Preface

The development of molecular medicine is closely linked with the rapidly growing knowledge in molecular biology, molecular genetics and genome research. Research findings in these fields have led to a shift in therapeutic targets. Whilst until recently only gene products such as enzymes and cell receptors represented targets of diagnostic processes, today the information carriers DNA and RNA themselves are evolving into target molecules, or medicinal drugs. Alongside researching into interactive processes on a cellular level – drawn from the biochemical advances made in the past century – mutation and disorders of mechanisms of gene expression are becoming the object of clinical research and of application in diagnosis and therapy. Hence, genomics and proteomics are developing into new fields of research, and their results are substantially influencing the future orientation of the fundamentals for diagnosis and therapy.

These new research fields including molecular biology have generated a huge amount of new terms, abbreviations (acronyms) which need explanation. Therefore these encyclopedic references are aimed at making all those acquainted with selected terms most frequently used in genomics and proteomics in molecular medicine who are not directly involved in those termini by their research.

The theoretical background of molecular medicine is based on the assumption that one or more molecular and/or genetic causes (e.g. changes caused by point mutation, deletions, shift in the reading frame etc.) underlie the outbreak of all diseases. Inversely, however, this does not necessarily imply that every mutated gene leads to a disorder in the sense of genetic determinism. There are forms of mutation that result in a transformed gene product without triggering any disease. For an illness to take shape many other factors besides a changed gene play a role, such as the endogenous disposition (e.g. inherent damage caused by previous illnesses) and exogenous factors (of environmental nature, strain through incompatibility of medication, drinking and smoking etc.). Genomics and proteomics are evolving into key technologies of advances in molecular medicine.

The transfer of molecular biological knowledge into therapeutic treatment is still at the initial stage. So far, results in gene therapy have fallen short of high-flying expectations. Instead, diagnostic methods based on molecular biology have found their way into medical practice.

Molecular medicine is scientifically based both on classical medicine, which is characterized by a phenotypical description of symptoms, and on the specific genotypical characterization of methods employed in molecular biology and genetic engineering. For the first time, this enabled a systematic analysis of the molecular causes of illnesses in a precise and rapid manner hitherto unattained. Molecular biological methods such as high-throughput techniques based on biochips are already being applied in various medical fields, and have significantly improved diagnosis, for instance in the prediction of risk estimation in certain illnesses, or with regard to sensitivity and specificity of treatment. This widens diagnostic scope in areas such as hereditary diseases of monogenetic origin, which until now could only be described phenomenologically, and enables preventive treatment and causal therapy of such diseases in the future. Evidently, even the molecular causes of uninfluenceable pleiotropic diseases are becoming increasingly tangible, moving their therapeutic treatment within reach.

This has a decisive impact on medical work. Nevertheless, molecular medicine, too, will retain its basic character which is precise clinical observation and integral medical care. Without thorough medical examination and detailed phenotypical description neither phenotype-genotype association of any significance can be derived, nor can the possibilities of detailed gene standardisation be fully exploited. The conventional physical examination and the analysis of the gene profile remain of equal importance in the domains of both research as well as medical care.

The spectacular publication on the human genome comprising 3.2 billion base sequences, which appeared simultaneously in the journals “Nature” (International non-commercial project, Head: Francis Collins) and “Science” (Genetic engineering company Celera Genomics, Head: Craig Venter) on the 50th anniversary of the double helix discovery by James Watson and Francis Crick in April 2003, marked a new era in biological basic research and in the knowledge of the components of human life. The successful decoding of the sequence raises the question about its function in the organism.

Recent sequencing of the human genome (published in 2004; Nature 431, p.915, p.927, p.933) revealed that (with an accuracy of 99.999%) 2.85 billions of base pairs out of a total of 3.08 billions of base pairs have been determined; thus 99% of the genome which contains the genes have been identified. Consequently, the number of genes had to be corrected to 20,000-25,000 from the estimated 100,000 genes in the 90's, and 30,000-40,000 in 2001. The genetic information for proteins comprises only 1.5% of the genome. 98.5% of the genome may be assigned to the so-called junk-DNA with so far largely unknown functions. Such data are erroneous. As parts of the gene expression products, introns, for example, contain regulative sequences for gene expression and sequences that are responsible for correct splicing. These sequences must be allocated to a specific gene as essential constituents and can therefore affect the assessment significantly.

Decoding the entire sequence of the genome is but the first step of a far more complex task: Understanding the functional significance of the sequences. So the determination of the sequences logically entails their functional deciphering as the following step. This field of research is known as "Functional genomics". It deals with the allocation of parts of the entire sequence to defined gene structures. This also includes the attribution of intron sequences to functions within the regulation process of gene expression that are only partly understood so far, as well as the control of all subsequent steps up to the final protein synthesis.

Alternative splicing is a major cause of transcriptome diversification. A single primary transcript yields different mature RNAs which lead to the production of proteins with various functions. This can be performed by alternative promoters. For 23,245 gene loci in the human genome over 43,000 transcripts are known. The alternative transcripts range from 2 to 40 (for details see Functional genomics).

Comparison with analysed genomes of other organisms are extremely useful in the process of allocating sequence parts to whole gene sequences. In the meantime a number of gene sequences have been fully deciphered, as for example those of prokaryote micro-organisms such as *Escherichia coli* and *Helicobacter pylori*, and eukaryote microorganisms such as baker's yeast *Saccharomyces cerevisiae* and of polycellular organisms like the worm *Caenorhabditis elegans*, or those of the fruit fly *Drosophila melanogaster* and of different vertebrates: e.g. man, mouse, rat and the green puffer-fish *Tetraodon nigroviridis*. Also the sequence of the bovine genome is available in a rough sketch with the exact decoding to be expected in 2005. These comparative studies revealed only 1183 species specific genes in the human genome. In all, about 200 genomes of various species have been sequenced and published.

The human chromosomes 21, 22, 14, 7, 6, and Y have been fully analysed and the results were published in 2003. Recently, an academic research team decoded the base sequence of the second smallest human chromosome 22 and made it accessible to the researching public. Chromosome 22 has 33 million base pairs with 545 genes. Defects on this chromosome are likely to be the cause of diseases such as schizophrenia, leukemia, immune deficiencies, bone cancer and brain tumours. Similarly, a German-Japanese research team succeeded in completely decoding the smallest carrier of genetic information in humans (chromosome 21) with 225 genes, some of which play a role in diseases like Alzheimer, ALS (amyotrope lateral sclerosis), myoclonic epilepsy, innate deafness, and Down's syndrome.

Two further chromosomes whose anomalies cause diseases are chromosomes 5 and 6. Chromosome 6 represents the largest human chromosome with 166.880 million base pairs. It has 1557 functional genes for, inter alia, the major histocompatibility complex (MHC), hereditary haemochromatosis with multi-organ dysfunction, juvenile-onset form of Parkinson's disease, and gene abnormalities are implicated as a contributory cause of schizophrenia, epilepsy, cancer and heart disease. Chromosome 5 has 177.7 million base pairs with 923 protein coding genes including for instance those for protocadherine and the interleukine gene families. In some regions deletion can generate disorders including spinal muscular dystrophy.

After enormous 12 years lasting efforts, recently (2005), the sequence of the human X-chromosome (the determining chromosome for women: XX = female, XY = male) was completely deciphered. It comprises 1098 native genes as compared with only 78 genes of the male Y-chromosome. It is of interest that about 10% of the X-chromosome play an important role in man and do not have any function in women. The X-chromosome contains only 4% of all human genes but is linked with every 10th hereditary monogenetic disease.

Recently, American scientists succeeded in introducing a human gene associated with the generation of Parkinson's disease into the genome of *Drosophila*, which produced impaired balance and other typical symptoms of nervous disease similar to those of people suffering from Parkinson's. This example demonstrates the immense significance of model organisms within the framework of functional genomics in the quest of grasping the human genome in its entirety.

So far a functional role could be allocated to specific gene products of about 5,000 genes, accounting for about 20% of the estimated total of 20,000 to 25,000 genes and about 3% of the total stock of human DNA. Thus a large number of genes still needs to be similarly allocated, and their molecular structures to be determined. This is the basic content of proteomics which in analogy to genomics has two complimentary objectives: the functional analysis and localization of gene products and the comprehension of their molecular structure.

As in the quest of the genome sequence which united scientists of six different nations to cooperate in a joint project, once again in 2001 a team of international researchers founded the Human Proteome Organisation (HUPO) to investigate into the significance of the enzymes coded by the genes. Proteome stands for the entire protein in a cell. In view of the magnitude of the task it seems quite plausible that the main project was split into 5 individual sub-projects: Human Plasma Proteome Project (HPPP), Sweden, USA; Human Liver Proteome Project (HLPP), Canada, China, France; Proteomics Standard Initiative (PSI), all countries; Human Brain Proteome Project (HBPP), Germany; International Mouse and Rat Proteome Project (MRPP) Canada, Germany.

All projects aim at decoding the functional network of proteins in the human organism, at the characterization and localization of proteins in normal and diseased humans and those of model organisms, and at disseminating knowledge and respective technologies so as to find clues for the treatment of diseases.

The second objective of proteomics is to determine the structure of gene products, a field that is primarily a part of basic research. Any overview of the latest developments in molecular medicine in this encyclopedia would be incomplete if it were restricted to clinical findings alone. The fundamental principles of molecular medicine are essentially based on the knowledge of cellular and molecular biological processes which are introduced into clinical practice through application in diagnosis. Moreover, the application of the whole range of genetic engineering tools resulted in radical changes in biotechnology and medical drug research. The application of genetic engineering in the pharmaceutical industry has led to a notable rationalization of production processes. In some cases the application of the processes made production of certain substances available that had so far been inaccessible for medical treatment. This marked the onset of the therapeutic use of medical drugs which could previously only be produced in chemical synthetic processes, rendering them unsuitable for large scale production.

The forthcoming gain in knowledge in functional genomics and proteomics with regard to very complex processes of growth, cell division and differentiation, and their respective mechanisms of regulation (such as first, second and third messenger, transcription factors and the corresponding cis-elements on the promoters) also pave the way for new strategies in the development of medical drugs.

Transforming these scientific results into useful medical drugs requires the knowledge of the structure of molecules, which is necessary for understanding the functional interaction of nucleic acids, proteins and ligands on a molecular level. This is made possible by ascertaining the molecular structures through X-ray radiation, synchrotrone radiation, nuclear magnetic resonance by super-conducting high performance magnets (up to 900 MHz) or other spectroscopic methods. All these processes complement each other in terms of applicability and significance of the evidence yielded. Another possibility of structure determination is the application of theoretical methods for predictive structure assessment of potential drugs. In this way pharmacological effects can be estimated. These techniques utilize highly sophisticated electronic simulation methods. When linking methods of the combination theory with the knowledge of the topography of bonding points, structure based drug design becomes feasible.

To date (i.e. in 2003) biotechnology and genetical engineering have brought forth approximately 10,800 products world-wide. Of these about 15% have been commercialized, a further 15-20% are in the licensing phase or are on the verge of coming on the market, 30% are in the clinical test phase (Phase III) and the remaining 40% are in the clinical study phase (Phase I and II). The decoding of the human genome and its functional analysis through genomics and proteomics will further enhance this process as a multitude of further molecule structures is

unravelling, thus considerably widening the range of rational drug development. It was the comprehension of biotechnological methods that made the production of certain therapeutic drugs possible as for example in the case of human insulin, erythropoietin, coagulation factor VIII, and interferon, resulting in their widespread therapeutic application.

Until now, however, only a few drugs have been developed with the help of structure based drug design. Among these are an inhibitor of HIV-1 protease 1 and an inhibitor substance of neuroaminidase of the influenza virus 2. These findings form the fundamental principles of molecular medicine. They enable rationally developed drugs to influence new target structures such as gene regulators (transcription factors), or the gene itself to become the object of therapeutic manipulation, for instance by functioning as a substance-producing drug.

We would like to point out that although substantial efforts were made to compose factually correct and well understandable presentations, there may be places where a definition is incomplete or a phrase in an essay is flawed. All contributors to this encyclopedia will be extremely happy to receive corrections or revised passages for inclusion in future editions of the “Encyclopedic Reference of Genomics and Proteomics in Molecular Medicine”.

This encyclopedia endeavours to accompany current developments and convey the present level in knowledge on molecular causes of illnesses from a practice-oriented point of view. Acknowledged experts from various specialized fields such as human genetics, molecular biology, cell biology, biochemistry, physics and other bioscience disciplines explain the most important terms, complementing information by topical surveys, numerous figures and tables, and keywords. It is to be hoped that this compendium may contribute to understanding the advances in molecular medicine and may find many interested readers.

AAA ATPase

Definition

AAA ATPases form a large and extremely heterogeneous family of enzymes belonging to the AAA superfamily containing a ring-shaped NTPase domain. These enzymes are involved in a wide variety of cellular processes, hence the name (ATPases Associated with various cellular Activities).

Absorption Coefficient

Definition

The absorption coefficient (a.c.) is defined as the fraction of light absorbed per unit distance in an absorbing medium. The unit is cm^{-1} . The a.c. of a solution is a measure for the general ability of the dissolved molecules to absorb photons and act as potential dyes.

Absorption Edge

Definition

The absorption of X-rays by an atom varies with the wavelength. When an x-ray photon is absorbed by an atom, it enters an excited state for an extremely short period of time. When the atom de-excites it will emit an electron from near the core of the atom. This will only happen if the energy of the x-ray is higher than the energy level that is binding that electron to the core of the atom. When the x-ray has an energy equal to that of the binding energy of an electron, there is a sharp rise in the absorption, referred to as the absorption edge and this indicates that a photo-electron has been released. An X-ray photon of lower energy may be absorbed by an inner-shell electron (e.g. from the K-shell) which is elevated to a free place in a higher electron shell. If an electron returns to the K-shell immediately, a photon will be re-emitted at the same energy (strong coupling to absorption-edge energy), but the scattered photon is phase-shifted compared to a normally scattered photon, i.e. the scattering factor (atomic form factor) of the atom acquires an imaginary component. Thus, the f'' scattering coefficient becomes non-zero, and the scattering factor is no longer a scalar quantity but a complex number. The imaginary scattering component f'' is proportional to the directly measurable absorption and fluorescence. The real scattering component f' is related to f'' via the Kramers-Kronig relationship.

Acousto-Optical Filters

Definition

Acousto-optical filters refer to electro-optical devices that allow the modulation of the light intensity as well as wavelength. Light penetrating the optical crystal is deflected depending on its wavelength and the wavelength of the ultrasonic field applied to the crystal.

► [Fluorescence Microscopy: Spectral Imaging vs. Filter-Based Imaging](#)

Acousto-Optical Modulator

Definition

An acousto-optical modulator is an optical device for regulating the power of a laser beam in response to an incoming dc-voltage. It includes a refractive crystal and an electronic driver. The driver generates an ultrasound wave, which is transferred onto the crystal by means of a piezo element. The sound wave propagating through the crystal creates a regular pattern of dense and less dense material, which represents a diffractive grating. The amplitude of the sound wave determines the strength of the density differences proportional to the dc signal, which is fed into the driver. A light beam passing through the crystal is diffracted at the density grating, with the intensity of the diffracted beam proportional to the amplitude of the density wave, and hence the incoming dc-signal.

► [Fluorescence Microscopy: Single Particle Tracking](#)

Acousto-Optical Tunable Filter

Definition

An acousto-optical tunable filter (AOTF) is an extended version of an acousto-optical modulator

(AOM). Like the ►AOM, the AOTF comprises of a refractive crystal and an electronic driver. The AOTF, however, simultaneously operates on several co-linear laser beams with different wavelengths in response to incoming dc-voltage signals. It is usually employed in combination with lasers run in a multi-line operation, emitting light at different wavelengths simultaneously. By means of the AOTF, one or more of the lines can be selected, and their power can be defined.

►Fluorescence Microscopy: Single Particle Tracking

Acquired Immunity

►Adaptive Immunity

Acquisition Time

Definition

Within all methods that work via the detection of a signal, the time necessary to record the signal is called acquisition time. In the context of multidimensional NMR spectroscopy, the acquisition time is the time interval during which the free induction decay (FID) is recorded. The length of the acquisition time is determined by the width of the spectral window and the number of data points that are recorded, and ranges from several milliseconds to seconds. It occurs in all NMR pulse sequences regardless of the dimensionality of the experiment.

►Multidimensional NMR Spectroscopy

Acrocentric Chromosome

Definition

Acrocentric chromosome defines a chromosome on which the centromere is located closer to one end, so that the two arms flanking the centromere are of unequal length. Human chromosomes 13, 14, 15, 21 and 22 are acrocentric.

►Centromeres

►Chromosome 21 Disorders

►RNA Polymerase I

Acrosome

Definition

Acrosome is a large, membrane-bound, lysosome-like vesicle that is located in the anterior region of the sperm head, just beneath the plasma membrane and above the nucleus.

►Acrosome Reaction

►Mammalian Fertilization

Acrosome Reaction

Definition

Acrosome reaction refers to a form of cellular exocytosis that is induced by binding of sperm to the zona pellucida of the egg during ►fertilization. It involves multiple fusions of sperm plasma membrane with the outer acrosomal membrane, resulting in exposure of the inner acrosomal membrane and acrosomal enzymes.

►Mammalian Fertilization

ACTH

►Adrenocorticotropin

Actin

Definition

Actin is a major component of the cytoskeleton and is present in all eukaryotic cells. Its most characteristic feature is the reversible polymerisation of globular actin monomers (G-actin) into filaments (►F-actin). Filaments can be associated into stem fibers that are anchored in focal contacts. Monomeric actin has a molecular mass of about 42,000 Daltons. The actin cytoskeleton is required in many cellular processes like cell migration, axonal growth, phagocytosis, cytoplasmic streaming and organelle transport.

Actin Cytoskeleton

RAJESH ARASADA, MICHAEL SCHLEICHER
 Adolf-Butenandt-Institute / Cell Biology,
 Ludwig-Maximilians-University, Munich, Germany
 schleicher@lrz.uni-muenchen.de

Definition

The ▶actin ▶cytoskeleton is a network of actin and actin binding proteins that together with the other components of the cytoskeleton such as microtubules and intermediate filaments is responsible for essential cellular processes like cell migration, axonal growth, ▶phagocytosis, cytoplasmic streaming and organelle transport (1, 2). It was first isolated as a part of the actomyosin complex from muscle cells. Actin was subsequently identified in all eukaryotic cells. Its most characteristic feature is the reversible polymerization of globular actin monomers (G-actin) into filaments (F-actin) that build either a relatively permanent structure as in sarcomeres of fully differentiated muscle cells or, in nearly all other cell types, a continuously restructured filamentous meshwork. Given its role in many essential cellular processes, the amino acid sequence of actin is highly conserved throughout evolution. Deletion of the single actin gene in yeast is lethal. In many other organisms more than one gene codes for this protein. In humans for example there are at least six isoforms of actin that differ only slightly in their protein sequence and cell type specific expression.

Characteristics

It is very helpful for understanding actin functions in the living cell if one considers major features of the protein in the test tube. Actin has a molecular mass of about 42,000 Daltons and can be stored in its monomeric form. As soon as simple salts like KCl or $MgCl_2$ are added, the monomers form filaments and turn a sol into a gel with extremely high viscosity in a matter of minutes.

The polymerization of G-actin into F-actin occurs in three phases (Fig. 1):

• Lag Phase

The polymerization of actin requires trimeric intermediates ('actin nuclei') which are highly unstable

and therefore delay rapid elongation. It is obvious that a cellular factor with a nuclei-stabilizing activity drastically shifts the G:F-actin ratio towards a high viscosity of the cytoplasm.

• Elongation

The elongation of ▶actin filaments is very rapid and continues until it reaches an equilibrium at which nearly all of the actin molecules are part of filaments. A cellular factor which blocks this elongation by, e.g. capping filament ends, will delay elongation and thus cause higher fluidity of the cytoplasm.

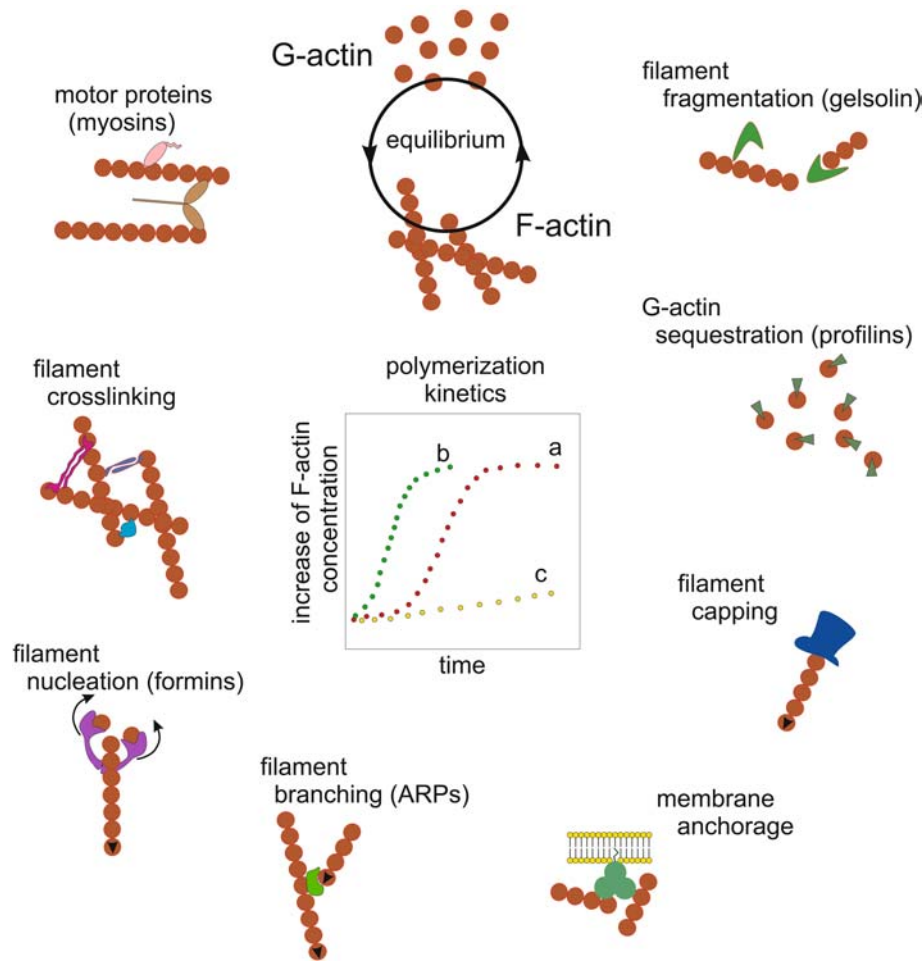

• Steady State

At the steady state a continuous exchange of actin monomers occurs at both ends of filaments but the net polymerization of actin is zero. This constant concentration of G-actin that remains in equilibrium with filament ends is termed the 'critical concentration'. Under these conditions a cell would be able to finely tune the cytosolic viscosity. If a cellular factor binds to actin monomers and thus lowers the critical concentration of free monomers at steady state, then depolymerization of filaments occurs and continues until the critical concentration is reached again. This decreases the number and length of actin filaments and leads to a less viscous cytosol.

Actin filaments are polar with the two ends being different from each other. The polarity of the filaments can be observed by decorating the filaments with myosin. Coating with myosins gives the filament an appearance of an arrowhead hence the names 'pointed' and 'barbed' ends. The growth of the filaments differs at the two ends with actin monomers being added at the barbed end about $10\times$ faster than at the pointed end. The critical concentrations also differ for the ends, with barbed ends having a critical concentration of about $0.1\ \mu M$ in contrast to the pointed ends of approximately $0.6\ \mu M$ G-actin.

The ability of actin to polymerize under conditions normally used to generate crystals made it difficult to obtain actin's atomic structure. However, crystals could be obtained for actin in complex with actin binding proteins such as DNase I, ▶profilin and ▶gelsolin, or when it was covalently modified with small molecules that inhibit ▶actin polymerization and do not change the overall conformation of actin. The actin monomer consists of two major lobes that are connected by a hinge region; they form the ATP binding cleft, and harbor sites for the binding of metal ions.

ATP-actin has a higher affinity for the barbed end than ADP-actin. However, ATP hydrolysis is not required for polymerization. The very end of an actin filament at the fast growing side consists of a small stack of ATP-actin units, followed by a stretch of hydrolyzed ADP/ P_i -actin complexes. After the release of P_i , actin

Actin Cytoskeleton. Figure 1 Kinetics of actin polymerization and function of actin-binding proteins. The graph in the center shows three typical kinetics of actin polymerization *in vitro*. Actin alone (curve a) starts to polymerize with some delay because the formation of trimeric actin seeds is highly unfavourable. After this lag-phase, filaments elongate rapidly until almost all actin monomers are part of filaments, only a typical critical concentration of G-actin is at equilibrium with filaments. A nucleating protein favors filament formation and shortens the lag time (curve b). Capping proteins inhibit the addition of monomers at filament ends and thus delay polymerization (curve c). Numerous classes of actin-binding proteins finely tune those kinetics or change the strength of existing filamentous networks. This leads to altered viscoelasticities in the cytoplasm and consequently to major changes in cell migration, cell morphology, tissue formation and other essential cellular reactions.

filaments consist almost entirely of ADP-actin, which leads to remarkably decreased stability if certain cellular proteins, e.g. actin-depolymerization factor/cofilin, attack the filament. Thus ATP serves as a timer for the depolymerization and filament turnover.

As compared to the ordered organization of actin- and myosin-filaments between the Z-disks in a sarcomere, the dynamic rearrangements of the actin cytoskeleton in a migrating cell are very complex and integrate numerous intra- and extracellular parameters (1). A superb model for chemotactic movement is the migration of *Dictyostelium* amoebae (3). Like migrating leukocytes, *Dictyostelium* amoebae are, at

a certain developmental stage, polar and show directed movement in a gradient of chemoattractant (Fig. 2). The moving front extends the membrane towards the higher concentration of chemoattractant and is characterized by an extreme polymerization of actin. The filament meshwork is so dense that even small vesicles are excluded and the leading pseudopodium appears hyaline. At the rear the cellular reactions are completely different because only contraction and depolymerization of F-actin guarantee cellular integrity and directed movement. It is amazing how quickly this pattern can be changed if the extracellular gradient is readjusted. In Fig. 2a a chemotactically active *Dictyostelium* cell

A

Actin Cytoskeleton. Figure 2 Cytoskeletal dynamics during cell migration. A *Dictyostelium* amoeba migrates towards a microcapillary which is filled with the chemoattractant cAMP. The moving front of the polarized cell is filled with a dense F-actin meshwork. At time 0 sec the capillary was relocated to the rear of the cell, and already after 4 sec the cell starts to reorganize and to create a new moving front. This quick reaction suggests extremely efficient signal transduction and cytoskeletal rearrangement.

moves towards a microcapillary that is filled with cAMP as chemoattractant. The gradient is sensed by cAMP receptors in the plasma membrane that transfer the signal *via* G-proteins to intracellular effectors. After replacing the capillary at the rear end of the cell, it takes only 2–4 s before the cell transforms the rear into a new front. This is a drastic example of the dynamics in the actin cytoskeleton, which involve not only the polymerization patterns of actin but also signal transduction and other cytoskeletal proteins.

Molecular Interactions

The actin cytoskeleton interacts constantly with various other proteins that either regulate the polymerization, stability and length of the actin filaments or perform specialized functions. The interaction of actin and myosin in the skeletal muscles during muscle contraction is well characterized. In non-muscle cells actin and myosin II interaction plays a very important role in the cleavage furrow. Studies from *Dictyostelium* cells show that myosin I is localized at the moving front of the cell whereas myosin II is at the rear end. In erythrocytes actin interacts with spectrin and ankyrin, two membrane associated proteins. Tropomyosin interacts with the actin filaments in the muscle cells providing mechanical strength to the filaments.

The presence of actin in the nucleus was under debate for a long time. Failure to find any phalloidin stained actin in the nucleus argued against its presence and actin obtained from nuclear extracts was seen as a cytoplasmic contamination. *In vivo* crosslinking using cell permeable chemical crosslinkers recently showed close association of actin with the nuclear matrix. Using ▶**leptomycin B**, a cell permeable nuclear export inhibitor, nuclear actin filaments could even be stained with phalloidin. A large number of actin binding proteins like cofilin, profilin,

protein 4.1 and c-Abl were also found in the nucleus. Protein 4.1 was immunoprecipitated along with the components of the RNA splicing machinery suggesting a role of this protein in RNA splicing. ▶**Actin related proteins** were reported to exist as subunits of larger protein complexes that are involved in chromatin remodeling. All these recent findings suggest that studies on the function and regulation of actin in the nucleus will speed up tremendously, opening a completely new field of actin's role during replication and transcription.

Regulatory Mechanisms

The average eukaryotic cell contains a large number of actin-binding proteins of different function, location and concentration; only a few can be described here. These proteins themselves are regulated, in most cases by phosphorylation, changes in free Ca^{2+} or interaction with lipids (4, 5). The physiological concentrations of Mg^{2+} or K^{+} are such that in the absence of such proteins all actin would be polymerized and the cells immobile due to their high cytoplasmic viscosity.

- Only the presence of G-actin sequestering proteins like profilin or thymosin $\beta 4$ keeps the G-actin concentration at about 50% of total actin and thus maintains the cell's ability to react quickly to external signals.
- Another important class of actin-binding proteins is the already mentioned capping proteins. They usually cover the fast growing end of an actin filament, inhibit elongation and keep cytoplasmic viscosity low. The complexity of cytoskeletal dynamics becomes obvious if one considers 'uncapping' of a locked filament upon a signal. In this case the cap is suddenly removed and the large number of now free filament ends triggers elongation at high

speed due to bypassing the lag-phase (see above). Uncapping of filaments would be a reasonable mechanism to create a new moving front in a ►[chemotaxis](#) gradient in a few seconds.

- c) A very well known example of a third class of actin-binding proteins is gelsolin, whose name describes the transformation of an actin gel into a less viscous sol. Gelsolin severs the filaments into short fragments and leads to a weakening of sub-membranous actin cortices. In higher vertebrates including man, gelsolin is also present at high concentrations in the bloodstream, most probably to remove F-actin aggregates that originate from broken cells and might be harmful in capillaries.
- d) In addition to the above mentioned actin binding proteins that regulate its polymerization, numerous other proteins like fimbrin, α -actinin, filamin and cortexillin regulate the 3-dimensional architecture of the meshwork by bundling or crosslinking the filaments.
- e) Actin related proteins (Arps) 2 and 3 were identified as part of a complex of 7 different proteins that functions as a nucleator of filament formation and initiates branching of filaments. The family of ►[WASp/SCAR](#) proteins regulates the activity of the Arp2/3 complex, probably by inducing a conformational change.

Cytoskeleton and Diseases

In view of the importance of the cytoskeleton for major cellular functions it is not surprising that many diseases can be traced back to aberrant cytoskeletal components. Only a small number can be mentioned in this context. Actin is an essential gene and mutations in actin usually lead to severe pathological alterations. The familial hypertrophic cardiomyopathy (FHC) mutation was mapped to the actin domain that might bind myosin. The mutation prevents adequate contraction leading to hypertrophy. In idiopathic dilated cardiomyopathy (IDC) the mutation was mapped to the immobilized region of actin that binds to other thin filament binding proteins like troponin I and α -tropomyosin that are involved in force transmission.

Mutations in actin binding proteins also lead to severely altered phenotypes. Profilin I minus mutants of mice are defective in cytokinesis and die at an early stage of embryogenesis. Profilin II null mice show behavioral impairments resembling a hyperdopaminergic phenotype. The mutant mice are hyperactive and show reduced anxiety. This is similar to the ADHS (attention deficient hyperactive syndrome) in humans. Changes in myosin genes are often the basis for disturbed dynamics of the actin cytoskeleton. Among others the ►[shaker/Usher syndrome](#) is of special interest because a myosin VII mutation results in aberrant cochlear hair cells and consequently deafness.

Recently, mutations have been identified in the filamin A gene that lead to otopalatodigital (OPD)-spectrum disorders. These missense mutations were mapped in the highly conserved regions of the actin-binding domain (ABD) and in the rod repeats which recruit multiple proteins. Mutations in the same regions were also reported in the ABDs of other cytoskeletal proteins like dystrophin (Duchenne and Becker muscular dystrophy), β -spectrin (hereditary spherocytosis) and α -actinin-4 (focal segmental glomerulosclerosis). Bacterial pathogens exploit the cytoskeleton either to gain entry into the cell or to propagate. *Listeria monocytogenes* recruits the actin machinery for its intracellular motility and to infect neighboring cells (6). Toxins produced by certain bacteria disorganize the cytoskeleton and change the permeability of the cell barrier leading to severe gastrointestinal diseases. Toxins produced by the members of the *Clostridium* family influence the cytoskeleton directly by ADP-ribosylation of G-actin thus inhibiting its polymerization at the barbed end, or indirectly by modifying regulatory small GTPases by ADP-ribosylation, glucosylation or deamidation (7).

Actin Filaments

Definition

Actin filaments are helical protein filaments that are formed by polymerization of globular actin (G-actin) molecules. Actin filaments (F-actin) are a major constituent of the eukaryotic cytoskeleton and part of the contractile apparatus of skeletal muscle.

Actin can exist as a monomer, but in the presence of simple salts like KCl or MgCl₂, it polymerises in a head to tail fashion forming filaments. Actin filaments are polar, with the two ends being different from each other. The polarity of the filaments can be observed by decorating the filaments with myosin. Coating with ►myosins gives the filament an appearance of an arrow head, hence the names ‘pointed’ (slow growing) and ‘barbed’ (fast growing) ends.

►Actin Cytoskeleton

►Rho, Rac, Cdc42

Actin Polymerisation

Definition

Polymerisation of actin initially requires the formation of dimeric and trimeric actin nuclei, which are highly unstable. Once formed, the elongation is rapid and continues until the equilibrium between F- and G-actin is attained. At this stage a distinct concentration remains monomeric. For ATP-actin, this ‘critical concentration’ is about 0.1 mM at the barbed end. Actin polymerisation works best with ATP-actin, but ATP hydrolysis is not required for elongation. Hydrolysis of ATP is delayed, thus the very end of a filament is composed of about 5–10 ATP-actin units. The vast majority of an actin filament consists of ADP-actin.

►Actin Cytoskeleton

Actin Related Proteins

Definition

Actin related proteins (ARPs) are ubiquitous among eukaryotes and share significant sequence and structural similarities with conventional actins. ARPs are generally larger molecules than the conventional actins, and are involved in various cellular processes like actin nucleation, transport of vesicles and control of gene expression.

►Actin Cytoskeleton

Action Potential

Definition

Action potential is the electric signal generated in a neuron by the activation of voltage-gated Na⁺ channels

in an all-or-none manner, and terminated by the activation of K⁺ channels. The rate of action potentials is the neuronal signalling code. Apart from neurons, certain types of cardiac muscle cells are able to generate action potentials.

►Heart

►Neurons

Action Potential Backpropagation

Definition

Dendrites, in particular apical dendrites pyramidal neurones in the cortex, may sustain the propagation of Na⁺ action potentials generated at the axon initial segment. These ‘backpropagated’ action potentials play an important role in the initiation of synaptic plasticity.

►Neurons

Activation (of a Molecule)

Definition

In order to participate in biochemical pathways, some molecules must gain chemical energy so that the reaction(s) in which the molecule in question is involved is thermodynamically favoured. The activation is realised by an enzyme generally through the hydrolysis of ATP, which is thus covalently bound to the molecule in the form of AMP.

►Genetic Code

Activators of G-Protein Signaling

Definition

Activators of G-protein signaling (AGS) are structurally diverse proteins, which engage G-protein-dependent signaling pathways in the absence of a classical receptor.

►G-Proteins

Active Site

Definition

Active site designates a region on the surface of an enzyme to which substrate molecules bind. In molecular motors, the active site is the binding site for ATP.

► [Molecular Motors](#)

Activin

Definition

Activin is a member of the ► [TGF- \$\beta\$](#) superfamily, which plays a critical role in early embryogenesis as a mesoderm inducer, as an inhibitor of erythropoiesis and an inducer of ► [follicle stimulating hormone](#) (FSH) in the pituitary gland.

Acute Intermittent Porphyria

ULRICH GROSS

Veterinary Clinics Dr. Schäfer, Bad Nauheim, Germany
ulrich.gross@arana.de

Definition

► [Porphyrias](#) are diseases of metabolism, which develop mostly from genetic disturbances of heme biosynthesis. Eight enzymes are involved in the biosynthesis of heme. With the exception of the first enzyme, δ -aminolevulinic acid synthase, every step of this cascade correlates with a porphyria. The enzymatic diminutions of the activities are not fully expressed. A complete loss of heme biosynthesis would not be consistent with life. However, in rare cases homozygous or ► [compound-heterozygous](#) genotypes may occur with nearly complete enzyme deficiencies.

Typical for porphyrias is the overproduction of heme precursors in liver and bone marrow. Thus, hepatic and ► [erythropoietic porphyrias](#) are distinguished. This distinction depends on the localization of the enzymatic deficiency. Porphyrias are divided into acute and non-acute types from the clinical aspect. The non-acute forms are often called chronic porphyrias.

Four types of acute hepatic porphyrias are known, acute intermittent porphyria, ► [hereditary coproporphyria](#), ► [variegate porphyria](#) and ► [Doss porphyria](#). Acute porphyrias show abdominal, neurological and cardiovascular symptoms. Non-acute, chronic hepatic porphyrias such as ► [porphyria cutanea tarda](#) or the erythropoietic porphyrias show skin symptoms. Porphyria cutanea tarda is the commonest porphyria in Europe, followed by acute intermittent porphyria and ► [erythropoietic protoporphyria](#).

The molecular genetics of porphyrias are heterogeneous. In acute porphyrias a large number of mutations have been described, especially in acute intermittent porphyrias. Nearly every family carries its own mutation. The genes for the different enzymes are localized on different chromosomes.

Characteristics

In acute porphyria patients the following triggering factors were noted. Drugs and alcohol were factors in 54% of all patients, followed in frequency by fasting and alcohol, ►[premenstrual manifestation](#), estrogens, anticonvulsant treatment, several infections and stress. In this context two issues in clinical porphyrinology demand investigation. These are the pathogenesis of neuropsychiatric symptoms and the wide individual variability in biochemical and clinical expression of porphyria including unexplained individual differences in porphyrinogenic response with a similar enzyme deficiency (1). Acute porphyria has been considered to be a permanent system overload of oxidative stress, with long-term effects on hepatic and renal tissue and with instances of a periodic overload of free radicals giving rise to acute neurological involvement. Oxidative stress triggered by δ -aminolevulinic acid in the brain accompanied by iron metabolism alterations and GABAergic receptor damage may be implicated in the neuropsychiatric manifestations of the acute hepatic porphyrias. The precipitating factors may be either of endogenous or exogenous origin. They can be divided into five classes (1).

1. Inducers of non-specific δ -aminolevulinic acid synthase in the liver. An overproduction of δ -aminolevulinic acid affects the partially deficient and the secondary controlling functions of porphobilinogen deaminase and causes it to become rate limiting.
2. Endocrine factors include cyclical premenstrual exacerbations. Estrogens and gestagens are capable of inducing porphyria. On the other hand, the beneficial effect of low dose, gestagen-accented hormonal oral contraceptives has been observed and such doses recommended as a therapeutic measure (5).
3. Calorie intake. Fasting, often in combination with alcohol intake is a very important ►[precipitating factor](#). This agrees with the benefit of early consideration of the “glucose effect” and nutrition management.
4. Certain drugs and chemicals foreign to the human body have the potential to induce cytochrome P450. Depletion of the regulatory heme leads to an induction of hepatic δ -aminolevulinic acid synthase and the initiation of the porphyria disease process resulting in an exacerbation of acute hepatic porphyria. A compilation of safe and unsafe drugs in acute porphyrias is given by Doss et al. (2).
5. Stress in all its variable forms can lead to a manifestation of acute hepatic porphyria. Stress may result from strong emotions, alcohol excess,

surgery, intercurrent illness or social problems (e.g. stress of relatives, examinations etc.).

It should be noted that in some porphyria patients, not just one but several factors, acting cumulatively, are the cause of the manifestation of symptomatic acute porphyria.

Cellular and Molecular Regulation

Molecular Genetics of Acute Intermittent Porphyria

Acute intermittent porphyria is an autosomal dominant disorder resulting from a partial deficiency of porphobilinogen deaminase activity. In acute intermittent porphyria a lot of different mutations have been identified. More than half of these mutations were single-base substitutions and a quarter of them consist of small insertions or deletions (3). Founder effects of single mutations from selected geographic areas have been reported (4).

The porphobilinogen deaminase gene shows that two different ►[isoenzymes](#) may be coded by a single gene. Such a single gene with two different ►[promoters](#) produces two different mRNAs, which differ in their 5' ends.

With respect to porphobilinogen deaminase activity in erythrocytes, three different groups can be distinguished. In Germany 87% of the observed gene carriers with acute intermittent porphyria show a lowered porphobilinogen deaminase activity, 8% develop an activity within an intermediate range and 5% have a normal porphobilinogen deaminase activity in erythrocytes (6).

The variant of acute intermittent porphyria in which patients have normal erythroid activity, but half-normal activity of the housekeeping isozyme which is also representative in the liver, results from three different splicing defects located in the intron 1 donor splice site. The mutations entailed in the activation of a cryptic splice site 67 bp downstream in intron 1 lead to a ►[frameshift](#) and a premature stop codon in exon 4 (9). The steady state mRNA levels of the porphobilinogen deaminase gene were analyzed in patients with acute intermittent porphyria. The levels of the mutant transcripts show large variations independent of the class of cross-reacting immunological material, the location of the mutation or the clinical phenotype.

In rare cases conventional biochemical techniques have limited ability to discover asymptomatic gene carriers, as porphobilinogen deaminase activity can be normal. Furthermore in some gene carriers, affected children or under therapy with heme arginate, the urinary excretion of heme precursors may be borderline. In these instances, direct mutation testing is the definitive method for the diagnosis of acute intermittent porphyria (7).

An association between acute intermittent porphyria and hepatocellular carcinoma was reported. However, the porphobilinogen deaminase gene does not function as a tumor suppressor gene. Intrinsic aberrations in acute intermittent porphyria, including a reduced heme synthesis and endogenous oxidative damage to DNA, may incite carcinogenic mutations in the genome of the liver cells.

Molecular Dysregulation and the Disorder-Disease Process

Acute hepatic porphyrias (Table 1) are considered to be molecular regulatory diseases in contrast to non-acute, chronic hepatic porphyria, appearing clinically as porphyria cutanea tarda, which is always associated with liver injury. Porphyrins do not accumulate in the liver in acute porphyrias, whereas in chronic hepatic porphyrias they do. Thus, porphyria cutanea tarda is a porphyrin-accumulation disease – comparable with congenital erythropoietic porphyria – whereas acute hepatic porphyrias are heme-pathway-dysregulation

diseases, which are characterized by the induction of δ -aminolevulinic acid synthase in the liver.

In the disorder-disease progression of acute intermittent porphyria, four phases may be differentiated.

1. The enzyme deficiency alone or the genetic phase,
2. a compensated latent phase with a slight to moderate increase in metabolite excretion, but without clinical symptoms,
3. followed by the decompensated latent phase with a remarkable increase in porphyrin precursor and porphyrin excretion,
4. and the phase of the acute syndrome.

A relationship has been established between the extent of heme precursor excretion, and acute symptoms and the probability of clinical precipitation. As drugs can be disease-inducing factors, acute hepatic porphyrias are classed as pharmacogenetic diseases.

The enzyme deficiency (Table 1) itself is not the factor causing illness in acute hepatic porphyrias. Hereditary enzyme deficiencies lead to a destabilization of the

Acute Intermittent Porphyrria. Table 1 Hereditary enzyme defects in the heme biosynthetic pathway as genetic causes of the porphyrias

*Acute hepatic porphyrias

heme control on hepatic δ -aminolevulinic acid synthase. δ -Aminolevulinic acid synthase is regulated by endogenous heme and glucose and can be repressed by exogenous glucose and heme. A decrease in regulatory liver heme, caused by drugs for example, is followed by an induction of the enzyme. This mechanism is considered to be a counter-regulatory modulation compensating for the specific enzyme deficiency. By these means, porphyrinogen synthesis should be maximized, providing sufficient hepatic heme biosynthesis. Furthermore, induction of δ -aminolevulinic acid synthase will be stimulated by high porphyrinogen substrate loss from hepatocytes. When δ -aminolevulinic acid synthase is induced, δ -aminolevulinic acid and porphobilinogen will be overproduced, but their metabolic conversion into porphyrinogens is limited by the secondary controlling sequence of porphobilinogen deaminase. This limiting function of hepatic porphobilinogen deaminase explains the simultaneous increase in porphyrin precursors (δ -aminolevulinic acid and porphobilinogen) in all three types of dominant acute porphyrias in the acute clinical syndrome. Addition of protoporphyrinogen IX and coproporphyrinogen III to human lymphoblasts or to purified human erythrocyte porphobilinogen deaminase lowered this enzyme activity. This may be an explanation for the increased δ -aminolevulinic acid and porphobilinogen during acute attacks.

Clinical Relevance

Clinical findings include gastro-intestinal, neurological and cardio-vascular symptoms. Colicky abdominal pain, associated with vomiting and constipation or diarrhea is very common and in most cases an initial sign of an acute crisis. ► **Tachycardia** is observed in about one third of all patients. Tachycardia is a very sensitive sign of the clinical activity of the porphyria disease process. Neurological symptoms, which follow the abdominal manifestation, are highly diverse. Peripheral neuropathy leads to paresis in arms and legs. In cases with a severe course, the cranial nerves are involved, leading to a bulbar paralysis and respiratory impairment. In the acute porphyria syndrome, seizures can occur, especially in patients with hyponatremia due to the Schwartz-Bartter syndrome (inappropriate antidiuretic hormone release). Early regulatory treatment of the acute symptomatic expression of acute intermittent porphyria is the treatment of choice to avoid a complicated course. There is no general rule for the appearance and disappearance of clinical symptoms. The course of the acute hepatic porphyria syndrome is highly diverse in the previously undiagnosed and known porphyria patients.

Diagnosis

The clinical manifestation of acute intermittent porphyria is due to the induction of hepatic δ -aminolevulinic acid synthase. The manifestation occurs mostly in the third decade of life. The course of the disease follows latent and acute phases. The latent phase lacks symptoms more or less. However, the excretion of heme precursors is enhanced. δ -aminolevulinic acid synthase is induced by various drugs, alcohol, fasting and stress as well as hormones. Thus the synthesis of porphyrin precursors and porphyrins becomes stimulated. The excessive amounts of these metabolites lead to an abdominal, neurological and cardiovascular syndrome. The results of clinical examination and the anamnesis lead to systematic studies of the urinary and fecal heme precursors. In the acute phase of acute intermittent porphyria, the urinary excretion of δ -aminolevulinic acid, porphobilinogen, uroporphyrin and coproporphyrin is excessively enhanced, whereas the fecal excretion of porphyrins is normal.

The secondary coproporphyrinurias, which are characterized by a mild to moderate coproporphyrinuria without uroporphyrinuria, δ -aminolevulinic aciduria, or porphobilinogenuria are the most frequent disturbances of heme biosynthesis. They arise as a result of the variable and complex effects that many disorders and conditions have on normal porphyrin biosynthesis. These secondary asymptomatic coproporphyrinurias do not develop clinical symptoms by themselves. Therefore, secondary porphyrinurias cannot explain clinical symptoms, even acute porphyria-like symptoms. Thus, porphyrinuria does not necessarily mean porphyria. Treatment of these subclinical disturbances of porphyrin metabolism is not indicated (with the exception of subclinical lead poisoning); instead, the underlying associated disease has to be diagnosed and treated. From the clinical point of view the over-interpretation of secondary coproporphyrinuria as hepatic porphyria is the most frequent reason for errors in diagnosis and therapy in this field.

Therapy

Treatment of acute porphyrias includes the omission of precipitating factors, symptomatic measures according to drug lists and regulatory treatment by glucose or heme (1) (the procedure for the therapy of the acute clinical porphyria crisis is listed below). Both glucose and heme effects on the porphyrin pathway have a proven experimental basis in studies both *in vitro* and *in vivo* (1). In all four types of acute porphyrias, the “glucose effect” by itself causes a significant decrease of between 50 and 90% in urinary δ -aminolevulinic acid, porphobilinogen and porphyrin excretion. This

biochemical response is associated with the clinical response when intravenous glucose is administered in the ascending phase of the acute porphyria manifestation.

Prerequisite

1. Confirmation of diagnosis by urinary δ -aminolevulinic acid and prothobilinogen excess
2. Elimination of all precipitating factors

Regulatory Treatment

3. High dose glucose (400 g per day per os or i.v.)
4. Heme arginate (3 mg/kg body weight per day i.v. for 4 days)

Symptomatic Treatment

5. Pain: opiates
6. Hypertension, tachycardia: beta-blockers (e.g. propranolol)
7. Nausea, vomiting: chlorpromazine or other phenothiazines
8. Psychosis: neuroleptics or other antipsychotic drugs
9. Epilepsy: diazepam, check for hyponatremia
10. Hyponatremia: saline infusion, fluid restriction if signs of inappropriate secretion of antidiuretic hormone
11. Motor neuropathy: physiotherapy

Instability of hematin was one of the possible reasons for the variable clinical experience that has dampened initial enthusiasm. Heme arginate, however, is a stable and safe heme preparation. Its clinical importance has been mentioned in an investigation (8).

Apart from glucose and heme, another therapeutic approach should be mentioned. It concerns the application of long-acting synthetic luteinizing-hormone-releasing hormone-agonistic analogues in those porphyric women who have clinical manifestations of acute porphyria in relation to their menses. Application of luteinizing-hormone-releasing hormone-agonistic analogues prevents ovulation and the resultant progesterone production to prevent cyclical attacks of porphyria.

It was shown that three females with repeated premenstrual clinical expressions of an acute hepatic porphyria (acute intermittent porphyria and hereditary coproporphyria) could be treated successfully with a hormonal oral contraceptive or other exogenous hormones to stabilize the latent, subclinical phase of the disease (5). Luteinizing-hormone-releasing hormone-agonistic analogues cause menopause. Thus, luteinizing-hormone-releasing hormone-agonistic analogues should be used to treat only those patients in whom the application of hormonal oral contraceptives does not improve the metabolic status of porphyrin

parameters and the clinical symptoms. We recommend a restriction of the application of luteinizing-hormone-releasing hormone-agonistic analogues to patients not responding to hormonal oral contraceptives. Finally, research was undertaken into certain synthetic heme analogues in which the central iron is replaced by another element. Tin-protoporphyrin, a potent inhibitor of heme degradation by inhibition of heme oxygenase, suppresses chemically induced hepatic porphyria; unlike heme derivatives, tin protoporphyrin is neither degraded nor does it induce the activity of heme oxygenase. These circumstances may have potential clinical implications for the future. However, photosensitivity is a side effect of treatment with tin protoporphyrin.

Acute Lymphoblastic Leukaemia

Definition

Acute lymphoblastic leukaemia is a clonal malignant disorder of lymphoid progenitor or precursor cells. Blockade of lymphoid cell differentiation can occur at distinct stages of B- or T-cell development, including primitive cells with multilineage potential, and leads to persistent proliferation, defective cell death, and accumulation of leukaemic lymphoblasts in tissues, causing organomegaly and bone marrow failure.

► [Leukemia](#)

Acute Myeloid Leukaemia

Definition

Acute myeloid leukaemia is a clonal malignant disorder of haematopoietic tissue in the bone marrow that is characterized by: (1) the proliferation and accumulation of abnormal (leukaemic) blast cells, principally in the bone marrow; and (2) the suppression of normal stem cell expression resulting in impaired production of normal blood cells. Most cases of adult AML probably arise in a primitive, multipotent stem cell, whereas childhood AML might derive from somewhat more differentiated, lineage-restricted stem or progenitor cells that are active in early development.

► [Leukemia](#)

Acute Phase Proteins

Definition

Acute phase proteins are a group of proteins whose concentration in the blood plasma changes (minimally with 25%) during (certain) inflammatory disorders/reactions. Acute phase proteins are predominantly produced in the liver, and include, for example, C-reactive protein (CRP) and serum amyloid A (SAA).

► [Interleukins and Their Receptors, a Role in Regulating Hematopoietic Stem Cells](#)

Acute Phase Reaction

Definition

The acute phase response (APR) of inflammation is a well-known clinical phenomenon, characterized by an increased white blood cell count (leukocytosis), fever, alterations in the metabolism of many organs, and changes in the plasma concentrations of various so-called acute phase proteins like ► [C-reactive protein \(CRP\)](#) (in humans).

► [Inflammatory Response](#)

Acute Promyelocytic Leukaemia

Definition

Acute promyelocytic leukaemia is a form of acute myeloid leukaemia, and is characterized by an increase of enzyme-containing granula in pathological promyelocytes, which may lead to severe bleeding due to hyperfibrinolysis. Complications comprise of cerebral bleedings, therefore early therapy with antibiotics is indicated.

Adaptive Immunity

Definition

Adaptive immunity collectively comprises of immune responses mediated by T and/or B lymphocytes that are antigen-specific, and results in either the production of antibodies (by B lymphocytes) or in cellular activation (of T lymphocytes). Adaptive immune responses generally lead to long-lasting immunological memory, in which re-exposure to the same antigen results in a rapid recall response.

Adaptor Complexes

Definition

Adaptors are heterotetrameric protein complexes (AP-1 - AP-4) that serve in the sorting of proteins in several different intracellular transport steps, through direct binding to distinct di-leucine or tyrosine-based trafficking motifs present in the cytoplasmic tails of cargo proteins. Proteins with adaptor-like functions that do not possess the classical AP structure have also recently been identified, e.g. GGAs.

► [Vesicular Traffic](#)

Adaptor Protein Complexes

Definition

Four different adaptor protein complexes with homologous structural organization have been identified (AP1, AP2, AP3, AP4). They are hetero-tetramers composed of two large, one medium and one small subunit. AP1 and AP2 bind to cargo proteins present at the *trans*-Golgi network (TGN) and the plasma membrane, respectively. They also recruit clathrin, thereby promoting the formation of clathrin-coated vesicles. AP3 and AP4 have been less well characterized. Both are believed to be recruited in an ARF-dependent manner to distinct regions of the TGN. AP3 may also associate with a

subpopulation of endosomes. Although AP3 has been shown to associate with clathrin *in vitro*, it is not yet clear if it functions as a clathrin adaptor *in vivo*. AP4 is most likely part of a non-clathrin coat.

► [Protein and Membrane Transport in Eukaryotic Cells](#)

Adaptor Proteins

Definition

Adaptor proteins contain several protein-protein interaction domains that serve to assemble a multiprotein complex. They contain an SH2 domain that binds to phosphotyrosine residues of activated tyrosine kinase receptors, and an SH3 domain that binds to proline rich regions of effector proteins

Addiction, Molecular Biology

WALTER ZIEGLGÄNSBERGER

Max Planck Institute of Psychiatry, Munich, Germany
zieglgaensberger@mpipsykl.mpg.de

Synonym

Drug abuse

Definition

Addiction is a sociological term that refers to a chronic relapsing disease that is characterized by ► [compulsive drug seeking](#) and use. Following periodic or chronic intoxication the addict loses control of drug-taking behavior despite being aware of the adverse health, social or legal consequences. Drugs of abuse change the way the brain works. Under the influence of addictive drugs such as ► [cocaine](#) and ► [amphetamines](#) (psychostimulants), ► [heroin](#) (opiate) or ► [alcohol](#) and ► [nicotine](#) the brain changes its structure and function. The various molecular targets responsible for the habit-forming action of drugs of abuse in humans and in experimental animals are similar and are presently examined by various techniques.

Characteristics

The recent advances in addiction medicine illustrate the analytical power of modern neurosciences in a field

previously accessible only to methods of systems biology. The introduction of the concepts of neuronal plasticity mediated, e.g. *via* the activation of L-glutamate-, ►GABA-, opioid- and dopamine-receptors or transport mechanisms for the re-uptake of transmitters after synaptic release has already led to important therapeutic consequences. Drug use pervades all life activities and becomes central to the life of a user, who will continuously lose social compatibility (e.g. loss of social contacts, job etc.). At present it is not possible to predict an individual's predisposition to develop an addiction.

Addictive Drugs

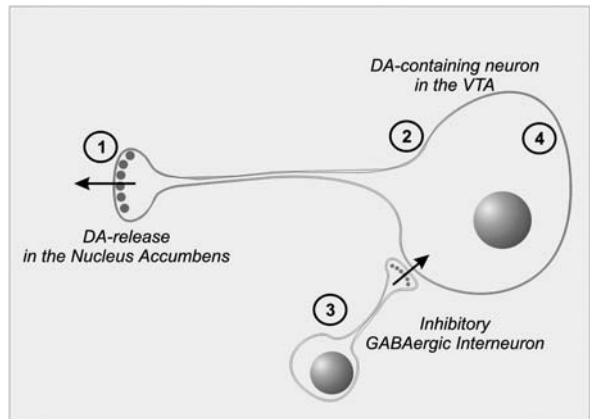

All psychoactive drugs that are abused are ►positive reinforcers and can act as a discriminative stimulus. Positive reinforcement is rewarding. Typical natural reinforcers are e.g. food, water and sex. Drugs of abuse usurp the brain's rewarding system. With most drugs of abuse only brief learning about the significance of the effects is necessary; the brain will soon start to respond differently to environmental stimuli. Formerly neutral stimuli such as a bottle or certain instruments or smells gain saliency through a learned association. These stimuli will become putative triggers for relapse and further compulsive drug taking. Drugs are good tutors; their lessons rarely get forgotten. This teaching of the brain to take drugs will finally result in a loss of control of drug-taking behavior (conditioning). It should be noted that brains cannot discriminate between illicit and legal drugs, the latter being optimally supported by advertising. Legal drugs are the more deleterious to society.

Cellular and Molecular Regulation

The Brain's ►Reward System

Internal states and memories of previous psychoactive reinforcing events are the main gateways to drug use. These processes involve learning and memory in numerous neuronal structures of the central nervous system.

One of the major targets of all drugs of abuse is a brain circuit called the reward system. The activation of this neuronal assembly reinforces behaviors. The key players are ►dopamine (DA)-containing neurons that have their cell bodies in the ventral tegmental area (VTA) and send their axons to the nucleus accumbens, the frontal cortex and parts of the striatum. When this neuronal circuit is activated dopamine is released into these structures. DA release probably induces the reward-associated feelings of pleasure in humans. There are various ways by which DA concentrations in the vicinity of neurons can be influenced (Fig. 1). Actions that increase DA release tend to be repeated. The sensitization process that follows early drug consumption is characterized by a pronounced increase in dopamine levels. There is evidence that the release of DA increases after repeated drug use and is reduced

Addiction, Molecular Biology. Figure 1 Drugs of abuse increase extracellular dopamine concentrations in midbrain structures, such as the nucleus accumbens. Cocaine (1) blocks the presynaptic dopamine transporter and the serotonin transporter and increases the extracellular dopamine by blocking reuptake. Nicotine (2) activates DA-containing neurons directly. Opioid receptor (3) agonists (μ or δ) increase the release of dopamine in the nucleus accumbens by reducing the activity of inhibitory GABAergic interneurons. Like opioid-induced dopamine release alcohol also (4) disinhibits neurons in the VTA. Transcription factors are up- or down-regulated—the excitability of the neurons is altered.

during withdrawal from the drug. It has to be noted that the responses of midbrain dopaminergic neurons represent learning signals. Rather than signaling pleasure, DA highlights significant stimuli and their motivational significance, suggesting that drug addiction might be a DA-dependent associative learning disorder. Activity-dependent gene regulation is involved in drug addiction. Many kinds of drugs of abuse can increase transcription factors in neurons of reward-related structures.

The increase of extracellular DA in the nucleus accumbens, striatum and the frontal cortex, which is of pivotal importance for the initiation and the maintenance of drug-seeking behavior, is controlled by endogenous opioids. Most principal components of the brain reward system also receive glutamatergic input from heterogeneous structures such as the medial prefrontal cortex and are influenced by local GABAergic interneuronal activity. Inhibitory GABAergic interneurons control the neuronal discharge activity of DA-containing neurons in the VTA. Drugs such as alcohol or opioids inhibit these inhibitory interneurons. A reduction in their activation leads to disinhibition of DA-containing neurons and the subsequent release of DA (Fig. 1). The reward system is linked to numerous other neuronal circuits in the brain. Drugs of abuse influence the brain as a whole.

Tolerance, Dependence and Withdrawal

The brain adapts to the continued presence of the drug of abuse. ► **Tolerance** to a drug of abuse is usually characterized by the need to take increasing amounts of the drug to elicit the same effect as this dose evoked previously. Tolerance is a more general phenomenon and does not only develop with drugs of abuse. There is evidence that in the case of some receptors, G proteins uncouple from the receptor inducing desensitization.

► **Dependence** describes the physical and/or psychological reliance on drugs. The repeated or prolonged presence of an addictive drug induces alterations in neuronal signaling cascades. After this adaptation the brain and the body will require the presence of the drug to function properly (psychological and physical dependence). Chronic administration of opioids and alcohol leads to physical dependence. This is in contrast to the effects following chronic administration of psychostimulants, which are highly addictive but hardly express physical dependence.

After cessation of drug use, the addict usually undergoes ► **withdrawal**, which is often associated with very aversive physical symptoms. For the addict it becomes now even more difficult to choose to take the drug or not, since the reduction of these aversive symptoms becomes a rewarding signal. In general, most drug-taking behavior is not cognitively perceived and controlled. Environmental situations can become conditioned to withdrawal and neutral stimuli can become motivationally significant signals that evoke ► **craving** and relapse. After chronic consumption of opiates the application of the antagonist induces dramatic withdrawal symptoms. Most importantly, after the physical withdrawal symptoms have disappeared and the drug addict is detoxified he/she is still an addict. The neuroplastic changes, which took place during the formation of the memory of addiction, are still functioning. To help an addict to finally quit drug taking and to permanently kick the habit, detoxification will be useless if it is not combined with psychotherapy and extensive long-term case management. Only the combination of these procedures will help the addict to regain the skills for successful living. It should be noted that detoxification processes are uncomfortable and no trivial interventions even under hospital supervision.

A relapse to drug taking behavior can occur after many years of abstinence. Stress can induce the reinstatement of drug-seeking behavior and self-administration.

Chronic alcohol abuse can induce chronic disorders in learning and memory (Wernicke's syndrome or so-called Korsakow's psychosis), which are characterized by confabulation as a key symptom and delirium characterized by neuron hyperactivity, tremor, insomnia and anxiety. Following chronic administration the brain gets hyperexcitable and the susceptibility to

seizures is massively increased. Neural hyperactivity can destroy neurons by overexcitation (excitotoxicity).

Craving

Craving is the uncontrollable desire for a drug of abuse. Drug-taking usually induces feelings of pleasure, alters emotional responsiveness and perception and impairs judgment and performance. Drug-induced learning and robust long-term memory consolidation in reward-related structures take place. Previously neutral stimuli acquire the ability to trigger craving. This hunger for drugs may then become an important gateway to relapse. However, there is evidence that relapse occurs without any obvious craving and that even strong craving signs are not necessarily followed by relapse. Potentially independent pathways may induce alcohol craving and relapse by negative motivational states including conditioned withdrawal and stress. These systems involve the glutamatergic systems and the corticotropin ► **CRH system**. Cues, which are associated with prior alcohol intake but are not followed by actual drug consumption, may induce conditioned withdrawal. Withdrawal symptoms are alterations in blood pressure, pulse rate and body temperature, restlessness, diarrhea, weight loss, anxiety, and depressive mood.

The ► **limbic system**, a heterogeneous nuclear system that is involved in the generation of feelings, emotions and motivations is intimately involved in learning and memory consolidation related to drug effects. Following repeated drug use these brain structures lay down and store memories in various circuits. Functional imaging techniques in humans demonstrate that craving for drugs of abuse involves areas predicted from animal experiments.

Craving as a multi-dimensional phenomenon is most readily measured through language-based descriptions following e.g. the presentation of cognitive stimuli or by inducing certain mood states. It is difficult to measure craving in laboratory animals and in each model only aspects of craving might be described. Most animal models measure the behavioral responses rather than internal states and are therefore better models for relapse rather than craving *per se*. However, some of the available animal models can serve as powerful tools for designing human craving studies.

Clinical Relevance

Drug Substitution and Anti-Craving Medication

To prevent withdrawal and craving that often provoke relapse, drug addicts are treated with either substitution or anti-craving compounds. Both substitution and anti-craving drugs prevent relapses and through this effect will help to regain control over behavior. Deconditioning is one of the strategies in the treatment of addicts. This process can either neutralize the

learned cues or can help to relearn other cues, provided no relapse occurs which might then reinstate the previous behavior. A stimulus is said to reinstate drug-seeking behavior if it causes renewed responding. Various conditions can reinstate drug taking, drug priming, i.e. the injection of a small dose of the drug, stress or conditioned stimuli. Acquisition and storage of memories is one of the basic principles of nervous systems. In the absence of reinforcement the behavioral response will gradually diminish, to be finally extinct. It is well established that the activation of the brain's ►glutamate circuitry contributes to the learning of addictive behavior. Drugs that block glutamatergic activity may help the addicts to kick their habit.

Anti-craving Substances

After several months of voluntary alcohol consumption the drug taking behavior following deprivation (withdrawal) is characterized by increased alcohol intake and preference. This behavior of animals is interpreted as craving.

In this model for craving, several months of alcohol availability are followed by a period of alcohol deprivation (i.e., a withdrawal phase). When alcohol is subsequently made available the animals increase their alcohol consumption and preference for alcohol. These animals clearly demonstrate a preference of alcohol over water and exhibit changes in their alcohol intake pattern. This alcohol deprivation effect leads to consumption of highly concentrated alcohol solutions, even at inappropriate times during the inactive light phase when drinking activity is usually low. These data show that there is a high motivation to drink alcohol following a period of deprivation. Animals will continue to work to obtain alcohol significantly longer than they would before the alcohol deprivation.

Anti-craving substances have been registered for relapse prophylaxis in weaned alcoholics in various European countries (acamprosate) and the United States (naltrexone). Acamprosate and the opiate antagonist naltrexone most probably reduce ethanol abuse through different neuronal mechanisms. ►Acamprosate, the Ca-salt of N-acetyl-homotaurinate interacts with NMDA-receptor mediated glutamatergic transmission in various brain regions. Naltrexone most probably interferes primarily with the mesolimbic/mesotelencephalic dopaminergic brain-reinforcement systems. This structure, more recently attributed to the extended amygdala, involves the shell of the nucleus accumbens, the bed nucleus of the stria terminalis and the central nucleus of the ►amygdala.

Ethanol (alcohol) can be seen as an ►NMDA receptor antagonist at concentrations reached in the brains of alcohol abusers. There is some *in vitro* evidence that the effects of ethanol may be related to selective actions

at NR2B subunit containing ionotropic glutamate receptors. We found in a recent study that the enhanced and delayed stress-induced alcohol drinking in mice lacking functional CRH1 receptors is associated with an up-regulation of the NR2B subunit (3).

The anti-craving compound acamprosate acts as a weak glutamate (NMDA)-receptor antagonist and modulates the number of specific glutamate (NMDA)-receptor subunits.

Taken together these data indicate that NMDA receptor activation is probably involved in plastic changes following chronic ethanol-induced receptor adaptation and that the inhibitory effects of acamprosate on neuronal excitability are more important for its therapeutic effects. Acamprosate produced similar increases in glutamate receptor expression *in vivo* to those seen following acute treatment with the use-dependent open-channel blocker MK-801 and memantine indicating that acamprosate may produce changes in the CNS which are similar to those seen following NMDA receptor antagonists and that these changes may, in turn, underlie the effects of both kinds of drugs in the treatment of alcohol abuse.

Moreover, it is important to note that acamprosate lacked both reinforcing properties and discriminative stimulus properties suggesting that it has little or no abuse potential in its own regard. Not all neurobiological phenotypes can be treated sufficiently for relapse prevention.

Adherens Junction

YASUYUKI FUJITA, CATHERINE HOGAN
MRC Laboratory of Molecular Cell Biology and Cell Biology Unit, and Department of Biology, University College, London, UK
y.fujita@ucl.ac.uk

Definition

Adherens junctions are large multiprotein complexes that join the actin cytoskeleton to the plasma membrane to form adhesive contacts between cells, or between cells and extracellular matrix. Adherens junctions occur in different cell types, and either form plaque-containing linear (zonula adhaerens) or punctate (punctum adhaerens) intracellular junctions. The junctions are composed of transmembrane cell-cell adhesion proteins of the cadherin family (cadherins and catenins), and of plaque-forming proteins such as plakoglobin and β -catenin, and are attached to actin microfilaments.

In vertebrates, cells adhere to their neighbouring cells through three types of junction, ►tight junctions (TJ), adherens junctions (AJ) and ►desmosomes, which together constitute the intracellular junctional complex. TJ act as a diffusion barrier that regulates epithelial or endothelial permeability and restricts the apical-basolateral diffusion of membrane components. AJ and desmosomes are adhesive junctions that anchor to actin and intermediate filaments, respectively. TJ generally localise to the apical side of the lateral membrane of cells and AJ localise just basal to TJ (Fig. 1). Desmosomes are generally localised basal to AJ. The basic structure and components of AJ are conserved

Adherens Junction. Figure 1 Electron micrograph of cell-cell contact (epithelium of small intestine). TJ: tight junction, AJ: adherens junction. (The image was kindly gifted by Dr. Sh. Tsukita, Kyoto University).

during evolution and they are found from lower organisms (e.g. *Drosophila*) to mammals. In contrast, *Drosophila* does not have TJ or desmosomes, but has septate junctions that are structurally comparable to TJ. AJ were originally identified by EM analyses as electron dense plaques of closely opposed membranes between epithelial cells, anchored to a belt of cortical actin. This structure has been well characterised in epithelial cells, however, AJ are also present in other types of cells such as endothelial cells and neuronal cells where they form synapses. AJ are fundamental to tissue development, organisation and function. AJ play a major role in the establishment of tight cell-cell adhesions. The adhesiveness of AJ is conferred by two families of single transmembrane proteins, cadherins and nectins. The extracellular domains of these proteins form homophilic interactions and the cytoplasmic domains are connected to actin filaments *via* binding proteins, thus linking the cell adhesion complex to the actin cytoskeleton.

Characteristics Components

As described above, there are two families of membrane proteins that are involved in the formation of adherens junctions (Fig. 2).

Cadherin System

►Cadherins are a family of calcium-dependent cell-cell adhesion molecules that exist in both vertebrates and invertebrates. The cadherin superfamily contains >80 members and can be sub-divided into several groups, classical cadherins, desmosomal cadherins, protocadherins and atypical cadherin-like domain containing proteins. Among them, classical cadherins are found at AJ. Many classical cadherins have been identified and each of them shows a characteristic tissue distribution. For example, E-cadherin, the prototype and the best-characterised classical cadherin, is primarily expressed in epithelial cells. N-cadherin is expressed in neuronal and fibroblastic cells, while VE-cadherin is in endothelial cells.

During development, cadherin expression is highly regulated, as the pattern of expression of cadherin determines tissue and organ morphogenesis (for a review, see 5). The important role of cadherin in development was confirmed by the phenotype of E-cadherin- or N-cadherin-KO-mice that died at an early stage of embryogenesis. Cadherin expression is also important for maintaining tissue integrity since loss of cadherin adhesive activity is highly correlated with many invasive carcinomas.

Cadherin is synthesised as an inactive precursor molecule that must be proteolytically cleaved to generate a functional, mature protein. This processing

Adherens Junction. Figure 2 Molecules in adherens junctions.

involves cleavage of a propeptide fragment at the N-terminal end of an immature protein, mediated by a family of calcium-dependent endoproteases that recognise a specific recognition sequence. Expression studies have shown that the precursor forms of cadherin do not have adhesive activity.

The extracellular domain of classical cadherins is composed of five structurally homologous domains, EC1-EC5. Each of the five extracellular domains contains Ca^{2+} binding motifs. The current model of cadherin-mediated cell-cell adhesion has been derived from crystallographic analyses of the EC1 and EC2 domains of E-cadherin and N-cadherin and of the entire extracellular domain of *Xenopus* C-cadherin. In this model, cadherin molecules form a *cis* dimer between monomers aligned in a parallel orientation. Binding of calcium ions induces *trans* dimerization between the amino terminal domains of *cis*-dimers in an anti-parallel orientation, which eventually leads to a 'zipper'-like structure between cadherin-expressing cells. Single amino acid mutations that affect the formation of *cis*-dimers abolish cadherin adhesive activity, indicating that the formation of the *cis*-dimer is essential for the formation of a functional *trans*-dimer. The extracellular domain of cadherins only forms homophilic ligations, i.e. a cell expressing a certain cadherin will only interact with another cell expressing the same type of cadherin. This idea was supported by the following experiment; when cells

expressing E-cadherin or N-cadherin were mixed, E-cadherin-expressing cells were segregated from N-cadherin-expressing cells, leading to the formation of two separate cell aggregates.

The cytoplasmic domain of cadherin includes two domains, the CH2 domain (located in the proximal region) and the CH3 domain (located in the distal region). CH denotes cadherin homology and these domains are found in most of the classical cadherins. The CH2 and CH3 domains of cadherins interact with p120^{ctn} and β -catenin, respectively. The juxtamembrane domain of E-cadherin interacts with Hakai. (For details on cadherin-binding proteins, see below.) Although the extracellular domain of cadherin induces cell-cell adhesion in the presence of Ca^{2+} , interaction between the cytoplasmic domain of cadherin and the underlying actin cytoskeleton is also required for construction of tight and compact cell-cell adhesions. β -catenin binds to α -catenin, which in turn associates with actin filaments. The anchoring of cadherin-catenin complex to the actin cytoskeleton promotes the clustering and stabilisation of AJ proteins to form the initial cluster or punctum. Additional adjacent complexes assemble to form the 'zipper'-like structure, which seals the membrane between neighbouring cells. In polarised epithelial cells, this assembly of a 'zipper'-like structure occurs at the apical side of the lateral membrane. However, it remains unclear how this process of AJ formation is regulated.

Nectin System

Nectin is a Ca^{2+} -independent immunoglobulin-like cell-cell adhesion molecule that comprises a family of at least four members, nectin -1, -2, -3 and -4, all of which, except nectin-4, have two or three splice variants (for a review, see 4). Nectin-1 and -2 were originally identified as poliovirus-receptor-related proteins and were named PPR-1 and -2, respectively. However, neither PPR-1 nor PPR-2 has been shown to act as a poliovirus receptor itself. Nectin is conserved from frog to human. Nectin-1, -2 and -3 are ubiquitously expressed in a variety of cells including epithelial cells, fibroblasts and neurons, while nectin-2 and -3 are also expressed in cells that lack cadherins such as monocytes and B cells.

Nectin is a single transmembrane protein of which the extracellular region comprises three immunoglobulin-like domains. Each nectin family member forms a homo-*cis*-dimer in a Ca^{2+} -independent manner, before forming an intercellular homo-*trans*-dimer. The formation of *cis*-dimer is essential for that of a *trans*-dimer. In addition, nectin-3 can form hetero-*trans*-dimers with nectin-1 and -2, while nectin-4 can also form hetero-*trans*-dimers with nectin-1. Nectin is associated with the actin cytoskeleton through binding at the cytoplasmic tail to the F-actin binding protein afadin. Afadin has two splice variants, l-afadin and s-afadin. S-afadin, the smaller splice variant, does not contain the F-actin binding domain. L-afadin is ubiquitously expressed, whereas s-afadin is mainly expressed in neural tissue. Human s-afadin is the protein product of *AF-6*, a gene associated with acute myeloid leukemias. Mice deficient in afadin show severe developmental defects at stages of gastrulation, particularly in structures derived from the ectoderm and the mesoderm. In the ectoderm and embryoid bodies of afadin-deficient mice, the organisation of AJs is highly impaired, indicating the important role of afadin in the formation of AJ.

Several lines of evidence show that the nectin-afadin and E-cadherin-catenin systems are physically and functionally associated. Both systems function cooperatively to induce the formation of AJ, where the nectin-afadin system induces the recruitment of E-cadherin to AJ. However, the molecular mechanism by which nectin-afadin and E-cadherin-catenin systems associate has not been fully elucidated.

Cadherin-mediated Signalling Pathways

Several data suggest that cadherin functions not only as “glue” but also as a signalling centre to transmit several signalling pathways. For example, inhibition of cadherin-based cell-cell adhesions, by a dominant-negative cadherin protein or a blocking antibody,

induces up-regulation of cell proliferation and apoptosis, and modifies cell differentiation. Other experiments have shown that E-cadherin^{-/-} ES cells have no capability to form organized structures. Interestingly, this phenotype can be rescued by constitutive expression of E-cadherin, which results in the formation of epithelial structures. In contrast, rescue by constitutive expression of N-cadherin leads to formation of neuroepithelium and cartilage. These data indicate that cadherins can mediate common and/or specific signalling pathways. Downstream signals from cadherins is still not very clear, but recent reports have revealed several molecular mechanisms (for a review, see 6).

Signalling Through ► Rho GTPases: Rac, Cdc42 and Rho

There is accumulating evidence showing both inside-out and outside-in signals between cadherin and Rho GTPases. Rac and Cdc42 positively regulate cadherin adhesive activity, while Rho negatively regulates cadherins. In addition, cadherin-mediated cell-cell contacts activate Rac and Cdc42, depending on the experimental systems. The modulation of Rho GTPases may regulate the actin cytoskeleton, closely connected to cadherin-based adhesions, during establishment and disruption of cell-cell contacts.

Signalling Through Cadherin-binding Proteins

There are several cadherin-binding proteins identified. Among them, β -catenin and p120^{ctn} (ctn: catenin) have a signalling role in the nucleus. Interaction with cadherin may regulate their localization and nuclear function (For details, see below).

Signalling Role of the Cleaved Cytoplasmic Domain of Cadherin

The cytoplasmic domain of cadherin is cleaved by several ►proteases, such as presenilin, caspase and calpain. A recent report showed that the cytoplasmic domain of N-cadherin cleaved by presenilin has a signalling role (3). It binds to the transcriptional factor CBP and promotes its proteasomal degradation, inhibiting CRE-dependent transactivation. The functional role of the cleaved form of other cadherins remains unexplored.

Molecular Interactions

Cadherin Complex

As described above, the cytoplasmic domain of cadherin interacts with β -catenin, p120^{ctn} and Hakai. The domain structure of each cadherin-binding protein is shown in Fig. 3.

Adherens Junction. Figure 3 Domain structures of cadherin-binding proteins.

β-catenin

In the central region, **β-catenin** has eleven arm-repeats, characteristic 40–44 amino acids repetitive domains, which are responsible for the interaction with cadherins. It is still not very clear how cadherin-β-catenin interaction is regulated. However, crystal structure analyses suggest that the phosphorylation of serine residues in the CH3 domain of cadherin enhances the binding affinity for β-catenin. The N-terminal region of β-catenin interacts with α-catenin that binds to the actin filament. Through this interaction β-catenin mediates the interconnection between cadherin and the actin cytoskeleton, and this connection gives cadherin-based cell-cell adhesions strength.

In addition, β-catenin plays a central role in Wnt/Wingless signalling pathways (**Wnt/Beta-Catenin Signaling Pathway**). β-Catenin in the cytosol is constitutively phosphorylated by GSK-3β and the phosphorylated β-catenin is ubiquitinated and degraded in **proteasomes**. Upon activation of Wnt/Wingless pathways, GSK-3β-induced phosphorylation is blocked and the amount of β-catenin increases. The stabilized β-catenin interacts with a transcriptional factor Lef/Tcf and is transported into the nucleus. In the nucleus, the β-catenin-Lef/Tcf complex regulates the expression of several proteins affecting cell proliferation and differentiation. As the binding of β-catenin to cadherin and to Lef/Tcf is mutually exclusive, cadherin could regulate Wnt signalling by sequestering β-catenin. Indeed, the inhibitory role of cadherins in Wnt signalling pathways has been suggested in several experimental systems.

p120^{ctn}

p120^{ctn} also has ten arm repeats, which are responsible for the interaction with cadherins. p120^{ctn} has two functional roles in the establishment and maintenance of cadherin-based cell-cell adhesions. Firstly, p120^{ctn} regulates the cis-dimer formation of cadherins. As described above, cadherin forms not only trans-dimers (*via* the extracellular domain), but also cis-dimers on the cell surface. p120^{ctn} activates or inhibits the cis-dimerization depending on experimental conditions.

Secondly, p120^{ctn} inhibits endocytosis of cadherin, thus stabilizing cadherin-based cell-cell adhesions, though the molecular mechanism of this inhibitory role still remains to be resolved.

Several data suggest the involvement of p120^{ctn} in the regulation of cytoskeleton. p120^{ctn} can regulate the activity of Rho GTPase family members. Over-expression of p120^{ctn} in mammalian cells inhibits Rho activity and stimulates Cdc42 and Rac activity, leading to production of long neurite-like protrusions. In addition, p120^{ctn} interacts with kinesin and through this interaction p120^{ctn} is involved in microtubule-based vesicle transport.

Since p120^{ctn} and β-catenin share a similar domain structure (arm-repeats), p120^{ctn} has been postulated to have a functional role in the nucleus similar to β-catenin. Indeed, nuclear localization of p120^{ctn} has been reported under several experimental conditions. However, p120^{ctn} does not play a role in the Wnt signalling pathway and the functional role of p120^{ctn} in the nucleus is still largely unknown.

Hakai

Hakai has RING-finger, SH2 and polyproline domains (Fig. 3). *Via* the **SH2 domain**, it interacts with the juxtamembrane domain of E-cadherin in a tyrosine phosphorylation-dependent manner (2). *Via* the **RING finger domain**, it functions as an **E3 ubiquitin-ligase** for the E-cadherin complex and is involved in destruction of E-cadherin-based cell-cell contacts (For more details, see below). Hakai and p120^{ctn} compete for interaction with E-cadherin. Hakai interacts with E-cadherin, but not with other classical cadherins such as N- or VE-cadherin.

Nectin Complex

The C-terminus of the cytoplasmic domain of nectin contains a consensus amino acid sequence (Glu/Ala-X-Tyr-Val) that binds **PDZ domains**. The PDZ domain of afadin interacts with this domain. Afadin has an actin-binding site at the C-terminus, thus connecting nectin complexes to the actin cytoskeleton. Afadin also interacts with the small GTPase Rap and a deubiquitinating enzyme Fam, however the functional significance of these interactions remains unclear.

Regulatory Mechanisms

Cadherin-based cell-cell adhesion is not always static, but is quite dynamically modulated during several processes. During epithelial-mesenchymal transition (EMT) in embryonic development (e.g. gastrulation), E-cadherin protein expressed on the plasma membrane is endocytosed, and furthermore, the transcription of the *E-cadherin* gene is suppressed. In malignant cancer cells, the expression of cadherins is frequently

down-regulated (for a review, see 1). Thus, the expression level or subcellular distribution of cadherin is tightly regulated at transcriptional and posttranslational levels. Among the cadherin family members, the regulation of E-cadherin has been most intensively studied.

Transcriptional Regulation of E-Cadherin

Expression of the *E-cadherin* gene is regulated by several elements located in the 5' proximal sequences of its promoter. Among them, an E-pal element containing two adjacent E-boxes plays a vital role in the regulation of E-cadherin expression. Several proteins, such as Snail, Slug, E47 and SIP-1, have been identified as transcriptional repressors of E-cadherin acting through interaction with the E-pal element. Over-expression of these repressors in epithelial cells leads to a loss of E-cadherin expression and triggers transformation with fibroblastic and invasive phenotypes. Indeed, up-regulation of these molecules has been found in several malignant cells. Interestingly, some of these E-cadherin repressors were previously characterized as crucial regulators during the epithelial-mesenchymal transition of embryonic development. Taken together, these *E-cadherin* repressors are involved in down-regulation of E-cadherin during tumour progression and embryonic development.

Post-translational Regulation of E-Cadherin

The half-life of E-cadherin in epithelial cells is 8–12 h, and the stability or subcellular localization of the E-cadherin protein is regulated by several mechanisms.

Endocytosis

E-cadherin is endocytosed during several processes such as epithelial-mesenchymal transition and cell division. The molecular mechanism for E-cadherin endocytosis is still unclear, but the activation of tyrosine kinases including receptor tyrosine kinases (EGFR, HGFR, etc.) and src induces endocytosis of E-cadherin, leading to disruption of cell-cell adhesions. The RING-finger type E3-►ubiquitin ligase, Hakai, is involved in this process (2). Activation of ►tyrosine kinases induces tyrosine phosphorylation of the cytoplasmic domain of E-cadherin with which Hakai interacts *via* its SH2 domain. Upon interaction, Hakai mediates ubiquitination of the E-cadherin complex, leading to endocytosis and lysosomal degradation of the E-cadherin complex.

In addition to tyrosine kinase activation, there are several stimuli that cause endocytosis of E-cadherin, such as low calcium treatment and activation of cPKC.

It remains to be clarified whether the Hakai-ubiquitin system is also involved in these processes.

Proteolysis by Several Proteases

Cadherins can be cleaved by several proteases. The extracellular domain is cleaved by ►metalloproteases, resulting in secretion of the cleaved extracellular domain into an extracellular space. The secreted extracellular domain would act as a dominant negative protein to block the homophilic interaction of intact cadherins, resulting in disruption of cell-cell contacts. The cytoplasmic domain is also cleaved by presenilin (γ -secretase), calpain and ►caspase. The physiological significance of these cleavages is still not very clear. However, a recent report suggests that the presenilin-mediated cleavage liberates the cytoplasmic domain of cadherin from the membrane fraction. This free cytoplasmic domain could in turn play a role in signal transduction pathways (see above).

kerstin.danker@charite.de

Definition

Cell adhesion is critical for the genesis and maintenance of both three-dimensional structure and normal function in tissues. The biochemical entities mediating cell adhesion are multiprotein complexes comprising three broad classes of macromolecules, the adhesion receptors, the ►extracellular matrix molecules and the adhesion plaque proteins.

Cell adhesion receptors are transmembrane cell surface proteins that mediate cellular interactions with neighboring cells or with the extracellular matrix. These interactions, called cell-cell or cell-matrix adhesion, profoundly influence a variety of signaling events including those involved in mitogenesis, survival and differentiation.

Signal transduction cascades induced by adhesion receptors are regulated by the cytoplasmic sequences of the receptors and by cis-interactions with other transmembrane receptors, thereby forming organized structures or scaffolds that permit the efficient flow of information in signaling pathways.

Characteristics

Adhesion Receptor Families

Receptors that mediate adhesion can be divided into at least five different families (Fig. 1) whose key characteristics are described in the following.

Integrins

►Integrins are heterodimeric transmembrane receptors consisting of one α and one β subunit each subunit having a large extracellular domain, a single

membrane-spanning region and, in most cases, a short cytoplasmic sequence (Fig. 1). The integrin receptor family of vertebrates includes at least 18 distinct α subunits and 8 β subunits, which can associate to form more than 20 distinct integrins. The pairing of the two subunits determines ligand specificity. Integrin ligands are extracellular matrix proteins, counter-receptors on other cells, soluble plasma proteins or microorganisms (1). The strength of ligand binding is modulated by divalent cations, by receptor clustering and by the association of integrins with accessory molecules (2). The name integrin was originally coined to denote the function of these proteins in linking the extracellular matrix (ECM) with the cytoskeleton. However, these receptors can regulate many other aspects of cell behavior. Signaling enzymes, adaptor and cytoskeletal proteins regulated by integrin engagement control physiological processes through interactions with the cytoskeleton and with other receptors. The cytoplasmic domains of the integrin subunits are key nexuses of interactions between the extracellular environment and intracellular structures and signaling cascades. Upon activation by ligand binding, integrins cluster and recruit cytoplasmic proteins, forming structures called focal adhesions. ►Focal adhesions can be considered as integrin-specific signal transduction entities, which serve as starting points for F-actin stress fibers and signaling cascades.

Both the α and the β subunit cytoplasmic sequence make important contributions to various aspects of overall integrin function, including cytoskeletal reorganization, cell motility, signal transduction and modulation of

Adhesion Molecules. Figure 1 Schematic presentation of the structures of the five families of adhesion receptors (modified from Hynes and Landers, 1992).

integrin affinity for the ligand. A large number of cytoskeletal, adaptor and signaling proteins can therefore interact with integrin cytoplasmic domains (2).

Cadherins

Cadherins are a superfamily of adhesion molecules that mediate Ca^{2+} -dependent homotypic cell-cell adhesion. This superfamily contains: 1. classical cadherins, which form the major class of cell-cell adhesive junctions; 2. desmosomal cadherins (desmocollins and desmogleins); 3. protocadherins; 4. some other cadherin-related molecules. Members of the cadherin family consist of a large extracellular domain, a single membrane-spanning region and a cytoplasmic sequence. The extracellular domain consists of repeats of an approximately 100 amino acid cadherin-specific module. Members of the classic cadherin subfamily, such as N-, P-, R-, B- and E-cadherins contain five such modules. The conformation of the cadherin molecule is stable only in the presence of Ca^{2+} , whose binding with the extracellular portion of the polypeptide chain is prerequisite for cadherin-mediated cell-cell adhesion. The N-terminal module is essential for homophilic interaction between two cadherin molecules. Classic cadherins localize in specialized sites of the membrane, such as the **▶zonula adherens**, where they can establish linkages with the F-actin cytoskeleton. Cadherin binding to the cytoskeleton is mediated by a group of intracellular proteins known as **▶catenins** (3). The β -catenin is directly attached to the cytoplasmic domain of cadherin *via* its central region, which contains so-called armadillo repeats (4). Other cytoplasmic proteins directly associated with cadherins are tyrosine phosphatases and the protein p120^{cas}.

In many studies it has been shown that, in addition to cell adhesion, cadherins also have roles in signal transduction processes. These include changes in cytoplasmic Ca^{2+} and activation of **▶G-proteins** and tyrosine kinases, as well as ligand-independent activation of the EGF receptor. Cadherins are connected to the Wnt/wingless signal pathway *via* β -catenin (**▶Wnt/Beta-Catenin Signaling Pathway**).

Many studies have correlated changes in cadherin expression or function with the onset of morphoregulatory processes such as the establishment of tissue boundaries, metastasis, tissue rearrangement, cell migration and cell differentiation. Misregulated cadherin expression or function disrupts embryonic morphogenesis and can alter the characteristics of differentiated cells. The capacity of tumor cells for uncontrolled growth, migration, invasion into surrounding tissues and metastasis is often associated with disruption of cadherin-dependent cell-cell junctions. E-cadherin expression is usually decreased in undifferentiated "aggressive" carcinomas with a high invasive potential.

Immunoglobulin Superfamily Cell Adhesion Molecules (IgCAMs)

Cell adhesion molecules of the **▶immunoglobulin superfamily** (IgCAMs) comprise a large, heterogeneous group of adhesive receptors mediating Ca^{2+} -independent homotypic and heterotypic cell-cell adhesion. Members of this family are defined by the presence of at least one **▶Ig domain**. IgCAMs possess a large amino terminal extracellular part containing the Ig domains, a single transmembrane helical segment and a cytoplasmic tail (5). Adhesion receptors of the Ig superfamily have important roles in development, the maintenance of adult tissue, including neurite fasciculation and neuronal plasticity, and the regulation of the immune response. The best-known example of Ig adhesion receptors is the neuronal cell adhesion molecule (NCAM), which contains five Ig domains in its extracellular portion and functions as a homotypic, calcium-independent cell-cell adhesion receptor. The members of the intercellular cell adhesion molecule subfamily (ICAM1-3) bind heterotypically to integrins of the $\beta 2$ -subfamily, thereby regulating the binding of lymphocytes to endothelial cells or antigen presenting cells.

Relatively little is known about the interactions of IgCAMs with cytoplasmic proteins. The receptor L1 is coupled to the **▶cytoskeleton** *via* binding to ankyrin. Members of the intercellular cell adhesion molecule (ICAM) subfamily interact **▶PIP2**-dependently with the protein **▶ezrin**, mediating a linkage to the cytoskeleton. Many IgCAMs contain **▶ITIM** motifs that serve as docking sites for **▶SH2 domains** of certain phosphatases. PECAM-1, a homotypic IgCAM receptor present on endothelial cells, platelets and some types of leukocytes and involved in the extravasation of leukocytes, interacts with SHP-1 and SHP-2 tyrosine phosphatases and the inositol phosphatase SHIP.

Like other classes of cell adhesion receptors, IgCAMs are able to induce signaling cascades. For NCAM a cooperation/interaction with the FGF receptor has been suggested, in which the phospholipase C is activated, leading to the production of diacylglycerol and eicosanoids, activation of calcium channels and an increase in intracellular calcium. One isoform of NCAM associates with the cytoplasmic tyrosine kinases pp59^{fyn} and pp125^{FAK}. Furthermore, NCAM fulfils its role in neurite outgrowth by signaling *via* the Erk/MAP kinase pathway. Cooperative interactions with other adhesion receptors, the integrin $\alpha\beta 3$ and cadherins, have been described for PECAM-1.

Another interesting subfamily of IgCAMs, the CEA (carcinoembryonic antigen) subfamily, is altered during epithelial tumor progression. The prototypic carcinoembryonic antigen, a glycosylated protein, which contains seven Ig domains and a GPI anchor, is

expressed in a controlled manner during development. In many tumors its expression is abnormally increased.

Syndecans

The syndecans are a four-member family (syndecan-1/syndecan, syndecan-2/fibroglycan, syndecan-3/N-syndecan, syndecan-4/ryudocan (amphyglycan)), of cell surface **▶heparan sulfate proteoglycans** (HSPGs) expressed on all adherent cells.

By way of their HS chains, syndecans can bind a wide variety of soluble and insoluble extracellular ligands including morphogens, growth factors and chemokines as well as ECM components and cell adhesion molecules. Syndecans have diverse functions ranging from participation in cell-cell adhesion, regulation of the signaling of heparan sulfate binding growth factors and organization of cell-matrix adhesion and signaling. The syndecan family members are type I integral membrane proteins with homologous transmembrane and cytoplasmic domains. The combined transmembrane/cytoplasmic domains contain four well-conserved tyrosine residues, which might have important roles in biological function.

The syndecans may function with several types of receptors. They are expressed at cell-cell adhesion sites, e.g. syndecan-1 on epithelial cells and syndecan-2 in neuronal synapses (6). Here, they are expressed with the PDZ protein CASK and the cytoskeletal protein 4.1 and β -catenin linked to cadherins. All three of these cytoplasmic proteins have nuclear functions and CASK binding to syndecans has been shown recently to alter its nuclear targeting. This suggests that coregulation of cadherins and syndecans may be important in the nucleus.

Selectins

Selectins are a small family of lectin-like adhesion receptors containing three members, L-, E- and P-selectins, expressed on leukocytes, endothelial cells and platelets (7). These adhesion receptors mediate heterotypic leukocyte adherence to endothelial cells and platelets during normal immune system cellular trafficking or during inflammation. For these adhesion processes, selectins are required for the very first cell-cell contact and the leucocyte rolling on the endothelium. Subsequently, selectins are involved in the activation of β 2-integrins that are responsible for firm adhesion of leukocytes to the vessel wall.

Selectins contain an amino terminal domain homologous to that of calcium-dependent animal lectins, followed by an epidermal growth factor (EGF)-type domain, two to nine complement regulatory protein repeats, a transmembrane helical segment and a short cytoplasmic sequence. The conserved lectin domain

mediates Ca^{2+} -dependent cell-cell adhesion by binding to sialylated glycans. Physiological selectin ligands include sialyl-Lewis^x saccharides in the context of macromolecular scaffolds. For example, PLGL-1, a ligand of P-selectin, is a mucin-like transmembrane glycoprotein expressed on leukocytes and lymphoid cells.

Selectin expression and function are tightly regulated in time, so that leukocytes can stick to the vessel wall only when it is necessary. Mediators and cytokines are also involved in this regulation of expression.

Recent studies indicate that selectins can also function as signaling receptors, but compared with the other adhesion receptor families relatively little is known about signaling by selectins.

Adipogenesis

Definition

Adipogenesis describes the process of formation of fat tissue (adipose tissue). It follows a multistep process, beginning with the clonal expansion of mesenchymal cells. These cells are capable of forming muscle, bone or fat cells (adipocytes). Some of these mesenchymal cells differentiate into preadipocytes and proliferate at the site of adipogenesis. In a second differentiation step, preadipocytes begin to fill with lipid. Initially, the lipid accumulates inside the cell in small droplets and later on the droplets fuse into one large droplet. By this

lipid accumulation, mesenchymal cells with an average diameter of 10–20 μm can reach diameters of up to 100–200 μm , thereby increasing the cell volume as much as thousand times. Molecular regulation of adipogenesis occurs via a complex transcription factor cascade. Transcription factors such as C/EBP α , C/EBP β , C/EBP δ , PPAR α/δ , and ADD1/SREBP1c have been shown, under various circumstances, to influence the extent of adipogenesis. Among the earliest events following hormonal stimulation is the induction of Krox20, which in turn, either directly or indirectly through a homeobox factor, activates the expression of C/EBP β and possibly C/EBP δ . C/EBP β and C/EBP δ then activate the expression of KLF (Kruppel-like factor) 5 that, in concert with C/EBP β and δ , activates the PPAR γ 2 gene and triggers conversion of preadipocytes to adipocytes. PPAR γ then activates the expression of C/EBP α that feeds back and regulates the [PPAR \$\gamma\$](#) gene. PPAR γ is the terminal factor that controls adipogenesis and the ultimate expression of genes expressed in mature adipocytes, including those encoding fatty-acid binding protein, lipoprotein receptor, lipoprotein lipase, glycerol kinase, and phosphoenolpyruvate carboxykinase. Endogenous negative regulators of adipocyte differentiation are Pref-1 and Wnt-10b.

Adipose tissue participates in the regulation of energy homeostasis as an important endocrine organ that secretes a number of biologically active factors, termed “adipokines”, which include [tumor necrosis factor \(TNF\)- \$\alpha\$](#) , [leptin](#), resistin, and [adiponectin](#). There is growing evidence that adipocyte secretory products are important determinants of insulin resistance, through either a traditional (circulating) hormonal effect or local effects on the adipocyte.

[►Obesity](#)

[►Wnt/Beta-Catenin Signaling Pathway](#)

Adiponectin

Adiponectin is an insulin-sensitizing, anti-inflammatory protein exclusively produced and released by adipocytes (fat cells). It is encoded by the APM1 gene which maps to chromosome 3q27. By regulating the metabolism of glucose and lipids adiponectin has central effects on energy homeostasis. Several studies have examined plasma adiponectin levels in humans and have found decreased levels in obese and diabetic subjects and significant inverse associations with some measure of insulin resistance. High adiponectin levels are associated with a reduced risk of heart attack.

Adult Stem Cells

Definition

Adult stem cells are multipotent and can differentiate into several types of tissues. They are synonymic to precursor or progenitor cells. It is generally assumed that these cells are already genetically committed to a certain cell type. Adult stem cells occur in various tissues of the adult body, and have the physiologic function to be able to regenerate some tissues which obey a strong degradation. For example, the hemopoietic stem cells regenerate blood and immunologic cells since they are quickly degraded.

Synonyms

Affinity separation; Interaction chromatography

Definition

► [Affinity chromatography](#) exploits the specific binding of a biomolecule, e.g. a protein or nucleic acid, to a

ligand that is immobilised on a solid support. It is a powerful means of preparative protein isolation, but also a valuable tool for scientific discovery. The combination of affinity chromatography approaches and ► [mass spectrometry](#) is an efficient approach for identification and characterisation of protein complexes.

Characteristics

Affinity chromatography is a technique for isolation of biomolecules by virtue of their specific binding properties (1). The technique involves pairs of biomolecules, which specifically interact with and bind to each other, such as antibody/antigen, receptor/ligand and enzyme/substrate pairs or complementary nucleic acids (Fig. 1). Affinity chromatography is a common protein separation technique and is also used for analytical purposes and studies of protein interactions. As a prerequisite, one of the interacting biomolecules, the ligand, has to be immobilised on an inert support. The standard supports for affinity chromatography are natural polymers – ► [agarose](#) (Fig. 2), dextran and cellulose – which form gels with large diameter, non-rigid particles. More recently, small rigid particles of silica or synthetic polymers, suitable for high performance liquid chromatography (► [HPLC](#)), have been adapted to affinity chromatography. These modern chromatography supports withstand the high pressures and flow rates of HPLC. Traditional affinity columns have to be operated at a low flow rate because of slow mass transport by diffusion into the pores of the large chromatographic support particles (‘► [beads](#)’). The particles of modern supports are either very small or have large pores which reach through the entire

Affinity Chromatography and *In Vitro* Binding (Beads). Figure 1 Affinity chromatography applications. The photo shows a simple affinity chromatography column operated by gravity flow. More sophisticated columns are connected to pumps and UV-detectors with tubing. The schematic shows the isolation of an antigenic protein on an affinity column of immobilised antibodies.

Affinity Chromatography and *In Vitro* Binding (Beads). **Figure 2** Agarose. Structure of the agarose polymer. Agarose is found derivatised in natural sources. For chromatography, agarose beads are stabilised by chemical cross-linking.

Coupling reaction:

Affinity Chromatography and *In Vitro* Binding (Beads). **Figure 3** Immobilisation via flexible linkers. A typical preparation of an affinity resin with a flexible linker/spacer is shown. The linker carries a reactive group for immobilisation of ligands. The ligand (R) is covalently attached to the linker *via* its amino group. The affinity resin is then ready for purification of biomolecules that bind the ligand.

particle, allowing the liquid phase to flow through. Binding equilibrium is therefore established fast and overall run times are minimised.

Usually small molecules are immobilised, but antibodies, proteins and nucleic acids are also used as ligands. Spacer groups/flexible linkers attach the ligand to the solid support, allowing for sterically unimpeded access of the solutes (Fig. 3). When a protein mixture is applied to an affinity chromatography column, only proteins with specific affinity to the immobilised ligand are retained, while other proteins are washed away. Captured proteins are then released ('eluted') by a change of pH or ionic strength or with an excess of the soluble form of the immobilised ligand.

►Affinity Tags

Affinity tags are proteins or peptides that are known to work well in an affinity chromatography system. An affinity tag is fused to a protein of interest by genetic engineering to obtain a fusion protein that is easily purified by a well established affinity chromatography system. Examples for affinity tags and corresponding affinity chromatography systems are glutathione-S-transferase and glutathione Sepharose (glutathione cross-linked to Sepharose), maltose binding protein and amylose, calmodulin binding peptide (CBP) and calmodulin beads, and the FLAG[®] epitope peptide tag and chromatography material carrying the anti-FLAG[®] antibody. The ►His-tag is a peptide of six or more histidines that binds to immobilised nickel or cobalt ions.

Identification of ►Protein Complexes

Oligomeric protein complexes are ideally studied under physiological, native expression levels and conditions (2). Over-expression of the subunits of a protein complex might lead to artificial results. Protein complexes have traditionally been isolated by ►immunoprecipitation or '►GST pull-down experiments'. Immunoprecipitation is a powerful approach for identification of a protein's binding partners. It requires a specific antibody of high affinity, which captures its antigen together with any bound proteins from a cell or tissue extract. Protein A of *Staphylococcus aureus* cross-links and precipitates antibody-protein complexes which are then isolated by centrifugation. Alternatively, Protein A bound to agarose beads is used. Captured proteins are separated and visualised by gel electrophoresis and identified by mass spectrometry (Fig. 4).

The GST pull-down approach uses a recombinant protein as a bait that is fused to an affinity tag to capture ('pull down') binding partners out of a cell lysate. The cell lysate is applied to the immobilised bait protein or, alternatively, bait protein and lysate are mixed in solution and complexes captured afterwards. Glutathione-S-transferase (GST) has most often been used as the affinity tag, but other tag systems have also been used successfully. Pull-down experiments are readily performed and do not require specific antibodies. However the high concentration of the recombinant bait protein might lead to non-physiological protein interactions. A potential binding partner of the recombinant bait protein might not be available for binding, if it is already sequestered in a complex with endogenous binding partners.

To circumvent the limitations of the GST pull-down and the requirement of immunoprecipitation for specific antibodies, novel approaches have been developed. The ►TAP tag (tandem affinity purification) is a highly

Affinity Chromatography and *In Vitro* Binding (Beads). Figure 4 Isolation of protein complexes and protein identification by mass spectrometry.

specific ‘double’ affinity tag that combines protein A of *Staphylococcus aureus*, which binds ►immunoglobulin G antibodies (IgG), and a calmodulin binding peptide (CBP). Both of these tag systems allow the efficient capture of proteins present in low concentrations. The combination of the two tags results in a highly specific isolation of protein complexes of low cellular abundance.

The TAP tag is typically used to isolate protein complexes from yeast cells but also works in mammalian cells. By genetic engineering of a cell’s genome, the open reading frame coding for a protein complex subunit is fused to the TAP tag coding sequence. The resulting fusion protein is expressed in native amounts from its original promoter and is incorporated into a protein complex. The complex is then isolated by two subsequent steps of affinity chromatography (Fig. 5) using immobilised IgG antibodies and calmodulin. First the protein complex

Affinity Chromatography and *In Vitro* Binding (Beads). Figure 5 Isolation of protein complexes with the TAP tag.

is captured on immobilised IgG. Since the interaction of protein A with immobilised IgG is not readily reversible, the TAP tag contains a cleavage site for the highly specific protease of tobacco etch virus (TEV). Treatment with TEV protease cleaves the TAP tag between protein A and CBP and releases the protein complex (Fig. 5). The released protein complex is still contaminated with unrelated proteins at this stage and a second affinity purification is required. The complex, still carrying the CBP tag, is captured on calmodulin beads. CBP binding to calmodulin is calcium-dependent. The immobilised protein complex is eluted with a calcium-chelating reagent, separated by electrophoresis and identified by mass spectrometry. The TAP tag is usually fused to the C-terminus of a protein complex subunit, but an N-terminal fusion can also be chosen if the tag interferes with protein function or complex assembly.

Affinity tags and mass spectrometry were used for genome-wide screens for protein-protein-interactions in the yeast *Saccharomyces cerevisiae*. Yeast genes were systematically genetically engineered to fuse their gene products with affinity tags. The TAP tag and the FLAG[®] epitope tag, the epitope of the anti-FLAG[®] antibody, were used. Thousands of new protein-protein interactions were discovered by this approach (3, 4).

Clinical Relevance

Affinity chromatography plays an important role in scientific discovery, clinical research and diagnostics and, more recently, in the preparation of therapeutic proteins (►[biopharmaceuticals](#)).

Clinical Diagnostics

In clinical research and diagnostics, affinity chromatography is used to isolate and quantitate various classes of biomolecules (5). When compared to ►[ELISA](#), affinity chromatography has the advantage of a direct linear correlation of signal strength and biomolecule concentration. When combined with modern HPLC equipment, affinity chromatography is a reliable and very fast method of high precision. It permits the assaying of a sample for more than one component – the flow through of a column containing ligand A can be directly forwarded onto a second column with a different ligand B and so forth. HPLC runs are fast, but are performed sequentially in contrast to ELISAs, which are usually performed in microtiter plates on hundreds of samples in parallel. Therefore, affinity chromatography is less ideal for diagnostic applications that require measurement of large numbers of samples. A classical clinical application of affinity chromatography is boronate affinity chromatography, which is used for capture and quantification of glycosylated proteins. The concentration of glycosylated serum proteins, namely ►[glycohemoglobin](#), is an important parameter in the therapy of ►[diabetes](#). Glycosylated haemoglobin isolated by boronate affinity chromatography is specifically monitored and quantified by absorption measurement at 410 nm.

Lectins are used in affinity chromatography to study ►[glycoproteins](#) and to separate ►[isoenzymes](#) and other closely related, but differently glycosylated proteins. Examples include alkaline phosphatase isoforms separated by wheat germ agglutinin affinity chromatography and lipoproteins separated by immobilized concavalin A.

Probably the most common application of affinity chromatography is the isolation and analysis of immunoglobulins from antisera, performed with immobilized protein A from *Staphylococcus aureus* or protein G of *Streptococcus*. Different immunoglobulin classes and subclasses can be differentiated by their affinity for protein A or protein G. Generally class G immunoglobulins are bound most strongly, but other classes can also be isolated.

Purification of Biopharmaceuticals

The introduction of proteins for clinical therapy, so-called biopharmaceuticals, ►[biologics](#) or ►[biologicals](#), requires safe, reliable and cost-effective methods for

protein purification (6). Proteins used in therapy have to be purified by robust methods that are compatible with harsh cleaning and sterilization procedures. Immobilized proteins or antibodies are not ideal since their stability is limited and they require careful quality control. They might contain contaminants from the biological source they originate from, such as pyrogens or viruses. Synthetic ligands, including peptides, are well suited for purification of biopharmaceuticals. Synthetic ►[biomimetic ligands](#) are designed on the basis of known ligand-protein interactions. The rational *de novo* design of such ligands makes use of three-dimensional structures of protein-ligand complexes. The most important class of biopharmaceuticals are immunoglobulins. Synthetic peptides and chemical compounds that mimic the contact region of protein A bound to immunoglobulin G have been developed. These compounds were designed according to the three-dimensional structure of a protein A-immunoglobulin complex. Useful synthetic ligands were obtained that were further refined by screening compound libraries created by combinatorial chemistry on the basis of the original ligands. This screening resulted in ligands that are used in affinity chromatography to isolate immunoglobulin G from plasma in excellent purity and yield. Synthetic ligands have also been successfully developed for insulin and ligands mimicking specific peptide substrates of proteases such as kallikrein or elastase have been designed.

Scientific Discovery

Affinity chromatography is not only a convenient means of protein purification, but also a very important tool of scientific discovery. It was and is being used to isolate and identify novel enzymes, antibodies and antigens, hormones and receptors. The isolation of the ►[insulin receptor](#), which was at that time unknown, using immobilised insulin, is an impressive example of the power of this technique.

More recently, affinity chromatography has been used in combination with mass spectrometry to identify large sets of novel protein-protein interactions.

Akt refers to a serine threonine kinase [also called protein kinase B (PKB)] which functions as an intracellular signaling molecule in the ▶ PI3K pathway.

- ▶ Breast Cancer

Alagille Syndrome

Definition

Alagille syndrome is a rare hereditary disorder (1:50,000 newborns) caused by functional loss of one allele of the JAG1 gene (▶ Jag1 and 2), in 99% of the cases by molecular mutation and ~1% by chromosome 20p12 deletion. Characteristic signs include arteriohepatic dysplasia, cholestasis, and facial and vertebral anomalies. Infants may die from hepatic and cardiac

malformations, and older patients from complications of cholestasis and hypercholesterolemia.

Albright's Hereditary Osteodystrophy

Definition

Albright's hereditary osteodystrophy (AHO) is a complex clinical syndrome that is characterized by short stature, obesity, skeletal abnormalities, mental retardation, and often subcutaneous ossification. It frequently concurs with resistance to parathyroid hormones and to other hormones acting via G_s -coupled receptors. Loss-of-function mutations in $G\alpha_s$ are the molecular cause of the disease.

- ▶ G-Proteins

Alcohol Abuse, Consequences

Definition

Chronic alcohol abuse can induce chronic disorders in learning and memory (Wernicke's syndrome or so-called Korsakow's psychosis), which are characterized by confabulation as a key symptom and delirium characterized by neuron hyperactivity, tremor, insomnia and anxiety. Following chronic administration, the brain gets hyperexcitable and the susceptibility to seizures is massively increased. Neural hyperactivity can destroy neurons by overexcitation. Alcohol can be seen as an N-Methyl-D-Aspartate (NMDA) receptor antagonist at concentrations reached in the brains of alcohol abusers. There is some *in vitro* evidence that the effects of ethanol may be related to selective actions at NMDA receptor 2B subunit containing ionotropic glutamate receptors.

Aldosterone

Definition

Aldosterone is a small hydrophobic molecule and belongs to the class of steroid hormones. Aldosterone is the major mineralocorticoid in the body. Its receptor belongs to the superfamily of steroid hormone receptors that are located intracellularly, and upon binding translocate into the cell nucleus, where they regulate the transcription of those genes that contain the appropriate responsive regulatory element. In the intestine, and in particular in the distal tubules of the kidney, aldosterone increases the expression of proteins that modulate the activity of the sodium-potassium ATPase and the amiloridsensitive sodium channel. As a consequence, sodium-reabsorption and secondarily potassium excretion increase.

Synonyms

O⁶-Alkylguanine-DNA Alkyltransferases; AGT;
O⁶-Methylguanine-DNA Methyltransferase; MGMT

Definition

In prokaryotic and eukaryotic cells a group of DNA repair proteins, termed DNA alkyltransferases, have evolved that are capable of repairing DNA by damage reversal. The repair proteins remove methyl, ethyl and even larger alkyl groups from the O6 position of guanine and O4 position of thymine. *E. coli* alkyltransferases can also remove methyl groups from the phosphate in the DNA backbone. Repair occurs in a single-step reaction, by direct alkyl group transfer from DNA to a cysteine residue in the active centre of the repair molecule. Thereby the alkyltransferase becomes inactivated and guanine (and thymine) in the DNA is restored. As the repair enzyme is used up during the repair reaction, alkyltransferase repair proteins are considered as suicide enzymes. Since O⁶-alkylguanine is a highly pro-mutagenic and pro-carcinogenic DNA lesion, alkyltransferases play an important role in cellular defence against alkylating mutagens and carcinogens.

Characteristics

In all organisms, the DNA is subject to harmful damage by alkylation, notably methylation. This occurs by endogenous methylating species such as methyl

adenosine, by metabolic processes and the exposure to environmental carcinogens (e.g. nitrosamines in food and tobacco smoke). Alkylation can occur on 15 sites in DNA. One of the minor alkylation products, O⁶-alkylguanine, amounting to less than 8% of total alkylations, is repaired by O⁶-methylguanine-DNA methyltransferase (MGMT). Since MGMT also removes larger alkyl groups from O6 of guanine, MGMT is also referred to as O⁶-alkylguanine-DNA alkyltransferase (AT or AGT). With the increasing chain length of the alkyl group, the repair reaction becomes less efficient. Alkyltransferases also remove methyl groups from the O⁴-position of thymine. Both O⁶-methylguanine and O⁴-methylthymine are mispairing lesions that give rise to mutations. As already mentioned, methylation of DNA is performed by endogenous cellular reactive species. Therefore, the repair of DNA methylation lesions is presumably the principal role of alkyltransferases. Since O⁴-methylthymine is much less formed than O⁶-methylguanine, its repair by alkyltransferases might be less important than the repair of O⁶-methylguanine.

DNA alkyltransferases belong to the group of DNA repair enzymes that repair DNA by damage reversal. This occurs in a one step reaction without excising the alkylated base from DNA. During the repair reaction, the methyl (alkyl) group from O⁶ of guanine and O⁴ of thymine is transferred to an internal cysteine residue within the active center of the alkyltransferase (Fig. 1). This results in the restoration of guanine and thymine within genomic DNA. Besides methyl groups, larger alkyl groups, which include ethyl, propyl and chloroethyl groups, can also be removed from the O6 position of guanine by alkyltransferases (1). Benzyl groups are also subject to transfer to the enzyme. The efficiency of the transfer reaction decreases with the size of the alkyl adduct. The alkyl group transfer leads to irreversible inactivation of the alkyltransferase and targets it for ►[ubiquitination](#) and proteasome-mediated degradation. Therefore, alkyltransferases are characterized as suicide enzymes. Due to the stoichiometry of the repair reaction, the repair capacity of a cell is determined by the amount of preexisting alkyltransferase molecules and their re-synthesis.

DNA alkyltransferases are ubiquitously distributed in prokaryotic and eukaryotic organisms. Many of them have been cloned; the genes of some of them are summarized in Table 1. Interestingly enough, alkyltransferases have not yet been discovered in plants, and it remains enigmatic whether they exist there or not. In the bacteria *E. coli*, two alkyltransferases were found, Ada and Ogt. Ogt is constitutively expressed at low levels (less than 50 molecules per cell), whereas Ada is normally not expressed but can be induced to high

Alkyltransferases. Figure 1 Methyl group transfer from the O6 position of guanine to MGMT.

expression levels (>1000 molecules per cell) following exposure of the bacteria to methylating agents. This provokes adaptation of cells to simple alkylating agents, and Ada plays a key role in this phenomenon

called adaptive response. During adaptation of *E. coli*, four genes *ada*, *alkA*, *alkB* and *aidB* are upregulated (2). Unlike other DNA alkyltransferases, the Ada protein contains two active sites with reactive cysteine residues at position 69 and 321, respectively. Cysteine 321 binds methyl groups from O⁶-methylguanine and O⁴-methylthymine, whereas cysteine 69 binds methyl groups from the phosphate, thus repairing the methyl phosphotriesters that are formed in higher amounts than the O-methyl purines upon methylation of DNA. Binding of alkyl groups to cysteine 69 leads to a conformational change of the Ada protein. Thereby, Ada is able to bind to the promoter of the *ada* operon and to activate the corresponding genes that are involved in the adaptive response (i.e. *ada* itself, the glycosylase *alkA*, the iron dependent dioxygenase *alkB* and a gene with yet unknown function, *aidB*). The Ogt protein of *E. coli* contains only one active center, which corresponds to Cys 321 of Ada. It does not repair methyl phosphotriester and thus resembles the human MGMT protein.

Human cells contain only one alkyltransferase species. The human MGMT gene is located at the chromosomal position 10q26. It consists of one non-coding and four

Alkyltransferases. Figure 2 Cytotoxicity and mutagenicity induced by O⁶MeG and protection mediated by MGMT.

coding exons with a size of about 145 kb. The gene encodes an mRNA with 866 nucleotides, which codes for a protein containing 207 amino acids and a molecular weight of 24 kDa.

Protection Mediated by MGMT

MGMT protects cells from the cytotoxic, genotoxic (i.e. clastogenic and SCE-inducing), mutagenic and carcinogenic effects of alkylating agents. This is because O⁶MeG lesions in DNA mispair during replication with thymine, which results in GC to AT transition mutations (Fig. 2). These transition mutations are the main cause for the carcinogenic potential of simple alkylating agents. Cytotoxicity and genotoxicity of O⁶MeG requires an additional DNA repair mechanism, termed **mismatch repair**, to operate on O⁶MeG-thymine mispairs (3). Mismatch repair removes thymine from O⁶MeG-T mispairs. Due to the mispairing properties of O⁶MeG, thymine is again inserted, which results in a futile erroneous repair cycle. This may lead to single-strand DNA repair patches that block DNA replication, and finally result in cytotoxic and genotoxic DNA double-strand breaks (4). O⁶MeG is also a powerful apoptotic lesion. Due to the pleiotropic consequences of O⁶MeG, it is evident that

DNA repair by MGMT is most important in the cellular defence against the various effects provoked by simple alkylating agents.

Cells that lack MGMT are highly sensitive to O⁶-alkylating agents. MGMT transfection provokes expression-dependent protection against alkylation-induced cell kill, gene mutations, SCEs and chromosomal aberrations (5). MGMT knockout mice are viable, show a high frequency of spontaneous tumors, and are sensitive to treatment with O⁶-alkylating agents. Conversely, MGMT over-expressing mice show a reduced frequency of tumors in liver, thymus and skin. MGMT over-expression in the skin of mice specifically protects against tumor initiation and tumor progression, without affecting tumor promotion in two-stage skin carcinogenesis experiments.

Regulation of MGMT

MGMT was the first mammalian DNA repair gene shown to be inducible by genotoxic stress. The MGMT promoter represents a classical promoter without TATA and CAAT boxes, but contains a 59 bp enhancer element located at the first exon/intron boundary. Induction of MGMT was shown *in vivo* in the rat liver upon ionising radiation exposure, and *in vitro* upon

exposure of rat hepatocytes to different genotoxins. Besides genotoxic stress, MGMT can also be induced by glucocorticoids that activate the MGMT promoter via a glucocorticoid responsive element. Negative regulation of the MGMT promoter was shown upon transfection with wild-type p53. On the other hand, p53 is required for the induction of the MGMT gene in response to genotoxic stress, at least in the rat and mouse model systems. Whether MGMT gets upregulated in human tissues in response to genotoxic stress is still an open question. With respect to transcription factors, MGMT was also shown to be regulated by AP-1. Posttranslational regulation of MGMT has been demonstrated, which includes phosphorylation and ubiquitination. The latter provokes degradation of the alkylated protein.

An important pathway for the regulation of MGMT gene activity is the promoter methylation (related to the formation of 5-methylcytosine in ►CpG islands). Hypermethylation of the *mgmt* promoter provokes transcriptional silencing. The *mgmt* promoter contains several guanine- and cytosine-rich regions, consisting of ten hexanucleotide motives (CCGCCC). These CpG-islands are positioned between -249 and -103 and between position +107 and +196 of the gene. They represent the CpG methylation hot spots that are responsible for silencing of the promoter. Under non-methylation conditions of the *mgmt* promoter, the transcription start site is flanked by 4 precisely positioned nucleosome-like structures. These structures enable the transcription of the gene. Methylation of the CpG-islands results in heterochromatization, which is accomplished by a re-arrangement and random positioning of the nucleosome. This process of heterochromatization leads to shielding of the transcription start site. MGMT promoter methylation correlates with lack of mRNA expression, loss of MGMT protein and enzymatic repair activity. In contrast to the methylation of the MGMT promoter, methylation of MspI/HpaII sites in the exon-containing regions of the MGMT gene can result in up-regulation of MGMT activity.

Variable Expression of MGMT in Tumors and Normal Tissue

The activity of MGMT has been determined in various human tumor and normal tissue types, including brain, colon, ovary, testis and breast. The studies also showed a high variability in expression notably in tumor tissue (6). High levels of MGMT expression were found in colon cancer, melanoma, pancreatic carcinoma and lung cancer. Brain tumors display, on average, low MGMT expression. Comparison of MGMT activity of tumor versus surrounding normal tissue often shows higher activity in the tumor. For ovarian cancer, MGMT expression correlates with grading and staging.

In gliomas, MGMT activity appears to increase in higher-grade tumors. It also increases during the formation of metastases in skin and lymph nodes.

In normal (non-tumor) tissue, the expression of MGMT is tissue- and cell-type regulated. Thus, in rat and human, liver expresses the highest MGMT level, followed by lung and kidney. The amounts of MGMT protein can also differ between individuals, and in the same individual as a function of time. Thus, a long-term study with peripheral blood mononuclear cells (PBMC) from healthy individuals revealed high inter-individual (7.6-fold) and intra-individual (1.4-fold to 3.5-fold within 42 days) variability of MGMT expression. A comparison on the inter-individual MGMT activity in lung and colon samples also revealed a 4 to 5-fold variation.

MGMT and Resistance to Chemotherapy

Anticancer drugs that belong to the group of methylating and chloroethylating agents target DNA, and act by the formation of O⁶-alkylguanine. Consequently, when MGMT repairs these lesions the killing effect will be counteracted. MGMT must therefore be considered as a very important marker of alkylating drug resistance. In brain tumors, MGMT promoter methylation and activity was shown to correlate with tumor resistance towards chemotherapy with the alkylating drugs carmustine and temozolomide. Since low MGMT activity in tumors appears to correlate with promoter methylation, the methylation status of the MGMT promoter is considered predictive of the success of chemotherapy. Silencing of MGMT by promoter hypermethylation can occur early in human tumorigenesis. It was observed in several tumor types such as lung cancer, bladder cancer, cervix cancer, retinoblastoma and non-small cell lung cancer.

Clinical Applications: MGMT Inhibitors and MGMT Gene Transfer

The finding that MGMT activity has an impact on the sensitivity of tumors led to therapeutic approaches, aimed at inhibiting MGMT activity in the tumor tissue in order to increase the tumor response to chemotherapy. At the same time, strategies were being developed to increase the MGMT level in the normal tissue, in order to protect it against the deleterious side effects of chemotherapy.

A highly specific inhibitor of MGMT, which is in clinical trial, is O⁶-benzylguanine (O⁶-BG). O⁶-BG is a pseudo-substrate for MGMT, which inactivates the protein by direct transfer of the benzyl group to the cysteine of the active site of MGMT. O⁶-BG enhances the cytotoxicity of chloroethylating and methylating agents *in vitro* and *in vivo*. Cancer therapy with the administration of O⁶-BG in combination with alkylating

drugs is currently under investigation. To date, no toxicity of O⁶-BG has been observed in clinical studies, and a 30-fold therapeutic window exists between doses that induced toxicity in animals, and those that depleted MGMT in normal tissue. In pre-clinical studies, it was shown that O⁶-BG, at levels of 1 to 5 μ M, was sufficient to deplete MGMT in tumor cells, and potentiate the cytotoxicity of carmustine and temozolomide. O⁶-BG inhibits human tumor xenograft growth in the nude mouse system. Here, MGMT is depleted within 30 minutes after administration, and depletion is maintained for 6 – 8 hours, after which re-synthesis does occur. Beside O⁶-BG, several other highly efficient MGMT inhibitors have been developed. One of them, O⁶-(4-bromothienyl)guanine, has also currently been proved in a clinical trial.

The protection of stem cells from the mutagenic and cytotoxic potential of chemotherapeutic drugs is highly desired in tumor therapy (7). Myelosuppression is known to be dose limiting during tumor therapy with alkylating agents, which is due to the low amount of MGMT expressed by hematopoietic stem cells. Stem cell toxicity to O⁶-alkylating drugs could be attenuated by *mgmt* gene transfer into blood stem cells. For transduction, mutant variants of *mgmt* are available that harbour a change of amino acids in the active site of the MGMT molecule. This mutant form of MGMT cannot be inhibited by MGMT inhibitors. The two MGMT mutants most commonly used are P140K and G156A. The application of MGMT that is insensitive to O⁶-BG allows the combination of both strategies during cancer therapy: stem cell protection by MGMT gene transfer and inhibition of MGMT in the tumor. In preclinical studies, transduction of hematopoietic progenitor cells with MGMT has been shown to confer protection against O⁶-BG administered together with carmustine or temozolomide. A further promising tool is MGMT inhibitor targeting in order to specifically sensitise the tumor tissue. MGMT gene transfer as a supporting tool in the therapy with O⁶-alkylating drugs is just beginning to enter the clinic field.

Allele

Definition

Allele refers to a DNA sequence variation of a gene at a specific locus (location) on a chromosome. In a diploid cell each gene has two alleles, each occupying the same position (locus) on homologous chromosomes. A sequence with two to several alleles in the population is called a polymorphic sequence.

Allergy

Definition

Allergy is a medical condition in which a normally innocuous environmental antigen provokes an immunological Type I reaction. This is characterised by the production of specific Immunoglobulin E (IgE), raised against the allergen inducing activation of mast cells and release of histamines. In sensitised atopic

individuals, allergen exposure gives rise to the manifestation of hypersensitivity; an exaggerated immune response with various degrees of severity ranging from a mild local inflammation to anaphylactic shock and even death. Most allergies are caused by pollen, dust particles, mould spores, food, latex rubber, insect venom, or drugs.

Alpha-Helix (α -Helix)

Definition

The alpha-helix (α -helix) is one of the different types of protein secondary structure, the other ones being β -pleated sheets and turns. An alpha-helix is a tight helix that results from intrastrand hydrogen bonding of the carboxyl (CO) group of one amino acid, to the amino (NH) group of another amino acid. Seven amino acid residues, (a-g) in the polypeptide chain, form just under two turns of the helix, with the eighth residue (the 'a' residue of the next heptad) falling in line with residue one. The propensity for formation of coiled-coil dimers is associated with the location of hydrophobic residues at the 'a' and 'd' positions, giving a run of hydrophobic residues twisting around the surface of the cylindrical helix and making the long rod structure unstable in the aqueous cytoplasm, unless it twists together with another similar helix (► [Leucine Zipper](#)).

Alternative Splicing

STEFAN STAMM

Institute of Biochemistry, Erlangen, Germany

stefan@stamms-lab.net

Definition

Alternative splicing is the alternate inclusion of ► **exons** or ► **introns** from the primary transcript (► **pre-mRNA**) into mature mRNA. pre-mRNA splicing is a maturation event in which parts of the pre-mRNA sequences are joined and exported into the cytosol as exons and the intervening sequences are removed as introns. The majority of human genes are alternatively spliced, i.e. contain sequences that can be used either as an exon or as an intron. ► **Alternative splicing** creates different mRNA isoforms from a single gene. Mostly, but not always, these mRNA isoforms encode distinct protein products.

Characteristics

Nomenclature

The removal of an exon from pre-mRNA is termed exon skipping. When an exon is included in mRNA, it is referred to as exon inclusion or exon usage. Several basic types of alternative splicing can be distinguished: alternative cassette exons, retained introns, alternative 5' and ► **3' splice sites** and mutually exclusive exons (Fig. 1). Internal alternative cassette exons are the largest group. However, more complicated patterns such as multiple 5' or 3' splice sites, coordinated usage of internal exons and combinations of the basic types are frequently observed. mRNAs that arise from the

same gene but differ in parts of their sequence are called isoforms. Exons that are always included in mRNA and introns that are always excluded from it are termed constitutive exons and introns. If their usage is different between cells or between mRNA isoforms in a single cell, they are termed alternative. Different mRNA isoforms can also be generated by mechanisms other than alternative splicing, such as alternative promoter usage, RNA editing or alternative polyadenylation. Usually, the most abundant or first discovered isoform is termed the "normal" form and less abundant forms are described as "alternative forms". However, there are no clear rules defining which isoform is normal or alternative.

Abundance of Human Alternative Splicing

An average human gene spans 27 kb and contains a mean of 8.8 exons (average size 145 nt) interrupted by introns (average size 3365 nt) and flanked by 5' and 3' untranslated regions of 770 and 300 nt, respectively. To form mRNA, exons are joined by splicing. On average, they comprise only less than 5% of an average pre-mRNA. The completion of the human genome and comparative analysis with ESTs (expressed sequence tags, corresponding to sequences from actual transcripts) has demonstrated that the majority of genes undergo alternative splicing. Most genes located on chromosomes 21 and 22 undergo alternative splicing, and array analysis indicates that 74% of multi-exon genes are alternatively spliced. The number of mRNAs generated by a gene varies. On average, a human gene generates 2–3 transcripts. However, extreme cases exist; the human *neurexin3* gene can potentially form 1728 transcripts due to alternative splicing at four different sites. In *Drosophila*, the Down syndrome cell

Alternative Splicing. Figure 1 Types of alternative exons. Boxes indicate exons, horizontal lines indicate introns. The alternative exons are shaded in gray. Splicing patterns are indicated by solid lines; alternative splicing patterns as dashed lines.

adhesion molecule DSCAM can potentially generate 38016 isoforms due to alternative splicing. This number is larger than the number of genes present in *Drosophila*. Alternative splicing is observed in all tissues, but it is most prevalent in cells of the immune system and in the brain. It is frequently observed that alternative exon usage changes during development or cell differentiation.

Function

The exact function of the majority of alternative splicing events is not clear. Judging by data published in the literature or obtained by comparison of ►expressed sequence tags (EST) with genomic sequences, about 25–35% of alternative exons introduce frameshifts or stop codons into the pre-mRNA. Since approximately 75% of these exons are predicted to be subject to nonsense mediated decay, an estimated 18–25% of transcripts will be switched off by stop codons caused by alternative splicing and nonsense mediated decay. This process has been termed regulated unproductive splicing and translation. It is currently the function of alternative splicing with the most obvious biological consequences. The biological consequences of protein isoform generation caused by alternative splicing are more diverse and mostly not understood. They include: the generation of soluble rather than membrane bound receptors, the inclusion of novel binding sites leading to alternative exon dependent interaction, the formation of enzymes with altered ligand affinities or catalytic properties, the expression of ion channels with altered electrophysiological properties, the formation of short isoforms that often act as dominant negative forms, the formation of isoforms with different intracellular localization and the formation of proteins with altered pharmacological properties.

The best understood example for the physiological role of alternative splicing is the sex-determination of *Drosophila*. A cascade of splicing regulatory proteins – sex-lethal, transformer and transformer-2 – determines the sex specific alternative splicing of the transcription factor doublesex, which results in male or female specific doublesex isoforms. This cascade of splicing decisions ultimately results in sex specific development. Another well-characterized system is programmed cell death (apoptosis). A number of programmed cell death regulatory genes undergo alternative splicing. The resulting protein isoforms are functionally distinct and sometimes even act antagonistically.

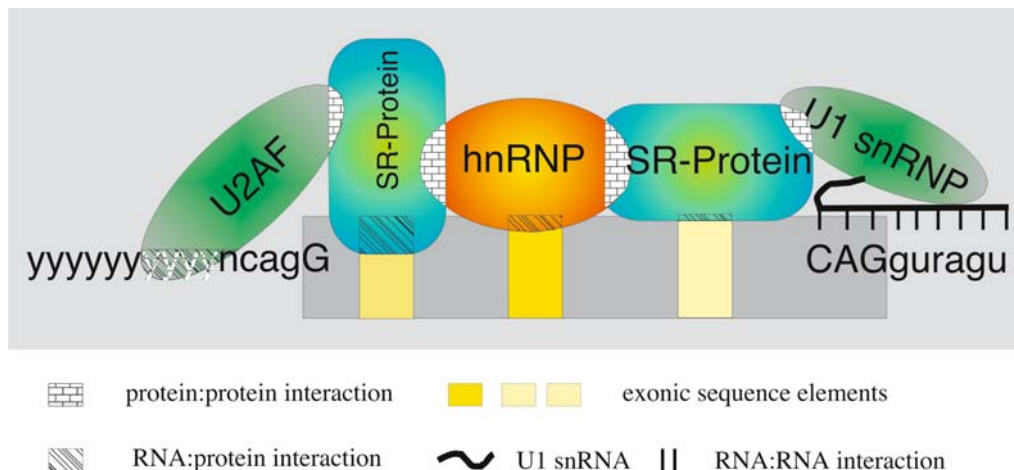

Splice Site Selection

It is still not fully understood how splice sites, especially alternative splice sites, are selected. It is not currently possible to predict accurately which parts of genomic DNA will form exons or alternative exons.

The major problem is that the regulatory sequences that determine an exon, the 5', 3' splice site and the branch point, can deviate significantly from a consensus sequence (3' splice site: $y_{10}ncagG$, ►5' splice site: $CAGgtragt$, branch point: $ynyryay$; intronic sequences: small letters, exonic sequences large letters, invariant nucleotides: bold). 98% of all introns are flanked by invariant GT-AG dinucleotides. The other positions of the splice sites can differ significantly from consensus sequences. 0.76% of introns are flanked by GC-AG dinucleotides and are predominantly alternatively spliced. In a smaller group of introns, these sequences are AT-AC. Alternative exons are often characterized by splice sites that deviate more strongly from the consensus. Since their mutation to the consensus leads to constitutive exons they are referred to as weak splice sites.

Enhancer/Silencer

Since splice sites are so poorly defined, additional sequence elements in the exons (ESE: ►exonic sequence element) or in introns in close proximity (ISE: ►intronic sequence element) are needed for proper recognition. Depending on whether they promote or inhibit the inclusion of an exon, they are named enhancers or silencers (ESE: exonic sequence enhancer, ISE: intronic sequence enhancer). The elements located on the RNA are called cis-elements. They are short (5–8 nt) and can be only described by a loose consensus sequence. Since most exonic elements are in coding regions of genes, flexibility in sequence composition minimizes interference with coding requirements. This ensures that the usage of amino acids is not determined by exonic splicing regulatory sequence elements. Exonic and intronic sequence elements bind to protein factors that are named ►trans-acting factors. The majority of these trans-acting factors belongs to two groups of proteins, ►SR-proteins and hnRNPs. These protein groups contain RNA binding domains and various protein:protein interaction domains, which allow the interaction between individual members of these protein families. As a result, protein-networks on the pre-mRNA can form around exons or introns and aid in their recognition by binding to components of the spliceosome (Fig. 2). The individual interactions between cis and trans-elements involved in splice site selection are weak. Only through several such interactions forming either across an intron or an exon, recognition is achieved. The relative concentration of trans-acting factors varies between cell types and tissues as well as during development. This leads to cell type-specific or developmental stage-specific regulation of alternative exons depending on which proteins assemble on the exon. Due to this combinatorial control, a large number of alternative exons can be regulated by a limited number of regulatory proteins.

Alternative Splicing. Figure 2 Elements responsible for recognizing an exon. The exon is indicated as a gray box. The consensus sequences for the 3' and 5' splice sites are indicated. Capital letters are exonic, small letters intronic. Exonic elements are shown as yellow boxes. Two major groups of proteins bind to exonic elements: SR-proteins and hnRNPs (binding regions hatched). These proteins can interact with each other via several protein:protein interaction domains (region marked with bricks). The 3' splice site is recognized by U2AF (U2 auxiliary factor) that can bind to SR-proteins of exonic enhancer complexes. Components of the constitutive splicing machinery, e.g. U1 snRNP can bind to these proteins as well and define the 5' splice site by base pairing (short vertical lines) between U1 snRNA (thick line) and the 5' splice site. The individual interactions are weak, however in combination they are strong enough to define an exon with high fidelity.

Regulation by External Signals

Alternative splice site selection is often controlled by extracellular factors, e.g. cellular stress, neuronal activity, hormonal stimulation of a receptor and developmental state. Studies performed in animals demonstrated that alternative exon usage changes after physiological stimulation, such as stress evoked by forced swimming or pavlovian fear memory. This indicates that the regulation of alternative exon usage represents a normal adaptation of the cell to environmental changes.

Connection to Other Cellular Processes

Several proteins implicated in alternative splicing also fulfill a role in other aspects of RNA metabolism, such as nuclear export, RNA ►polyadenylation, RNA editing or cytoplasmic mRNA stability. Several proteins regulating alternative splice sites bind to RNA polymerase II or transcription factors. As a result, alternative splice site selection is coupled to transcription and other steps of pre-mRNA processing.

Clinical Relevance

Alternative Splicing in Disease

The splicing process has to be very precise, as the addition or removal of a single nucleotide will alter the reading frame of the mRNA. Normally this process

occurs with high fidelity, meaning that almost no errors are made. Errors in splice site selection can be detrimental for cells and alternative missplicing has been shown to be the cause or consequence of an increasing number of human diseases. Diseases can be caused by mutation in regulatory ►cis elements, and by altering the concentration or structure of trans-acting factors. Mutations in splice sites are the most frequent cause of disease. These mutations can cause exon skipping, intron retention or activation of cryptic 3' or 5' splice sites near an exon. Each of these events changes the protein structure, often causing frameshifts and non-functional mRNAs or proteins. The next class of mutations affects enhancer or silencer regions located in an exon or in the nearby intronic regions. Mutations in exons are often silent and do not change the coding properties of an mRNA. However, since they affect a regulatory pre-mRNA processing element, they induce abnormal splicing. As a result, the mRNA and most frequently the protein structures are changed. Since most exons contain regulatory elements, a significant fraction of disease-causing exonic mutations are probably splicing mutations (Table 1). Mutations in trans-acting factors are far less frequent and complete loss of essential splicing factor function is generally lethal. One exception is retinitis pigmentosa, which is caused by alterations in the splicing factor PRPF31.

Alternative Splicing. Table 1 Some alternative missplicing events associated with human disease caused by mutations in exonic enhancers

Disease	Gene
Acute intermittent porphyria	Porphobilinogen deaminase
Beta-Thalassemia	Beta-globin
Breast and ovarian cancer	BRCA1

Neurofibromatosis type I	NF-1
Occipital horn syndrome	ATP7A
Sandhoff disease	Beta-hexaminidase
Spinal muscular atrophy	SMN2
Tyrosinemia, Type I	Fumarylacetoacetate hydrolase

Frequently, alternative splicing patterns are changed in diseases without obvious mutations, indicating alternations in trans-acting factors (Table 2). The best known examples are changes in splicing patterns of many genes associated with neoplasia and metastasis. In models of mouse mammary gland tumorigenesis the ratio of various SR-proteins changes and correlates with altered splicing patterns, e.g. the use of variable exons of the hyaluronic acid receptor CD44. Changes in trans-acting factors can be caused by indirect effects. Myotonic dystrophy type I is caused by a CTG expansion in the 3' untranslated region of the myotonic dystrophy kinase. These additional repeats sequester CUG binding proteins that normally regulate alternative splicing of other pre-mRNAs (cardiac troponin T, insulin receptor, muscle-specific chloride channel and myotubularin-related), which causes aberrant splicing of these pre-mRNAs resulting in the disease. Finally, alleles carrying mutations in regulatory elements of the pre-mRNA can have a different phenotype depending on the genetic

Alternative Splicing. Table 2 Some human diseases associated with changes in the ratios of alternative spliced products

Disease	Gene

Wilms tumor	WT1

background, indicating that alternative splicing can be a modifier of disease severity.

Therapeutic Approaches

Different therapeutic approaches have been tested in models of diseases caused by missplicing. These include chemically modified oligonucleotides, ribozymes, expression of trans-acting regulatory factors and application of low molecular weight drugs. Oligonucleotides have been used to correct missplicing seen in beta-thalassemia, Duchenne muscular dystrophy and acetylcholine esterase missplicing. Several of these agents are now undergoing clinical trials.

finckh@labmed.de

Synonyms

AD; Alzheimer dementia; Senile dementia/Alzheimer's type (SDAT)

Definition

Alzheimer's disease (AD) is defined by a clinical history of dementia and a characteristic pattern of

histopathological changes in the brain. These changes include ►senile plaques (SP), ►neurofibrillary tangles (NFT), neuropil threads (NT), and neurodegeneration. Current criteria for the clinical diagnosis of AD were defined by the National Institute of Neurologic and Communicative disorders and Stroke – Alzheimer's Disease and Related Disorders Associations (NINCDS-ADRDA) (1). Criteria for a neuropathology diagnosis of AD were defined by the Consortium to Establish a Registry for Alzheimer's Disease (CERAD) (2). Neuropathological stages (I–VI) are based on the frequency and distribution pattern of NFT and NT (3). A definite diagnosis of AD requires fulfillment of the clinical criteria of probable AD and histopathological evidence (1, 2). Dementia is defined by the loss of cognitive abilities. There exist two types of AD, common sporadic and mostly late-onset AD (►LOAD) and autosomal dominant familial AD (►FAD) with mostly early onset (Table 1).

Characteristics

AD is characterized by progressive dementia with early (<65 years, EOAD) or late onset (>64 years). The duration of clinical disease may exceed 10 years. Clinical manifestation of dementia is preceded by an accumulation of SP, NFTs and NT over many years. The major component of SP consists of extracellularly aggregated β -amyloid ($A\beta$) (►Beta-Amyloid (β -Amyloid)), i.e. a fragment of mostly 40 or 42 ($A\beta_{40}$; $A\beta_{42}$) residues of the amyloid precursor protein (►APP). NFTs and NTs are formed by helical filaments of abnormally phosphorylated microtubule-associated tau proteins. Neuron loss in AD is typically observed first in the entorhinal cortex affecting its afferent and efferent connections with the hippocampus. It is most likely this "isolation" of the hippocampus that causes the characteristic loss of memory functions, an early clinical sign of AD. To date, there exists no specific biomarker that allows a definite diagnosis of common AD before death. Clinical diagnosis of AD based on neuropsychological testing, brain imaging and the exclusion of other known dementing conditions reaches an accuracy of 85–95%.

Epidemiology and Risk Factors

AD is the most frequent cause of dementia (54–74% of all dementias) of the elderly with an ageing-dependent exponentially increasing frequency (4, 5). Less than 5% of sporadic AD arises before 60 years of age. In the groups between 65 and 85 years of age, prevalence and incidence of AD double every 4.5–5 years (Table 2). The higher prevalence of AD in women compared to men may be due to the higher life expectancy of women. Furthermore, there may be an increased risk of AD in association with overweight in women. Proven

65+	4,4		~ 1	

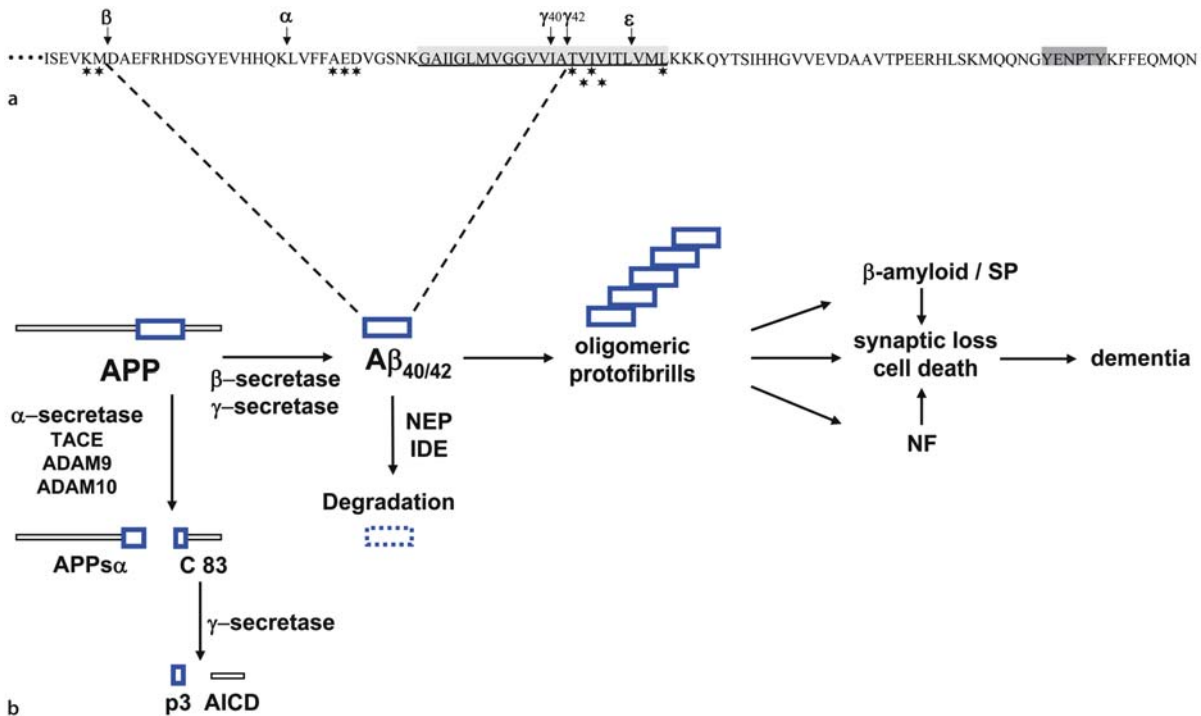

risk factors for sporadic AD are age, education and the $\epsilon 4$ allele of the **▶gene** for apolipoprotein E (Apo E; **▶APOE**) (6, 7, 8). The etiology of sporadic AD is therefore considered to be multifactorial. Mutations causative for FAD, rare monogenic forms of AD, have been described in the genes for APP (**▶APP**), presenilin 1 (**▶PS1**; **▶PSEN1**), and presenilin 2 (**▶PS2**; **▶PSEN2**). FAD contributes to less than 1% of all AD. Typical histopathological features of AD are found in a high proportion of 30–40 year old subjects with trisomy 21 (Down syndrome) or partial trisomy 21 including the chromosomal region harboring *APP* (21q21).

Genetics

Twin and family studies suggest a high proportion of AD is attributable to genetic factors. The relative risk (RR) for AD in first-degree relatives of AD is elevated (RR = 2–6). 50–60% of Caucasian AD patients and 20–30% of non-demented age-matched controls carry one or two *APOE* $\epsilon 4$ alleles. In the population aged 55+, the average life time risk for AD of 8% in males and 20% in females increases to 19% and 33%, respectively in subjects carrying one or two *APOE* $\epsilon 4$ alleles.

10–20% of all AD is attributable to *APOE* $\epsilon 4$. The frequency of the three common alleles of *APOE* ($\epsilon 2$, $\epsilon 3$, $\epsilon 4$) varies between populations. $\epsilon 4$ is considered to represent the archetypical form. $\epsilon 3$ being the most prevalent allele in all populations studied is considered the normal allele, whereas $\epsilon 2$ confers protection and $\epsilon 4$ risk with respect to AD. Compared to $\epsilon 3$ homozygotes, the odds ratio (OR) for AD in Caucasians reaches values of 1.8–3 in $\epsilon 4$ heterozygotes, 6–15 in $\epsilon 4$ homozygotes and ~ 0.5 in $\epsilon 4$ negative carriers of the $\epsilon 2$ allele. The odds ratios may differ with ethnic or geographic background, with $\epsilon 4$ being the risk allele in all populations studied. Since a substantial proportion of elderly non-demented subjects carries *APOE* $\epsilon 4$ and a significant proportion of sporadic AD patients does not carry $\epsilon 4$ alleles, risk alleles of other genes are assumed to exist. To date, no other gene has been shown to be associated unambiguously with sporadic AD.

FAD due to mutations in *APP*, *PSEN1* or *PSEN2* is inherited as an autosomal dominant disorder. To date, databases list 133 different pathogenic mutations in *PSEN1*, 16 in *APP*, and seven in *PSEN2*. No nonsense or loss of function mutation has been found in these three genes. All mutations found to date – mostly missense mutations – are associated with the expression of altered proteins. In patients with suspected FAD based on a positive family history of EOAD and screened for mutations in the three genes, the mutation detection rate is 46–71%. This suggests that there exist yet unknown FAD genes. The functions of APP, PS1 and PS2 are largely unknown. Structural and experimental data suggest multifunctional roles for these proteins in signal transduction, protein processing, apoptosis and calcium homeostasis and as cell surface molecules. APP is a single-pass transmembrane (TM) protein. Structural modeling of the presenilins, highly homologous members of a protein family functionally related to signal peptide peptidases (SPP), predicts eight TM domains. *app* knockout mice (*app*^{-/-}) are fertile, display reduced synaptic plasticity and develop hippocampal gliosis accompanied by

Alzheimer's Disease. Figure 1 (a) Amino acid sequence of the C-terminal part of APP flanking the transmembrane (TM) domain (gray, underlined) and the major secretase cleavage sites β , α , γ_{40} , γ_{42} , and ϵ . The γ -secretase complex cleaves at variable sites between residues 39 and 50 downstream from the β -site. The major cleavage products $A\beta_{40}$ and $A\beta_{42}$ are usually secreted and may aggregate (see part b). The intracellular C-terminal γ -secretase cleavage product of APP, AICD (APP intracellular domain) may act as a transcription factor by interacting via a YENPTY motif (dark gray) with Fe65 and Tip60. Positions with known pathogenic mutations are labeled with an asterisk. (b) Alternative processing of the C-terminal part of APP via non-amyloidogenic α -secretase or amyloidogenic β -secretase pathways. α -Secretase cleaves APP between the β - and γ -sites thus liberating soluble neurotrophic APPs α . After cleavage of the remaining TM-spanning C-terminal fragment C 83 by γ -secretase, non-amyloidogenic peptide p3 and AICD are released. Candidates for α -secretase are TACE (tumor necrosis factor- α converting enzyme; synonym: ADAM17), ADAM9, and ADAM10. Members of the ADAM family share common features like a secretory signal peptide sequence, a disintegrin and a metalloproteinase domain. $A\beta_{42}$, the major amyloidogenic product of consecutive cleavages of APP by β - and γ -secretases, may be degraded by neprilysin (NEP) or insulin degrading enzyme (IDE), a neutral metalloproteinase. Non-degraded $A\beta$ may form submicroscopic oligomeric protofibrils with potentially neurotoxic features. Activation of microglia by these protofibrils may also mediate neurotoxic inflammatory processes. Early in $A\beta$ -associated neuronal degeneration there is an accumulation of neurofibrils (NF) consisting of abnormally phosphorylated tau protein. NFs may accelerate cell death. $A\beta$ protofibrils further aggregate and form the major component of senile plaques (SP). Dementia is associated with synaptic loss, axonal degeneration and cell death.

learning deficiencies. *psen1*^{-/-} embryos display lethal malformations of the skeletal system and CNS. *psen2*^{-/-} mice develop a minor pulmonary disorder and are fertile. *psen1*^{-/-} plus *psen2*^{-/-} embryos resemble the phenotype known from notch 1 deficiency. Presenilins are essential components of the γ -secretase complex. There is complete loss of γ -secretase activity in *psen1*^{-/-} *psen2*^{-/-} cell lines. The γ -secretase complex cleaves APP within its TM domain thus liberating $A\beta$. Mutations in APP cluster in the TM domain downstream of the major γ -secretase cleavage sites and close to the other secretase cleavage sites (Fig. 1a). Mutations

in *PSEN1* are distributed over a broad range of codons with some preference for residues located in TM domains and the first hydrophilic loop (HL1). Mutations in *PSEN2* are very rare and are associated with a high phenotype variability.

Trisomy 21, APOE $\epsilon 4$ and mutations in any of the three known FAD genes are all associated with an abnormally elevated ratio of $A\beta_{42}/A\beta_{40}$ in tissue or supernatant of primary or transgenic cell lines (for a more detailed review on the molecules involved in AD see ref. 8) (Table 3). Compared to $A\beta_{40}$, $A\beta_{42}$ is highly amyloidogenic. Thus, genetic data point to a central

Alzheimer's Disease. Table 3 Genes involved in AD-related pathology

Gene	Protein	Locus	disorder	risk factor	Presumed pathomechanism

role of APP processing in the pathogenesis of AD. Experimental data suggest presenilin is the catalytic subunit of the γ -secretase complex. To date it is not understood, how the high diversity of mutations in the presenilins and in *APP* is associated with a similarly altered or elevated γ -secretase activity causing the abnormally elevated ratio of $A\beta_{42}/A\beta_{40}$.

Cellular and Molecular Regulation

APP is processed alternatively by non-amyloidogenic α -secretase or amyloidogenic β -/ γ -secretase pathways. Candidate molecules for physiological α -secretase are TACE, ADAM9, and ADAM10 (Fig. 1). α -Secretase cleaves APP between the sites for β - and γ -secretase thus generating neurotrophic APPs α and preventing the generation of $A\beta$. The initial and rate limiting step of amyloidogenic APP processing is performed by β -secretase, the β -site APP cleaving enzyme (BACE), which cleaves APP at the amino terminus of the $A\beta$ domain. The cleaved ectodomain is secreted (APPs β). The remaining TM-spanning part of APP is further processed by the γ -secretase complex. Known components of this protease complex are presenilin, nicastrin, \blacktriangleright PEN-2, and \blacktriangleright APH-1 (Fig. 2). Experimental missense mutations in nicastrin are associated with an elevated production of $A\beta$, whereas the deletion of one of its domains abolished $A\beta$ generation. The membrane-associated γ -secretase cleavage of APP is called regulated intramembranous proteolysis (RIP). This cleavage is not site specific, i.e. it produces $A\beta$ peptides ranging in size from 39–49 residues with the major forms being $A\beta_{40}$ and $A\beta_{42}$. γ -Secretase activity is modulated either directly or indirectly by glycogen synthase kinase 3 (GSK3). $A\beta$ is secreted; whereas the C-terminal part of APP called APP intracellular domain (AICD) may have intracellular signaling functions and act as a transcription factor. AICD interacts with Fe65 and Tip60 *via* the YENPTY motif, which is located close to its C-terminus. Additional interaction partners of AICD with a yet unknown biological function are known.

$A\beta$, particularly $A\beta_{42}$ may form soluble protofibrils that aggregate to insoluble oligomers. Most probably these

are submicroscopic molecular forms that mediate the neurotoxic effects of $A\beta$ associated with neurite dystrophy, synaptic loss and activation of astrocytes and microglia. SPs, one of the histopathological hallmarks of AD, have a diameter of 5–50 μ m and contain a dense core of fibrillary $A\beta$. Experimental data from transgenic mice suggest that $A\beta$ is involved in the induction of NFT formation in the neurons affected by loss of synaptic connections. This suggests that submicroscopic forms of $A\beta$ may induce neurodegeneration recognizable by NFTs before the formation of microscopically visible $A\beta$ plaques. NFTs are formed by abnormally phosphorylated paired helical filaments of tau, a microtubule-associated protein. Mutations in the gene for tau (*MAPT*) are known in autosomal dominant frontotemporal dementia linked to chromosome 17 (FTDP-17) but not in FAD.

Clinical Relevance

AD is a severe, progressing dementing disease leading in its final stages to complete helplessness and immobilization. The consequences of AD are devastating for the patients affected as well as for their families. Due to its very high and continuously increasing frequency, AD will be one of the major causes of death in the near future and one of the major economic and psychosocial burdens of general health care – if no significant progress is achieved in treatment or prevention. Within the next 50 years the incidence of AD will reach the level of that of cancer, the second most prevalent cause of death. Compared to non-demented age-matched subjects mortality in AD is more than doubled. The median survival time after first contact of a patient with a physician due to signs of dementia ranges from 3.1–3.5 years. Major causes of death in AD are secondary to immobilization or malnutrition and may depend on nursing quality. To date, there exists no curative treatment for AD.

Therapy

In AD, neuron loss leads to a cholinergic deficit, which is associated with dementia. Pharmacological inhibitors of acetylcholine esterase (\blacktriangleright ACH E) may be used to

Alzheimer's Disease. Figure 2 Molecular components and mode of activation of the γ -secretase complex. In the inactive complex, presenilin holoprotein is stabilized by APh-1 and nicastrin. Interaction with PEN-2 leads to cleavage of presenilin into its C- and N-terminal fragments (PS-CTF, PS-NTF) and activation of the γ -secretase complex. Transmembrane (TM) domains of APh-1, nicastrin, presenilin and PEN-2 are represented by cylindrical stretches. The locations of the catalytically essential aspartate residues of PS-NTF and PS-CTF are indicated by asterisks. The scheme suggests that the γ -secretase complex may cleave APP (APP-CTF) within its TM domain only after a preceding cleavage of APP by BACE (β -secretase) or an α -secretase (Fig. 1). If cleavage by BACE was the preceding step, γ -secretase may release amyloidogenic A β . The remaining fragment AICD (APP intracellular domain) may act as a transcription factor. Experimental data show a higher molecular weight of the γ -secretase complex than suggested by the scheme and indicate the presence of dimeric presenilin molecules in the complex, which has an overall unknown topology. Interestingly, none of the known pathogenic presenilin mutations is associated with a loss of γ -secretase activity. Functional or structural disturbance of presenilin dimers by presenilin missense mutations may be a mechanism underlying the dominant mode of action of these mutations.

reduce the physiological degradation of acetylcholine. In mild to moderate AD, progression of dementia may be delayed up to 1–2 years by second-generation inhibitors of **AChE** (donepezil, rivastigmine, galantamine) in a dose-dependent manner. 10–15% of the patients however, are non-responders. Neuron loss or malfunction may be related to tonic or excitotoxic NMDA receptor activation by its ligand, the neurotransmitter glutamate. Memantine, a moderate affinity NMDA receptor antagonist has been shown in clinical studies to slow down disease progression in moderate to severe AD. Possibly due to their different modes of action, i.e. cholinomimetic activity in AChE inhibitors and neuroprotection by memantine, the combined use of both drugs has been successful in a clinical trial. AChE inhibitors and memantine are both used for symptomatic treatment of AD and are of transient benefit. Other drugs of possible benefit in symptomatic treatment may be cholesterol lowering and nonsteroidal anti-inflammatory drugs. Intensive research activities are directed towards disease-modifying, curative or

preventive drugs. Promising strategies include active or passive immunization against A β or pharmacological inhibition of β - or γ -secretase. Preclinical and clinical studies are under way and there is hope that treatment of AD may be improved significantly in the near future.

Genetic Counseling

Molecular genetic diagnostics in suspected FAD requires careful genetic counseling. The detection of a fully penetrant FAD-causing mutation in a patient predicts a 50% recurrence risk in each of the patient's children and a 25% risk in grandchildren. This means that young adults (the children of FAD patients) may ask for presymptomatic testing, thereby possibly getting knowledge of a 50% risk in their children. Attitudes towards presymptomatic testing may change if there is prophylactic or preventive treatment available. Genotyping of *APOE* is not recommended in routine diagnostics, neither for patients nor presymptomatically since it does not allow an unambiguous

prognosis. Sometimes, *APOE* genotyping is considered for purposes of differential diagnostics in patients with dementia. The genotype of the patient may have an impact on the patient's relatives since e.g. all children of an *APOE* $\epsilon 4/\epsilon 4$ homozygous patient will be *APOE* $\epsilon 4$ positive. Therefore, prior to molecular genetic testing, genetic counseling including possible concerns of the patient's relatives is required.

Amadori Rearrangement

Definition

Amadori rearrangement is the isomerization of a double bond into a ketose derivative, by which a more stable structure is generated. Oxidative deamination of the ϵ -group of lysyl residues leads to the generation of an aldehyde group, which with amino groups of hydroxy-lysyl of an adjacent chain, can react to a Schiff-base.

AME

► Apparent Mineralocorticoid Excess

AMH / MIS

Definition

AMH/MIS stands for anti-müllerian hormone/müllerian inhibiting substance. It is a member of the TGF- β superfamily that regulates regression of the Müllerian duct in males.

► Receptor Serine/Threonine Kinase

AMHR-II

Definition

Anti-müllerian hormone Type II receptor.

► Receptor Serine/Threonine Kinase

Amide Bonds

Definition

An amide bond is a chemical bond formed between two molecules when the carboxyl group of one molecule

reacts with the amino group of the other molecule, releasing a water molecule (H_2O).

►PNA Chips

Amide-Linkage

Definition

Amide-linkage (N-acylation) characterises a stable amide-bond between the COOH -group of the fatty acid and $\alpha\text{-NH}_2$ -group, usually a glycine residue at the N-terminus of proteins. An amide-type linkage can be experimentally distinguished from a thioester-bond, by treatment of the acylated protein with hydroxylamine. This compound cleaves ester-linked fatty acids from the protein, whereas amide-linked fatty acids are not affected.

Definition

Amino acids are the building blocks of all peptides and proteins and determine many of their important properties. This paper describes the physicochemical properties of amino acids and tries to shed light on their role as the constituents of living cells, the proteins.

α -Amino acids are molecules that possess an amino group ($-\text{NH}_2$) and a carboxylic group ($-\text{COOH}$) attached to the same tetrahedral carbon atom, called an α -carbon (Fig. 1a). The α -amino acids differ from one another by distinct R-groups (referred to as side chains) that are attached to the same α -carbon. Table 1 gives the structures and names of the 20 most common amino acids found in proteins. Those marked 'e' in Table 1 are the essential amino acids, which are not

available to animals by biosynthesis and must therefore be provided in the diet.

Characteristics

In aqueous solution at neutral pH the carboxylic group of amino acids is dissociated into a carboxylate and a proton ($-\text{COOH} \rightarrow -\text{COO}^- + \text{H}^+$) and the amino group, which functions as a base, is protonated ($-\text{NH}_2 + \text{H}^+ \rightarrow -\text{NH}_3^+$). Therefore, the predominant form of amino acids consists of a carboxylate anion ($-\text{COO}^-$) and an ammonium cation ($-\text{NH}_3^+$) and is termed the dipolar ion form or the zwitterionic form, as shown in Fig. 1b.

The physical properties of amino acids are consistent with their dipolar ionic structure: They are non-volatile crystalline solids, which melt or decompose at fairly high temperatures, in contrast to amines and carboxylic acids. Amino acids possess high dielectric constants and high dipole moment, reflecting the discrete separation of positive and negative charges in their dipolar ionic forms. The high dipole moment accounts for the fact that amino acids are insoluble in non-polar solvents such as benzene, petroleum-ether and ether, but are appreciably soluble in water.

Classification of Amino Acids

The side chain (R group) of amino acids determines their chemical and physical characteristics. There are two broad classes of amino acids, categorized according to the hydrophilic or hydrophobic nature of the side-chain. Hydrophobic chemical groups tend to be dissolved in non-polar organic solvents, whereas hydrophilic groups tend to be dissolved more readily in water.

Knowledge of the hydrophobic or hydrophilic character of the amino acid side chains may be used to identify the chemical type of a given protein or a specific region of a protein. The hydrophobic or hydrophilic character of a solute is referred to as ►hydrophathy. The hydrophobic character of a protein segment is defined by a sum of the hydrophobic contributions of all of its constituent amino acids. The relative polarity of each of the 20 common amino acids has been estimated experimentally by several methods, usually by measuring the free energy change induced

by moving a given amino acid residue from water into a hydrophobic solvent or into gas. Table 2 presents the hydropathy scale of the common amino acids. It was obtained by measuring the free energy change of model compounds transferred from water into gas. In these compounds the α -carbon of the corresponding amino acid has been replaced by hydrogen (1).

A more specific classification of amino acids takes into consideration the chemical nature of their side chains, as outlined in Fig. 2. Group 1 includes amino acids with aliphatic side-chains (Ile, Val, Leu, Ala, Gly), group 2, aromatic side-chains (Phe, Trp, Tyr), group 3, basic (positively-charged) side-chains (Lys, Arg, His), group 4, acidic (negatively-charged) side-chains or their

Asp	Acetic acid	+42
Arg	Methyl guanidine	+79

^a The standard free energy for transfer of model compounds for amino acids from water at 25°C and pH 7 to the gas phase (1)

corresponding amides (Asp, Glu, Asn, Gln) and group 5, aliphatic hydroxyl side chains (Ser, Thr). The sixth group consists of proline alone, since it has a secondary amine group, which affects the protein backbone conformation in a unique way and the seventh group consists of Cys and Met, which have sulfur-containing side chains.

A disulfide bond that cross-links between two Cys residues is found in many proteins, particularly extracellular proteins such as insulin, immunoglobulins and antibodies. A disulfide bond is created by oxidation of the thiol (-SH) groups of two Cys residues to form the oxidized -S-S- bond. Disulfide bonds have an important role in protein-structure stabilization.

Rare Amino acids and Non-protein Amino Acids

In addition to the 20 common amino acids, proteins may contain non-common residues formed as a result of post-translational modifications of the common

**Amino Acids: Physicochemical Properties.**

Figure 2 Classification of the 20 common amino acids found in proteins, according to the chemical nature of their side-chains.

residues in the protein. Examples are 4-hydroxyproline and 5-hydroxylysine (Fig. 3), which are hydroxy-derivatives of proline and lysine found in the fibrous protein collagen and in some plant proteins. The hydroxyl groups of Tyr and Ser residues of proteins can undergo phosphorylation (Fig. 3), particularly in signaling pathways and controlling metabolic cycles in the cell. Methylation, acetylation and glycosylation can also occur. Desmosine (Fig. 3), found in the fibrous protein elastin, is a derivative of four lysine residues that form a substituted pyridine ring.

In addition to the amino acids that make up proteins, some 300 special amino acids have been found, particularly in plant cells (2). Many of these are β -, γ - or δ -amino acids (Fig. 4), in contradistinction to the α -amino acids, which are the building blocks of proteins. Some non-protein amino acids occur in the (D)-configuration, such as (D)-glutamic acid, found in the cell walls of bacteria.

Amino Acids: Physicochemical Properties.

Figure 3 Examples of modified amino acids found in proteins.

Electrostatic Characteristics of Amino Acids

The electrostatic characteristics of the various amino acids are determined by the charge present on the α -amino, the α -carboxy or the ionizable side-chain of the amino acid. The overall charge is determined by the ionization constant of these ionizable groups, as well as by the pH of the aqueous medium in which the amino acids function.

Dissociation of α -ammonium and α -carboxylic groups of an amino acid is shown in equations (1, 2):

Changes in the pH of a solution of an amino acid are accompanied by changes in the electric charge pattern of the amino acid, because of different ionization states. When the pH of a solution is equivalent to the isoelectric point (pI) of an amino acid, the net charge of the amino acid is zero.

The acidity constant of an acid (K_a) is equal to the apparent equilibrium constant of the dissociation reaction of the acid (K'_{eq}). Hence, in the dissociation reaction described in equation (1), K_a is given by

$$K'_{\text{eq}} = K_a({}^\alpha\text{COOH}) = \frac{[\text{H}^+][{}^+\text{H}_3\text{NCHR}\text{COO}^-]}{[{}^+\text{H}_3\text{NCHR}\text{COOH}]}$$

The larger the K_a the stronger the acid. $\text{p}K_a$ equals $-\log(K_a)$, thus the smaller the $\text{p}K_a$ the stronger the acid. Experimentally, it is rather easy to determine the $\text{p}K_a$ values of the various ionizable groups of amino acids by potentiometric titration of these groups with strong base or acid. The $\text{p}K_a$ value of the α -carboxyl group of amino acids is in the range of 1.8–2.4, and the $\text{p}K_a$ of the α -ammonium group is 9.0–11.0. Side chains of amino acids with ionizable groups have different acid strengths, as listed in Table 3.

Optical Characteristics and Stereochemistry of Amino Acids

With the exception of glycine, all amino acids that are obtained by acid or enzymatic hydrolysis of proteins show optical activity, i.e., they can rotate the plane of polarized light. Stereochemical studies of these naturally-occurring amino acids have shown that all have the same configuration about the α -carbon, which is the same as that of L-(–)-glyceraldehyde (Fig. 5). By convention, the two stereoisomers of glyceraldehyde are designated L and D. All stereoisomers of amino acids that are related to L-glyceraldehyde are designated L, whereas those related to D-glyceraldehyde are designated D, regardless of the direction of rotation of plane-polarized light produced by the isomers.

Amino acids with two **asymmetric carbon atoms** (for example isoleucine and threonine) have four stereoisomers. When more than one asymmetric carbon atom exists, it is the configuration about the α -carbon atom that is the basis for configuration assignment.

The **specific rotation**, $[\alpha]^{25}_D$ of some (L)- and (D)-amino acids in water (3) is given in Table 4. It is clear that at pH 7.0 some (L)-amino acids are dextrorotatory (i.e., their rotation of polarized light is positive) and some are levorotatory (negative rotation). Dextrorotatory compounds are designated (+), and levorotatory

Amino Acids: Physicochemical Properties. Figure 4 Examples of non-protein amino acids.

compounds by (-). According to the *RS* system of nomenclature, (rules for classifying the configuration as *R* or *S* (4)), most of the (L)-amino acids have an *S* configuration since the side chain nearly always has lower priority than COOH.

Although only (L)-amino acids are present in proteins, some (D)-amino acids are found in living cells in the cell walls of certain microorganisms and as part of peptide antibiotics such as gramicidin and actinomycin D.

Absorption Spectra of Amino Acids

None of the 20 amino acids found in proteins absorbs light in the visible range; however, amino acids with aromatic side chains absorb light in the ultraviolet

range, tryptophan ($\lambda_{\text{max}} = 279 \text{ nm}$ for the zwitterionic form in water; ►extinction coefficient (ϵ) of $5,580 \text{ M}^{-1} \text{ cm}^{-1}$), tyrosine ($\lambda_{\text{max}} = 275 \text{ nm}$, $\epsilon = 1,405$) and phenylalanine ($\lambda_{\text{max}} = 258 \text{ nm}$, $\epsilon = 195$) (5). Since most proteins contain tyrosine residues, measurement of absorption at 275 nm is a rapid means of estimating the protein content in a solution when the Tyr content is known. Phenylalanine generally contributes little to the absorbance properties of proteins. All amino acids absorb in the far UV range ($<220 \text{ nm}$) owing to their amide bond, peptide bond, and carboxylic groups. Tryptophan fluorescence is very easy to detect and is sensitive to solvent polarity. These properties make tryptophan a useful built-in probe for studying

polypeptide structure and interactions. In proteins, the emission maxima of fluorescence of Trp residues (λ_{em}) vary widely in the range of 308–350 nm, with an excitation wavelength (λ_{ex}) of 279 nm (5).

Chemical Reactions for Amino Acid Identification

The ninhydrin reaction with the α -amino group of amino acids (Fig. 6) is widely used to estimate amino acids quantitatively in very small amounts. Heating an amino acid with two equivalents of ninhydrin yields a blue-colored compound, which is very easy to detect by light absorption.

Dansyl chloride, dabsyl chloride and 1-fluoro-2,4-dinitrobenzene (Fig. 6) react with the amino group of amino acids, to yield derivatives that are stable to hydrolysis. The non-fluorescent compound fluorescamine (Fig. 6) readily reacts with primary amine groups of amino acids, yielding a strongly fluorescent derivative that permits detection of nanogram quantities of amino acids.

Analysis of Amino Acid Content and Determination of Amino Acid Sequence of Polypeptides and Proteins

The amino acid content of a given protein is determined after acid hydrolysis and chromatographic separation by **ion-exchange chromatography** of the resulting amino acid mixture. The amino-acid sequence of a protein is usually determined by the Sanger or the Edman degradation techniques. In Sanger's procedure, 1-fluoro-2,4-dinitrobenzene is used to label the N-terminal amino acid residue by coupling it to the α -amino group and consequently hydrolyzing the whole protein. The N-terminal modified amino acid is stable to acid hydrolysis and can be identified (Fig. 7). In the Edman degradation procedure the amino terminal residue is labeled and removed from a

polypeptide. The protein or polypeptide containing a free α -amino group is reacted with phenyl isothiocyanate, which removes the amino terminal residue as a phenyl thiocarbonyl derivative, which is identified, while leaving all other peptide bonds intact (Fig. 7). The remaining shortened polypeptide or protein is then reacted again with phenyl isothiocyanate and the next amino acid is identified. This procedure is repeated until the entire sequence is determined. Using present day automatic sequence machines, the amino acid sequence can be determined with less than 1 μ g protein.

Peptides, Structure and Conformation

Amino acids in proteins are linked covalently by peptide bonds. The peptide bond is the amide bond

formed by linkage of the carboxyl group of the first amino acid with the amino group of the second amino acid, while releasing water (Fig. 8). When many amino acids are joined by peptide bonds, they form a linear peptide chain.

By convention, the amino end is taken to be the beginning of the polypeptide chain, so that when the sequence of amino acids in a polypeptide is presented, i.e. its primary structure, it starts with the amino terminal residue. Thus in the tripeptide Ala-Gly-Trp, Ala is the amino terminal residue and Trp is the carboxyl terminal amino acid. The number of amino acids in the peptide chain determines its name. Thus the term “di-peptide” indicates that the peptide consists of two amino acid residues.

Amino Acids: Physicochemical Properties. Figure 8 Formation of the peptide bond between two amino acids, to form a dipeptide.

The Peptide Bond is Rigid and Planar

In the late 1930s, Linus Pauling and Robert Corey began x-ray crystallographic studies of the precise structure of amino acids and peptides. One of their important findings was that the peptide bond is rigid and planar (6). The hydrogen of the α -amino group is nearly always trans (opposite) to the oxygen of the

carbonyl group (Fig. 9). There is no freedom of rotation about the bond between the carbonyl carbon and the nitrogen atom of the peptide unit, because this link represents a characteristic partial double bond. In contrast, $^{\circ}\text{C}-\text{NH}$ and $^{\circ}\text{C}-\text{CO}$ are pure single bonds and possess a large degree of rotational freedom on either side of the peptide unit.

Amino Acids: Physicochemical Properties. Figure 9 Planar and rigid characters of the peptide group CO-NH. (a) A gray parallelogram marks the plane of the peptide group in a polypeptide. Standard bond distances are marked in Å. Note that the C-N bond in the peptide group is shorter than the α C-N bond, indicating a partial double-bond character of the peptide bond. (b) The electronic resonance of the peptide bond is presented.

The α -helix and β -pleated Sheet – Secondary Structures

Pauling and Corey proposed the periodic polypeptide structures, known as the α -helix and the β -pleated sheet. The α -helix is a rod-like structure. The tightly coiled polypeptide main chain forms the inner part of the rod and the side chains extend outward in a helical array (Fig. 10). The structure of the α -helix is stabilized mainly by intra-molecular **hydrogen bonds** (Fig. 10). The α -helices found in proteins are right handed. The number of amino acid residues per turn is 3.6 and the pitch of the helix is 5.4 Å.

Ten or more α -helices can entwine to form a cable. Such helical coiled-coils are found in **keratin** in hair, in **myosin** and tropomyosin in muscle, in epidermin in skin and in fibrin in blood clots. The helical cables in these proteins form stiff bundles of fibers serving a mechanical role in structures that need support.

Another structural element in proteins is the β -pleated sheet. A polypeptide chain in a β -pleated sheet is almost fully extended (Fig. 11).

Adjacent chains in a β -pleated sheet can run in the same direction (parallel β -sheet) or in opposite directions

(anti-parallel β -sheet). Silk fibroin, for example, consists almost entirely of stacks of the anti-parallel β -sheets.

β -turns

Most proteins have compact, globular shapes due to numerous reversals of the direction of their polypeptide chains. Many of these chain reversals are accomplished by a common structural element called the β -turn.

Methods Used to Determine the Tertiary Structure of Proteins

The geometry of secondary structures of polypeptides (α -helix, β -sheet) was first determined experimentally by X-ray diffraction analysis. Complete three-dimensional structures of proteins are determined by X-ray diffraction analysis of a single crystal and by **nuclear magnetic resonance** (NMR) analysis. To date, the three-dimensional structure of approximately 25,000 proteins had been elucidated by these techniques.

Amino Acids: Physicochemical Properties.

Figure 10 Models of a right-handed α -helix showing (left) only the α -carbon atoms and (right) the entire helix. Oxygen atoms of the carbonyl group are presented in red, nitrogen atoms are in blue and $^{\circ}\text{C}$ atoms are in black. The side-chain R groups are presented in colorless circles. The hydrogen bonds are shown as red dotted lines, combining the carbonyl oxygen with the hydrogen of the NH group. Both atoms are constituents of the peptide bond.

Poly- α -amino Acids – the Simplest of Protein Models

During the 1950s, linear polymers of amino acids, termed poly- α -amino acids, were synthesized by polymerization of the corresponding N-carboxy-amino acid anhydrides in solution in the presence of suitable catalysts. Linear poly- α -amino acids such as poly-Gly, poly-(L)-Ala, poly-(L)-Phe and poly-(L)-Glu, represent a rather sharp distribution of analogous homologous peptides of different chain lengths (7).

Under appropriate conditions, linear poly- α -amino acids, in the solid state and in solution, were found to acquire conformations of α -helix and β -parallel and anti-parallel pleated sheets or to exist as random coils (see therapeutic uses of poly-amino acids in the section on Clinical Relevance).

Knowledge of the physical and chemical properties of poly- α -amino acids played a major role in the work that led in 1961 to the cracking of the **genetic code** (see next section).

Protein Denaturation and Folding

Moderate changes in a protein's environment can bring about structural changes that affect its function. A change in its three-dimensional structure sufficient to cause loss of function is called denaturation.

Most proteins can be denatured by heat. Heat-stable proteins of thermophilic bacteria have evolved to function at the temperature of hot springs ($\sim 100^{\circ}\text{C}$). Proteins can also be denatured by extremes of pH, by certain miscible organic solvents such as alcohol or acetone, by certain solutes such as urea and guanidine hydrochloride or by detergents.

The Genetic Code

Polypeptide chains in living cells are synthesized by ribosomes, which handle and control peptide bond formation and the amino acid sequence in the peptide by a sophisticated enzymatic translation procedure. The amino acids appear in the form of their corresponding amino acyl-tRNA esters, whereas the amino acid sequence within the peptide is determined by messenger RNA. Messenger RNA represents a complementary nucleotide sequence to that of a DNA fragment bearing the gene to be expressed. Based on theoretical investigations as well as on a great variety of experimental results, the genetic code could be deduced. Each of the 20 protein amino acids is coded by a corresponding set of three nucleotides arranged in a specific order. The resulting genetic three-letter code dictionary is represented in Fig. 12.

The genetic code is a degenerative one, since all of the amino acids except tryptophan and methionine have more than one set of three nucleotides (codon). Moreover, it seems that the third nucleotide of each codon is less specific than the first two.

Finally, one should mention a conspicuous feature of the code, i.e. three of the 64 triplets (UAG, UAA, UGA) do not code for any known amino acid. These triplets are signals of the termination codon of the polypeptide chains formed.

Clinical Relevance

As was described above, some amino acids (marked 'e' in Table 1) are the essential amino acids, which are not available to animals by biosynthesis and must therefore be provided in the diet. Most amino acids in cells are in proteins, however, amino acids have additional functions. Ornithine and citrulline (Fig. 4) are key intermediates in the biosynthesis of arginine and in the urea cycle. β -Alanine (Fig. 4) is the precursor of the vitamin pantothenic acid and γ -amino-butyric acid is a transmitter of nerve pulses. The well-known thyroid hormones, thyroxine and 3,5,3'-triiodothyronine (Fig. 4) are derivatives of diiodo-tyrosine. Fungi and higher plants contain an extraordinary variety of amino acids. Some of them, such as canavanine, djenkolic

acid and β -cyanoalanine, are toxic to other forms of life.

The nature of amino acids, as well as their content and sequence in proteins, is of paramount importance in determining protein characteristics. (a) Knowledge of the amino acid sequence makes it possible to identify the protein; (b) it also enables the elucidation of the mechanisms involved in various specific activities of proteins such as enzyme catalysis, antigen binding by antibodies and ligand binding by receptors and (c) it enables detection of physiological disorders. Amino acid sequence determination of proteins represents a branch of molecular pathology, an emerging area of medicine. Alterations in amino acid sequence can produce abnormal function and disease. Fatal diseases such as sickle-cell anemia can result from a change in a single amino acid in a protein.

Four inherited neurodegenerative diseases are linked to the abnormally extended repeats of glutamine residues near the N-termini of affected proteins (see the essay '►Repeat Expansion Diseases', in particular the section dealing with polyglutamine disorders). These diseases include ►Huntington's disease (HD), spinal and bulbar muscular atrophy (SBMA), also known as ►Kennedy's disease, spinocerebral ataxia type I (SCAI), and dentatorubral-pallidoluysian atrophy (DRPLA) (8). All four diseases become more severe the longer are the glutamine repeats.

►Multiple sclerosis is a chronic inflammatory disease of the central nervous system in which infiltrating lymphocytes, predominantly T-cells and macrophages, cause damage to the myelin sheath. Sela and Amon discovered that Cop-I, a basic copolymer of (L)-alanine, (L)-glutamic acid, (L)-lysine and (L)-tyrosine at residue molar ratios of 6.0, 1.9, 4.7 and 1.0 respectively, prevents myelin destruction in humans. As a matter of fact, Cop-I is widely used to reduce the number of crises that usually affect multiple sclerosis patients.

There is evidence that a denatured conformational structure of the prion protein (Prion^{sc}) causes Alzheimer's disease and related diseases in humans, as well as in cattle and other animals (8).

Amphetamine

Definition

Amphetamines are a class of drugs that cause increased activity, decreased appetite, and a general sense of well-being. After an initial "rush," the state of high agitation can lead to violent behavior. From its parent drug, amphetamine, methamphetamine ("speed," "meth," and "chalk"; "ice," "crystal," "crank," and "glass") was developed, which has a similar chemical structure but has more pronounced effects on the central nervous system. Methamphetamine is a powerful addictive stimulant. The effects can last 6 to 8 hours.

Amplification

Definition

The term amplification is used in quite different senses, including even intramolecular magnification of a small movement in a protein to a larger movement at the surface, e.g. near the active center through solid body movement of a helix. It is usually reserved for when the single activated protein (e.g. the receptor) induces the generation of many copies of an interacting downstream component. Examples of such “particle” amplification include the generation of many copies of active G-protein by GDP/GTP exchange catalysed by a single receptor, or the enzymatic hydrolysis of cyclic GMP generating many molecules of 5'GMP by an effector. Note that the driving force in both cases is the free energy difference between GTP and GDP.

► [Photoreceptors](#)

Amyloid

Definition

Amyloid is a generic term that describes fibrillar aggregates that have a common structural motif: the β -pleated sheet conformation. These aggregates exhibit specific tinctorial properties, including the ability to emit a green birefringent glow after staining with Congo red, and the capacity to bind the fluorochrome thioflavin S. There are more than a dozen human diseases of different etiology characterized by the extracellular deposition of amyloid. The amyloid fibrils are usually composed of proteolytic fragments of normal or mutant gene products. So far there are over 16 different proteins involved in amyloid deposition in distinct tissues.

Analytical Ultracentrifugation

PETER SCHUCK

Division of Bioengineering and Physical Science, OD,
National Institutes of Health, Bethesda, USA
pschuck@helix.nih.gov

Definition

Analytical ultracentrifugation is a technique based on the application of a centrifugal force to a solution and the real-time observation of the resulting spatial redistribution of the dissolved molecules or particles. This permits the study of the thermodynamic and hydrodynamic properties of purified macromolecules, such as nucleic acids and proteins, in dilute solution and the characterization of protein sizes and shapes, as well as ►protein interactions.

Description

The most frequent application of modern analytical ultracentrifugation is the analysis of protein interactions, such as the characterization of protein oligomeric states and the study of reversible protein complexes, protein-ligand interactions and protein-nucleic acid interactions. This includes ligand-induced conformational changes in proteins, the size-distribution of protein complexes, protein filamentation and the study of detergent-solubilized membrane proteins. It is also applied in a wide variety of other areas, ranging from the study of the solution conformation of macromolecules at low resolution to the analysis of the nucleotide composition of genomes in evolutionary studies and the analysis of protein interactions in crowded media. Examples of current biotechnological applications are the size-distribution and aggregation behavior of protein pharmaceuticals and the study of small molecule binding to protein targets. It is also an important tool in several areas of chemistry.

Analytical ultracentrifugation is a classical method of physical biochemistry, developed in the 1920s by Svedberg (1, 2). Historically, for several decades it has been used as a standard tool to measure the molar mass of purified proteins, protein complexes and nucleic acids in dilute solution. For example, it provided the first demonstration that proteins are macromolecules by measuring the molar mass of hemoglobin and it was a central tool in the discovery of semiconservative replication by Meselson and Stahl. New instrumentation in the 1990s combined with computational advances greatly facilitated and extended the application to protein interactions.

While the basic idea of analytical ultracentrifugation is simple and it provides macromolecular information on biochemical systems rooted in first principles, a wealth of important knowledge has been accumulated regarding the technical implementation of ultracentrifuges, the theoretical foundation of ultracentrifugation in thermodynamics and physical chemistry of macromolecules and the mathematical analysis of ultracentrifugation experiments (3). Many variations of ultracentrifugal approaches have been described in the literature and the following is a short presentation of only the main concepts of the most commonly used configurations.

The principal difference between an analytical ultracentrifuge and a conventional preparative ultracentrifuge is an optical system that permits the observation of the dissolved macromolecules under study during the centrifugation and the real-time measurement of the concentration gradients which evolve in a radial direction as a response to the applied gravitational force. To allow for the optical detection, the sample is contained in an assembly that is optically transparent perpendicular to the plane of rotation. The optical systems are triggered by the revolution of the rotor, so that data are acquired only during the short intervals when the sample assembly is aligned with the optical light path (Fig. 1). The two main modern detection systems are a dual-beam UV/VIS spectrophotometer, which records the absorbance profiles at selected wavelengths and scans the sample in a radial direction and a ►laser interferometer that images the solution column and records the refractive index gradients caused by macromolecular redistribution. Typical samples are 100–400 µl of purified macromolecules or mixtures at concentrations of usually at least 0.05 mg/ml and usually up to 7 samples located at different angular positions in the rotor are studied simultaneously in one centrifugation run.

The purpose of the analytical ultracentrifuge is to observe the sedimentation process, i.e. the free fall of the dissolved macromolecules or particles in the absence of any matrix or supporting solvent density gradient. The gravitational force acting on the particles is proportional to their mass, reduced by the mass of the displaced solvent (following ►Archimedes principle). This requires knowledge of the ►partial specific volume of the macromolecules and in some cases involves the consideration of hydration and preferential solvent interactions. For particle densities smaller than the solvent, buoyancy will cause flotation instead of sedimentation. Opposing the gravitational force is the hydrodynamic friction, which is related to the shape of the macromolecule (e.g. its ►Stokes radius). The ratio of the resulting velocity of the sedimenting particles to the applied centrifugal field is a characteristic constant,

Analytical Ultracentrifugation. Figure 1 Schematic view of the rotor, the sample, and the detection system for measuring the macromolecular concentration distribution.

termed the ►sedimentation coefficient s . It is commonly measured in units of Svedberg, abbreviated S, which is related to the SI units by $1 \text{ S} = 10^{-13} \text{ s}$. Simultaneously with the sedimentation process, diffusion and possible chemical reactions take place. Since the extent of diffusion is also dependent on macromolecular shape, the diffusion constant D is related to the sedimentation coefficient s via the molar mass M , as expressed by the Svedberg equation

$$\frac{s}{D} = \frac{M(1 - \bar{v}\rho)}{RT}$$

(with \bar{v} denoting the partial-specific volume of the macromolecule, ρ the solvent density, R the gas constant, and T the absolute temperature). Typically, at high centrifugal fields of 200,000 g for the study of medium sized proteins, the macromolecular migration caused by sedimentation is of similar magnitude to the diffusional transport, so that the concentration profiles exhibit a moving sedimentation boundary that is broadened by diffusion (Fig. 2). Experiments that are aimed at observing the evolution of the concentration profiles with time under such conditions are termed ►sedimentation velocity experiments. Their duration is usually several hours.

Analytical Ultracentrifugation. Figure 2 Time-course of the macromolecular concentration distributions in a typical sedimentation velocity configuration. The sedimentation boundary migrates away from the center of rotation and is broadened by diffusion. In the plateau region, a second smaller sedimentation boundary is visible that migrates with a higher sedimentation coefficient.

At lower centrifugal fields, diffusion is predominant and the concentration distributions evolve more slowly and assume shapes with broader features, approaching an equilibrium state in which the sedimentation is effectively balanced by diffusion throughout the entire solution column (Fig. 3). This condition is termed ►sedimentation equilibrium. In ordinary configurations with 3–5 mm solution columns it is attained after one to two days.

Sedimentation equilibrium is characterized by exponential concentration distributions with a steepness determined by the molar mass:

$$c(r) = c(b) \exp \left\{ M \frac{(1 - \bar{v}\rho)\omega^2}{2RT} (r^2 - b^2) \right\}$$

(where the radius r denotes the distance from the center of rotation, b the radial position of the bottom of the sample column, and ω the rotor angular velocity).

By adjusting the rotor speed, sedimentation velocity and sedimentation equilibrium conditions can be achieved for a very large range of sizes, permitting the study of particles such as small molecules with molar masses of a few hundred Dalton, up to macromolecules, macromolecular complexes and small μm sized organisms.

Conceptually, the key to the exceptional utility of sedimentation experiments in the study of reversible protein interactions is that despite the gravitational separation, larger species always remain surrounded by the smaller species during the entire experiment. This is in contrast, for example, to the typical configuration in

Analytical Ultracentrifugation. Figure 3 Concentration distributions as observed in a sedimentation equilibrium experiment. Shown are experimental distributions obtained at three different rotor speeds.

chromatography, where different species in an initial mixture are separated and isolated during their migration. In sedimentation velocity the faster sedimenting protein complexes continuously migrate through the slower sedimenting free protein species and can therefore remain at all times in an [▶association-dissociation equilibrium](#). Similarly, in sedimentation equilibrium the complexes are localized (due to a steeper exponential) on average closer to the bottom of the solution column, but also the free species increase exponentially in concentration towards the bottom of the solution, such that chemical equilibrium is maintained simultaneously with the mechanical centrifugal equilibrium (and [▶mass action laws](#) are fulfilled at each position throughout the solution column).

As a consequence, reversible protein interactions can be studied. The oligomeric states of [▶protein self-association](#) can be elucidated and the respective equilibrium constants be determined. Likewise, the stoichiometry and affinity of complexes formed between two or more different protein components interacting in reversible hetero-associations can be studied. Affinities can typically range from $K_D \sim 10$ nM to mM (dependent on the molar mass and extinction properties of the reacting macromolecules). Although interactions mediated by specific molecular recognition sites are the focus of most studies, other interactions, such as those derived from protein-solvent interactions, steric repulsion of molecules at high

concentration, charge interactions or physical entanglement of fibers may be observed and characterized as well. Examples of such applications include studies on protein crystallization conditions, interactions in crowded media as a model for the intracellular environment and interactions of amyloid fibers.

Sedimentation Velocity

Sedimentation velocity experiments frequently utilize the strongly size-dependent hydrodynamic separation of macromolecules to study their size and shape, to characterize size distributions and to detect macromolecular complexes through their higher sedimentation velocity.

In principle, the sedimentation coefficient can be determined simply by measuring the displacement of the sedimentation boundary with time, for example by observing the position of the boundary midpoint or by integrating the concentration profiles and assessing the macromolecular depletion with time. Data transformation methods have been developed that are better adapted to the problem of size-distributions. High-resolution distributions can be obtained by boundary modeling with [▶Lamm equation](#) solutions (see below). For a single sedimenting species, the sedimentation coefficient reveals information on both mass and shape:

$$s = \left(\frac{M}{N_A} \right)^{\frac{2}{3}} \frac{1}{(f/f_0)} \frac{(1 - \bar{\nu} \rho)}{6\pi\eta} \left(\frac{4\pi}{3\bar{\nu}} \right)^{\frac{1}{3}}$$

where N_A denotes the Avogadro constant, η denotes the solvent viscosity and where the ►frictional ratio f/f_0 is a molecular constant that measures the shape asymmetry relative to a compact sphere of the macromolecular mass and density. If the molar mass is known, which is frequently the case from the known macromolecular composition or from mass spectrometry, f/f_0 gives information about the solution conformation. This can be compared with theoretical models of the solution structure, derived from low-resolution ►bead models, molecular shapes observed in electron microscopy or from known crystal structures. Information on the dynamics of the solution conformation may be obtained by detecting changes in f/f_0 dependent on solution condition and ligand binding. Conversely, a shape asymmetry f/f_0 may be assumed (possible values fall in a close range of commonly 1.2–1.5 for folded globular proteins, values <1 can be excluded as they are theoretically impossible and values of 2 or larger usually are associated with very extended structures or unfolded chains), which can be useful to obtain an estimate the molar mass of the macromolecular species. For a sedimenting mixture, the sedimentation coefficient derived from the time-course of macromolecular depletion represents a weight-average sedimentation coefficient s_w of the mixture. For reversibly interacting macromolecules, s_w will change with the concentration and composition of the loading mixture. The analysis of this dependence can reveal the binding energy (►affinity constants) between the macromolecular components (through the analysis of the ►binding isotherm with mass action law models). The weight-average sedimentation coefficient can also be obtained by integration of the differential sedimentation coefficient distribution $c(s)$ (see below).

Modern analysis techniques aim to utilize the evolution of macromolecular concentration distribution over the entire solution column, which represents a very rich source of additional information on macromolecular diffusion, molar mass, size-distribution of mixtures and the thermodynamics and kinetics of interactions. This is based on the equation for sedimentation and diffusion in the sector-shaped solution column

$$\frac{\partial c}{\partial t} = \frac{1}{r} \frac{\partial}{\partial r} \left[rD \frac{\partial c}{\partial r} - s\omega^2 r^2 c \right]$$

which was derived by Lamm in 1929 and was the subject of significant theoretical interest for several decades, but became widely applicable to routine analysis in the 1990s.

In the analysis of single sedimenting species, the information on diffusion from the boundary spread allows the direct determination of the molar mass. It also allows extending the sedimentation velocity analysis to configurations that do not produce clear

sedimentation boundaries, such as for small molecules. Extensions to the macromolecular sedimentation in self-forming density gradients from sedimenting cosolutes have been described, as well as corrections for the solvent compressibility.

For sedimenting mixtures, the mathematical modeling of the experimentally observed sedimentation profiles as a superposition of solutions of the Lamm equation permits the deconvolution of the diffusion from the sedimentation process and the determination of high-resolution differential sedimentation coefficient distributions $c(s)$ (4). It also reveals a weight-average frictional ratio f/f_0 that can be exploited to estimate the molar mass distribution of the sedimenting mixture. In practice, this typically leads to baseline-resolved peaks for stable oligomeric species (for $M_w > 10$ kD).

The Lamm equation analysis can be modified to account for chemical reactions between the sedimenting species and this can be utilized to study protein self-association and heterogeneous protein interactions. For such systems, the sedimentation velocity patterns at different loading concentrations exhibit shapes that are characteristic for the association scheme and the type of complexes formed. In addition, the global analysis of the sedimentation data from different loading concentrations allows determining the binding energy, as well as the low-resolution hydrodynamic shape f/f_0 of the reversibly formed complexes. Information on the binding kinetics and the stability of the complexes can also be extracted.

Sedimentation Equilibrium

Sedimentation equilibrium experiments are frequently applied where the determination of the molar mass of protein complexes and/or the measurement of affinity constants is of primary interest. The equilibrium state is only dependent on thermodynamic properties and is not affected by the dynamic processes from reaction kinetics or hydrodynamics. The steepness of the concentration profiles is directly related to the molar mass of the sedimenting species. For interacting systems the local concentration gradient is related to the local weight-average molar mass. Because a gradient spanning a large range of concentrations is established as a result of the centrifugation, ranging from very dilute conditions closer to the center of rotation to very high concentrations at the bottom of the solution column, information equivalent to an entire binding isotherm is gained from a single experiment. This permits the determination of the affinity constants for interacting systems.

The separation of different species in the exponential equilibrium distributions is not as strong as the hydrodynamic separation in sedimentation velocity, which generally imposes higher requirements on

sample purity for the sedimentation equilibrium experiments and can make the identification of the stoichiometry of the complexes more difficult. When studying interactions between components of dissimilar absorption spectrum, multi-wavelength detection can be applied to unravel the individual concentration profiles of each component. Frequently, the redistribution of a macromolecular mixture is observed for a series of loading concentrations and different centrifugal fields. This permits more stringent characterization of the molar mass of the populated species and their association behavior, through global mathematical analysis and mass conservation techniques.

More information on both modern sedimentation velocity and sedimentation equilibrium analytical ultracentrifugation can be found in (5) and the references cited therein

Anaphase

Definition

Anaphase describes a stage of mitosis, when the chromatids are split and become daughter chromosomes that move to opposite spindle.

- ▶ Centromeres
- ▶ Mitosis

Anaphase Movement

Definition

Anaphase movement refers to the initial movement of chromosomes to opposite poles of the spindle during anaphase.

- ▶ Centromeres

Anaphase Promoting Complex (APC)/Cyclosome

Definition

Anaphase Promoting Complex (APC/C) is a large multi-subunit ▶E3–ligase, which plays an essential role in initiating anaphase because it triggers sister chromatid separation. This is achieved by targeting proteins responsible for the progression through the cell cycle (e.g. securins and cyclins) for degradation by the 26S proteasome. Several APC activators (e.g. cdc20 or cdh1) can modulate the activity and specificity of the APC. Among those proteins targeted by APC/C are mitotic cyclins and the so called “cohesions” (which attach sister chromatids). Signalling of kinetochores to APC/C is required for destruction of the cohesions. If these are degraded, sister chromatid separation proceeds.

- ▶ Ubiquitination

ANAs

Definition

ANAs or anti-nuclear autoantibodies are usually found in SLE (Systemic Lupus erythematoses) and potentially also in rheumatoid arthritis and other rheumatic diseases, and represent antibodies that target nuclear antigenic components. These antibodies are believed to play an important role in affecting the pathology seen in these diseases.

- ▶ SLE Pathogenesis Genetic Dissection

Anchorage Dependence/Independence

Definition

Anchorage dependence of survival, growth etc. describes the need for cells to attach to a solid substrate in order to exert the activities indicated. Anchorage independence describes the property of transformed cells to form aggregates/colonies in semi-solid agar medium without adherence to the substrate. Normal adherent cells undergo a special form of cell death (called anoikis) under these conditions.

Androgen Insensitivity

Definition

Androgen insensitivity refers to reduced effects of substances with masculinizing activities such as testicular hormones.

► Repeat Expansion Diseases

Androgen Receptor (Gene)

Definition

The androgen receptor gene encodes a protein with the capability to combine specifically with androgen(s), transforming the hormonal signal into adequate stimuli for the target cells.

► Chromosome 21 Disorders

► Repeat Expansion Disease

Aneuploidy

Definition

Aneuploidy designates a chromosomal abnormality, arising when a diploid genome has either gained or lost some or all chromosomes from a diploid set.

► Centromeres

► Chromosome 21 Disorders

► Telomerase

► X-Chromosome Inactivation

Angelman Syndrome

Definition

Angelman syndrome is a relatively frequent disorder (1:15,000 newborns) caused by functional loss of ► **imprinted** genes on the paternal chromosome 15q11–q13 (in 70% by maternal 15q11–q13 deletion, 4% paternal uniparental disomy, 8% imprinting center mutation on the maternal allele, and 8% mutation of the UBE3A on the maternal allele). Patients show severe mental retardation, seizures, ataxia, and paroxysms of inappropriate laughter (“happy puppet syndrome”).

► Microdeletion Syndromes

Angiofibroma

Definition

Angiofibroma is a hamartoma (benign tumor) consisting of red to pink papules or nodules typically in a malar distribution, which first appear between the ages of 2 and 6 years, and progress to a variable extent during puberty. Histologic findings are dermal fibrosis and angiogenesis with occasional large glial appearing cells. Commonly seen in tuberous sclerosis.

► Tuberous Sclerosis

Angiogenesis

KARL H. PLATE

Neurological Institute, Clinical Center of the Johann Wolfgang Goethe University, Frankfurt, Germany
karl-heinz.plate@kgu.de

Definitions

► **Angiogenesis** is defined as sprouting of capillaries from pre-existing vessels. ► **Vasculogenesis** describes the *in situ* differentiation of endothelial precursor cells during development. ► **Bone marrow** derived vasculogenesis is defined as mobilization of endothelial precursor cells from the bone marrow and their integration and differentiation into sites of adult blood vessel formation. Somatic stem cell derived vasculogenesis is defined as mobilization of precursor cells from differentiated organs and their integration and transdifferentiation into growing blood vessels. ► **Lymphangiogenesis** describes the formation of the lymphatic system during development and in pathological conditions. ► **Vascular morphogenesis** describes the formation and maturation of functional blood vessels, e.g. the interaction of vascular endothelial cells with pericytes and smooth muscle cells.

Characteristics

All tissues in developing and adult organisms need a functional blood supply in order to receive sufficient amounts of oxygen and nutrients, which are necessary for their proper function. Blood vessels start to form early in embryonic development (e.g. E 8.5 in the mouse) before the heart starts to beat. All blood vessels are lined by a monolayer of endothelial cells, which provide a non-coagulant surface for the blood. In the brain, endothelial cells regulate the influx of extracellular

molecules to the brain parenchyma and thus constitute the morphological basis of the blood brain barrier. During development, endothelial cells form tube-like structures that are covered by pericytes and a basal lamina. Larger vessels form by apposition of contractile smooth muscle cells.

In the embryo, tissues are vascularized by vasculogenesis and angiogenesis. Both processes are almost absent in the adult organism. Transient and tightly controlled (physiological) angiogenesis in adult tissues occurs during the female reproductive cycle and during wound healing. In contrast, pathological angiogenesis is characterized by the persistent proliferation of endothelial cells and is a prominent feature of diseases such as proliferative retinopathy, rheumatoid arthritis and psoriasis. In addition, many tumors are able to attract blood vessels from neighboring tissues. Tumor-induced angiogenesis requires a constitutive activation of endothelial cells. These endothelial cells dissolve their surrounding extracellular matrix, migrate toward the tumor, proliferate and form a new vascular network, thus supplying the tumor with nutrients and oxygen and removing waste products.

Recent reports suggest that in adult tissues bone marrow derived ►[vasculogenesis](#) and somatic stem cell derived vasculogenesis may occur, but the extent of these processes compared to angiogenesis appears limited.

Molecular Interactions

Several molecules have been described to be essential for angiogenesis, vascular development and lymphangiogenesis.

VEGF's

The vascular endothelial growth factor family consists of ►[VEGF](#) (also called VEGF-A), VEGF-B, VEGF-C,

VEGF-D, VEGF-E and the related placenta growth factors PlGF-1 and -2. VEGF's bind differentially to three high affinity tyrosine kinase receptors VEGFR-1, -2 and -3 (Table 1). In addition, neuropilin-1 and -2 receptors play a role in modifying VEGF receptor function.

The vascular endothelial growth factor (VEGF)-VEGF receptor system is necessary for early vascular development. Although VEGF, a hypoxia-regulated secreted protein, is expressed by many cell types in the developing mouse, its correct spatial, temporal and quantitative expression appears to be a prerequisite for normal vascular development. Heterozygous inactivation of the *VEGF* gene in mice leads to early embryonic lethality, suggesting that early vascular development is critically dependent on VEGF availability. VEGF binds to two tyrosine kinase receptors, VEGFR-1 (flt-1) and -2 (KDR/flk-1). VEGFR-2 is essential for the generation of endothelial cells and blood cells and for endothelial cell proliferation, migration and survival. In mice, knockout of VEGFR-2 leads to embryonic lethality around embryonic day 8 with no endothelial cells or blood cells being formed. VEGFR-1 may act as a decoy receptor for VEGF and negatively regulate embryonic angiogenesis. General knockout of VEGFR-1 in mice resulted in embryonic lethality due to a disorganized vascular system and an overgrowth of endothelial cells. In contrast, a tyrosine kinase specific VEGFR-1 knockout showed no significant vascular phenotype suggesting that during development, the major VEGFR-1 function is the binding of VEGF and not signal transduction. VEGFR-1 however has been shown to regulate pathological angiogenesis by binding the VEGF homologue placenta growth factor (PlGF). VEGF also induces vascular permeability, but it is unclear which receptor transmits this signal.

Angiogenesis. Table 1 Angiogenic growth factors and receptors

Receptor	VEGFR-1	VEGFR-2	VEGFR-3	TIE1	TIE2
Putative functions	monocytes/macrophages: migration endothelial cells: negative regulation of VEGF? PlGF: stimulation of adult angiogenesis	vasculogenesis hematopoiesis angiogenesis permeability	assembly of large vessels permeability lymphangiogenesis	Vascular remodeling	sprouting angiogenesis vascular remodeling vascular permeability
Ligand(s)	VEGF	VEGF	VEGF-C	?	Angiopoietin-1
	VEGF-B	VEGF-C	VEGF-D		Angiopoietin-2
	PlGF	VEGF-D			Angiopoietin-3
		VEGF-E			Angiopoietin-4

VEGFR-3 (flt-4) serves mainly as a receptor for VEGF-C and -D and appears to have a major function in lymphangiogenesis, both during development and in pathological conditions. Both VEGF-C and -D have been shown to promote ►[lymphangiogenesis](#) and lymphatic metastasis in tumors. Possibly angiopoietin-2 (see below) cooperates in this process by acting as an additional stimulator for lymphangiogenesis.

TIE Receptors and Angiopoietins

Angiopoietins (Ang) 1-4 bind to Tie-2 receptors primarily expressed on endothelial cells. Angiopoietins 1 and 3 and 2 and 4 respectively, have opposing effects on the Tie-2 receptor but this may also be cell type dependent. Ang-1 and -3 stimulate Tie-2 phosphorylation in endothelial cells, whereas Ang-2 and -4 inhibit receptor phosphorylation. Unlike mice deficient in VEGF or VEGF receptors, mouse embryos lacking Ang-1 or Tie-2 develop a normal primary vascular structure but display defects in vascular maturation and vascular sprouting. The major function of Tie-2 appears to be vessel maturation/stabilization by regulating pericyte/endothelial cell interaction. Ang-2 by blocking Tie-2 signaling may lead to vascular destabilization by pericyte drop-off. Ang-2 action sensitizes the endothelial cell for angiogenic stimuli such as VEGF. If VEGF is not available in sufficient amounts, the destabilized vessels regress.

Ang-1 appears to be a major regulator of vascular permeability by stabilizing the vessel wall. The orphan receptor Tie-1 appears to have little function in early vascular development, but plays an important role in vascular morphogenesis as suggested by knockout studies. Whether independent ligands for Tie-1 exist or whether angiopoietins may, under certain circumstances, also bind to Tie-1 is unclear. In addition to angiopoietins and Tie receptors, platelet-derived growth factor receptor β has been shown to be involved in vascular maturation by recruitment of pericytes.

Ephrins

Eph tyrosine kinase receptors and eph ligands are cell bound molecules with a well-known function in neural development. Ephrin-B2 and Eph B4 receptors however have also been shown to play essential roles in vascular development. Studies in knockout mice suggest that ephrin-B2 and Eph B4 play an important role in establishing venous *versus* arterial identity and possibly later on in the development of arteries.

Regulatory Mechanisms

The growth of the vascular system correlates well with body mass and with the metabolic demands of tissues and organs. Hypoxia appears to be a major regulator of angiogenesis and possibly also of vasculogenesis in development. Hypoxia leads to accumulation and

nuclear translocation of ►[Hypoxia Inducible Factors](#) (HIF-1 and HIF-2) that transactivate a set of genes, including stimulators of angiogenesis such as VEGF. VEGF is formed by alternative splicing in five different isoforms (VEGF 121, 145, 165, 189, 204) of which only the three smaller isoforms are efficiently secreted. VEGF binds to VEGFR-1 with a ten-fold higher affinity than to VEGFR-2, but only VEGFR-2 shows significant tyrosine phosphorylation. After ligand binding, VEGFR-2 activates various intracellular signaling pathways in endothelial cells, including the PI3-kinase/Akt, PLC/PKC and ras/MEK/erk pathways.

Evidence suggests that VEGFR-2 can be induced by VEGF in a homologous fashion. The ets-1 and HIF-2 transcription factors appear to cooperate in the hypoxic regulation of VEGFR-2. VEGF is also regulated by MAP-kinase dependent mechanisms, independently of hypoxia. Low pH and low glucose as well as genetic alterations (loss of function of the von Hippel Lindau tumor suppressor gene, VHL) may also activate the HIF pathway and stimulate angiogenesis.

In tumors, hypoxia and hypoxia-independent mechanisms have been shown to trigger angiogenesis. In many cancer types, VEGF is specifically up-regulated in perinecrotic tumor cells, suggesting that hypoxia is a major driving force for ►[tumor angiogenesis in vivo](#). Other factors that may up-regulate VEGF in cancer cells include p53 mutations, epidermal growth factor receptor over-expression, PTEN mutations and ras and src mutations.

In patients with ►[VHL-\(von Hippel-Lindau\) Disease](#), a hereditary cancer syndrome characterized by highly vascularized tumors in the brain, retina and kidney and cysts in the pancreas, kidney and epididymis, VEGF is constitutively expressed in cells deficient in a functional VHL protein. VHL forms a multimeric complex with HIF-1, necessary for proteosomal degradation of the complex. In cells with VHL loss of function, HIF-1 accumulates, leading to VEGF expression and induction of angiogenesis.

The importance of VEGF for tumor angiogenesis and tumor growth has been shown by numerous studies inhibiting the VEGF function in animal models.

Autocrine inhibition of Tie-2 by endothelial Ang-2 expression appears to be a prerequisite for angiogenesis. Possibly, inhibition of Tie-2 by Ang-2 leads to loosening of endothelial cell / pericyte contacts and renders endothelial cells accessible to inducers such as VEGF. Neither the endothelial cell specific expression of Ang-2 nor its regulation is completely understood. Possibly VEGF and hypoxia up-regulate Ang-2, Ang-1 and Tie-2, but this regulation may be dependent on the cell type. In tumors, in contrast to Ang-2, Ang-1 and also Tie-2 appear to be constitutively expressed, suggesting that Ang-2 is the major regulator of the Tie-2 pathway.

In lymphangiogenesis, both Ang-1 and Ang-2 act as stimulators, suggesting that in certain circumstances both ligands can activate the Tie-2 receptor. The VEGF homologues VEGF-C and -D have been shown to bind to VEGFR-3 and to VEGFR-2 and to be major drivers of lymphangiogenesis. The regulation of VEGF-C, -D and VEGFR-3 is poorly understood but hypoxia does not appear to be involved in their regulation.

Anomalous Diffraction, Anomalous Scattering

Definition

Electron motions induced by incoming radiation re-emit radiation, thereby scattering it out of phase with the incoming radiation. However, if the incoming energy is near an electron energy transition, the induced electron motion may be retarded by (resonant) excitation of an electron into the higher energy state, thereby shifting the phase of the scattered radiation. Without anomalous scattering, the diffraction intensities from a crystal before and after a 180° rotation are identical; with anomalous scattering, differences arise that can be exploited in structure solution.

- ▶ [3D Structure Determination by X-Ray](#)

Anomalous Scatterer

Definition

Any atom becomes an anomalous scatterer if the wavelength of the exciting radiation (e.g. X-rays) is near its absorption edge. By resonance effects the wavelength remains unchanged (elastic scattering), but the amplitude is changed and the phase is retarded. The scattering effect is nearly independent from the scattering angle. Metal ions, lanthanides, and actinides are sources of high anomalous signals at their corresponding absorption edges.

Anticodon

Definition

Anticodon designates the three nucleotide sequence in a tRNA that is complementary to a triplet of mRNA (codon), which specifies a certain amino acid.

- tRNA

Anti-Craving Substances

Definition

Anti-craving substances are drugs that have been registered for relapse prophylaxis in weaned alcoholics in various European countries (acamprosate) and the United States (naltrexone). Acamprosate and naltrexone most likely reduce ethanol abuse through different neuronal mechanisms. Acamprosate acts as a weak glutamate (NMDA)-receptor antagonist and modulates the number of specific glutamate (NMDA)-receptor subunits. Naltrexone acts as a morphine antagonist and displaces morphine from its receptor.

- Addiction, Molecular Biology

Antigen

Definition

The term antigen denotes any foreign molecules, e.g. proteins, polysaccharides, liposaccharides or other small compounds, which trigger the generation of antibodies when introduced into the host organism. It can be recognized by antibodies produced by B-lymphocytes or by the T cell antigen receptor.

Antiparallel

Definition

Antiparallel designates that the two strands of DNA are chemically arranged in opposite directions, with the structure P–5'-sugar–3'-P in one strand opposing the structure P–3'- sugar–5'-P in the other strand. Antiparallelism and base-pairing rules determine the sequence and orientation of the complementary strand.

►Replication Fork

Antisense RNA

Definition

An antisense transcript is produced by the transcription of the DNA strand complementary to the coding strand. Antisense transcripts overlap, at least partially, with the transcript from the coding DNA strand. These RNAs are usually non-coding. They could play a role in the regulation of monoallelic gene expression. The best known examples include, the random monoallelically expressed Xist/Tsix transcript pair on the chromosome X, or the imprinted Igf2r/Air transcripts on the human chromosome 6.

►Catalytic RNA

►Genomic Imprinting

Antiretroviral Agents

Definition

Antiretroviral Agents (ARVs) are inhibitors of retroviral enzymes, receptors, or other important targets in the HIV–1 life-cycle, which are used therapeutically to suppress viral replication and delay the emergence of drug resistance.

►Reverse Transcriptase

Antisera

Definition

Antisera are animal or patient sera that contain specific antibodies, usually against an antigen that had previously been introduced by a natural infection or an intentional inoculation (immunization).

Apoptosis

Definition

Apoptosis is a form of highly regulated cellular self-destruction, whereby a cascade of signals eventually leads to the breakdown of the cellular DNA and to subsequent cell death (also known as programmed cell death). Apoptosis is characterized by distinct morphologic changes in the nucleus and cytoplasm (nuclear condensation and packaging of cell contents). When cells enter into apoptosis, they lose contact with their neighbours, shrink, and their nuclear DNA is

fragmented. At the end, cells break into vesicles that are engulfed by other cells. Cells with massively damaged DNA are prevented from continuing through the cell cycle by the induction of apoptosis, thus maintaining tissue homeostasis. Apoptosis occurs without causing inflammation and damage to neighbouring cells. In contrast to uncontrolled cell death after tissue injury (►necrosis), apoptosis is an evolutionarily conserved pathway for the elimination of cells during normal physiological processes.

Zurich, Switzerland
uwe.zangemeister@USZ.ch

Definition

►Apoptosis is the most common form of physiological cell death and serves to eliminate cells that are (a) genomically altered and therefore potentially harmful to the body, (b) senescent or (c) become replaced by functionally different cell types. It is defined by morphological criteria, including chromatin condensation, nuclear fragmentation, plasma membrane blebbing, organelle disruption, loss of adhesion and

rounding (in adherent cells) and cell shrinkage. Apoptosis is required for normal development and maintenance of tissue homeostasis and its dysregulation is associated with various pathological conditions. For instance, there is often too little apoptosis in cancer and chronic inflammation and there is usually too much apoptosis in neurodegeneration and acquired immune deficiency syndrome (►AIDS).

Characteristics

Apoptosis is characterized by the following biochemical features: high molecular weight and/or internucleosomal DNA fragmentation (DNA laddering), ►phosphatidyl serine externalization and intracellular proteolysis. Some of the plasma membrane changes are responsible for the rapid recognition of apoptotic cells by phagocytes (neighboring cells and resident tissue macrophages) before the release of intracellular pro-inflammatory substances into the surrounding tissue occurs. Therefore, in contrast to ►necrosis, which represents a common pathological form of cell death, apoptosis does not induce an inflammatory response. There are various apoptotic stimuli that are partially specific for distinct cell types. The susceptibility to apoptosis induction is modulated by several factors, such as the cellular environment, cell type-specific characteristics in gene expression, the differentiation state or the cell-cycle phase. However, once initiated, the cascade of morphological and biochemical events by which apoptosis proceeds is largely stereotypic and entails common mechanisms which are described below. Despite its emerging complexity in mammalian cells, apoptosis has also been described in lower organisms such as the nematode *C. elegans* and identified as an evolutionarily highly conserved mechanism, suggesting that it is crucial for species survival.

Molecular Interactions

The core cell death machinery is a complex structure of biochemical pathways, which includes death receptors, aspartate-specific cysteine proteases (►caspases), ►mitochondria, the ►Bcl-2 family and the family of ►inhibitors of apoptosis protein (IAP) as the most important regulators (Fig. 1). In principle, there are two alternative pathways that initiate apoptosis. One is mediated by death receptors on the cell surface (extrinsic pathway) (1); the other is regulated by mitochondria (intrinsic pathway) and triggered by stress responses such as genotoxic damage, hypoxia, free radicals or growth factor withdrawal (2). In both pathways, caspases are activated that execute cell death by cleaving cellular substrates to produce the structural and morphological changes described above.

To activate the extrinsic pathway, death receptors of the ►tumor necrosis factor (TNF)/nerve growth factor

Apoptosis, Regulation and Clinical Implications. Figure 1 Apoptotic signaling pathways can be divided into two main routes, the death receptor pathway (extrinsic) and the mitochondrial pathway (intrinsic). Both pathways involve the activation of initiator caspases such as caspase-8 and caspase-9 and converge at the level of effector caspase (caspases-3, -6 and -7) activation. The pathways can be blocked at several levels. In many cells, a cross-talk between the two pathways is provided by Bid, a BH3 only pro-apoptotic member of the Bcl-2 family.

(NGF) receptor family such as ▶Fas, TNF and ▶TRAIL receptors recruit, upon binding of their cognate ligands, molecules of the ▶death inducing signaling complex (DISC). Recruitment of pro-caspase-8 to the DISC results in its autoactivation and active caspase-8 then cleaves the BH3-only family member of the Bcl-2 family Bid to produce its truncated form tBid. Although the direct activation of pro-caspase-3 by caspase-8 may occur in cells expressing large amounts of caspase-8 (type I cells), in the vast majority of cells mitochondria are required for the efficient execution of death (type II cells). tBid either alone or in combination with other molecules induces oligomerization of the pro-apoptotic Bcl-2 family members Bax and/or Bak, thereby stimulating mitochondria to release a plethora of pro-apoptotic factors including ▶cytochrome c, ▶Smac/DIABLO, HtrA2/Omi and apoptosis-inducing factor (AIF), as a consequence of increasing outer membrane permeability. This critical step is blocked by anti-apoptotic Bcl-2 family members, including Bcl-2 and its homologues ▶Bcl-x_L, Bcl-w, Mcl-1 and A1. To this machinery further complexity is added by the presence of the BH3-only proteins Bim, Bmf or the p53 regulated Noxa and PUMA, which serve as sentinels that assist

the pro-apoptotic functions of Bax and Bak. Thus, at the mitochondria the extrinsic and the stress-induced intrinsic pathways converge into a complex switch-board where the life-death decision is made.

Upon release from mitochondria into the cytosol, cytochrome c initiates the formation of a complex known as the “▶apoptosome” by binding to an adapter molecule called Apaf-1, which further recruits ATP to activate pro-caspase-9. Activated caspase-9 cleaves the effector pro-caspases-3, -6 or -7, which then induce proteolysis of the final death substrates. Activation of effector caspases can be blocked by the IAP family members c-IAP1, c-IAP2, X-linked IAP and survivin, which bind to and inhibit the processing of death proteases. Although the presence of IAPs serves as a safeguard mechanism to avoid unwanted or premature induction of apoptosis, it is clear that their activities in turn must also be negatively regulated under conditions where progression of apoptosis is compelling. For this purpose, the “inhibitors of inhibitors” Smac/DIABLO and HtrA2/Omi, which bind to and inactivate IAPs, are released from activated mitochondria in conjunction with cytochrome c.

Normal cell turnover through properly regulated apoptosis is particularly important to maintain the

function of the immune system and other complex physiological processes in higher organisms. A look at the molecular basis of many diseases reveals an apoptotic component that either accounts for the disease or contributes to disease progression. The growing knowledge of the apoptotic machinery together with technological developments and advances in combinatorial chemistry and gene therapy have paved the way for the more effective treatment of diseases associated with deregulated apoptosis. The recent progress in apoptosis research and its implication for disease management and treatment are discussed below.

Clinical Implications

Cancer

Failure of proliferating tissues to maintain normal cell turnover may result in cell accumulation, neoplastic cell expansion and tumor formation. Moreover, defects in apoptosis signaling create a permissive environment for mutations and genetic instability. These alterations allow cells to disobey ►[cell-cycle checkpoints](#), facilitate growth factor and oxygen-independent survival and support anchorage-independent growth, e.g. during metastasis. Anticancer agents and ionizing radiation activate the apoptosis machinery in cells, a process that constitutes the main part of their cytotoxic effects (Fig. 2). Since apoptosis induced by anticancer agents converges into a final common death pathway, disruption of this mechanism may confer resistance to a broad spectrum of treatments. In addition, immune cells induce tumor cell apoptosis by binding with their death ligands to cognate death receptors on the tumor cell surface or by triggering the granzyme B/perforin pathway. Hence, apoptosis resistance also enables tumor cells to escape destruction by the immune system and recent evidence suggests that tumor cells can counterattack infiltrating immune cells (2).

Apoptosis resistance in cancer is mediated by diverse mechanisms that take effect at distinct points in the death pathway, resulting in its disruption. Many of the underlying molecules as well as their cancer-specific alterations have been identified and provide targets for rationally designed intervention approaches (3). In principle, they separate into two major classes: (a) (candidate) oncogenes with anti-apoptotic activity which are frequently over-expressed or amplified due to transactivation or posttranscriptional modulation, and (b) (candidate) tumor suppressor genes with pro-apoptotic potential which are underrepresented due to chromosomal deletions, negative transcriptional regulation, mutations or epigenetic events. In addition, as shown for TRAIL, death receptor signaling can be attenuated by the expression of inactive decoy receptors on the cell surface (1). Important molecular players and their alterations in cancer are shown in Table 1.

Apoptosis, Regulation and Clinical Implications.

Figure 2 Raster scanning electron micrograph of lung cancer cells undergoing drug-induced cell death. The extensive blebbing of the plasma membrane occurs as a consequence of cytoskeletal changes and represents a hallmark of apoptosis.

A number of apoptosis modulating therapeutics have shown efficacy in preclinical models, and, although only a few have finally reached the stage of clinical testing, this is significant progress, given that the field as a whole is only about a decade old. A strategy, which has already met with clinical success, is the use of ►[antisense](#) technology to down-modulate the expression of anti-apoptotic proteins or of protein kinases located in survival pathways or that posttranslationally activate anti-apoptotic proteins (reviewed in 4). Alternatively, strategies can be envisaged that enhance pro-apoptotic signaling in cells by transferring BH3 peptides or small molecule BH3 mimetics to inhibit Bcl-2/Bak interaction, by use of synthetic peptides derived from Smac/DIABLO to antagonize the effect of X-linked IAP or by transfer of inducible caspase genes. The death ligand TRAIL has attracted attention as a tumor-selective agent that spares normal tissues from cytotoxicity, albeit its clinical use is still disputed, due to the issue of potential hepatotoxicity. Which of these new approaches will eventually prove to be safe and effective in the clinic has to be awaited.

Bacterial and Fungal Infections

Neutrophils represent the most common granulocyte subtype in blood, and play an important role in anti-bacterial and anti-fungal defense. Apoptosis of neutrophils is an important mechanism that maintains appropriate neutrophil numbers under physiological conditions, since approximately 10^{11} mature neutrophils are generated every day in normal adults. Delayed neutrophil apoptosis has been associated with several acute and chronic inflammatory diseases (e.g. pneumonia, sepsis, cystic fibrosis) and appears to be largely mediated by excessive production of granulocyte

Apoptosis, Regulation and Clinical Implications. Table 1 Examples of major (candidate) oncogenes and tumor suppressor genes in cancer that negatively impact the apoptosis machinery

Oncogenes (gain of function)		Tumor suppressor genes (loss of function)	
Name	Type of alteration	Name	Type of alteration
Bcl-2	Over-expression (t14;18 translocation in follicular lymphoma)	Bax	Inactivation mutation; lack of transcriptional activation in p53 deficient cells
Bcl-x _L	Over-expression	p53	Inactivation/deletion mutations at various hot spots
Mcl-1	Over-expression	p14 ^{ARF}	Promoter hypermethylation
A1	Over-expression	PUMA, NOXA	Lack of transcriptional activation in p53 deficient cells
c-FLIP	Over-expression	Apaf-1	Promoter hypermethylation
Survivin	Expressed in tumors but rarely in normal adult tissues	Caspase-2	Over-expression of antagonistic short isoform
Mdm2	Prolonged half-life due to p14 ^{ARF} silencing	Caspase-3	Deletion mutation
PKCα	Over-expression	Caspase-8	Promoter hypermethylation
PKA-R1α	Over-expression	TRAIL-R1/R2	Inactivation mutation; decoy receptors
Clusterin	Over-expression	Fas	Inactivation mutation; promoter hypermethylation
HSP70	Over-expression	PTEN	Inactivation mutation
DNA methyl-transferase	Over-expression	DAPK	Promoter hypermethylation

colony-stimulating factor (G-CSF) and granulocyte-macrophage colony-stimulating factor (GM-CSF). The induction of neutrophil apoptosis during the resolution of a neutrophilic inflammatory response can be mimicked *in vitro* by culturing the cells in the absence of sufficient concentrations of survival factors, a process called spontaneous apoptosis. Most studies have been performed on purified blood neutrophils, aiming to understand the molecular events that control apoptosis in these cells (5). ▶Tyrosine kinases, phosphoinositide 3-kinase (▶PI3K), components of the mitogen-activated protein kinase (▶MAPK) pathways, the cyclic adenosine monophosphate (cAMP)/protein kinase A (PKA) pathway and protein kinase C (PKC) pathways all play a role. An early anti-apoptotic event is the phosphorylation of Bad, which leads to its translocation into the cytosol and its inability to interact with anti-apoptotic Bcl-2 family members. Later on further anti-apoptotic effects occur by modulation of the expression of apoptosis-regulating molecules of the Bcl-2 and IAP families.

Mechanisms that control the accumulation of neutrophils at sites of inflammation probably involve all events that limit the synthesis of neutrophil survival factors in inflammatory and structural cells. Intracellular inhibitors of cytokine signaling expressed in neutrophils are the Src homology domain 2 (SH2)-containing tyrosine phosphatase-1 (SHP-1) and cytokine-inducible SH2 (CIS) containing protein 1. Evidence for a functional role of SHP-1 as an inhibitory phosphatase activated by death receptors has been obtained by comparing neutrophils from normal and SHP-1-deficient mice. Inhibition of GM-CSF-mediated survival by simultaneous activation of Fas receptors was significantly reduced in SHP-1-deficient neutrophils, indicating that SHP-1 is important in limiting anti-apoptotic signals. Such a mechanism could largely explain why SHP-1-deficient mice demonstrate persistent neutrophilic inflammation. Further support for a role of SHP-1 in regulating neutrophil numbers was obtained by the observation that this phosphatase is over-expressed in patients with severe neutropenia.

Increased enzymatic SHP-1 may block cytokine effects important for both anti-apoptosis and differentiation, resulting in low neutrophil numbers. Moreover, decreased enzymatic SHP-1 correlates with inhibition of neutrophil apoptosis, since FMLP mediates PKC-mediated SHP-1 inactivation as well as delayed apoptosis in these cells.

In sepsis, accelerated T cell apoptosis can cause a condition called immune paralysis followed by death of the patient. Caspase inhibitors have been successfully applied as therapeutic agents to prevent immune paralysis and death in experimental models of sepsis.

Viral Infections

Viral infections can cause apoptosis in the infected cell, a scenario considered to be a cellular defense mechanism to prevent viral propagation. Apoptosis is often mediated by cytotoxic T cells, which activate caspases *via* Fas receptor ligation or delivery of granzyme B into the infected target cell. Too much apoptosis can result in organ dysfunction (e.g. hepatitis).

Some viruses are able to prevent apoptosis of the host cell. They either stimulate the host cell to synthesize anti-apoptotic proteins (e.g. Epstein-Barr virus, Sindbis virus) or they express their own anti-apoptotic genes which have great structural and functional similarities to host genes (e.g., baculoviruses, poxviruses). The anti-apoptotic genes involve FLIP-, Bcl-2- or IAP-like genes.

Allergic Inflammation

Eosinophils are prominent effector cells in many chronic allergic and parasitic inflammatory responses. Like other leukocytes, they are constantly generated in the bone marrow. To maintain cellular homeostasis, aged eosinophils must die by apoptosis and become removed in the absence of inflammation. Interleukin-5 (IL-5) appears to be a specific survival factor for eosinophils, at least within the human system. Therefore, and not surprisingly, eosinophilia and high IL-5 expression levels have often been associated, especially in chronic allergic disorders such as bronchial asthma and atopic dermatitis. The phenomenon of delayed eosinophil apoptosis has been demonstrated in nasal polyp explants as well as in purified blood eosinophils from patients with atopic dermatitis and some patients with the hypereosinophilic syndrome. Moreover, it appears that the severity of asthma negatively correlates with the amount of eosinophil apoptosis in the airways. These findings suggest delayed eosinophil apoptosis as a hallmark of tissue eosinophilia (6).

Besides eosinophils, T cells also have an increased life span at the site of allergic inflammation. IL-2, IL-4 and IL-15 are important survival factors that prevent apoptosis even in activated and Fas-sensitive T cells. Both T cells and eosinophils are believed to induce

apoptosis in epithelial cells by different mechanisms and the resulting epithelial damage may largely contribute to the symptoms seen in asthma and atopic dermatitis.

Autoimmune Inflammation

Rheumatoid arthritis (RA) is a frequent autoimmune disease in which patients suffer from chronic inflammatory synovitis that is dominated by the presence of macrophages, neutrophils, lymphocytes and synovial fibroblasts. Synovial macrophages are highly resistant towards apoptotic stimuli (7). TNF- α stimulation appears to participate in the anti-apoptotic effect, since it results in increased expression of (a) FLIP, (b) the Bcl-2 family member A1 and (c) the Bcl-2 family member Mcl-1 in these cells. Therefore, anti-TNF- α therapies might partially act *via* the promotion of macrophage apoptosis. Synovial fibroblasts have also been identified as important contributors to the pathogenesis of RA and apoptosis of these cells is rare. The relative insensitivity of synovial fibroblasts to undergoing apoptosis might be the consequence of high expression of FLIP and X-linked IAP, as well as inactivation of p53. Moreover, it has been demonstrated that the synovial fluid of RA patients delays neutrophil apoptosis and interferon- β and adenosine have been identified as the key mediators responsible for this effect. Although defective Fas ligand expression on activated synovial T cells has been reported, this finding may not be of pathogenic relevance, since therapies with depleting monoclonal antibodies directed against T cells have not been effective.

Patients with **systemic lupus erythematosus (SLE)** have increased levels of soluble Fas, which competitively inhibit the Fas ligand-Fas interactions. The resulting decrease in Fas-mediated apoptosis may contribute to the accumulation of autoimmune cells in this disorder. In patients with leukopenia or thrombopenia, autoantibodies that induce massive apoptosis (often in conjunction with the complement system) may cause the disease. In other circumstances, the expression of growth and differentiation factors might not be sufficient to prevent apoptosis of hematopoietic precursor cells. In autoimmune endocrine diseases, such as type 1 diabetes, β cells of islets of Langerhans in the pancreas undergo increased apoptosis due to attacks of autoreactive Fas ligand-expressing CD4⁺ and CD8⁺ T cells. There are many more autoimmune diseases for which published reports on deregulated apoptosis exist.

One example is the autoimmune lymphoproliferative syndrome (ALPS) in which dominant mutations in the Fas receptor, Fas ligand or other genes in the Fas pathway are found (8). ALPS is clinically characterized by massive lymphadenopathy and splenomegaly, which typically presents in childhood. These symptoms

are often accompanied by autoimmune hemolytic anemia, thrombocytopenia and other autoimmune manifestations. In addition, patients have markedly increased numbers of circulating double-negative T cells (CD4⁺CD8⁻). ALPS patients also have increased numbers of circulating B cells and polyclonal hypergammaglobulinemia.

Acquired Immunodeficiency Syndrome (AIDS)

Aberrant apoptosis has been identified as the major mechanism underlying the excessive immune cell depletion associated with the pathogenesis of AIDS. Infection with the human immunodeficiency virus (HIV) is associated with increased apoptosis of CD4⁺ T cells and the development of AIDS has been directly correlated with this process. CD4 acts as a receptor for viral attachment, thus facilitating HIV infection of CD4 expressing cells. How the apoptosis machinery responds to intracellular HIV and whether this is part of a cellular defense mechanism to prevent viral propagation is unclear. Strikingly, most T cells undergoing apoptosis are not HIV-infected. Recent studies suggest that depletion of CD4⁺ T cells is driven by a general immune activation process, leading to activation-induced death in this cell population (9).

Neurodegeneration

Developmental neuronal death occurs at least partially through the process of apoptosis, which modulates neuronal number, connectivity and neuronal volume. The role of apoptosis in neurodegenerative disorders, however, is less clear. Enhanced apoptosis signaling has been discussed in ►Alzheimer's disease and ►Parkinson's diseases, spinal muscular atrophy, amyotrophic lateral sclerosis, ►Huntington's disease and ischemic stroke, but recent evidence suggests that other forms of programmed cell death are also involved. In addition, it is unclear why aberrant cell death leading to disease is more frequently associated with neurodegeneration than with other degenerative processes. It is possible that neurons contain a death program that is more readily triggered than in other cells, e.g. neurons in the central nervous system are particularly susceptible to pro-apoptotic stimuli such as intracellular calcium or free radicals. Alternatively, excessive cell death may occur in various tissues of the organism but degeneration of the neuronal system is more serious, due to the low capacity for regeneration (10).

Neuronal death is accompanied by the activation of caspases and has been detected in Alzheimer's disease (caspases-3, -6 and -9), amyotrophic lateral sclerosis and Parkinson's disease (caspases-3, -8 and -9). In models of Alzheimer's disease it was shown that neuronal cell cultures lacking either caspase-2 or caspase-12 are resistant to β -amyloid-induced death, whereas, on the other hand, fragments of β -amyloid

down-regulate Bcl-2 and up-regulate Bax expression. In addition, using substrate inhibitors, dominant-negative constructs of caspases, death receptor adaptor molecules or over-expression of X-linked IAP, it was demonstrated that both the death receptor and the mitochondrial death pathways are distinctively implicated in the various neurodegenerative diseases.

The complexity and the myriad intertwining pathways involved in neuronal demise represent a fundamental challenge for the design of effective therapies. In principle, the blockade of pro-apoptotic pathways represents a valid strategy to impede neurodegeneration. For example, the drug selegiline, which has historically been used for the treatment of Parkinson's disease because it indirectly enhances dopamine signaling, was found to also up-regulate the expression of the survival factors Bcl-2 and Bcl-x_L. Another approach is to block the death pathway further downstream at the level of effector caspases, using competing peptides, small molecule inhibitors, dominant-negative constructs of caspases or inhibition of gene expression by antisense technologies. Whether similar approaches are useful for the management of slowly progressing neurodegenerative conditions, where neuronal function fails before cell death occurs, remains to be investigated.

Osteodegeneration

Osteoporosis and osteoarthritis are two degenerative diseases of the musculoskeletal system that frequently occur in elderly individuals. Increased apoptosis is seen ►in osteocytes in osteoporosis and in ►chondrocytes in osteoarthritis patients. Among other factors, the lack of hormones (e.g. estrogen, androgens), which are physiological inhibitors of apoptosis in these cells, might play a role.

Ischemic Injury

Myocardial infarction and stroke are common disorders associated with necrosis and increased apoptosis. These diseases result from an acute loss of blood flow. The central area of ischemia is characterized by necrotic cell death, whereas further distal from this area cell death is delayed and a consequence of apoptosis. Additional tissue injury frequently occurs during reperfusion. This is due to increases in oxygen radical production and mobilization of calcium that both trigger apoptosis. Clearly, the use of agents that can block apoptosis during reperfusion would be beneficial for these patients.

Apoptosome

Definition

The apoptosome is a cytoplasmic complex of molecules consisting of pro-caspase-9, Apaf-1 (apoptotic protease activating factor), and cytochrome c, leading to the activation of caspase-3 in the presence of either ATP or dATP.

Activation of the effector caspase-3 is a pivotal event in apoptosis induction. A variety of cellular stresses induce caspase-3 activation by triggering the release of pro-apoptotic mitochondrial proteins, among others cytochrome c. Cytosolic cytochrome c in turn initiates the formation of a caspase-3 activating multi protein complex named the apoptosome. The apoptosome consists of six or seven molecules of each of the scaffold protein apoptosis promoting factor 1 (Apaf-1), cytochrome c, dATP and caspase-9. So, formation of the apoptosome comes along with oligomerization and activation of caspase-9, which in turn is able to stimulate caspase-3 processing.

Apparent Mineralocorticoid Excess

Definition

AME is a mendelian hypertensive syndrome. The clinical signs are volume dependent salt sensitive hypertension, tendency to hypokalemia and metabolic alkalosis, low renin and low aldosterone values, responsiveness to both thiazides and spironolactone despite absence of aldosterone or any abnormal mineralocorticoid products and resemblance to licorice gluttony. The disease is caused by mutations in the renal-specific isoform gene for 11 β -hydroxysteroid dehydrogenase coding for an enzyme which is responsible for converting cortisol to cortisone. In the distal renal tubule this step is crucial for protecting the mineralocorticoid receptor which has the same affinity for cortisol as it does for aldosterone.

Aptamer

Definition

Aptamers are specific RNA or DNA oligonucleotides that are isolated from combinatorial synthetic libraries that consist of 15–60 nucleotides. Aptamers can adopt a vast number of three dimensional shapes. Due to this

property, aptamers can be produced to bind tightly to a specific molecular target. As an extraordinary diversity of molecular shapes exist within the universe of all possible nucleotide sequences, aptamers may be obtained for a wide array of molecular targets, including most proteins, carbohydrates, lipids, nucleotides, other small molecules or complex structures such as viruses. Aptamers are powerful tools for analytic, diagnostic and therapeutic applications. Aptamers are easy and cheap to synthesize, although their polyanionic character limits the number of useful applications.

Apurinic or Apyrimidinic (AP) Sites

Definition

AP site (apurinic or apyrimidinic site; commonly referred to as abasic site) describes sites in the DNA with an intact sugar phosphate backbone, but a lacking purine or pyrimidine residue.

- ▶ Base Excision Repair

AQP2

- ▶ Aquaporin-2

Aquaporin

Definition

Aquaporins are membrane water channels that play critical roles in controlling the water content of cells. These channels are widely distributed in all kingdoms of life, including bacteria, plants, and mammals. More than ten different aquaporin proteins have been found in the human body, and several diseases, such as congenital cataracts and nephrogenic diabetes insipidus, are connected to the impaired function of these channels.

Aquaporin-2

Definition

Aquaporin-2 (AQP2) is the vasopressin sensitive water channel that regulates water reabsorption in the distal nephron collecting duct. Inherited AQP2 mutations that disrupt folding, lead to nephrogenic diabetes insipidus by targeting newly synthesized protein for degradation in the endoplasmic reticulum (ER).

Association Studies

Definition

Association study refers to a genetic analysis method, which in its simplest form, tests whether a specific allele is more or less common in a test population compared to a control group. Association studies have been proposed to identify the genetic determinants of complex traits such as obesity or hypertension. DNA markers (usually a large number of ► [SNPs](#)) from selected populations of affected and non-affected (control) individuals are genotyped. A significant frequency change of typed markers indicates an association between these markers and the complex trait under investigation. Unfortunately, the reproducibility of most association studies to our understanding of a disease and its genetic determinants has been modest. Criteria for “high quality” association studies have been published (see for instance: Freely associating (1999) *Nat Genet* 22:1–2). These criteria are: large sample size, small P values, biological plausibility, functional significance, independent replication in several populations, confirmation in family-based studies and high odds ratios and/or high attributable risk. One difficulty also lies in the recruitment of ideal controls.

Atomic Force Microscopy

FILIPP OESTERHELT

Institute for Physical Chemistry II, AG Nanoanalytics,
Heinrich-Heine University, Düsseldorf, Germany
filipp.oesterhelt@uni-duesseldorf.de

Definition

The invention of the atomic force microscope (AFM) by Binnig, Quate and Gerber in 1986 opened up a new view of the world of small structures. In contrast to the previously invented ► [scanning tunneling microscope](#), the AFM allowed the imaging of non-conducting surfaces with molecular to atomic resolution for the first time. This was made possible by using the force acting on a pointed tip-probe as feedback parameter, while the tip was scanned across the sample.

For AFM imaging almost no sample preparation is needed. The sample surfaces can be imaged in any atmosphere and also in liquids. Thus, the AFM soon developed to a powerful standard technology that is used to investigate all types of biological surfaces. Single molecules such as nucleic acids and proteins and their supramolecular assemblies can be visualized adsorbed on solid surfaces. But whole living cells can also be imaged. Membrane proteins can be analyzed in their native environment. When imaging whole native cell membranes, the interaction and spatial arrangement of membrane proteins can be investigated. The small probe-sample interaction allows repeated scanning of the same area. This makes it possible to investigate dynamic effects from the cellular level down to single molecules. Beside this wide field of biological applications, the ability of the AFM to image any surface with high resolution also leads to broad applications in materials research and quality control.

Description

To measure the force acting on the pointed probe, it is mounted on the end of an elastic spring cantilever. Any forces acting on the probe lead to a deflection of the cantilever spring. To read minute deflections without touching the cantilever, the light pointer principle is used. A laser beam is focused on the end of the cantilever and the position of the reflex is detected with

a position sensitive photodetector. With this method, it became possible to measure deflections in the Å (10^{-10} meter) range and forces down to a few piconewton (10^{-12} newton), respectively.

The first AFMs used diamond splinters as probes. Today a variety of probes are commercially available. Produced by semiconductor etching technologies, they are made of crystalline silicon or silicon nitride having tip radii of a few nanometers. Tips with high aspect ratios, needed for imaging narrow and deep structures, are produced by growing secondary tips on top of the probe by ► [electron beam deposition](#) (EBD). Another alternative is carbon nanotubes that are attached to or catalytically grown on the probe. These tips provided for the first time an atomically well-defined probe.

The forces acting on the tip can be of any nature. This allows imaging of many different surface properties with nanometer resolution. When the probe is scanned across the surface, the repulsive force upon contact is used to measure the height profile of the surface. To minimize the probe induced sample damage that can occur when the tip hits higher structures from the side, different modes were introduced. Called tapping mode, intermittent contact or non-contact mode, they all oscillate the tip and measure the change in the oscillation amplitude or frequency, which gives a measure for the surface probe distance without touching the surface.

But advantage can also be taken of high surface-tip interactions. Scanning the tip across the surface with intensive contact, a lateral deflection of the cantilever can be measured, indicating the friction force between tip and surface.

Upon touching the surface with the tip, the cantilever is deflected away from the surface. The characteristics of this indentation dependent bending contain information about the softness of the surface. Performing a so-called force curve (approaching the tip to the surface, indenting and retracting again) at each position on a surface, an image of the surface softness can be obtained (called force volume imaging). Upon retraction of the tip, adhesive forces between tip and surface can also be measured. Depending on the chemical composition of the tip, hydrophobic, hydrophilic and other chemical interactions can be measured with high spatial resolution. Biomolecular interactions between a functionalized tip (e.g. with antibodies) and a protein bearing surface can be used in the same way to localize proteins on the surface due to their specific interaction. These procedures are usually called adhesion imaging. Magnetic forces can also be used to produce an image contrast. In the semiconductor industry, magnetic forces are used to characterize magnetic bits of data storage devices.

Beside its ability to image surfaces with nanometer resolution, the AFM is a spring scale that allows the

Atomic Force Microscopy. Figure 1 The atomic force microscope consists of three main parts. A scanning unit that scans either the probe or the sample with sub nanometer accuracy, the probe itself, mounted on a spring cantilever which serves as a sensitive force sensor and a deflection detection system that uses the light pointer principle to achieve sub nanometer sensitivity. This simple setup makes it possible to use the instrument in any atmosphere including liquids.

measurement of forces down to the piconewton range. This made it possible for the first time to measure the interaction force of single receptor-ligand pairs like biotin-avidin or any antibody-antigen interactions. A molecule clamped between the tip of the AFM and the surface can be loaded with different forces while measuring its change in length. These experiments, called force spectroscopy, revealed for the first time the characteristic mechanical properties of single polymer molecules, which could be correlated with their chemical structure. Proteins clamped between tip and surface, unfold at typical forces and show a characteristic unfolding pattern, which reveals the presence of different stable sub domains.

Clinical Applications

Due to its ability to work under biologically relevant conditions, the AFM is applied in all the areas of medical relevance such as pharmacology, biotechnology, microbiology, molecular biology and genetics. In pharmaceutical research, the application of force microscopy allows the characterization of small particles that play an important role in pharmaceutical forms of drugs. Force measurements between individual particles make a quantitative analysis of the interaction forces and energies possible (1).

Force microscopy can be applied to image living cells. This can reveal their three-dimensional structure as well as the consistency of the cell. Force volume imaging allows the visualization of the cytoskeleton and its dynamic growth and degradation. Long-term dynamic changes such as biomineralization or cell movement can be studied. Non-contact imaging and force pulling experiments on diatoms (2) revealed the characteristics of natural adhesives that are present on their surfaces.

To grow on surfaces, cells have special requirements with respect to surface roughness and chemical nature. This is an important issue especially for implants, where cells have to settle on the surface to guarantee its biocompatibility. The AFM is well suited and is often used to characterize the surface roughness and its change in the aging process of artificial bone materials to optimize them for cell adhesion. Specific cell-surface adhesion forces can be measured directly. Cells, attached to the end of a tipless cantilever can be brought in contact with the surface and kept there for a defined time. Upon retraction, the holding force and dynamics of the rupture process can be measured (3). Analysis of the cell morphology is an important tool in drug discovery. Besides measuring cell growth, atomic force microscopy can also be applied to measure time

Atomic Force Microscopy. Figure 2 An AFM contact-mode image of conjoined NRK daughter cells. The image was recorded about 30 min after cytokinesis. Dynamically and spatially-resolved changes in cortical stiffness that play a role in cell division can be observed with the force microscope. Scale bar 20 μm . (From: Matzke R, Jacobson K and Radmacher M (2001) Direct, high-resolution measurement of furrow stiffening during division of adherent cells. *Nat Cell Biol* 3:607–610).

resolved cell volume shifts. Oberleithner *et al.* used this technique to investigate the influence of hormone exposure on cells. They analyzed the dynamic changes by repeated imaging and calculating the volume shifts between cytosol and cell nucleus (4). In the same way, dynamic processes like degradation of lipid membranes

and outer cell walls by enzyme digestion can be monitored in real time.

Another important field where the AFM became an important tool is virology. The molecular structure of small viral particles and their distribution on living cell surfaces can be characterized on living cells at different stages of the cell-cycle. The structure of the viral particles themselves can also be investigated. Images of the human immunodeficiency virus (►HIV) and HIV-infected lymphocytes showed the protein surface structure and the thickness of its outer protein shell (5).

Therapeutic Consequences

Force microscopy will have an effect on therapeutics *via* its influence on medical research. The AFM is a tool that opens up new possibilities for investigation of biological samples. Research on living cells and the possibility of observing dynamic effects in real time as well as the possibility of analyzing the smallest surface structures under native conditions will greatly aid the search for new therapies.

Department of Human Genetics, Ruhr-University of Bochum, Bochum, Germany
sabine.hoffjan@ruhr-uni-bochum.de

Synonyms

Allergic Disorders, Genetics

Definition

Atopic disorders, including atopic dermatitis (AD), allergic rhinitis and asthma, are characterized by the development of immunoglobulin E (IgE) antibodies to ubiquitous, nonpathogenic allergens. Almost one-third of the population worldwide is affected by allergic symptoms today and the incidence of all three disorders has been on the rise over the past few decades. A genetic component for allergic diseases has long been suggested since they tend to cluster in families and twin studies have shown higher **▶concordance rates** for monozygotic compared with dizygotic twins. However, unraveling the genetic background of atopy has proven to be much more difficult than identifying genes for **▶Mendelian disorders**.

Characteristics

Atopic disorders belong to the group of **▶complex genetic disorders**, which means that no simple Mendelian pattern of inheritance can be identified as for single-gene diseases (e.g. **▶cystic fibrosis**). Complex disorders are multifactorial, with genetic as well as environmental factors contributing to disease development. Environmental factors influencing asthma/atopy development include, for example, smoke exposure, respiratory tract infections, and exposure to allergens and endotoxin in early childhood. Further, complex disorders are multigenic, which means that more than one gene influences susceptibility. Results from genome-wide screens (see below) suggest that probably many different genes are involved in risk for atopic disease, each gene contributing little to the overall atopy risk. Thus, identifying an “atopy gene”

with satisfying statistical significance can be a difficult task. Genetic studies on atopy are further influenced by the fact that expression of atopic phenotypes is variable and even members of the same family might show very different phenotypes (e.g. measurable IgE antibodies without clinical symptoms in some individuals; rhinitis, AD, asthma or often combinations of all three in other individuals). Even completely healthy individuals may carry the susceptibility gene, because in complex diseases the **▶penetrance** is usually reduced. An additional problem is the existence of so-called **▶phenocopies**, i.e. phenotypically identical diseases that are due to different underlying causes (genetic/environmental). Lastly, there is growing evidence that **▶gene-gene** as well as **▶gene-environment interactions** play an important role in asthma susceptibility. However, despite these problems, characteristic for the genetics of complex disorders, considerable progress in atopy research has been made over the last several years.

Cellular and Molecular Regulation

Positional Cloning

One approach to identifying disease-causing genes is to perform a **▶genome-wide screen**, in which several hundred markers spaced evenly throughout the genome are typed in families with the disease phenotype. Markers that are located close to the disease gene will be co-inherited (linked) with the disease. After a linked region has been found, **▶positional cloning** is performed to identify the susceptibility gene in the linked region. Alternatively, known **▶candidate genes** in the region of interest can be screened for variation directly, called **▶positional candidate cloning**. This approach is rather cost- and time-consuming, but can potentially identify all genes with detectable effects on asthma susceptibility, even if the gene function is unknown before.

Sixteen genome-wide screens for atopic disorders have been completed to date (Table 1). Because of the variability of atopic phenotypes, some studies use intermediate phenotypes [e.g. bronchial hyperresponsiveness (BHR), positive skin prick test (SPT) or total or specific IgE levels] instead of a dichotomous disease phenotype. Overall, the results differ quite substantially between study populations, but there are some chromosomal regions that are rather consistently linked to atopic phenotypes in many studies (Table 2). Among these are the **▶cytokine cluster region** on chromosome 5q, the human leukocyte antigen (HLA) region on chromosome 6p and regions on chromosomes 12q, 13q and 17q.

Recent reports of the first asthma genes identified by positional candidate cloning provide evidence that this approach can be successful. The **▶ADAM33** gene was identified as the asthma susceptibility gene in a linked

region on chromosome 20p13 (1). ►**ADAM** (a disintegrin and metalloproteinase domain) proteins are surface proteins involved in cell-cell adhesion as well as protein cleavage. *ADAM33*, which is expressed in bronchial smooth muscle cells, has been suggested to play a role in airway remodeling characteristic of chronic asthma, but functional studies have not been done yet. However, the associated variants in this gene were intronic rather than coding, and ►**haplotypes** rather than single nucleotide polymorphisms (►**SNPs**) conferred risk for asthma, with different haplotypes associated in different populations. Thus, the overall importance of this gene in asthma development might be rather modest.

Similarly, positional cloning of a quantitative trait locus on chromosome 13q14 that influences IgE levels and asthma recently identified the *PHF11* gene as another asthma/atopy gene (2). The gene product contains two

PHD (plant homeodomain) zinc fingers, which suggests that it might be involved in regulation of transcription. Three ►**SNPs** in *PHF11* were found to have independent effects on IgE levels, and these SNPs are located in introns and the 3' untranslated region of the gene, similar to the findings for *ADAM33*. Ongoing positional cloning efforts worldwide are likely to discover many more susceptibility loci, each of which has a small effect on the overall asthma or atopy risk.

Candidate Gene Studies

Candidate gene studies focus on genes with known functions that suggest they might be implicated in disease susceptibility. For atopic disorders, these are particularly genes encoding cytokines or chemokines and their receptors, IgE receptor, or transcription factors (Table 3). Genetic variation in these candidate

AD, atopic dermatitis; BHR, bronchial hyperresponsiveness; IgE, immunoglobulin E; SPT, skin prick test

genes, mostly coding SNPs leading to changes in the protein structure, is tested for ►association with atopic phenotypes. Most ►association studies are done in a case-control study design, by comparing allele frequencies in unrelated patients with unrelated controls. A significantly higher frequency of a certain allele in cases compared with controls suggests that either there is a causal relationship between variant and disease or that the variant is in ►linkage disequilibrium (LD) with the true disease-causing variant. LD is the nonrandom association of alleles at linked loci in populations and will usually only be detected over relatively small distances, indicating that the disease-causing variant must be located close to the marker. The advantages of candidate gene studies are that they do not require families and thus are easier to conduct and more cost-effective. Further, they could potentially identify variants with rather modest effects on susceptibility. However, these studies are limited to genes of known function and the present knowledge about physiological pathways important for atopy. Further, the results of association studies can be hampered by small sample sizes and population substructure.

Out of the many candidate genes that have been investigated so far, some have been rather consistently associated with atopic phenotypes across studies. These results will be reviewed in more detail.

HLA-DRB1

The human leukocyte antigen (HLA) class II genes, HLA-DR and DQ on chromosome 6p21, are intriguing atopy candidate genes because the main function of class II molecules is to present antigen to the T lymphocyte receptor. Thus, the very first genetic association studies with atopy focused on the role of these genes in specific IgE responses, and since the 1980s, many groups have reported an association of the *HLA-DRB1* locus with specific IgE responses to a wide variety of antigens, including ragweed pollen, birch pollen, rye grass pollen, cat dander, mold, olive pollen, *parietaria*, and house dust mites. More recent studies found associations of this locus with total serum IgE, atopy and asthma. Although the associations and phenotypes vary quite substantially between studies, overall most studies consistently imply that *HLA-DRB1* is an atopy susceptibility locus. However, there

Atopy, Genetics. Table 3 Candidate genes that have been associated with atopy and asthma-related phenotypes in at least two independent studies

Gene	Gene name	Chromosomal location
<i>IL10</i>	Interleukin 10	1q31

<i>RANTES</i>	Regulated upon activation, normally T-expressed and secreted	17q11–q12
<i>EOTAXIN</i>	Eotaxin	17q21
<i>ACE</i>	Angiotensin-1 converting enzyme	17q23
<i>TGFB1</i>	Transforming growth factor beta 1	19q13.1

are several other interesting candidate genes in the linked region on chromosome 6p21, including the tumor necrosis factor alpha (*TNF*) and lymphotoxin-alpha (*LTA*) genes both of which have been associated with atopy-phenotypes in several studies, although negative results have been reported as well. It is also possible, if not likely, that variation in another gene in

the HLA region confers atopy risk and is in LD with the reported variants.

Genes in the Interleukin (IL)-4/IL-13 Pathway

IL-4 and IL-13 are important T helper type 2 (Th2) cytokines that mediate inflammation in asthmatic airways. The genes encoding both cytokines are

adjacent and located in the cytokine cluster region on chromosome 5q31, which has been linked to atopy or asthma in five genome screens (see above). Their receptors share a common α -chain, encoded by the *IL4RA* gene on chromosome 16p12. All three genes have rather consistently been associated with atopy-related phenotypes.

IL13

Two functional SNPs have been described in the *IL13* gene: a promoter polymorphism at position –1112 that alters regulation of IL-13 production and increases binding of nuclear proteins to this region and an amino acid exchange in exon 4 (Arg110Gln). The –1112 SNP was associated with asthma, BHR and SPT in two different Dutch populations, and Arg110Gln was associated with total IgE levels, atopic dermatitis, asthma, and atopy in seven different studies. There are only a few studies that failed to replicate an association of this SNP with atopic phenotypes. Thus, *IL13* is likely to be an atopy susceptibility locus in the 5q31 region, even though no study to date has shown that variation in *IL13* accounts for the evidence of linkage to this region (3).

IL4

The *IL4* gene is another interesting candidate gene in the 5q31 region, but association results are not as consistent as for *IL13*. A functional SNP at position –509 in the promoter region has been associated with total and specific IgE, childhood asthma, asthma severity, AD, and lung function. However, negative results were reported for childhood asthma, atopic asthma, and AD and the promoter SNP did not account for the evidence of linkage to the 5q cytokine cluster. A second promoter region SNP at position +33 was associated with total IgE levels in one study but not with AD in another.

IL4RA

Ten amino acid substitutions have been described in coding regions of the *IL4RA* gene on chromosome 16p12, three of which were shown to be functional (Ile50Val, Ser478Pro and Gln551Arg). Association studies on single SNPs have been conducted in many populations with conflicting results; while overall most studies reported an association of *IL4RA* variation with asthma-related phenotypes, the associated alleles differed quite substantially between populations. Therefore subsequent studies evaluated multiple SNPs simultaneously in the form of haplotypes and found haplotypes to be more informative than single SNPs and significantly associated with atopy- or asthma-related phenotypes (4). Overall, associations between coding region variation and asthma or atopic

phenotypes in at least nine independent studies indicate that the *IL4RA* gene is an atopy susceptibility locus.

ADRB2

β_2 -adrenoceptor agonists that activate β_2 -adrenoceptors on the bronchial smooth muscle cells are the most widely used bronchodilator drugs in asthma. Since long-term treatment results in down-regulation and desensitization of receptors in some, but not all asthma patients, it was proposed that genetic variation in the gene encoding the β_2 -adrenoceptor (*ADRB2*) gene might influence drug response. Two common coding SNPs, Arg16Gly and Gln27Glu, have been shown to be functional, with the 16Gly allele leading to increased, and the Glu27 allele to decreased receptor down-regulation. Most case-control studies to date have not found an association between either of these variants and asthma *per se*, but rather implicate *ADRB2* as a disease-modifying gene (e.g. associations with steroid-dependent asthma, nocturnal asthma, asthma severity, and lung function). Clinical trials investigating the role of these polymorphisms in long-term drug response gave conflicting results. However, Drysdale et al. recently examined haplotypes comprised of 13 SNPs in promoter and coding regions of *ADRB2* and reported associations between certain haplotypes and *in vivo* bronchodilator response as well as *in vitro* expression levels, indicating that haplotypes might have a greater predictive power than individual SNPs as pharmacogenetic loci (5). Overall, there is evidence that variation at the *ADRB2* locus might indeed influence drug response, but the relative importance of this effect on treatment outcomes and the specific SNPs or haplotypes that influence response remain to be determined.

CD14

CD14 is the primary receptor for lipopolysaccharide (LPS, or endotoxin). LPS has attracted much attention recently because there is growing evidence that exposure to LPS in the first years of life might prevent allergic sensitization by stimulating the early development of a Th1-like immune response. Association studies with the *CD14* gene on chromosome 5q31 suggest that variation in this gene might interact with the environment (i.e. endotoxin levels) in conferring risk for atopic diseases. A functional SNP in the promoter region of this gene (–159C/T) was identified, and the –159T allele was associated with reduced levels of total serum IgE in the Tucson Respiratory Study (Arizona, USA) as well as in the Dutch population. However, the same allele was associated with increased risk for atopy in the Hutterites, a farming population, and neither allele showed an association with asthma phenotypes in a German allergy study or in the Icelandic population. Vercelli recently suggested an

intriguing explanation for these discrepant findings; it is possible that the amount of endotoxin load to which a population is exposed could modulate the effect of the genotype at this locus (6). While in the Tucson children with an intermediate exposure to LPS, the T allele seems to be protective by increasing soluble CD14 levels and lowering IgE levels, this protective effect might not be seen in a population that has a very low endotoxin load (German), and the opposite effect might be seen for a population that has constant contact with livestock and LPS like the Hutterites. This is an interesting example of a gene-environment interaction that needs to be confirmed in additional populations.

Clinical Relevance

Identifying genetic variation that influences the development of atopy could have several important clinical implications. First, knowledge about genetic susceptibility could help to identify individuals at risk for atopic disease at a very early age and develop specific prevention strategies. Second, since treatment response to certain pharmaceuticals might be influenced by genetic variation (as in the example of *ADRB2*, see above), specific treatments for genetically different individuals could be developed. Lastly, a better understanding about the complex genetic and molecular background that underlies atopic diseases could lead to the invention of new diagnostic and therapeutic strategies in the future (7).

ATP

Definition

Adenosine 5'-triphosphate (ATP) is the main source of energy in the cell. It is used to provide most of the cellular processes with energy. ATP is primarily produced within the mitochondria, but the glycolysis that takes place in the cytoplasm is of importance for ATP production.

► DNA Ligases

► Mitochondrial Myopathies

ATPase

Definition

ATPase is an enzyme that hydrolyzes ATP, releasing energy for other cellular activities.

► Splicing

ATP-Binding Cassette (ABC) Transporters

Definition

ABC Transporters comprise of a large protein family of transmembrane proteins that contain an ATP-binding cassette (ABC). ABC proteins are low capacity-but high affinity transporters able to transport substrates against a concentration gradient of up to more than 10,000 fold. Hydrolysis of ATP is required for substrate transport. ABC transporters are mainly either import or export pumps, bi-directional ABC proteins appear to be rare exceptions. Substrates include lipids, sugars, amino acids, peptides, proteins, metals, (in)organic ions, toxins, and antibiotics. Some ABC transporters are able to pump anticancer drugs out of the cells, thus making them drug resistant.

► Chromatin Remodelling

Atrophia Gyrate

Definition

Atrophia gyrate is a rare autosomal recessive disorder with clinical signs similar to those seen in Retinitis pigmentosa (RP), however, is characterized by sharply defined Garland shaped areas of chorioretinal atrophy. An elevation of the plasma ornithine level, caused by an ornithine aminotransferase deficiency, is involved in this disease.

► [Retinitis Pigmentosa](#)

Attention Deficit Hyperactivity Disorder

Definition

Attention deficit hyperactivity disorder (ADHD) is a condition affecting children and adults, which is characterised by problems with attention, impulsivity and overactivity. Today, it affects between 4–6 percent of schoolage children and between 2–4 percent of adults.

► [Fragile X Syndrome](#)

Attenuation

Definition

The term attenuation describes a mode of transcription regulation at the transcription elongation level, which is frequently used for feedback control of metabolic pathways in bacteria.

► [Transcription Elongation](#)

AUG Translational Start Site

Definition

AUG translational start site is the first translated codon within the gene/mRNA strand, and the position from which peptide synthesis starts.

AU-Rich Elements

Definition

AU-rich elements (ARE) are short regions rich in A and U nucleotides, which are located in the 3' untranslated regions of short-lived mRNAs, including many encoding cytokines, proto-oncoproteins, and growth factors.

► [RNA Stability](#)

Aurora Kinases

Definition

Aurora kinases represent a novel family of serine/threonine kinases. They have been identified as key regulators of the mitotic cell division process, and play a role in cell transformation and tumorigenesis. Three members of this kinase family have been identified so far, referred to as Aurora-A, Aurora-B and Aurora-C kinases. They are close homologues of the prototypic yeast Ip11 and Drosophila aurora kinases, which are known to be involved in the regulation of centrosome function, bipolar spindle assembly and chromosome segregation processes. Expression of Aurora kinases is elevated in human cancer cells.

► [Chromosome Condensation](#)

Autoantibody

Definition

Autoantibody refers to an antibody that is directed against a self-molecule.

► [Autoimmune Diseases](#)

Autoantigen

Definition

Autoantigen is a self-molecule (nucleic acid, protein, glycolipid etc.) that is recognized by an autoantibody or an autoreactive T lymphocyte.

► [Autoimmune Diseases](#)

Autocorrelation

Definition

Autocorrelation defines a mathematical measure to compare a single signal with itself at different times with respect to the information it carries. In fluorescence correlation spectroscopy (FCS) analysis, autocorrelation functions have distinct decay times reflecting characteristic temporal processes, e.g. the diffusion of a molecule through the measurement volume.

► FCS

► Molecular Dynamics Simulation in Drug Design

Autocrine

Definition

Autocrine refers to the action of small inducible polypeptides (e.g. cytokines in the immune system) that act on the same cells which produce them.

► Growth Factors

► Rheumatoid Arthritis

Autogenous Translational Control

Definition

Autogenous translational control describes a mechanism by which the protein product encoded by an mRNA, regulates the amount of its own synthesis, by altering the efficiency of its own translation.

► Translational Frameshifting, Non-standard Reading of the Genetic Code

Autoimmune Diseases

WESTLEY H. REEVES

Division of Rheumatology & Clinical Immunology,
Center for Autoimmune Diseases, University of
Florida, Gainesville, Florida, USA
whreeves@ufl.edu

Definition

The immune response to foreign ►antigens is generated in two steps: 1) an early (hours to days) ►innate immune response during which molecules expressed by the foreign invader (e.g. bacteria, virus, fungus, protozoa) but not by the host's cells are recognized as "dangerous" by pattern receptors on antigen presenting cells and 2) an adaptive immune response (days to weeks after antigen exposure) mediated by antigen-specific ►T and ►B lymphocyte receptors. The immune system has evolved to discriminate self from non-self; it must be tolerant to self-antigens while at the same time responding to and eliminating foreign (non-self) antigens. ►Autoimmunity (the abnormal production of self-reactive T cells and/or ►autoantibodies produced by B lymphocytes) may evolve into a state of ►autoimmune disease (tissue injury mediated by these abnormal cells).

Characteristics

There are close to 100 different types of autoimmune disease (Table 1). Autoimmune diseases are a major cause of serious chronic illnesses, affecting up to 3% of the general population (1). Nearly 75% of afflicted patients are women, making autoimmune disorders one of the 10 leading causes of death for women under the age of 65 (2). Autoimmune disease may affect nearly any organ system. Sometimes it affects a single organ, such as the thyroid gland (organ-specific autoimmune disease). In systemic autoimmune diseases such as ►rheumatoid arthritis or ►systemic lupus erythematosus, many organs are involved. The societal costs can be enormous. ►Rheumatoid arthritis afflicts 2.1 million Americans (1.5 million women and 600,000 men) and costs roughly \$6000 per patient annually in direct medical costs and indirect costs such as absence from work. Lupus affects 500,000 Americans and costs an estimated \$13,000 per patient, translating to an annual cost of \$6.5 billion.

Systemic Autoimmune Diseases

The systemic autoimmune diseases are primarily diseases of women (Table 1). The most common is rheumatoid arthritis, which has a female to male ratio of ~3:1. Rheumatoid arthritis is characterized by a chronic, symmetric and erosive synovitis in association with other less frequent manifestations, such as subcutaneous nodules, lung nodules, vasculitis, and hematological abnormalities. Pathologically, the disease is associated with ectopic lymphoid tissue (pannus) consisting of lymphocytes, macrophages, and fibroblasts. Although autoreactive T cells are thought to mediate the arthritis, characteristic autoantibodies are produced as well (Table 2), including rheumatoid factor and autoantibodies to citrulline-modified proteins.

Autoimmune Diseases. Table 1 Some Examples of Autoimmune Diseases

Disease	Organ	Prevalence per 100,000 ¹	Female: male ratio	HLA association (relative risk)
Organ specific autoimmune diseases				
Addison's disease	Adrenal gland	5	9:1	N/A
Autoimmune hepatitis	Liver	0.4	9:1	B1, B8, DR3, DR4

N/A, not available

Systemic lupus erythematosus (SLE) is the prototype of human immune complex disease. It causes inflammation of the kidneys, skin, joints, blood, brain and other organs, occurs mainly in young women (female to male ratio 9:1 in the 15–45 year old age group) and affects African-Americans, Native American, and Hispanics much more frequently than Caucasians. Immunologically, it is characterized by the production of antinuclear antibodies reactive with double stranded DNA, Sm antigen, and other antigens. Scleroderma (systemic sclerosis) is characterized by fibrosis of the skin and internal organs, including the

lungs, intestine, and other visceral organs as well as vascular disease (Raynaud's phenomenon) and kidney failure. It is associated with autoantibodies against DNA topoisomerase I, fibrillarin (U3 ribonucleoprotein), and RNA polymerases I and III. Although polymyositis is primarily an autoimmune inflammatory disease of skeletal muscle, it is frequently complicated by lung disease, vasculitis, and skin involvement (dermatomyositis). It is frequently associated with autoantibodies against the enzymes that charge transfer RNAs with the appropriate amino acid. These autoantibodies predict high a risk factor

for developing lung involvement. Sjogren's syndrome is a systemic autoimmune disease affecting the salivary and lacrimal glands and other organs that is associated with a 44-fold increased risk of lymphoma. It is associated with autoantibodies against the Ro (SS-A) and La (SS-B) antigens.

Organ-specific Autoimmune Diseases

There are many organ-specific autoimmune diseases, some of which are listed in Table 1. The thyroid gland is most commonly affected, and autoimmunity in this organ can lead to either ►**hyperthyroidism** (Graves' disease) or hypothyroidism (e.g. Hashimoto's thyroiditis). Graves' disease is induced by stimulatory (agonistic) autoantibodies that bind to the active site of the thyroid stimulating hormone receptor (TSHR), leading to the increased production of thyroid hormone. The IgG autoantibodies can be transferred transplacentally to the fetus, resulting in transient neonatal hyperthyroidism. Hashimoto's thyroiditis is a lymphocytic infiltration of the thyroid gland that occurs most frequently in middle-aged women. It leads to the formation of ectopic lymphoid tissue resembling rheumatoid pannus, followed by destruction of the gland and ultimately hypothyroidism. Autoantibodies against thyroid peroxidase, thyroglobulin, and other thyroid components are typical, but are not thought to be involved directly in the pathogenesis of the hypothyroidism. Type 1 diabetes is caused by immune-mediated destruction of the insulin producing cells in the islets of Langerhans. The onset of Type 1 diabetes is typically in childhood. As in Hashimoto's thyroiditis, the islet cell destruction is thought to be mostly T cell-mediated, even though the disease is associated with autoantibodies against a variety of islet cell antigens, most notably glutamic acid decarboxylase (GAD), islet cell cytoplasmic antigens, and insulin. Myasthenia gravis is caused by receptor antagonistic autoantibodies, which block the acetylcholine receptor (AChR), causing muscular weakness and fatigue. Immunization of experimental animals with AChR from the electric organs of *Torpedo* species causes a similar syndrome. Like Graves' disease, transplacental passage of IgG autoantibodies results in transient neonatal myasthenia gravis. Pemphigus vulgaris is an autoantibody-mediated autoimmune disease of the skin characterized by intra-epidermal blistering. It is caused by autoantibodies against desmoglein 3, a key desmosomal antigen. The titer of these autoantibodies correlates with the severity of the disease, which can be fatal.

Autoantibodies in the Early Detection of Autoimmune Disease

Autoimmunity may evolve to a state of autoimmune disease over a period of years. There is evidence in

healthy individuals that the production of disease-specific or associated autoantibodies (Table 2) frequently predates the onset of autoimmune disease. In some cases, the appearance of specific autoantibodies precedes the disease onset by years or decades. For example, anti-mitochondrial antibodies can precede the onset of biliary cirrhosis by decades and anti-Sm or anti-DNA antibodies may appear months or years before the onset of clinical manifestations of lupus. In a population at high risk for rheumatoid arthritis (Pima Indians), the rheumatoid factor titer is predictive of disease risk. Thyroid peroxidase antibodies are highly predictive of the development of hypothyroidism, and in family members of probands with type I diabetes, 30–60% of those with one of the diabetes-related antibodies develop the disease within 5–10 years (3). This pre-clinical phase of autoimmune disease argues for the screening of healthy, at-risk individuals. The early detection of autoimmune disease will probably involve both genetic screening and screening for early biological markers, such as autoantibodies.

Genetics

Autoimmune disease is influenced by genetic, environmental, and random (stochastic) factors (4). The risk of autoimmune disease is higher among family members of affected individuals than in the general population, consistent with a genetic component. The relative risk to siblings of affected probands *vs.* that of the general population (λ_s = disease prevalence in siblings of affected individuals ÷ disease prevalence in the general population) gives an indication of the importance of genetic factors. In most autoimmune diseases, the relative risk is between 5 and 50-fold higher in the siblings of affected probands (Table 3). MHC-linked genes account for a portion of this effect (Tables 1, 3). Studies of monozygotic *vs.* dizygotic twins also illustrate the importance of heredity. If the ►**concordance** rate for monozygotic and dizygotic twins is about the same, the genetic effect is small. Concordance rates are typically 15–30% for monozygotic twins *vs.* 2–5% for dizygotic twins (Table 3). It has proved difficult to identify mutations conferring susceptibility to autoimmune diseases because a) autoimmune disorders involve multiple genes, each with only a small effect, and b) autoimmune “diseases” actually are “syndromes” that may be caused by more than one gene. Even in inbred lupus-prone (NZB X NZW) F1 mice, 10 or more susceptibility loci may contribute to disease severity in an additive fashion, consistent with a ►**threshold liability model**. The same may be true in humans. Thus, the genetics of autoimmune disease are complex. Certain mutations, such as deficiency of the early complement components or Fc γ receptor gene polymorphisms in lupus, are

Autoimmune Diseases. Table 2 Some autoantibodies associated with autoimmune diseases

Disease	Antigens recognized by associated autoantibodies
Organ specific autoimmune diseases	
Autoimmune hepatitis	Liver-kidney microsomes (cytochrome P450 2D6), smooth muscle, soluble liver antigen
Diabetes (Type I)	Islet cells, glutamic acid decarboxylase
Goodpasture's disease	Glomerular basement membrane: type IV collagen, $\alpha 3(\text{IV})\text{NC1}$
Graves' disease	Thyroid stimulating hormone receptor
Hashimoto's thyroiditis	Thyroglobulin, thyroid peroxidase
Myasthenia gravis	Acetylcholine receptor
Pemphigus	Desmoglein 3
Thrombocytopenic purpura	Platelet glycoprotein IIIa
Systemic autoimmune diseases	
Biliary cirrhosis	Mitochondrial antigens
Polymyositis	Transfer RNA synthetases, signal recognition particle
Rheumatoid arthritis	Immunoglobulin (rheumatoid factor), citrullinated peptides
Scleroderma	DNA topoisomerase I, fibrillarin, RNA polymerases I/III
Sjogren's syndrome	Ro (SS-A) and La (SS-B) antigens
Systemic lupus erythematosus	Double stranded DNA, Sm antigen

Autoimmune Diseases. Table 3 Role of genetics in selected human autoimmune diseases

Disease	Concordance rates		Sibling risk/population risk (λ_s)	
	Dizygotic	Monozygotic	Overall	Attributable to MHC
Graves' disease	0%	36%	15	N/A
Type 1 diabetes	5%	33%	15	2.4
Multiple sclerosis	3.5%	21–40%	20	2.4
Rheumatoid arthritis	4%	12–15%	8	1.6
SLE	2%	24%	20	N/A

strong candidates for autoimmune susceptibility genes. Other loci have been mapped by genome-wide marker screening. Interestingly, there may be overlap in the susceptibility genes contributing to several clinically distinct autoimmune diseases (5). Linkage data

compiled from genome-wide scanning in a variety of systemic and organ-specific autoimmune diseases suggest that more than half of the linkages may map non-randomly into 18 chromosomal clusters, possibly explaining the occurrence of several autoimmune

disease in a given individual or family. For instance, Hashimoto's thyroiditis is associated with a variety of other autoimmune conditions, both organ-specific (e.g. type I diabetes, pernicious anemia, autoimmune hepatitis, and ►Addison's disease) and systemic (e.g. lupus, rheumatoid arthritis, and Sjogren's syndrome). Similarly, families with more than one systemic autoimmune disorder are not unusual. Of course, familial clustering also can sometimes be explained by shared environmental influences. The environment certainly plays a role in triggering disease in the susceptible host, as illustrated by the initiation of disease by ultraviolet light in a subset of lupus patients. The role of environmental factors is emphasized further by the induction of a murine lupus-like syndrome by the hydrocarbon pristane.

Genetic Screening in the Early Detection of Autoimmune Disease

The strong familial clustering exhibited by many autoimmune diseases suggests that genetic screening may ultimately hold much promise in the early detection of individuals at risk. Unfortunately, due to the genetically complex nature of these disorders, progress in this area has been slow. Genetic testing is an area of active investigation, but generally is not yet available.

Molecular Diagnostics

The molecular cloning of cDNAs encoding many of the relevant ►autoantigens recognized by disease-associated autoantibodies has greatly facilitated the development of molecular diagnostics in autoimmunity. Molecular cloning has frequently been accomplished using human autoimmune sera to screen expression libraries followed by sequence determination. These antigens can be expressed in bacteria or tissue culture cells. By attaching a purification tag, such as a 6-histidine sequence, sufficient quantities of purified recombinant autoantigens can be isolated for a variety of immunodiagnostic tests. Synthetic peptides carrying self-►epitopes can also be used. For detecting autoreactive T-cells, which recognize short peptides in the context of major histocompatibility antigens, peptides are ideal. But this approach is not widely employed due to the technical difficulty of detecting T-cell responses. Autoantibody assays are more widespread. Peptides may not be the optimal antigens for detecting autoantibody responses. Although examples exist of linear B-cell epitopes, typical B cell epitopes are conformational and/or discontinuous sequences. Full-length recombinant autoantigens therefore are often preferable for ►antibody immunoassays, though they are not without problems, such as the absence of antigenically important post-translational modifications (e.g. phosphorylation, methylation, or glycosylation). Recombinant

autoantigens have been used in enzyme linked immunosorbent assays for many years. More recently, multiplexed fluorescent bead assays (e.g. Luminex) have been developed. Although at present used primarily for cytokine assays (6), they should be readily adaptable to autoantibody testing and will permit the rapid screening of sera against a battery of autoantigens. Carrying this principle a step further, proteome arrays made up of hundreds of protein autoantigens and/or peptides are being developed (7). These newer approaches raise hope that screening for multiple autoantibodies will become a cost-effective means of identifying individuals at the pre-clinical stage of autoimmune disease when therapy aimed at preventing evolution into autoimmune disease may be most likely to succeed. Advances in this area may come more quickly than advances in genetic screening for autoimmune disease, at least in the near-term. The question of whether early intervention can prevent autoimmune disease altogether is timely and is an active area of investigation.

Automated High Throughput Functional Characterization of Human Proteins

High throughput functional characterization of proteins is the analysis of gene function in mammalian cell cultures. Technically it means the automated transfection and over-expression of single ►cDNAs – or alternatively for knock down purposes ►RNAi constructs – in cell cultures grown in microplates. Subsequently the modulated cellular phenotype of interest is monitored, using a high throughput ►cell-based assay. The robotics platform is designed to handle huge amounts of parallelized transfection, expression and read-out processes. This allows analysis of large cDNA libraries comprising whole ►transcriptomes and their related ►proteomes with reasonable time and cost. Cell cultures modeling aspects of human diseases could be used to identify cDNAs likely to be involved in disease processes and thus to define novel drug targets.

Characteristics

Transfecting cDNAs into cell cultures is old hat to cellular biologists. The rather new feature of automated experimentation is that no attention has to be paid to the identity of a cDNA, before its gene product exerts a function in cells. The guiding interest of screening lies in a predefined cellular phenotype and the effect of a modulating protein on it.

The automation allows screening of the phenotypic consequences of protein expression of about 100,000 clones a month with a single robotics infrastructure.

The capability provided to test all cDNAs known and available makes it an exquisitely comprehensive approach. The ►Human Genome Project has led to the identification of an estimated 30,000 different human genes, though this number does not account for numerous ►splice variants. Still growing ►cDNA collections currently comprise up to 35,000 different cDNAs (1). ►cDNA libraries that contain all expressed genes of a certain cell type or tissue, might easily reach a million cDNA clones. Though there is large redundancy in cDNA libraries, at least some hundreds of thousands of clones have to be screened to find rare transcripts in a cell-based experiment.

Despite the growing information on the sequence of the human genome and the possibility predicting new genes and gene products, there is only poor annotation of function(s) to this expanding list of genes. Lack of functional information does not necessarily mean that the specific task of a protein, e.g. exhibiting an enzymatic activity or a being structural protein, is not apparent. Frequently, information as to its involvement in a certain cellular phenotype is not known. Automated cell-based assays reveal such functional roles by looking for modifications of a cellular phenotype.

Cell-based assays are *in vitro* systems that can be set up to reflect aspects of an *in vivo* situation either in healthy or diseased individuals.

Other highly parallelized techniques have been developed recently to describe disease conditions from a genomic perspective. Differential expression analyses between healthy and diseased individuals describe clusters of concertedly regulated genes/proteins, e.g. ►nucleotide-microarrays or protein arrays. Changed expression of a single gene in a disease condition could be interpreted as increased or reduced cellular function of this gene.

Clear and decisive information about function, interdependence and hierarchy of genes and their related transcripts and proteins cannot easily be obtained from these differential expression analyses. They require testing of numerous candidate genes in rather cumbersome follow-up analyses. The difficulty in straightforward interpretation is a serious bottleneck in identifying genes that are causative for a disease and its progression. This bottleneck hampers the definition of new drug targets.

The automated high throughput screening of proteins, as described here, could cope with the comprehensiveness of array-technologies. Furthermore it provides insight into the function of the gene products. The shortening of the list of candidate genes enabled by expression analyses is of paramount importance. Ultimately confirming animal experiments need be carried out with only a very few of the most promising candidates (2).

The modeling of a disease relevant cellular phenotype in an *in vitro* cell culture model is central to a disease-oriented strategy of cellular screening.

The cell-based model is a package of the cDNA source, type of cell culture and phenotype of interest. Transfectability issues and the development of a high throughput amenable assay are the key technical hurdles that have to be overcome.

Technical Considerations for Set-up of a Disease-relevant Screening

Choice of cDNA source

As noted above, two different sources of cDNA are to hand. First, cDNA collections, where each cDNA is represented singly and already known by sequence. They are built up to collect all available cDNAs in expression vectors usually regardless of their tissue origin. Second, cDNA libraries that comprise all transcribed genes of certain cells or tissues – from healthy or diseased individuals. But they exhibit redundancy due to numerous mRNA copies of a gene per cell. Smaller subcollections of cDNAs are conceivable. They might comprise only secreted proteins (3), G-protein coupled receptors, kinases or proteases from the outset. Here, sequence information is a must to

select by sequence-similarities (e.g. protein-family domains) or by consensus-sequences (e.g. leader sequences of secreted proteins). This inevitably bears the risk of missing cDNAs that slip under the threshold of sequence comparison or prediction algorithms. Unknown genes/transcripts are not included at all. High throughput analysis of cDNA libraries supplemented by a cDNA collection can most effectively compensate for avoiding limited cDNA sub-collection approaches that might fail to be comprehensive.

Naturally a protein could be characterized not only by its (over-) expression but also by its functional knock down. The transfection of antisense-RNAs or small-interfering double stranded RNAs (►siRNAs) leads to the elimination of a protein by destroying or blocking the transcript and thereby its translation. Depending on the protein turnover rate, consequences for a monitored cellular phenotype might occur. Approaches to build up siRNA collections – vector based or pure ►dsRNA moieties – to exploit the RNAi-effect, are currently under intense development. But collections will yield sufficient comprehensiveness for true genome-wide screenings only in the near future.

Arrayed cDNAs and Tracked Transfections into Cell Cultures

As depicted in Fig. 1a, cDNA expression vectors are arrayed on microplates (from the 96- to the 1536-well formats). Vector types commonly used are viruses or eukaryotic expression plasmids, the latter propagated and stored in bacteria, from which they are individually prepared before transfection. Transfections are usually carried out as transient transfections, where cells are allowed to express the encoded protein for some time, before the changed cellular phenotype is assessed (Fig. 1a). Incubating monitor cells with supernatants of easily transfected producer cells (see legend to Fig. 1 and an example below) is valuable not only as a resort for poorly transfectable cells, but also permits focusing on the secreted part of the proteome.

Each well gets only one type of cDNA during transfection. Transfection efficacy is crucial as it mainly determines the sensitivity of the assay. Single transfections *per se* improve sensitivity for cDNA related effects compared to pooled transfections. Pooled transfections of several different cDNAs in one cell culture vessel were frequently done in the pre-automated era. There, a single cDNA caused a phenotype in only some of the transfected cells leading to poor sensitivity in the subsequent assay. Furthermore cDNAs had to be obtained rather clumsily from the selected cells to determine their sequence. Non-selectable functions as for instance ►apoptosis, where the transfected vector inevitably gets lost in a dying cell, were impossible to screen at all. In the automated system, the ►laboratory informatics management

system (LIMS) ensures tracking of each vector by machine-readable barcodes through the whole screening cascade. In order to obtain sequence information for a cDNA-library hit, it can be backtracked to the originating DNA well, isolated and sequenced.

Cell-based Assays

The type of transfected cells is preset by the screening objective and only limited by the effort of cell culture and transfection methodology. To model a human condition as closely as possible, cell cultures of human origin are preferred over those from other species. Assays interrogate the cellular phenotype of interest and in the following some examples may illustrate the rationales.

Disease conditions, like tumorigenesis, might be investigated by screening for proteins that enhance *in vitro* tumor cell viability, proliferation or metastasis, hence driving tumor establishment, growth or spreading. Proteins found to exert this function would have to be inhibited to ameliorate the condition. In contrast, if death of tumor cells were the criterion, functional proteins would be active principles for therapeutic intervention. From a pharmaceutical point of view, the inhibition of protein function is still easier to achieve than its activation, which would normally mean the induction of expression. Secreted proteins binding to cellular receptors exerting a desired function are an exception.

More complex cellular interactions could be modeled as well. For instance, all tumors rely on enhanced supplies of oxygen when growing and this is supplied by the vasculature. Tumors tend to get control over the process of vessel formation by directly stimulating vessel growth. A tumor cell derived cDNA-library might be specifically screened for potentially novel, secreted endothelial cell proliferation factors. The cell-based assay would be a supernatant assay (see also legend to Fig. 1a). A producer cell line would be transfected with the cDNAs and the supernatants would be transferred to human endothelial cells. Their rate of proliferation would be monitored after a couple of days. Revealing the proliferative activity of a factor might provide a basis for intervention in tumor growth by developing inhibitory antibodies.

► **Homogeneous assay** formats, i.e. simple mix and read assays, are applied whenever possible to minimize handling steps by robots. Favored read-out principles are therefore colorimetric, fluorescent or luminescent detection methods determining the cell number, enzymatic activity of reporter genes or the staining patterns of specific cellular structures or marker proteins. Usually modern standard microplate reader devices could easily be integrated into a robotics and informatics infrastructure. A recent trend is the

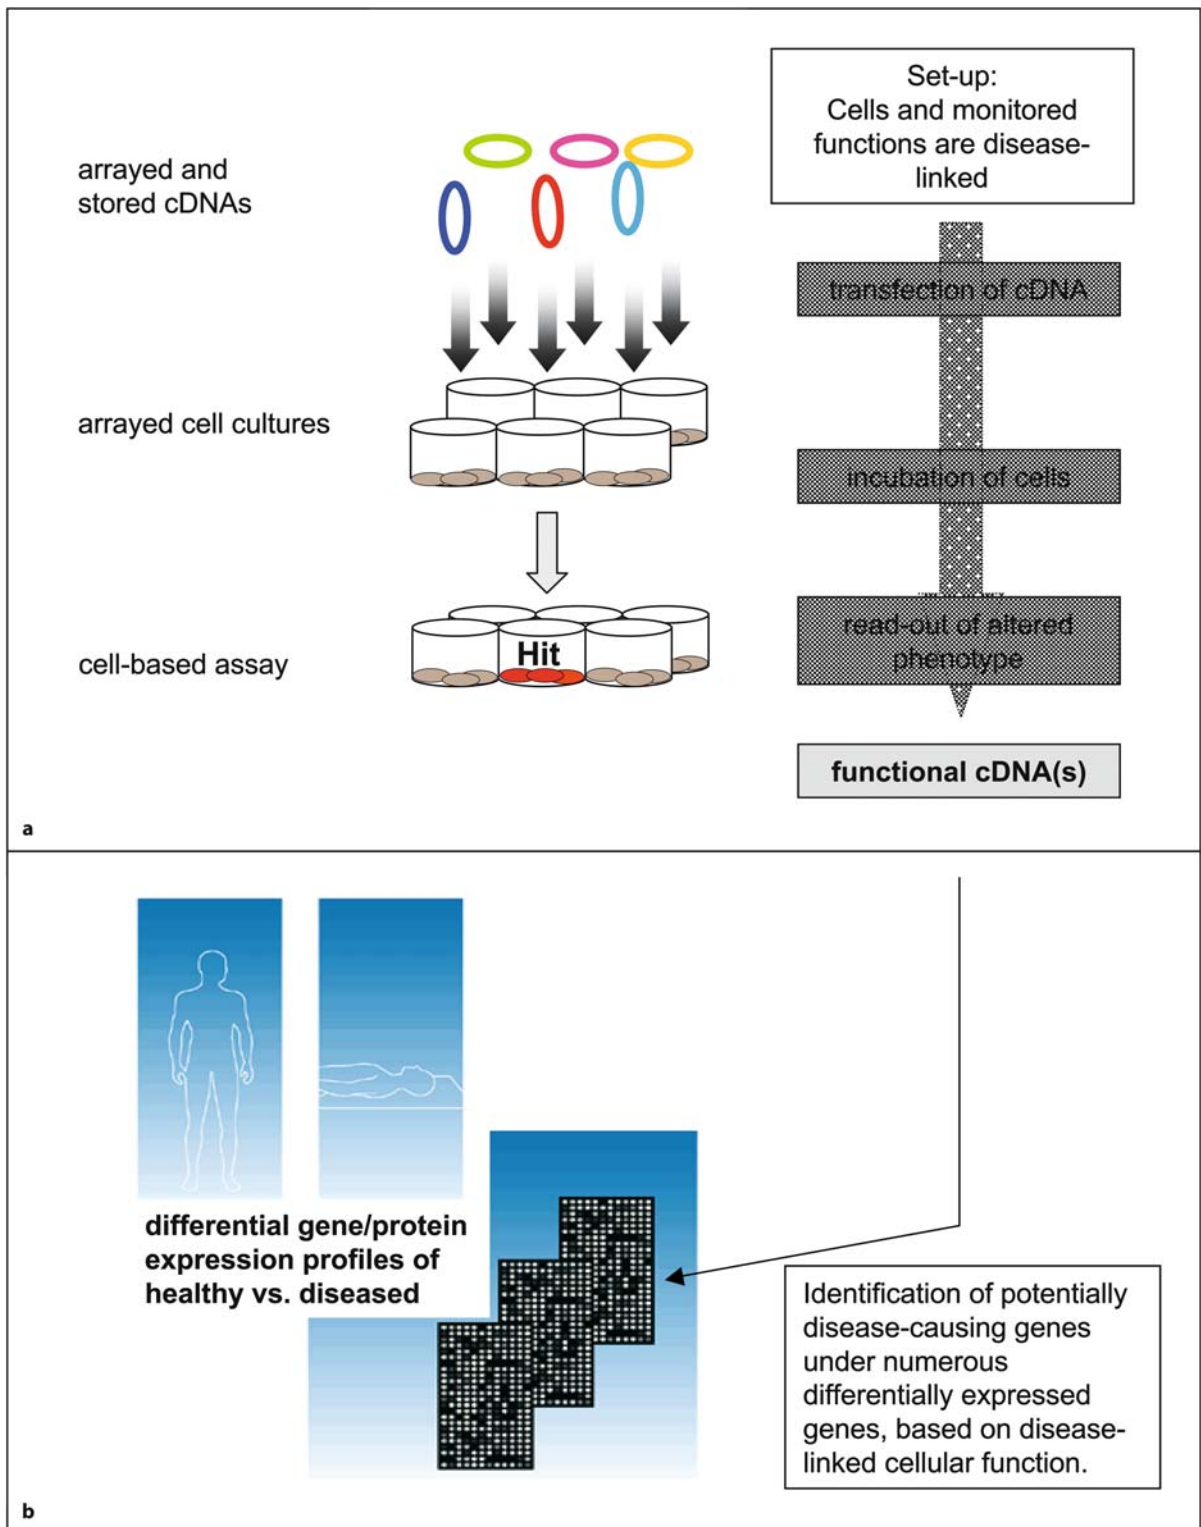

application of ► **high content screening** methodologies mainly by using highly automated imaging technologies. This automated microscopy allows monitoring of more than one parameter or object in one read-out step (4, 5). These options might be used to assess the same cellular phenotype with more accuracy or different phenotypes or objects at the same time. Current improvements in automation technologies reach these goals without considerable loss of speed.

In any case, assays have to be specifically adapted from the bench to automation. Samples (here cDNAs) will not usually be tested in triplicate. Thus, assays should exhibit a sufficient dynamic range of measurement. To discriminate between positive hits and negative ones, a measurement threshold is set. Primary hits exceed this threshold by definition. Subsequent retestings have to confirm this finding. The occurrence of false positive clones is expected since any results will yield a normal distribution in the course of multiple measurements. A small number of measurements therefore will always exceed the threshold without qualifying the hit as truly positive. To minimize such false positive events, the Z' -factor, a quantitative parameter describing the capability of an assay to discriminate between positive and negative hits could be calculated and used for assay comparison (6).

Clinical Relevance

Functional cellular screenings are located rather early in the drug-development chain. But, as shown above, they allow proceeding very fast to decisive animal experiments.

Any results of clinical sample analyses – e.g. protein level determinations in body fluids, protein expression analyses in cells and tissues with array or histological techniques or even pharmacogenomic data connecting inherited mutations with disease conditions could be interpreted in the light of novel augmented functional data (Fig. 1b). Novel hypotheses based upon the functional findings could also be obtained by comparison with expression data from clinical sample material. A close collaboration of screening institutions and clinical research is obviously desirable. Cellular functions with disease relevance should be determined in cooperation for the design of screening experiments. Clinicians could assist in making relevant cell cultures available for screening purposes or they could provide cDNAs derived from normal or diseased tissues. Screening itself will mainly be performed in the biotech or pharmaceutical industry, since it takes a considerable investment in robotics and human resources to set up the necessary screening infrastructure. Again, there is inevitably a need to prove therapeutic concepts, like inhibition or activation of function, in animal experiments prior to the entry into clinical phases.

Automated High Throughput Functional Characterization of Human Proteins. Figure 1 High throughput functional analysis of protein function and how to find and identify genes causing a disease or its progression. (a) Rationale and sequence of handling steps during cell-based screening. Given that the type of cell cultures and the cellular function under investigation are set up to model aspects of a disease, the screen validates hits as genes potentially involved in disease etiology. Single arrayed cDNAs are transfected automatically into cell

Further Applications with Clinical Relevance

The technology described here is not only able to deliver proteins with new cellular functions; de-orphanisation is an interesting mode of application of this technology as well. Finding a chemical drug's target, a receptor's ligand or a ligand's receptor is sometimes challenging (2). Such problems might be solved by analyzing the transcriptome of a cell type, where the drug or protein is known to exert effects. Assays would take advantage of an inhibited or enabled cellular function or more directly of binding studies using labeled drug or protein.

If the protein's function is causative for disease etiology and has to be blocked for therapeutic reasons, the rational would be to look for inhibitors. These might be antibodies in the case of secreted or extracellularly exposed proteins. But, with a high throughput cell-based assay performed successfully, the same assay could be used to screen for low molecular weight (LMW) compounds. These chemicals will show up directly in a cell culture assay as inhibitors of the cDNA exerted function. Finally optimization of a protein with regard to improved or altered activity, stability or specificity could be achieved by screening the respective cDNAs, in which experimentally random mutations had been introduced by mutagenesis. Numerous different mutated clones could be screened in a short time to select for the altered but desired protein properties in an appropriate cell-based assay.

Finally, a list of selected companies performing human cell-based high throughput screenings of cDNAs is: Galapagos Genomics, Mechelen/Netherlands, www.galapagosgenomics.com; Human Genome Science, Rockville, MD/USA, www.hgsi.com; Kalypsys LaJolla, CA/USA, www.kalypsys.com; Xantos Biomedicine AG, Munich/Germany, www.xantos.de.

Autonomic Nervous System

Definition

The autonomic nervous system (ANS) is part of the peripheral nervous system, which conveys involuntary motor innervation to viscera and glands. The ANS is divided into three parts, the sympathetic nervous system, the parasympathetic nervous system and the enteric nervous system.

► Neural Crest Cells and their Derivatives

cultures grown on microplates. Transfected cells are allowed to express the cDNA and incubated to let the cellular phenotype change. Finally, depending on the kind of cell-based assay chosen, a phenotype is read out from each well. If the measurement exceeds the predefined threshold, the respective cDNA clone is termed a primary hit. The corresponding cDNA clone can be obtained from the stored cDNA library in order to get sequence information and to repeat the assay several times to dissect truly positive clones from false positives (see text). Variant approaches (not shown): In a supernatant-screen transfected cells and monitored cells are different. The supernatant of transfected cells is transferred to similarly arrayed monitor cell cultures, regardless of their transfectability. Such supernatant-screens allow focusing exclusively on the secreted part of the proteome (for an example see text). Naturally the whole automated process could also be used to define protein functions by experimentally knocking down a gene transcript rather than over-expressing it. This would be done for instance by expressing or adding short double stranded RNAs exerting a functional knock down based on the *RNAi* principle. (b) Synergism with other disease linked data. Differential expression profiles list numerous changes of transcript or protein levels in cells or tissues of affected versus unaffected individuals. The value of such results could be drastically increased by the data from a functional screen. Comparison of data allows identification of those genes that are potentially causative for a disease or its progression. Shortening the list of candidate genes from expression analyses is of paramount importance. Ultimately confirming animal experiments could be carried out with only a very few and the most promising candidates.

Autonomous Transposable Element

Definition

Autonomous transposable element denotes a mobile DNA element encoding enzyme(s) necessary for its proliferation in the host genome. All other transposable elements are called non-autonomous.

- ▶ Repetitive DNA
- ▶ Transposons

Autonomously Replicating Sequence

Definition

Autonomously replicating sequences (ARSs) have been identified in budding yeast as specific DNA sequences acting as replication origins. The ORC can bind ATP-dependently to an ARS through the 11-bp ARS consensus sequence, found within the A element of ARS1. These ARS-regions are not generally transferable to other yeast genera, mostly due to instabilities and possible integration at one or more unspecific chromosomal loci.

Autosomal

Definition

Autosomal refers to any of the chromosomes other than the sex-determining chromosomes (i.e., the X and Y) or the genes on these chromosomes.

- ▶ Bone and Cartilage

Autosomal Dominant (Inherited Disorder)

Definition

The term autosomal dominant describes a trait or disorder in which the phenotype is expressed in those who have inherited only one copy of a particular gene mutation, except from sex chromosomes (heterozygotes). For example, in MODY, inheritance of one copy of a mutant gene is usually enough to cause this autosomal inherited disorder in a child.

- ▶ Diabetes Mellitus, Genetics
- ▶ Tumor Suppressor Genes

Autosomal Dominant Hypercholesterolemia

- ▶ Familial Hypercholesterolemia

Autosomal Dominant Polycystic Kidney Disease

- ▶ ADPKD

Autosomal Recessive (Disorder)

Definition

The term autosomal recessive describes a trait or disorder that requires the presence of two copies of a mutated gene at a particular locus in order to express observable phenotype; specifically refers to genes on one of the 22 pairs of autosomes (non-sex chromosomes). The mutation may hereby occur in a homozygous or compound heterozygous state, and only in this case cause the autosomal recessive disorder.

- ▶ Familial Hypercholesterolemia
- ▶ Mitochondrial Myopathy
- ▶ Neurotrophic Factors

Autosomal Recessive Spinal Muscular Atrophy

► Spinal Muscular Atrophy

Autosome

Definition

Autosome describes any chromosome that is not a sex chromosome; they exist in somatic cells, normally in pairs.

► Diabetes Insipidus, a Water Homeostasis Disease

Auxotrophic

Definition

If an essential catabolic gene in an organism, e.g. bacteria or yeast, is made inoperable, the organism is not viable without addition of this catabolic product; it is auxotrophic. Upon replacement by an intact gene or a foreign gene coding for the same function, it is possible to complement this deficiency.

► Recombinant Protein Expression in Yeast

Avascular

Definition

Avascular means that no blood vessels are present.

► Bone and Cartilage

Avidin

Definition

Avidin is a 70 kDa protein found in egg white. It has a very high affinity for biotin, and is therefore

often used in coupling procedures for bioanalytical purposes.

► Surface Plasmon Resonance

Avidity/Affinity

Definition

Avidity is defined as the binding strength of multimeric or clustered molecules. The binding strength of a single molecule is called affinity.

► Focal Complexes/Focal Contacts

Axial Element

Definition

Following DNA replication in the premeiotic S-phase, the chromosomes start to condense and a proteinaceous core, called axial element, forms between the sister chromatids of unpaired chromosomes at ► Leptotene/ ► Zygotene.

Axin/Conductin

Definition

Axin and conductin (also termed axin2, axil) are scaffold proteins of the β -catenin destruction complex, and serve as negative regulators of Wnt signaling. Both proteins share 45% identical amino acids and have similar binding domains for other proteins. They bind to APC with an N-terminal RGS (regulator of G-protein signaling) domain, to GSK3 β and β -catenin with central domains, and to the Wnt signaling component dishevelled via a C-terminal DIX domain. Axin/conductin facilitate phosphorylation of β -catenin by GSK3 β and hence promote degradation of β -catenin.

Axis Formation – Formation and Function of the Dorsal Organizer

MASAHIKO HIBI

Center for Developmental Biology (CDB) RIKEN,
Laboratory for Vertebrate Axis Formation, Hyogo,
Japan
hibi@cdb.riken.go.jp

Definition

During vertebrate development, the embryonic axes, consisting of the dorso-ventral (DV), anterior-posterior (AP), and left-right (LR) axes, are established through a series of inductive signals that are followed by the concerted movement and differentiation of groups of cells. Axis formation is the process that generates these body axes.

Characteristics

Roles of the Dorsal Organizer in the Formation of Dorso-ventral and Anterior-posterior Axes

The dorsal **▶organizer** plays a major role in the process of axis formation (1). In 1924, Spemann and Mangold observed that equatorial cells derived from the dorsal lip of an early newt gastrula grafted onto the ventral side of an isochronic host, elicited the development of a secondary neural tube with a well-formed AP axis, as well as the formation of a secondary notochord, somites, and, in some cases, gut. In these embryos, the graft differentiated into notochord, prechordal plate, floor plate and somites, but most parts of the secondary axis, including the neural plate and somites, were derived from host cells. The dorsal equatorial cells having this activity were named the “Spemann organizer,” the “Spemann-Mangold organizer,” or simply the “dorsal organizer.” The dorsal organizer is a cell population that can generate a complete axis, in part by self-organizing, but primarily by emitting inductive signals that are involved in forming the DV and AP axes. While the original work was carried out in amphibians, an organizer region has been identified in all vertebrate embryos, including **▶zebrafish** (embryonic shield), chick (Hensen’s node), and mouse (node) (1, 2, 3). The organizer and its derivatives are also involved in the establishment of the LR axis.

Left-right Axis Formation

LR asymmetry is observed morphologically as the looping of the heart and gut, and positioning of the associated organs, such as blood vessels, lung, spleen, liver, and pancreas. Studies in model animals have shown that the LR axis is established through several

steps (4). Although there are several reports showing that LR asymmetry is initiated at the beginning of development, it is believed that the breaking asymmetry, which takes place near the organizer derivatives during or after gastrulation, contributes to the LR axis formation. In the mouse, cells on the node (the mouse organizer) have a monocilium that rotates in a counterclockwise direction and generates a leftward flow of the extra-embryonic fluid (nodal flow). The nodal flow has been shown to play a pivotal role in biasing the left-side signal on the left side. The left-side signal is transferred to the left lateral plate mesoderm (LPM), and the signal is expanded within the left LPM, resulting in asymmetric development (cell movements and differentiation) of LPM-derived tissue and associated organs.

Mechanisms that Generate the Dorsal Organizer: Dorsal Determinants

Specification of DV polarity is initiated soon after fertilization in amphibians and teleosts. In *Xenopus*, the sperm enters anywhere in the animal hemisphere of the egg. During the first cell cycle, the egg cortex rotates about 30° relative to the underlying cytoplasm along a meridian determined by the sperm entry point in a process called, “cortical rotation.” During this process, parallel microtubule arrays are formed below the cortex, with their plus ends oriented toward the future dorsal side. Although the rotation is limited to 30°, small particles, such as membrane-bound organelles, are transported about 60° along the microtubule arrays. In zebrafish, although the sperm enters at the animal pole and no cortical rotation ensues, a microtubule array arises in the vegetal region. Disruption of this microtubule array in *Xenopus* or zebrafish by ultraviolet (UV) irradiation, low temperature or the microtubule-depolymerising drug nocodazole leads to a defect in the organizer formation. Removal of the vegetal cortex material in *Xenopus* and zebrafish before the microtubule array formation results in embryos that display dorsal deficiencies. Transplantation of the vegetal cortical materials can generate a secondary axis. These studies indicate that dorsal determinants are located at the vegetal pole of amphibian and teleost eggs, and transferred to the dorsal blastomeres shortly after fertilization, leading to the dorsal organizer formation.

Wnt Signalling

Although the molecular nature of the dorsal determinants remains unknown, **▶Wnt signalling** is believed to function downstream of the dorsal determinants and to be involved in the formation of the dorsal organizer. Wnt signalling was recently categorized into two cascades: the canonical and non-canonical pathways. The canonical Wnt pathway induces the nuclear

accumulation of β -catenin and activates transcription through a complex of β -catenin and the transcription factors Tcf and Lef. The non-canonical pathway leads to the up-regulation of cytoplasmic calcium and protein kinase C, and/or the activation of small G proteins and the JNK protein kinases. Activation of the canonical pathway in *Xenopus* and zebrafish leads to ectopic induction of the dorsal organizer, and inhibition of this pathway leads to defects in the dorsal axis formation. It is still controversial at what points in the canonical pathway it is activated by the dorsal determinants. However, ►**Dishevelled** and GBP (Frat), which participate in the Wnt canonical pathway, are reported to move in a microtubule-dependent manner. A nuclear accumulation of β -catenin on the future dorsal side is observed at the midblastula stage in both *Xenopus* and zebrafish, and marks the prospective organizer region and ►**Nieuwkoop centre**. The Nieuwkoop centre is a conceptual domain that can induce the organizer non-cell-autonomously, and it resides in the dorsal-vegetal blastomere and dorsal yolk syncytial layer in *Xenopus* and zebrafish, respectively. β -catenin-mediated zygotic transcription has been shown to be required for the organizer induction. The Wnt non-canonical pathway functions to inhibit the canonical pathway that leads to dorsal axis formation. Inhibition of the calcium pathway in *Xenopus* or a mutation in the zebrafish *wnt5a* gene leads to the expansion or ectopic formation of dorsal structures, suggesting a role for the antagonistic interaction between the canonical and non-canonical pathways in early dorsal specification.

Targets of the Wnt Canonical Pathway

Several genes are reported to be direct targets of the canonical pathway during the early development of *Xenopus* and zebrafish. These include the homeobox genes *siamois* and *twin*, and the *nodal*-related TGF- β cytokine genes, *Xnr3*, 5, and 6 in *Xenopus*, and the homeobox gene *bozozok/dharma* and the *nodal*-related gene *squint* in zebrafish. These gene products are involved in the non-cell-autonomous induction at the Nieuwkoop centre and cell-autonomous establishment of the dorsal organizer. In *Xenopus*, *Twin* directly binds the promoter region of the organizer-specific gene *goosecoid*, and activates its transcription. *Xnr5* and 6 are expressed in dorso-vegetal blastomeres in a manner dependent on β -catenin as well as the T-box protein *VegT*. *Xnr5* and 6 are thought to bind serine/threonine kinase receptors and induce the expression of organizer genes. *Xnr3* functions as an inhibitor of BMP signaling, although no homologues of *Xnr3* have been reported in other vertebrate species. In zebrafish, *Squint* functions similarly to *Xnr5* and 6, and is involved in forming the dorsal organizer and mesoderm. *Bozozok* functions as a transcriptional repressor that interacts with a co-repressor, *Groucho*, and

represses the expression of the ventrally expressed homeobox genes, *vox*, *vent* and *ved*. *Vox*, *Vent* and *Ved* function as transcriptional repressors and decrease the expression of the organizer genes. De-repression of the organizer genes by *Bozozok* is involved in restricting the organizer domain in the dorsal region.

Early Axis Formation in Mouse

Analyses of mutant mice have revealed that Wnt signalling is involved in the organizer formation and early axis formation. β -catenin-deficient mice display strong abnormalities in axis formation, abnormal specification and movement of anterior visceral endoderm and defects in the formation of mesoderm and head structure. Deficiencies in *Axin1* and *APC*, which regulate the phosphorylation and degradation of β -catenin, lead to axis duplication. These reports indicate a conserved role for Wnt signalling in early axis formation. *Nodal* is required for the organizer formation in mouse. Homologues of *Siamois*, *Twin*, and *Bozozok* have not been reported in mammals. The functions of repressor-type homeobox genes, including *bozozok*, *vox*, *vent*, and *ved*, in the organizer formation and axis formation remain to be elucidated.

Molecular Interactions

Molecular Nature of the Organizer

Many genes have been identified that are expressed and function in the organizer (1, 2).

Transcription Factors (*goosecoid*, *lim1*, *foxa2/hnf3 β* /axial, and *floating head/Xnot*)

goosecoid encodes a repressor-type ►**homeobox** gene. It is expressed first in the organizer region and later in the prechordal plate. *Goosecoid* has been shown to be involved in the migration of the prechordal plate. Due to its sequence similarity to *Bozozok*, *Goosecoid* has also been suggested to function as a repressor for ventral factors, such as *Vox*, *Vent*, and *Ved*. *Lim1* is a transcriptional activator that contains both a LIM domain and a homeodomain. *Lim1* functions with *Ldb1*, which interacts with the LIM domain of *Lim1*, forming a tetramer (two *Lim1* and two *Ldb1* proteins). *lim1* is expressed throughout the mesoderm, and strongly in the dorsal organizer region and the visceral endoderm in the mouse; it is later expressed in the pronephron and a subset of neurons. *Lim1* is involved in the regulation of signalling molecules expressed in the organizer, and a *lim1* deficiency in mouse shows defects in head formation. *Foxa2* is a Fork head-type transcriptional activator that is required for the formation of the organizer and organizer-derived tissues, such as the notochord and floor plate. *foxa2* is also expressed in the endoderm. *floating head/Xnot*

is a homeobox gene that is expressed in the superficial layer of the organizer and later in the notochord. Mutations in the *floating head* gene in zebrafish lead to loss or reduction of the axial structures, including the notochord and floor plate, and instead the midline cells are fated to become paraxial mesoderm. Floating head is thought to function to repress the genetic programming for formation of the paraxial mesoderm, in which the T-box gene *spadetail* (a homologue of ►*Xenopus VegT*) is involved.

BMP Inhibitors (chordin, noggin, follistatin, cerberus, ogon/sizzled, and twisted gastrulation)

Chordin, Noggin, Follistatin, and Cerberus directly interact with ►BMPs and prevent the interaction of BMPs with their receptors. *chordin* and *noggin* are expressed in the organizer in *Xenopus* and zebrafish. *follistatin* is expressed in the *Xenopus* organizer. *cerberus* is localized to the anterior endomesoderm in *Xenopus* and the anterior visceral endoderm in mouse. Cerberus also inhibits Wnt8 and the ►Nodals. The inhibition of BMP signalling by these molecules is involved in the dorsalization of the mesoderm and endoderm, and in the induction of the neuroectoderm. The roles of the antagonistic interactions between BMP and the BMP inhibitors are supported by gain-of-function studies in *Xenopus* and the analysis of zebrafish mutants that display abnormalities in DV patterning. Mutations in the BMPs or BMP signalling components (*bmp2b/swirl*, *bmp7/snail house*, *smad5/somitabun*, or *alk8/lost-a-fin*) lead to the dorsalization and expansion of the ►neuroectoderm (dorsalized mutants). There are only two mutants, *dino* and *ogon*, that have been reported to display ventralized phenotypes. The *dino* locus encodes the *chordin* gene, and the *ogon* locus was recently shown to encode Secreted Frizzled, which is a secreted protein homologous to the ►Wnt receptor, Frizzled. Unlike the other ►BMP inhibitors, *sizzled* is expressed on the ventral side in a manner dependent on ►BMP signalling. Sizzled requires Chordin to inhibit ►BMP signalling and dorsalize embryos. Thus, Sizzled functions as a negative ►feedback regulator of BMP signalling. The precise mechanism by which Sizzled inhibits BMP signalling is not known. Chordin has been shown to be required for the development of dorsal tissues, including the neuroectoderm, in *Xenopus* and zebrafish. The activity of Chordin is modulated by the metalloproteinase Tolloid, which cleaves and inactivates the Chordin protein, and Twisted gastrulation (TSG), which can make a complex with BMP and Chordin.

Wnt Inhibitors (frzb1 and dickkopf1)

The Wnt inhibitors Frzb (sFrp3) and Dickkopf1 (Dkk1) are expressed in the *Xenopus* and zebrafish organizers. Both Frzb1 and Dkk1 inhibit the signalling of Wnt8,

which is expressed in the ventro-lateral marginal blastoderm in zebrafish (the marginal zone in *Xenopus*), and promotes dorsalization (specification of the notochord and prechordal plate) and anteriorization of the neuroectoderm. Frzb inhibits Wnt8 signalling by interacting either with Wnt8 or the Wnt receptor Frizzled, whereas Dkk1 inhibits it by interacting with the Wnt co-receptor LRP (lipoprotein receptor-related protein) 5 and 6. It is reported that Dkk1 interacts with the transmembrane proteins Kremen1 and 2 and thereby promotes the endocytosis of LRP6. *dkk1*-deficient mice show a headless phenotype, implying that Dkk1's role in head formation is conserved. In addition to these secreted molecules, Tcf3 functions as a transcriptional repressor in the absence of Wnt stimulation and inhibits the expression of targets of the Wnt canonical pathway, and Tcf3 is required for head formation in zebrafish. Wnt8 is involved in the posteriorization of neuroectoderm, and the inhibition of Wnt signalling plays a role in the formation of anterior neuroectoderm (5).

Fibroblast Growth Factors (FGFs)

►FGFs are involved in many aspects of development and have roles in mesoderm induction and patterning of the nervous system. *fgf3* and *fgf8* are expressed in a characteristic dorso-ventral gradient within the margin. The misexpression of FGF8 suppresses *bmp* expression (also BMP signalling), leads to dorsalization, and can induce a partial secondary axis. FGFs induce the expression of Sprouty4 and Sef, which function as feedback regulators of FGF signalling. The misexpression of Sprouty4 or Sef ventralizes the embryos and the inhibition of Sef in zebrafish leads to dorsalization, indicating that FGF signalling is involved in the dorsal specification.

Nodal and Nodal Inhibitors

There are three reported *nodal*-related genes in zebrafish (*cyclops*, *squint*, *southpaw*), six in *Xenopus* (*Xnr1-6*), and one in mouse (*nodal*). The *nodals* are expressed in the organizer and mesendoderm (and in the visceral endoderm in mouse). In addition to the organizer-inducing ability, the Nodals have been shown to be involved in the induction of mesoderm and endoderm, the posteriorization of neuroectoderm, and the LR patterning. Nodals bind type I and type II activin-like receptors and thereby activate Smad2 and/or Smad3. Phosphorylated Smad2 and Smad3 make a complex with Smad4 and enter the nucleus, where they bind specific DNA elements either directly or through FoxH1 and regulate gene expression. Nodal regulates the expression of *nodals* by themselves (autoregulation) as well as the feedback inhibitors Lefty1 and Lefty2. Antagonistic interactions between Nodals and Lefty1/2 are proposed to participate in the reaction-diffusion

mechanism that controls cell fates at the proper position. *lefty1* and *cerberus*-like, a mouse homologue of *cerberus*, are expressed in the anterior visceral endoderm. A deficiency in both genes in the mouse leads to ectopic formation of the primitive streak, indicating that Nodal inhibitors function to restrict the domain that generates the mesoderm and organizer. Nodal signalling is also involved in the left-right axis formation (4). *nodal* (*southpaw* in zebrafish) is expressed in the region adjacent to the definitive node. Nodal signalling is considered to be the major left-side signal, which functions first in the node region and then in the left LPM. Within the left LPM, the left-side signal is expanded through the Nodal signalling, in which Nodal activates expression of the homeobox gene *pitx2*, *left2*, and *nodal* itself. In zebrafish, the Nodal signal is transmitted to the left diencephalon and is involved in the LR-asymmetric development of the parapineal body and habenula nuclei. The LR asymmetry is maintained by a midline barrier composed of the notochord and floor plate, which express the Nodal inhibitor Lefty. A downstream target of Nodal signalling, such as *pitx2*, is involved in the induction of the LR-biased morphology.

Prospects

In the past decade, many transcription factors and signalling cascades that are involved in axis formation have been elucidated. However, several important questions remain to be answered. The nature of the dorsal determinant is still uncertain. The interactions between the gene and signalling cascades are not well understood. Cell movements, such as the convergent-extension that occurs during gastrulation and the looping of the internal organs that takes place during LR specification, have important roles in axis formation; however, the molecular mechanism that controls such cell movements is poorly understood. The involvement of additional components in early axis formation also remains an open issue. Future studies will seek to answer these questions.

Axon

Definition

The axon is a long cellular process of the neuron that carries the outgoing action potential from the soma (cell body) to the target neuron, and is thus the primary output station of a neurone. Axons display a high degree of structural diversity from local circuit to projection axons. Axons are usually surrounded by a myelin sheath.

Bacteriophage

Definition

Bacteriophages include any virus whose host is a bacterium. The group of bacteriophages (or phage) is highly diverse and many hundred different are known. Most bacteriophage are specialised to infect only a small range of bacteria, and the consequence of infection depends on the phage and the host. Generally, phage can be classified into three groups: virulent, temperate and non-lytic phage. Virulent phages induce the lytic cycle and eventually kill their host. Temperate phages can establish a stable, non-lytic and generally

latent relationship (lysogeny) until exogenous triggers activate the lytic cycle. Non-lytic phages can replicate and produce progeny without killing the host but hampering its growth.

Base Excision Repair

MARIA KARTALOU, LEONA D. SAMSON

Division of Biological Engineering and Center for Environmental Health Sciences, Massachusetts Institute of Technology, Massachusetts, USA
lsamson@mit.edu

Definition

Base excision repair (BER) is one of the mechanisms that cells use to defend themselves when challenged by exogenous and endogenous physical and chemical DNA ► [damaging agents](#) (1). It is involved in the repair of a wide variety of damaged or inappropriate (mismatched) bases. BER substrates include damaged bases that arise spontaneously through hydrolytic deamination, oxidation and alkylation reactions and mismatched bases that arise during ► [DNA replication](#). BER also deals with ► [apurinic/apyrimidinic \(AP\) sites](#) that are formed during spontaneous depurination reactions and after enzymatic and chemical reactions. The persistence of any of these lesions in DNA would increase the mutagenic burden of a cell as these lesions frequently mispair during DNA replication. Finally BER deals with single strand breaks that can be formed after free radical attack; such strand breaks may lead to cell death if left unrepaired.

Characteristics

Mechanism

The first step in BER is catalyzed by a class of enzymes called DNA ► [glycosylases](#) (2). These are typically small monomeric proteins that do not require cofactors for substrate recognition or activity. DNA glycosylases catalyze the cleavage of the N-glycosidic bond between the damaged base and the deoxyribose phosphate backbone, leaving behind an apurinic/apyrimidinic (AP) site. The AP site is processed by an ► [AP endonuclease](#), which hydrolyzes the phosphodiester bond 5' to the AP site, thereby generating a 3'OH end that can serve as a primer for a ► [DNA polymerase](#) and a 5'-deoxyribose phosphate group. The deoxyribose phosphate residue can be excised by a 5'-deoxyribose phosphodiesterase activity. Alternatively, extension from the 3'OH can displace a single stranded DNA flap several nucleotides long and this flap containing the 5'-deoxyribose phosphate can be removed by a flap endonuclease. Sealing of the nick by a ► [DNA ligase](#) completes the repair reaction.

Bifunctional glycosylases can not only catalyze base release, they also possess an additional AP lyase activity that cleaves the phosphodiesterase backbone 3' to the AP site leaving a modified 3' end at the nick that

can be trimmed by an AP endonuclease to leave a 3' OH. The combined activities of a bifunctional DNA glycosylase and an AP endonuclease result in a single nucleotide gap flanked by 3' OH and 5' phosphate ends. The resulting single-nucleotide gap is filled by a DNA polymerase, and a DNA ligase completes the repair reaction.

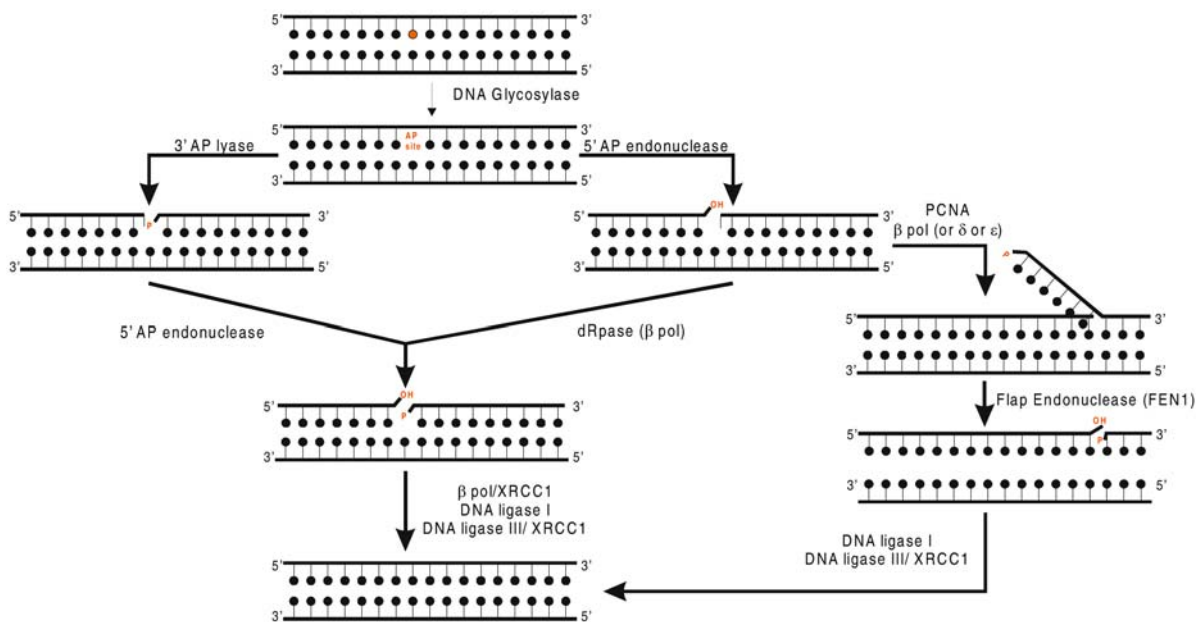

In mammalian cells, AP sites are processed *via* two alternative pathways, the short patch base excision repair and the long patch base excision repair (3). In short patch base excision repair, DNA polymerase β removes the 5'-deoxyribose phosphate and adds a nucleotide followed by DNA ligase I or DNA ligase III/XRCC1 sealing the nick. The short patch base excision repair pathway requires the action of DNA polymerase β and can be reconstituted *in vitro* using human UDG, APE1, DNA polymerase β , XRCC1 and DNA ligase I or DNA ligase III. The long patch base excision repair results in the displacement of 2–13 bases surrounding the AP site and involves the activity of DNA polymerase β or δ/ϵ (pol β or δ/ϵ), flap endonuclease 1 (FEN1) and PCNA. Strand displacement synthesis by pol β or δ/ϵ , generates a flap like structure that can be cleaved by FEN1. PCNA interacts with FEN1 and stimulates its nuclease activity. PCNA can also function as a clamp for pol δ/ϵ . Complete repair occurs when DNA ligase I or DNA ligase III/XRCC1 seals the nick. Although the relative contribution of these two pathways has yet to be elucidated, long patch BER occurs when the deoxyribose phosphate moiety is refractory to excision by pol β . Long patch base excision repair also occurs at oxidized or reduced AP

sites, while normal AP sites are processed by the short patch pathway. Additionally, the type of DNA glycosylase that excises the lesion can also determine which pathway will be followed as single nucleotide gaps generated by the activity of a bifunctional glycosylase are refractory to displacement synthesis. A schematic representation of base excision repair is shown in Fig. 1.

Substrates and Structure of DNA Glycosylases

In humans ten DNA glycosylases have been identified (Table 1). Some glycosylases like the human 3-methyladenine DNA glycosylase (AAG) can remove a variety of chemically and structurally diverse bases from DNA (including normal bases) whereas others like uracil DNA glycosylase (UDG) are only involved in the repair of a limited number of base lesions.

The structure of UDG, T4 endonuclease V, MutY, OGG1, AAG and AlkA DNA glycosylases reveal a novel mechanism of substrate recognition. In the enzyme-substrate complex, the DNA is distorted so that an unpaired nucleotide containing the substrate base is rotated out of its stacked position in the DNA helix and into the active site of the enzyme, thus enabling chemical reactions to occur on atomic centers that would have otherwise been inaccessible. The following model has been proposed for damage recognition. Glycosylases, which have basic DNA recognition surfaces, track along the surface of DNA under the attractive influence of electrostatic forces. While scanning the surface of DNA, the glycosylase encounters a locally destabilized site containing a base

Base Excision Repair. Figure 1 Schematic representation of base excision repair.

Base Excision Repair. Table 1 Base Excision Repair

Name	Acronym	Size (amino acid residues)	Location	Major substrates	<i>E.coli</i> homologue	<i>S. cerevisiae</i> homologue	AP lyase activity
Alkyladenine DNA Glycosylase	AAG (MPG, ANPG)	293	16p	3MeA, 7MeG, 3MeG, εA, Hx,	<i>alkA, tag</i>	MAG1	No
Endonuclease III homologue 1	NTH1	312	16p13.2–p13.3	Tg, 5-OHU, 5-OHC, DHU, Fapy G	<i>nth</i>	NTG1/OGG2 NTG2	Yes
Methyl CpG binding domain 4	MBD4	580	3q21	U or T opposite G at CpG sequences			No
MutY homologue	MYH	535	1p32.1–p34.3	A opposite 8-oxoG	<i>mutY</i>		Maybe
Nei like 1 DNA glycosylase	NEIL1	390	15q25	5-OHU, 5-OHC, DHU, Tg, 8-oxoG, Fapy G, Fapy A	<i>nei, fpg</i>		Yes
Nei like 2 DNA glycosylase	NEIL2	332	4q35	5-OHU, 5-OHC	<i>nei, fpg</i>		Yes
8-Oxoguanine glycosylase 1	OGG1	345	3p25	8-oxoG	<i>fpg (mutM)</i>		Yes
Single stranded selective mono-functional DNA glycosylase 1	SMUG1	270	12q13.1–q14	U			No
Thymine (T:G) mismatch DNA glycosylase	TDG	410	12q24.1	U or T opposite G, ethenocytosine			No
Uracil DNA glycosylase	UDG	313	12q24.1	U, isodialuric acid, 5-OHU, 5-fluorouracil	<i>ung</i>	UNG1	No

Abbreviations: 3MeA, 3-methyladenine; 7MeG, 7-methylguanine; 3MeG, 3-methylguanine; εA, 1,*N*⁶-ethenoadenine; Hx, hypoxanthine; Tg, Thymine glycol; 5-OHU, 5-hydroxyuracil; 5-OHC, 5-hydroxycytosine; DHU, 5,6-dihydrouracil; Fapy, formamidopyrimidine; 8-oxoG, 7,8-dihydro 8-oxoguanine

lesion that is perhaps already in an extrahelical position. The enzyme then causes a kink in the DNA by compressing the lesions surrounding the damaged base, resulting in the flipping out of the nucleotide with the damaged base. Subsequently, the active site is locked on the lesion and catalytic chemistry ensues. Damaged bases might be more susceptible than normal bases to being flipped out of the double helix. Alternatively a DNA glycosylase might flip nucleotides out of the double helix indiscriminately, but only those damaged sites that fit precisely into the substrate-binding site of the enzyme would be subject to hydrolysis.

Mouse Models

The genes for several DNA glycosylases including Aag, Ogg1, Myh, Mbd4, Ung and Nth have been

knocked out in mice (4). To date these mice display normal development and do not have increased cancer incidence. This result is not surprising since there is functional redundancy; DNA glycosylases have overlapping substrate specificity. It seemed likely that combining [▶mutations](#) in glycosylases involved in the repair of the same type of damage, e.g. an *Ogg1*^{-/-} *Myh*^{-/-} mouse, might reveal more dramatic phenotypes. This is indeed the case, mimicking what was found in *E. coli* (7). *mutM* and *mutY* mutant *E. coli* cells each display a moderate [▶mutator phenotype](#) presumably because of their inability to repair 8-oxoG: A mismatches whereas there is a synergistic effect of combining the two mutations; *mutM mutY* double mutant cells have a mutation rate much greater than the sum of the rates for each single mutant.

In contrast to glycