte molecules are ionized.

water-soluble matrices such as DHB and precluding reversed-phase sample purification directly prior to sample preparation.

MALDI-TOF Mass Spectrometry

MALDI is used in conjunction with several different mass analysers (4), however the most commonly used in biological and medical laboratories is the time-of-flight (TOF) analyser. Fig. 2 shows the basic principle of a MALDI-TOF instrument. The ions generated following the laser pulse are accelerated by an applied electric field. All ions carrying the same charge acquire the same kinetic energy (E_k) after passage through the accelerating field:

$$E_k = \frac{mv^2}{2} = zU$$

where m = the mass of the ion, v = its velocity, z = the number of charges, and U = the accelerating voltage. Thus, their resulting velocity will be inversely proportional to the square root of their mass:

$$v = \sqrt{\frac{2zU}{m}}$$

The ions then pass into the field-free drift region, typically 1–2 m in length, where their velocity differences result in a spatial separation. Because the ions spend most of their time in this region, their time-of-flight measured at the detector is approximately:

$$t = D\sqrt{\frac{m}{zU}}$$

where D is the length of the field-free drift region. To obtain a high mass accuracy, the mass scale is usually calibrated by using well-defined molecular mass standards.

There are several reasons why MALDI MS has become a widespread technique in biological and medical research laboratories in the last 15 years. Pico- to femto-moles of analyte molecules can be routinely detected; amounts that are sufficiently low for the technique to be adequate for the detection of many compounds of interest when isolated from biological or clinical samples. The high mass accuracy of modern mass spectrometers (e.g., typically better than 50 ppm for MALDI-TOF MS peptide analysis) often makes it possible for one to derive detailed chemical structural information on the analyte molecules. The production of analyte ions by laser irradiation of a solid sample on a metal plate lends the technique well to automation. Several hundred samples can be automatically analysed on a single sample plate on currently commercially available MALDI-TOF instruments. In the following, a

Mass Spectrometry: MALDI. Figure 2 The principle of MALDI-TOF MS: In the figure, two positively charged ions of mass m_1 and m_2 , where $m_1 < m_2$, were generated following a laser pulse. The ions are accelerated by an electric field applied between the sample plate and an extraction grid. After passing through the acceleration region, the ions' velocities are proportional to the square root of the inverse of their respective masses. In the field-free drift region, the ions are separated by their different velocities and thus arrive at the detector at different time points. The impact of the ions on the detector results in a current that is recorded over time and constitutes the time-of-flight spectrum. By calibration, the time-of-flight spectrum is converted into a mass spectrum.

few examples are given of analytical strategies involving MALDI MS.

Protein Identification by MALDI MS Peptide Mass Fingerprinting

MALDI ▶peptide mass fingerprinting (PMF) is a widely used technique for identification of proteins isolated by, e.g. gel electrophoresis or chromatography. The unknown isolated protein is cleaved by a protease of high specificity. Commonly used is trypsin, which cleaves polypeptides at the C-terminal side of lysine and arginine residues, unless the next amino acid in the sequence is proline. MALDI MS analysis of the resulting mixture of peptides yields a peptide mass fingerprint; a set of measured molecular masses of tryptic peptides derived from the analysed protein. In a database search, these mass values are matched against sets of masses calculated for all protein sequences in a sequence database. The search returns a list of the sequence entries with the highest number of matching mass values, and various algorithms are used to rank the sequences and determine the probability that the highest-ranking sequence entry is the true identity of the analysed protein. Recording a peptide mass fingerprint instead of a measuring the molecular mass of the intact isolated protein has several advantages. For example, if a protein carries post-translational modifications, contains mutations or is processed, its

measured molecular mass will not match the mass calculated based on its sequence in the database and consequently its identification will fail. The same will happen if the protein's sequence in the database contains an error. With a peptide mass fingerprint in contrast, only signals corresponding to the peptides that carry the modified amino acid or containing the mutation site, will be affected. The recorded m/z values of the other signals will match the masses calculated based on the protein's amino acid sequence, thereby rendering the identification procedure rather robust. In addition, detection sensitivity as well as mass accuracy is higher for peptides than for proteins.

Structural Characterization by MALDI MS/MS

MALDI MS is not limited to measuring the masses of intact analyte molecules. Many instruments provide the possibility of isolating a selected analyte and, by different activation methods, transferring energy to the analyte, thereby inducing fragmentation of the molecule. Mass analysis of molecular fragments derived from a single selected analyte can provide detailed structural information and is termed tandem-MS or MS/MS analysis. For proteins and peptides, this information can for example be used to verify a postulated amino acid sequence and to pinpoint a protein modification to a certain amino acid. On MALDI mass spectrometers, analyte fragmentation can be induced by increasing the laser energy above the desorption threshold. Fragment ions produced by this method are termed post-source-decay (PSD) fragments.

Clinical Relevance

In the last 15 years, MALDI mass spectrometry has matured into an analytical technique with many applications in the clinical field. In the following, a few examples of established and emerging analytical strategies using MALDI MS are given.

2-DE and MALDI MS

Of particularly widespread use is the combination of two-dimensional gel electrophoresis (2-DE) and MALDI MS. 2-DE has the resolving power to separate and visualize over 10,000 proteins in crude cell or tissue extracts in a single experiment. 2-DE protein spot patterns for different samples, e.g. from patients and healthy controls, can be compared to reveal aberrances in normal protein abundance and modification. Proteins of interest can be hydrolysed by a protease *in situ*, i.e., while immobilized in the gel sample, and readily identified by MALDI MS PMF and MS/MS analysis of the produced peptides. The combination of 2-DE and MALDI MS has been used extensively for detection and identification of biomarkers for many different

diseases, including cancer, Alzheimer's disease, allergy and inflammatory diseases.

Protein Interaction Analysis

The combination of the above-described PMF and MS/MS techniques with various affinity enrichment methods or non-denaturing separation techniques has made it possible to study protein-protein, protein-DNA and protein-carbohydrate interactions. These experiments start with the isolation of the complex, followed by MS analysis of each constituent component. The relatively high throughput of MS makes it possible to perform such studies on a large scale (5).

Genotyping by MALDI MS

Although less established than gel-based methods, MALDI MS is capable of sequencing oligonucleotides of lengths up to 30–50 base pairs. Advantages of MALDI MS include short analysis times and that no chemical labels are required for detection. Furthermore, mass spectrometric detection is unaffected by secondary structure, which can pose problems with gel-based methods, e.g., for sequencing GC-rich regions. MALDI MS is therefore often used when large numbers of short sequences are to be determined. Several schemes for detection of single-nucleotide polymorphisms (SNPs) using MALDI MS have been developed (6). High-throughput genotyping of SNPs has the potential to become a routine technique for clinical applications.

MALDI MS Screening of Diagnostic Fluids

Due to the ability of MALDI MS to detect biomolecules in complex mixtures and in the presence of relatively high salt concentrations, several methods have been developed in which MALDI MS is used as a tool for rapid, direct screening and detection of modifications of proteins in small volumes of diagnostic fluids. For example, several proteins with links to Alzheimer's disease have been detected in cerebrospinal fluid in which they are present at nano-molar (nM) concentrations.

Analysis of Protease Activity in Diagnostic Fluids

While many enzymes in biological fluids are present at concentrations too low for their detection by MALDI MS, their activity can be measured indirectly. A substrate (protein or peptide) is added to a sample of the diagnostic fluid at a concentration at which it can be detected by MALDI MS. Samples of the mixture are then analysed at time points following the addition and the activity and specificity of the native proteases in the fluid can be monitored by their action on the added molecule. This technique has for example been employed in the study of the processing of neuropeptide Y in cerebrospinal fluid.

Fingerprinting of Whole Microorganisms

In microbiology, MALDI-TOF MS is employed to analyse samples prepared from whole viruses, bacteria and spores. The microorganisms are lysed when mixed with the MALDI matrix solution, allowing the direct desorption of peptides and proteins in the sample. The mass spectra acquired from such samples are complex and usually cannot be interpreted directly. However, with a reproducible sample preparation, the mass spectrum constitutes a characteristic fingerprint by which a microorganism can be distinguished from others. One application of clinical relevance is the detection of biomarkers for taxonomic identification of bacteria by MALDI-TOF MS.

MALDI-TOF Imaging Mass Spectrometry

MALDI-TOF imaging mass spectrometry is an emerging technique, made possible by the development of high-repetition rate desorption/ionization lasers and fast data acquisition systems. Thin slices of tissue samples are attached to the MALDI sample plate and coated by MALDI matrix. A MALDI-TOF instrument is then used to acquire mass spectra in a dense pattern on the sample surface. Parallel to the way in which a picture produced by an optical scanner consists of pixels each assigned an intensity value, the mass spectrometric image also consist of pixels, each represented by one mass spectrum. By assigning different colours to selected m/z values, the mass spectrometric image can be used to visualize the spatial distribution of selected compounds in the studied tissue. The spatial resolution, limited by the diameter of the desorption/ionisation laser, is approaching 1 pixel/ μm . MALDI-TOF imaging mass spectrometry can be used to map the distribution of selected compounds in tissue.

Synonyms

Tandem mass spectrometry; mass spectrometric fragmentation

Definition

Tandem mass spectrometry (MS/MS) is a method for obtaining sequence and structural information by measurement of the mass-to-charge ratios of ionized molecules before and after dissociation reactions within a mass spectrometer which consists essentially of two mass spectrometers in tandem. In the first step parent or precursor ions are selected for further fragmentation by energy impact and interaction with a collision gas. The generated daughter or product ions can be analyzed by a second scan step. MS/MS measurements of peptides can be performed using electrospray or matrix-assisted laser desorption ionization in combination with triple quadrupole, ion trap, quadrupole-TOF (time-of-flight), TOF-TOF or ion cyclotron resonance (FTICR) MS. Tandem mass spectrometry of peptides generated by proteolytic digestion of proteins provides amino acid sequence-specific ions and can be used to identify and characterize proteins (1).

Characteristics

Dissociation of Molecules in Mass Spectrometry

The development of so-called “soft” ionization techniques such as electrospray ionization (►ESI) and matrix-assisted laser desorption/ionization (►MALDI) has enabled the generation of gas-phase ions of non-volatile, sensitive biopolymers without fragmentation which allows mass analysis of e.g. proteins, peptides, carbohydrates and oligonucleotides. Using these techniques, intact molecular ions are measured, but no structural information is obtained. In order to obtain specific fragments during MS analysis which are interpretable in terms of molecular structure, MS/MS (or tandem MS) experiments can be performed. Valuable fragmentation requires that the energy transmitted to an ion exceed the vibrational energy of a specific bond. This can be achieved by accelerating the ion of interest into a collision cell where it can undergo multiple collisions with an inert gas (collision-induced dissociation, CID). Two types of CID are used. Triple quadrupole and ion trap instruments typically utilize low-energy collisions (<35 eV) whereas tandem time-of-flight instruments employ high-energy

collisions (keV range). Low-energy conditions are particularly useful in the analysis of protonated peptides and proteins. Such conditions produce fragmentation at the amide bonds and provide spectra which are characteristic of the primary structure (2). The recently described electron capture dissociation (ECD) method uses an entirely different fragmentation mechanism with the advantage that backbone cleavages are preferred and side-chain modifications, such as phosphorylation or glycosylation, remain unaffected.

MS/MS Instruments

Tandem MS experiments can be performed by different types of mass spectrometers, which consist of the four basic types of mass analyzer as well as various combinations thereof. Triple quadrupole (QqQ) instruments use three quadrupoles in series such that the first and third quadrupoles are operated as mass analyzers. The second quadrupole is used as a collision cell in order to generate various fragments. QqQ instruments can be utilized to perform any kind of MS/MS analysis, but are characterized by the relatively low resolution of the mass analyzer. In a quadrupole time-of-flight mass spectrometer the second mass analyzer is replaced by a TOF analyzer which allows extremely fast acquisition of spectra, high mass resolution (up to 25,000 FWHM), and low femtomole sensitivity. Because of the high mass resolution, the quadrupole TOF instrument enables exact charge state assignments. The recently introduced TOF-TOF analyzer equipped with a MALDI ion source combines very accurate and sensitive mass measurements with sequencing capability by high energy CID. Such an analyzer allows reliable peptide and protein analyses of complex samples and the process can be easily automated.

Quadrupole ion trap (IT) and Fourier-transform ion cyclotron resonance (FTICR) mass spectrometers use one mass analyzer and the tandem-in-time concept to perform MS/MS measurements. In the IT mass spectrometer, the ions of interest are first captured and then dissociated in the ion trap by low energy CID prior to acquisition of the fragment ion spectrum. Ion traps are robust, sensitive and enable multi-stage tandem MS (MS^n). However, they are considered to be low mass accuracy instruments. FTICR mass spectrometers capture ions at high magnetic fields and allow MS and MS/MS measurements to be made with high sensitivity and outstanding mass accuracies (better than 5 ppm). However, because of operational complexity and limited fragmentation efficiency, this kind of instrument is rarely used in proteome research. In general, most MS/MS mass analyzers can use both ESI- and MALDI-ion sources. ESI- and MALDI-MS/MS experiments are advantageously combined on-line and off-line respectively, with capillary liquid chromatography for analysis of complex mixtures.

Tandem MS Modes

Product ion scanning is the most frequently used type of MS/MS experiment. A precursor ion, i.e. the ionized molecule of interest, is isolated by a first mass analyzer. After dissociation in the collision cell, a mass spectrum of fragment ions is acquired by a second mass analyzer. The most commonly used technique for the dissociation of peptides is collision-induced dissociation (CID) which involves the collision of accelerated ions with an inert gas (argon). Under these conditions, peptide ions are basically cleaved at the amide bonds along the amino acid sequence (Fig. 1). The product ion spectrum consists of ladders of sequence ions either from the N-terminus (b-type ions) or from the C-terminus (y-type ions). Amino acid sequences can be derived by subtracting the masses of adjacent ions. The fragment ion pattern depends strongly on the sequence and the presence of specific amino acids. In the case of tryptic peptides (from proteolytic digestion of proteins by trypsin and having the basic amino acids arginine or lysine at the C-terminus), the spectra are dominated by y-ions, thus facilitating the interpretation. In contrast, internal fragmentation, preferential cleavages and the loss of neutral groups increase the complexity and hamper the interpretation of product ion spectra. Product ion scanning of peptides generated by proteolytic digestion of proteins using both low- and high-energy collision conditions gives at least partial information about the amino acid sequence. In particular, this has led to the development of sequencing methods which can be used to identify proteins by searching protein sequence databases or nucleotide databases (EST).

For precursor ion scanning, the first mass analyzer is used to scan the entire mass range of interest and to transmit the ions into the collision cell. The second mass analyzer is used as a mass filter which allows only specific fragment ions to be transmitted to the detector. The detector only registers signals when fragment ions of interest (reporter ions) are split off from precursor ions. Using this MS/MS mode, ions which share a structural feature (a particular class of compounds) can be analyzed and resolved from other molecular ions. For [post-translational protein modifications](#) which can produce characteristic fragment ions (phosphorylation, glycosylation, Cys-palmitoylation, etc.), precursor ion scanning of the proteolytic digest of the protein can be used to identify the sites of attachment (3).

Similar to precursor ion scanning, neutral loss scanning is generally used to analyze peptide and protein modifications. This scan mode can be employed if characteristic neutral fragments are formed upon CID. The mass of the product ion differs from the mass of the precursor ion by the neutral fragment. Neutral loss can be detected by scanning simultaneously the first and the

Mass Spectrometry: MS/MS. Figure 1 MS/MS peptide fragmentation by collision induced dissociation.

Mass Spectrometry: MS/MS. Figure 2 MS/MS analysis of native G protein α_s . The protein was in-gel digested by trypsin and the resulting peptides analysed by electrospray tandem mass spectrometry. The mass peak with m/z 973.6 corresponded to the N-terminal modified sequence GCLGNSK of G_{α_s} . The b- and y-ions of the MS/MS spectrum show that native G_{α_s} carries an additional group at the N-terminal amino acid with a mass of 238 that corresponds to the palmitoyl moiety (5).

second mass analyzer with an offset which corresponds to the mass of the neutral fragment. For example, in order to determine the phosphorylation of proteins, the loss of phosphoric acid (neutral loss of 98 mass units) from phosphoserine or phosphothreonine is measured.

Tandem Mass Spectrometry in Proteomics

Proteome research, which includes (i) analysis of molecular networks in a cell following functional

stimulation, (ii) differential display effects for the comparison of protein expression and (iii) determination of post-translational modifications, requires efficient methods for the identification and characterization of proteins. In addition to methods for the separation, visualization and quantification of proteins, MS/MS techniques provide sensitive and efficient tools for the identification and characterization of proteins and thus play a central role in proteomics.

MS/MS in conjunction with capillary liquid chromatography (LC) has been used for identification of proteins excised from 1-D or 2-D gels. The automated nature of protein database searching using uninterpreted MS/MS data (4), the low femtomole sensitivity and the ability to identify a protein based on a single MS/MS product ion spectrum allow the identification of more than 100 proteins per day. Thus, extensive protein identifications have been performed for example to identify cancer-related proteins or to study human pathogens. During a study of MHC-associated peptides the use of LC-MS/MS methods for the analysis of complex peptide mixtures was developed.

In combination with novel stable isotope-tagging methods (metabolic labeling using amino acids, enzymatic incorporation of ^{18}O , chemical reactions using ▶ICAT) and multi-dimensional capillary LC (strong cation exchange/reversed phase), tandem mass spectrometry enables quantification of differences in protein expression. In order to study multi-protein complexes, techniques which include LC-MS/MS and tandem affinity purification (TAP) tags for identification of proteins have been established (1).

Since MS/MS-generated fragment ion spectra provide a “structural fingerprint” of particular peptides resulting from enzymatic degradation of the protein by specific endoproteases, MS/MS can be used to determine the site of post-translational modification. Numerous reports show that functionally important modifications such as phosphorylation, glycosylation, methylation, myristoylation and palmitoylation are accessible to analysis *via* tandem mass spectrometry in such a way that sequences and modified amino acid side chains can be deduced from C- and N-terminal fragment ions of product ion spectra (Fig. 2).

Clinical Relevance

Proteomics technologies which include highly sensitive and high-throughput MS/MS methods for efficient identification and characterization of proteins have the potential to increase our understanding of the molecular basis of diseases. This could lead to new disease-specific targets. Tandem mass spectrometry directly contributes to protein profiling, the identification of diagnostic markers and toxicity studies and thus has a profound impact on clinical diagnosis and drug discovery. In addition to its implications for proteomics, MS/MS is becoming an increasingly important method in therapeutic drug monitoring (immunosuppressants, antidepressants) and analysis of metabolic pathways. It is expected that substantial increase in MS/MS sensitivity as well as nano scale LC techniques will further expand the range of applications.

ofiehn@ucdavis.edu

Definition

Mass spectrometry is widely used in proteomics for protein identification, mostly after tryptic digestion into peptides (1). For decades, mass spectrometry has also served for determining the absolute or relative amounts of components of complex matrices. There are countless reports on absolute quantification of target molecules by external or internal standards, often by use of stable isotope markers. For some application areas, semi-quantitative methods have been added that aim at comparative assessments of a wide range of compounds rather than ultimate precision for a very few targets. However, in biological contexts, such classical quantitation strategies have only recently been adopted. When sample preparation is aiming at metabolites, such approaches have been named ‘metabolomics’ (2) (and, for historical reasons, ‘metabonomics’ in biomedical applications). In the last couple of years there are also reports on quantitative approaches to proteomics using mass spectrometry. All quantitative methods must follow certain guidelines, termed method validation (3). Starting from the definition of the validity area (i.e. the exact description of the scope and objective of the analysis), each method must give certain minimum characteristics such as how compounds of interest can be distinguished from chemical or biological background noise (‘selectivity’),

the lower limit ('sensitivity') and the dynamic range where quantitation can be achieved, a robustness assessment and, eventually, the method reproducibility. For each of these prerequisites, mass spectrometric methods may face problems due to instrumental constraints such as ▶**duty cycles**, or lack of tandem mass spectrometric capabilities. More severe, however, are fundamental constraints of ionization suppression and adduct formation that may ultimately undermine any precise comparative quantitation.

Characteristics

There are more than 50 types of mass spectrometer used for biological determinations, each having specific characteristics limiting their use outside pre-defined applications. Some features of mass spectrometers, however, are common to all of them, enabling performance comparisons of the instruments and simultaneously, setting fundamental constraints on the analysis of complex mixtures. Firstly, and looking trivial at first sight, mass spectrometers can only detect ions, not neutral species. Therefore, the details of the ionization method are an integral part of any quantitative mass spectrometric method. The same argument is fundamental for another aspect of mass spectrometric detection; pure or 'naked' ions only survive a very short time if they undergo collision, for example at high gas pressures. Therefore, compounds must reach vacuum pressures immediately after, or even before, ion formation. Secondly, all mass spectrometers are able to distinguish different masses; this is called mass resolution $R = m/\delta m$. Since chemical and most physical properties of the molecules are almost identical, if only a few atoms are exchanged for stable isotopes (^{13}C , ^{18}O , ^2H , ^{15}N), such stable isotope marker compounds are the ideal reference for exact quantitation in mass spectrometry. This is especially true when they are added at the earliest possible time point in sample preparation in order to account for potential losses due to adsorption, precipitation or oxidation. Today, all mass spectrometers are able to distinguish nominal masses (e.g. m/z 212 from m/z 213). A few types of mass spectrometers, for example some time-of-flight instruments, have a higher ▶**resolution** of $R = 5,000$ to 50,000 or, ultimately, there are FT-ICR mass spectrometers with a resolution of up to $R > 1,000,000$. Such resolution enables the differentiation and quantitation of co-eluting isobaric compounds that have identical nominal masses but different exact masses due to small differences in the exact atomic weights ($^{16}\text{O} = 15,994915 \text{ u}$, $^1\text{H} = 1,008725 \text{ u}$, $^{14}\text{N} = 14,003074$).

GC/MS

One of the oldest and most classical methods is electron impact ionization of molecules in the gas phase. This technique gives robust ionization with reasonable

efficiency, but obviously requires volatility of the compounds. Therefore, it is restricted to small molecules such as metabolites and is usually coupled to ▶**gas chromatography**. In a single run, up to 20,000 components can be detected by GC x GC coupling prior to MS detection if time-of-flight mass spectrometers are utilized. Due to the large energy excess ('hard ionization'), the ionization efficacy is not hampered by co-eluting compounds over a wide range of concentrations. Therefore, quantitation can be reliably achieved even by external calibration. Higher precision can be achieved by adding stable isotope labeled compounds as outlined above and this technique has been used for over 40 years. A rougher estimation of differences in metabolite abundances uses direct comparisons of relative peak areas between two or many experiments; this is then called 'relative quantitation' for metabolomic use. This strategy is comparable to approaches undertaken in proteomics or transcriptomics where dye labeling or staining of 2D gel spots is compared without particular calibration curves. By relative quantitation, up to 1,000 metabolites can be compared between various biological tissues by GC/TOF analysis. Unlike 2D gel approaches in proteomics however, the sample throughput is much higher (and costs are lower). This enables a good estimation of reproducibility and its distinction from inherent biological variability – a field of the utmost importance, which has yet to be extensively covered in proteomics (see below). Quantitation in metabolomics by GC/MS regularly achieves 2–10%CV for identical extracts (technical error due to the instrument) or 20–30%CV for the total process (including errors in the extraction and sample preparation process), with typically some 3–4 orders of magnitude dynamic range, good robustness even in high-throughput operations, excellent selectivity due to the good chromatographic resolution (which is some 10-fold higher than in typical liquid chromatography applications) and good sensitivity due to low chemical noise. However, GC/MS is restricted to thermostable, small compounds (up to ~500 u) that can be made volatile, usually by chemical derivatization. Therefore, other approaches must complement GC/MS. As a complementary option, metabolomics by capillary electrophoresis coupled to MS detection detected 1,600 compounds from *B. subtilis* cultures with an overall method precision of 30▶%CV for 65 identified metabolites. Other approaches utilizing novel column types for LC/MS are lacking method validation so far.

LC/MS

The most difficult aspect of quantitation in LC/MS is the ionization process. Unfortunately, this has not always been sufficiently acknowledged, although there are numerous fundamental publications showing the

quenching effect of co-eluting compounds on the ionization efficiency of the target molecules. This phenomenon is called ion suppression and is fundamental to all 'soft' ionization techniques, especially for the most often used electrospray interface. Basically, the ionization efficiency of a particular molecule in a droplet eluting from the LC system is directly related to its hydrophobicity and its susceptibility to receiving a charge; more hydrophilic compounds will preferentially locate in the interior of the droplet, decreasing the likelihood of undergoing desolvation before reaching the skimmer of the mass spectrometer. If a slightly more hydrophobic molecule (or non-volatile component) is present at the same time as the more hydrophilic one, it will suppress ionization of the hydrophilic compound. Quantitation between experiments is inevitably hampered (especially when many peak abundances are different between the two experiments) and a prediction of the severity of ion suppression is impossible. The same effect results from differences in the ability of molecules to become charged (e.g. basicity/acidity). This and other factors impairing ionization efficiency and quantitation, like geometry and size of the nozzle tip, have been nicely demonstrated by Karas and co-workers using model metabolites (4). This phenomenon is specifically a problem whenever the total composition of a specimen (often called the 'matrix') is believed to be altered, i.e. in any typical biomedical experiment such as comparing \blacktriangleright WT to mutant tissues or healthy to diseased samples.

On top of the difficulty of assessing the effects of ion suppression come alterations in adduct formation. Most biomolecules are only ionisable after adduct formation. The simplest form is protonation or deprotonation, but dozens of further adducts are known in LC/MS, ranging from adducts to the LC eluent (e.g. $[M + \text{acetonitrile} + H]^+$, or $[M + NH_4]^+$ in ammonium acetate buffered LC eluents) to more complex and less predictable adducts like $[M + M + H]^+$, or, in case of co-elution or direct infusion, $[M_1 + M_2 + H]^+$. For quantitation, the preferred adduct species must be known for each target molecule and its ratio to less abundant adducts must be monitored, since subtle alterations in matrix composition (e.g. minor quantities of Na- or K-salts in the LC buffer eluents) may have caused significant alterations in adduct ratios. The presence of basic amino groups in peptide mixtures diminishes the danger of variable adduct formations in proteomics compared to metabolomic studies.

Due to the unpredictability of the effects of changes in overall matrix compositions on ion suppression and adduct formation, claims that are made for direct LC/MS quantitation of peptides from complex mixtures without internal standards have to be treated with great caution (5). Instead of direct quantitation, use of stable

isotope labeled samples has been extensively studied during the last four years. The idea is to combine a control sample with a test sample that consists of stable isotope labeled peptides. Then, both samples are combined and each peptide pair is quantitatively compared based on the abundance ratio of the labeled sample to the unlabeled control. Two basic approaches can be distinguished: either biological (*in vivo*) or chemical (*in vitro*) (6) incorporation of stable isotopes into the peptide test mixture. The advantage of the *in vivo* strategy is the uniformity of protein labeling which is independent of the protein primary structure but it must be seen as a disadvantage that *in vivo* labeling is restricted to use in growing cell cultures. *In vitro* labeling has gained more interest in the past few years. The idea here is to carry out chemical derivatisations with and without stable isotope linkers for specific peptide moieties (such as carboxylic acids, cysteine residues or amino groups). This labeling can also serve to reduce the complexity of mixtures before the LC/MS runs are carried out, without loss in proteomic information. For example, at least one cysteine is present in more than 90% of all predicted yeast \blacktriangleright ORFs and the thiol group of cysteines can readily be used for chemical derivatisations. A biotinylated derivative of iodoacetamide that included a stable isotope marked linker was used for quantitative proteomics. After derivatization, crude protein (or peptide) mixtures can then be purified over streptavidin columns, resulting in a much less complex mixture prior to LC/MS quantitation of each labeled/unlabeled peptide pair. However, disadvantages have been recognized in that thiol residues tend to be so reactive (specifically against oxidation), that the recovery from 2D gels may be irreproducible and that slight differences in the oxidative states of the control/test comparisons may result in high method errors. A variety of other reagents have been tested for proteomic surveys, for example by applying D₂O during tryptic digestion. Other approaches have been specifically focused on post-translationally modified targets such as phosphorylated proteins. However, important parts of the validation of quantitative proteomic methods are still lacking, including in-depth robustness testing. So far, no study has been published focusing on the overall method % CV from different matrices. Reproducibility testing has so far been restricted to the LC/MS errors alone, which have been found to be 10–20%CV. However, it is known that sample preparation usually accounts for the largest error in analytical methods and this can also be assumed to be true for proteomics.

If specific proteins are targeted instead of trying to gain proteomic overviews, the classical analytical method guaranteeing selectivity and sensitivity involved using antibodies for Western blots. It has been shown, that even in this area of protein quantitation, classical

strategies can be complemented by LC/MS approaches. The concomitant characteristics of specific retention times for peptides in LC as well as the unique mass and mass fragmentation have been exploited by a 'mass Western' method. This method utilizes the selectivity power of tandem mass spectrometers by carrying out the quantitation on the ►MS/MS level, i.e. on fragment masses that are highly specific for each compound. If the mass spectrometric detection is then set to the characteristic masses of a peptide and to one of its most abundant daughter ions at the typical LC retention time of this peptide, the increase in signal-to-noise ratios enables the reliable quantitation even of very low abundance proteins after tryptic digestion, because any chemical noise molecule is very unlikely to undergo the same fragmentation at the same fragmentation energies. However, due to potential ion suppression effects, the synthesis and spiking of a stable isotope form of this 'mass Western peptide' is still advantageous for exact quantifications.

Matrix Assisted Laser Desorption/Ionization-TOF

One of the most often applied techniques for identifying proteins after 1D or 2D gel separations is the in-gel digestion of proteins followed by peptide mass fingerprinting using matrix assisted laser desorption/ionization ►TOF mass spectrometry. For the MS detection, the sample is co-crystallized with a UV absorbing matrix on a plate. When a high-energy UV laser is then pulsed onto such crystals, the matrix immediately sublimates concomitantly with the desorption and ion formation of the target molecules. It is commonly believed that quantitation cannot be done using ►MALDI-TOF, due to differences in analyte/matrix distribution from crystal to crystal. However, modern MALDI-TOF instruments are capable of collecting and averaging spectra from many crystals per sample, enabling at least semi-quantitative fingerprint analysis in mutant screens. If internal standards were added, quantitation by MALDI-TOF was shown to result in identical data to that garnered through LC/MS applications, for example for toxic secondary plant metabolites like potato glycoalkaloids. If stable isotope labeling is included, MALDI-TOF was demonstrated to result in 5–20%CV on protein quantification after tryptic digestion from 2D gels.

Significance in Quantitation

Apart from the actual choice of direct or stable isotope labeling quantifications in LC/MS, the next and very practical question is how many samples do I need to run to find significant differences between control and test samples? Just a few studies have been published on this topic, although this ultimately should be done in any method validation. Finding statistically significant differences relates to comparing mean values and their

corresponding deviations from the means. These deviations are now composed of errors of the analytical method (instrument errors + sample preparation errors) and the inherent biological variation. Unfortunately, the latter is very often underestimated by biologists, and furthermore, it may vary from genotype to genotype and from organ to organ. Molley et al. have found a large contribution of biological variation on top of instrumental errors, which may reach a total error of up to 70%CV in proteomic applications (7). In some cases, appropriate sample pooling strategies may compensate for unwanted biological variation. On the other hand, however, there is inherent information in biological variation that is lost if only mean values are compared. For example, if co-regulation of gene expression transcripts, protein and metabolite abundances are to be analyzed in system biology approaches, the possibility of finding and the significance testing of such co-regulations require a certain amount of variability in the network data sets. For such cases, the analysis of biological snapshots from minute amounts of samples would be more suitable than pooling strategies.

Instrumentation

For many purposes, the choice of the actual type of mass spectrometer being used for proteomic (or metabolomic) studies is less important than is commonly believed. Each instrument has its own advantages and disadvantages, depending on the actual application. For example, if quantitation is supposed to be verified by peptide identifications, a fast switching between full scan MS and (data dependent) MS/MS fragmentations must be achievable, the so-called duty cycle. Some of the instruments do not allow a convenient way to do MS/MS experiments but are very fast at acquiring full scan spectra (like TOF MS), whereas others have good mass resolution and mass accuracy for *de novo* peptide identification (like QTOF hybrid instruments) but lack high duty cycles. Others like FT-ICR-MS instruments are known for ultimate sensitivity, mass resolution and mass accuracy, but again come with low duty cycles and additionally, prohibitive prices and technical problems causing long down times over the year. Further, mass accuracy may depend on frequency perturbations and charge repulsions and quantitation may also be very difficult by FT-MS if too many ions are present at one time point. MS/MS spectra may vary dramatically between different instrument types due to the differences in the methods used for compound fragmentations. The best comparable spectra across instruments from different manufacturers are gained by ion trap mass spectrometers, and compilation of MS/MS libraries have therefore started with ion traps. Ultimately, the chromatographic (or electrophoretic) resolution, the type and maintenance of the electrospray interface and the sample

preparation method including stable isotope markers are more important than the actual instrument that is eventually employed.

Clinical Relevance

Modern clinical research relies in all areas on the precision of quantitative and qualitative biochemical analysis for diagnostic purposes, biomarker validation and mechanistic studies. With current methodologies, quantitative metabolite and protein profiling may go far beyond classical diagnostic tests like automated recognition of metabolic diseases or newborn screening. It is the task of analytical chemists and biochemists to serve clinicians by accurately assessing standard operating procedures and critical steps in the process in order to achieve validated quantitative methods with low overall method %CVs. From a technical perspective, current mass spectrometers are able to fulfill such requirements.

SELDI; SELDI-TOF-MS; SELDI-ProteinChip technology; ProteinChip technology

Definition

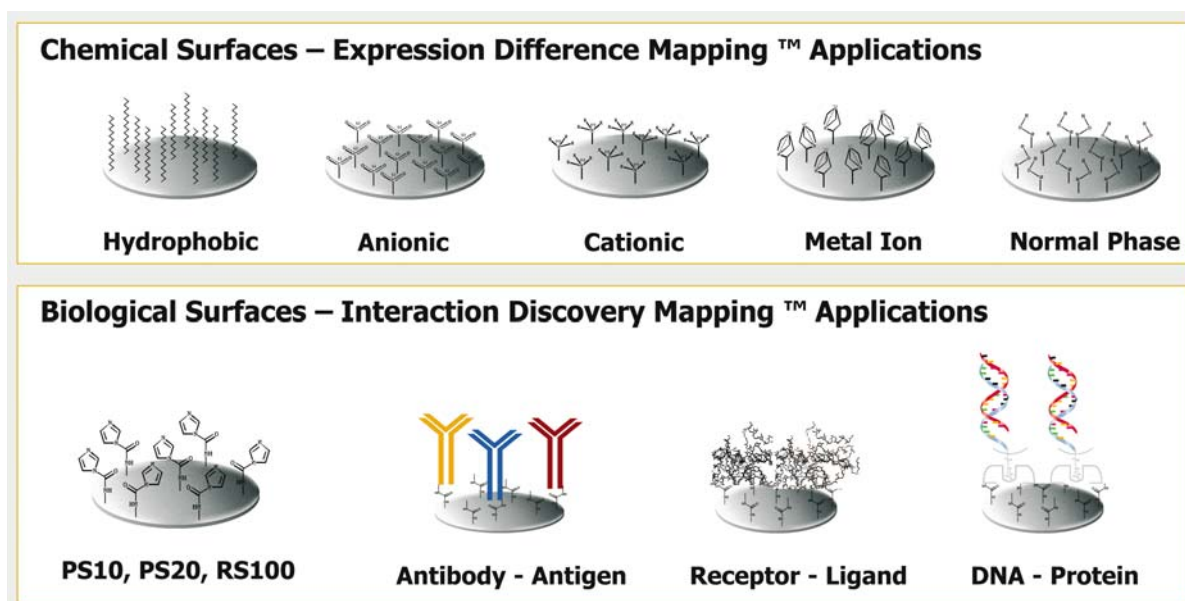

SELDI (surface-enhanced laser desorption and ionization) is a method of protein capture and enrichment on a chemically or bioaffinity active solid phase surface, often followed by selective washing steps and then followed by laser “elution” of the proteins into a detector, usually a time-of-flight mass spectrometer. The whole method is often referred to as SELDI-TOF MS or SELDI ProteinChip technology. With similarities to ►MALDI technology (in which the sample probe is not an active binding partner to protein analytes), an energy absorbing molecule or protein co-crystallization matrix is typically added on top of the captured proteins to assist ionization *via* laser excitation. SELDI is commonly used to discover disease associated protein ►biomarkers and to develop diagnostic assays.

Characteristics

The key components of SELDI ProteinChip technology are the ►ProteinChip Arrays, the ►ProteinChip Reader and the associated software. ProteinChip Arrays contain various chromatography or biological surfaces to capture proteins from complex biological mixtures. Chromatographic surfaces are composed of hydrophobic, hydrophilic, ion exchange, immobilized metal or other chemistries. These surfaces are often used for profiling of proteins from biological mixtures, for biomarker discovery and for assay development. The activated surfaces contain covalently immobilized specific bait molecules such as antibodies, receptors or oligonucleotides and are often used for bio-molecular interaction studies such as protein-protein and protein-DNA interactions. Users of the activated surface arrays are enabled to customize them with their own bait molecules *via* a simple incubation procedure.

The primary ►Expression Difference Mapping™ application of SELDI involves applying a biological sample such as serum, urine, cell lysates or tissue extracts to a spot on a ProteinChip Array and allowing proteins to bind to the surface. The unbound proteins and mass spectrometric interfering compounds are washed away and the proteins that are retained on the array surface are analyzed and detected by laser desorption/ionization TOF-MS using a ProteinChip Reader (Fig. 1). A variety of statistical techniques and bioinformatic software systems are then used to analyze the data and to detect the differences between the protein profiles of two sample sets (1).

The SELDI ProteinChip technology is a versatile platform that can be used for the discovery of disease associated protein biomarkers and for their purification and identification. In addition, the same platform can be used for ►Interaction Discovery Mapping™ applications to detect proteins that interact with the newly discovered biomarker and also to develop predictive

Mass Spectrometry: SELDI. Figure 1 ProteinChip® Array surfaces. These are used for Interaction Discovery Mapping™ studies.

diagnostic assays. In either case, a major benefit of the technology is that the discovery applications lead immediately to the creation of an assay that can be implemented in repetitive studies on large sample populations. This is in contrast to other discovery technologies that often require the search for or creation of a new antibody post-discovery to create an assay.

Clinical Relevance

One of the key applications of SELDI ProteinChip technology is the discovery of disease-associated proteins from crude biological samples. This is achieved by comparing the expression profiles of proteins from normal cells and diseased cells (or normal/diseased fluid samples) and selecting the proteins that are differentially expressed. Proteins can be either over- or under-expressed; SELDI allows the detection of both cases simultaneously. The proteins that are differentially expressed in the diseased cells, once validated on a clinically relevant sample set, can be used as protein biomarkers for disease diagnosis. Since many of the diseases are complex often more than one protein biomarker is needed for accurate diagnosis of the disease. In other words, each disease has specific pattern of proteins or a “protein fingerprint”. These disease specific protein fingerprints can

be analyzed and identified by pattern recognition software that is part of the SELDI ProteinChip technology or by a variety of other software algorithms. A major advantage of the SELDI platform is throughput, enabling a statistically significant population of samples to be analyzed rapidly to uncover specific disease-associated protein peaks and/or disease specific patterns. Alternative protein expression monitoring technologies (e.g. 2-D gel analysis) typically offer significantly lower sample throughput although the elucidation of protein identification often comes more quickly. The concept of the SELDI Expression Difference Mapping approach is that attention is drawn quickly to only the proteins that are relevant to the disease under investigation. Once the fingerprints establish the proteins of highest relevance, the SELDI analysis protocol provides a short list of relevant proteins to be identified as well as establishing a route to rapid purification for the purposes of protein identification.

Petricoin, Liotta and colleagues from FDA-NCI Clinical Proteomics Program published a landmark paper in February 2002 in which they used the SELDI ProteinChip technology to discover a signature pattern of proteins that are specific to ovarian cancer. These protein patterns were used for early detection of ovarian

cancer with more than 90% [specificity](#) and [sensitivity](#) (2). Similar studies in their laboratory and other laboratories discovered specific protein patterns that are used for early detection of breast and prostate cancer with more than 90% specificity and sensitivity. Detection of differentially expressed protein can also lead the discovery of protein based drug targets. For example, David Ho and colleagues at the Aaron Diamond AIDS Research Center published a paper in Science in November 2002 in which they used ProteinChip technology to discover the protein-based inhibitors of HIV replication that appear to be responsible for the fact that 2–5% of HIV-positive patients do not progress to AIDS even over many years (3).

Following Expression Difference Mapping procedures to detect disease specific protein biomarkers, it is important to identify the relevant proteins uncovered. SELDI assisted purification is the key to biomarker identification. Utilizing the wide range of chromatographic chemistries that are present on the ProteinChip Arrays, binding and elution conditions of proteins can be worked out right on the ProteinChip Array thus enabling high speed purification of proteins from crude samples. Once the protein of interest is enriched either “on spot” on a ProteinChip Array or in solution, it is digested with proteases and the masses of the resulting peptide fragments are measured and submitted to a database for protein identification. For confirmation of protein identification, ProteinChip Arrays can be coupled to tandem mass spectrometers through a ProteinChip Interface and the sequence of the peptides can be determined.

Most diseases are caused by functional dysregulation of protein-protein interactions. Understanding the role of protein-protein interactions or protein networks is essential for accurate diagnosis of the disease and for development of targeted therapeutics. SELDI ProteinChip technology can be used to discover the proteins that interact with the newly discovered biomarkers and to decipher the protein networks. Once the protein biomarker is discovered and identified, either the protein biomarker itself or its antibody can be covalently coupled to a ProteinChip Array and used as a bait to discover interacting proteins and protein complexes. Since many of the protein biomarkers are processed products of intact proteins or are post-translationally modified (phosphorylated, glycosylated etc), identification of proteins that interact with biomarkers can lead to the discovery of enzymes that either process or modify these biomarkers. Discovery of the interacting proteins can lead to a better understanding of the biology of the disease. Moreover, these interacting proteins can be the new targets for drug discovery.

MDR

Definition

Multidrug resistance (MDR) is the simultaneous resistance to structurally and functionally unrelated natural product anticancer drugs. MDR in tumor cells can occur intrinsically without treatment, and/or can be acquired by therapy-related modalities, particularly by chemotherapy, followed by a cross-resistance to further chemotherapeutic drugs to which they had never been exposed before. MDR still represents one of the major causes for failure of chemotherapy.

- ▶ [Multi-Drug Resistance](#)

MDR Modulators

Definition

The majority of hydrophobic drugs and chemicals have been demonstrated to interact with membrane transporter proteins MDR1, MRP1 or MRP2, which produce resistance against chemotherapy by actively

extruding a wide range of anticancer drugs from the resistant tumor cells. MDR1-mediated multidrug resistance (MDR) can be reversed by the action of a group of compounds known as MDR modulators or chemosensitizers. First-generation MDR (multidrug resistance) modulators are molecules which affect the drug transport out of a multidrug resistant cell by competitive binding, and thereby inhibiting one or more [▶ABC transporters](#). These modulators are used as reversal strategy for cells and tumors possessing the multidrug resistance phenotype. Clinical administration was limited by adverse drug effects due to the requirement of high modulator concentrations.

Definition

The recent completion of whole genome sequences provides the data that allow the study of gene function at a genomic scale. On the one hand, comparison of genomes is very important to confirm gene annotations and to identify novel genes on the basis of conserved open reading frames (1). On the other hand, sequence

comparison of whole genomes allows identification of conserved non-coding regions that may be functionally relevant. Thus the functional genomics of a given species profits from the availability of data that allow interspecies sequence comparison. Furthermore annotated genomes are the basis for tools that are essential for functional genomics such as [▶unigene libraries](#) and [▶cDNA](#) [▶microarrays](#) or [▶oligo microarrays](#).

In the near future, functional genomics of vertebrates will profit especially from the whole genome sequences (WGS) of three teleosts, namely puffer fish (*Fugu rubripes*), medaka (*Oryzias latipes*) and zebrafish (*Danio rerio*). Both medaka and zebrafish are well-established genetic vertebrate model systems and the sequencing of their genomes will be finished in the near future. The genome of the puffer fish is already available. This represents a unique situation for comparative genome analysis and for the functional analysis of vertebrate genomes.

Characteristics

Medaka as a Model System

Medaka is a small, egg-laying freshwater fish found primarily in Japan, which combines the advantages of a short generation time, small genome size, well-established genetics and easy husbandry (2). The eggs and the embryos are transparent and allow easy observation by standard microscopy. Under laboratory conditions, the generation time is 8 weeks. The genome size of medaka corresponds to approximately 800 Mb, 1/3 of the human genome and less than half of the zebrafish genome. Medaka is a well-established genetic system. Inbred lines of two highly polymorphic populations are available and protocols for large-scale mutagenesis and efficient [▶transgenesis](#) have been published. Furthermore, reverse genetic approaches for interference with gene function are established (see below).

Medaka is also of special interest with respect to comparative genomics. The genome sequence of the relatively closely related puffer fish (40 Myr) has been determined. The other teleost genetic model system, zebrafish is more distantly related (180 Myr) and its genomic sequence will be available in the near future. Thus, medaka provides an important complementary teleost genetic model system for both comparative sequence analysis (3 teleost genomes) and functional genomics (2 teleost genetic systems). This offers a unique possibility for addressing questions relating to the evolution of genomes, such as gene contents and organization and the identification of regulatory elements and combining these with a functional analysis (2).

Functional Analysis of Genomes

Functional genomics requires tools to test for possible functions of coding and non-coding elements of the

genome. Most widely used are systematic mutagenesis screens, such as have been carried out in invertebrates and vertebrates (zebrafish, see (3, 4); medaka, see (5) and mouse, see (6)). In most of these cases, these forward genetic approaches were chemical mutagenesis screens designed to induce point mutations that affect coding regions of genes or splicing of transcripts. Regulatory regions are not usually identified by such an approach. The advantage of this approach is the efficiency with which random mutations can be induced, which allows screening of large numbers of genomes in a short time. The disadvantage is the difficulty of identifying mutation afterwards, which often requires tedious and time-consuming positional cloning strategies.

Recently, a medaka large-scale mutagenesis screen using ENU as a mutagen has been carried out as a collaborative effort by a number of Japanese and European laboratories (H. Kondoh, M. Furutani-Seiki, pers. communication) (7). The conditions were previously established in a pilot screen (5). The aim of this screen was to identify recessive lethal mutations that affect various aspects of embryonic development. Morphological criteria as well as molecular markers were used to identify mutants.

Other approaches to induce mutations that are easier to identify involve viral or transposon mediated insertional mutagenesis. Insertional mutagenesis using a ►pseudotyped virus has been carried out in zebrafish (8). Currently, these vectors are also being tested in medaka. An alternative system is provided by the ►transposon mediated ►gene trap and ►enhancer trap experiments (9) that have successfully trapped genes and led to the generation of insertional mutants in medaka (Arenz and Wittbrodt, unpublished).

Reverse Genetics

Reverse genetic approaches have also been established for medaka (10). The most reliable method is the morpholino based gene knock-down. Morpholinos are small anti-sense oligonucleotides (about 25 bp) with a morpholine backbone that strongly reduces their enzymatic degradation. These oligos hybridize sequence specifically to their target mRNA and block translation over several days. As in zebrafish, RNA interference (RNAi) appears to result in mainly unspecific developmental defects (Loosli and Wittbrodt, unpublished), precluding the application of this method.

Genetic Tools

To identify the causative gene underlying a given mutant phenotype involves the establishment of linkage between the mutated locus and a polymorphic marker. This requires the use of polymorphic strains. Molecular analyses of different medaka wild catches

consistently indicated the presence of two highly polymorphic populations, the Northern and Southern Japanese populations (2). Recent sequence comparison of the respective loci from the Southern and Northern populations revealed single base pair polymorphisms as high as 3% for intronic regions and about 1% for coding regions. This means in practical terms that for any gene of interest, polymorphisms can be detected between the two.

Inbred Lines

Linkage analysis requires that polymorphisms within a given strain are reduced to a minimum, as achieved in inbred strains. By definition, an inbred strain is homozygous at 99% of all loci; it is isogenic. Such a strain can be obtained after at least 20 generations of successive brother-sister mating. One inbred strain, the *Cab* strain (Southern population) (2), has been established from medaka fish initially obtained through the Carolina Biological Supply Company (North Carolina). A second strain was established using a stock derived from the Northern population that was kept as a closed stock over 10 years (5) (Wittbrodt, unpublished). Further inbred lines from these two populations have been established by other laboratories and successfully used in mutagenesis and mapping experiments (2). Thus, uniquely for lower vertebrate genetic systems, at least two inbred strains with high fecundity and easy breeding are available for the two polymorphic populations of the medaka.

Transgenesis

For conventional production of transgenic fish the foreign DNA is, as in other lower vertebrates (fish and amphibia), injected into the cytoplasm of the one to two cell stage embryo. Although the injected DNA is distributed in a mosaic fashion over the whole embryo, the analysis of a sufficient number of embryos gives a clear picture of a temporal and spatial expression pattern by using reporter genes such as ►GFP or β -gal. The ratios reported for obtaining stable transgenic lines by injecting circular plasmid DNA into the cytoplasm of the two-cell stage embryo vary between 1–5%.

For medaka, a novel approach has been developed to integrate DNA into the genome efficiently (11). It is based on *in ovo* linearization of circular plasmid DNA, containing the transgene of interest flanked by two ►I-Sce I meganuclease recognition sites. Co-injection of this construct together with the I-Sce I meganuclease at the early one-cell stage leads to integration of the transgene at the 1–4 cell stage. The promoter dependent expression pattern can be studied in more than 80% of the injected embryos. Furthermore a striking increase in germline transmission was observed (more than 30%). Therefore, both expression analysis by transient transgenesis and generation of stable transgenic lines

are greatly facilitated by the meganuclease method. Combined with the available genomic resources and comparative approaches this method is mandatory for the efficient analysis of non-coding DNA (promoter and enhancer/silencer elements) of medaka in particular and in comparative approaches with other species in general.

Enhancer/Gene-Trapping

At a very low rate, the meganuclease protocol leads to enhancer trapping effects, where novel patterns are detected that are most probably due to enhancer elements in the vicinity of the integration site (11).

A much higher frequency of enhancer trapping in medaka has recently been described using a transposable element (9). This transposon, an artificially reconstructed member of the *Tc-1* superfamily, *Sleeping Beauty* (*SB*), mediates reporter construct integration in vertebrate tissue culture and in medaka facilitates highly efficient reporter gene integration into the targeted genome (35% transgenesis) at early cleavage stages (1–16 cell stages). The transgene is stably transmitted to and expressed in the subsequent generations. In contrast to the meganuclease approach outlined above, the SB system leads to a high rate of specific spatial and temporal expression patterns (30% of stable lines) indicative of integration in the vicinity of regulatory genomic elements.

The encouraging experimental approaches described above have been used to generate a large number of stable transgenic lines expressing GFP in specific patterns. The advantages of these lines are manifold. They allow the following of the fates of cells and tissues *in vivo* in wild type or mutant embryos and they allow the isolation of the labeled cells from dissociated embryos by ►FACS to either propagate them in culture or to use them as a specific mRNA source for subtractive cloning or expression profiling experiments. Furthermore, ubiquitously expressing fish lines have been successfully used as donor lines for cell transplantation experiments (2).

Libraries, Microarrays and Databases

Systematic sequencing of the medaka genome in a whole genome shotgun approach is under way and will be anchored on a BAC contig map. In this contig the key markers from the genetic map (12) are physically localized. In addition several approaches have been followed to provide tools for functional genomics.

On the transcriptome level, the approach is the systematic identification of all transcripts in two parallel but complementary approaches. Firstly, large numbers of expressed sequence tags (ESTs) are generated by a number of laboratories and deposited in a public database (NCBI). Secondly, a “unigene” set

is generated using oligo fingerprinting on cDNA libraries (Himmelbauer, Berlin).

The combination of these approaches so far has led to the identification of more than 20000 individual transcripts/genes. This information was used to establish cDNA macro-arrays and oligo (70 mer) micro-arrays. It is planned to complete the entire “►transcriptome” of medaka within the next year.

The expression patterns of all genes represented in the “unigene” set are systematically determined by whole mount *in situ* hybridization in a collaborative effort and the information is deposited in a database (13) (►<http://medaka.dsp.jst.go.jp/MEPD/>). The aim is to annotate the genome not just by name and potential function, but also with the expression patterns of the respective genes.

The unigene cluster established allows further applications for functional studies on a genomic scale as the cDNAs represented are enriched for full length clones and the cloning vector allows the *in vitro* generation of mRNAs as well as expression in cell culture, thus extending the possible range of application of this library.

Comparative Approaches

The rate of divergence in neutrally evolving genomic regions is relatively low. Therefore it is necessary to compare genomes of diverged vertebrates to detect functionally conserved regions. The existing teleost model systems provide the required material for such an approach.

Another important source for comparative approaches will be the growing number of mutations that are isolated and identified in medaka and zebrafish. Of special interest will be mutations in these two species that affect ►orthologous genes. This will allow directly comparison between the similarities and divergence of gene function. Recently, such a pair of mutations has been identified in medaka and zebrafish. The medaka *eyeless* mutation has been shown to affect the homeo-domain transcription factor *rx3* (14) and the orthologous zebrafish *rx3* gene is mutated in the recently identified *chokh* mutation (15). Sequence and expression of both *rx3* genes are highly conserved and morphologically both mutations are indistinguishable in their consequences. However at the molecular level, these mutations result in significant differences in that other orthologous genes are differentially affected by loss of *rx3* function. This indicates that *rx3* function has diverged in these species. Thus these mutations offer a unique paradigm for study of the divergence of gene function by changes in gene regulation by cross-species comparison at the molecular level. The ongoing whole genome sequencing projects of medaka and zebrafish provide the tools to compare the regulatory

elements of these genes and to address the evolution of regulatory interactions in vertebrates molecularly .

Clinical Relevance

Taken together the combination of the genomic and genetic tools available in medaka in particular and fish in general facilitate approaches that have not so far been possible in vertebrates. It puts fish into a position that is ideal (and unique) for functional and comparative genomics and as a model system to study human diseases.

Meiosis

Definition

Meiosis is the type of cell division by which germ cells (eggs and sperm) are produced from oogonia or spermatogonia. Meiosis involves a reduction in the amount of genetic material to one half. In a two-step process, comprising of two successive nuclear divisions with only one turn of ►DNA replication, one parent cell produces four daughter cells that have half the number of chromosomes found in the original parent cell. Due to cross-over events and recombination, the genetic content of all descendants is not identical (as opposed to Mitosis).

►Cell Division

►Fragile X Syndrome

►Meiosis and Meiotic Recombination

Meiosis and Meiotic Recombination

CHARLES TEASE

Department of Biological Sciences, University of Warwick, Coventry, UK

ctease@btinternet.com

Definition

Meiosis is a cell division process that occurs only in germ cells (oocytes in females, spermatocytes in males) and is central to the formation of gametes. The principal purpose of this specialized cell division is to produce gametes that are haploid, i.e. with a single set of chromosomes. Thus, in humans, meiosis generates eggs and sperm with 23 chromosomes (a haploid set) from a diploid oocyte or spermatocyte that contained 46 chromosomes (i.e. 2 sets of 23 chromosomes). Germ cells achieve this reduction in chromosome number by undergoing two rounds of nuclear division after DNA replication, rather than one as is normal in somatic cells undergoing mitosis. In the first meiotic division, the two sets of chromosomes separate and one complete set passes to each of the resulting daughter cells. This division therefore achieves the halving of chromosome number. In the second meiotic division, the 2 chromatids of each replicated chromosome separate and segregate to different daughter cells. The end product of meiosis is therefore cells with a haploid number of unreplicated chromosomes. Restoration of the normal diploid number occurs after fertilization of an egg by a sperm.

In addition to reduction in chromosome number, meiosis also increases the genetic variation in the population. This increased variation is achieved in two ways, random assortment of maternally- and paternally-derived chromosomes at the first meiotic division and recombination, a process of reciprocal exchange of material between a pair of chromosomes.

Characteristics

The Stages of Meiosis

By convention, cellular division is described as a series of stages that are defined by the appearance and behavior of the chromosomes. Thus prophase describes condensing chromosomes, metaphase the period when the chromosomes are attached to the microtubules of the spindle and are oriented on the spindle equator, and anaphase the period when the chromatids separate. Meiosis follows this convention, the two division cycles being termed meiosis I and meiosis II; the principal features of the different stages of meiosis are described in Table 1 and Fig. 1. The longest stage of

Stage	
Premeiotic DNA synthesis	Replication of DNA. Cohesin laid down between the newly formed sister chromatids.
Prophase I	Prophase I takes up by far the largest part of the time that a cell spends in meiosis. The crucial events of homologous chromosome pairing and crossing-over occur at this time. Prophase I is conventionally divided into 5 sub-stages:
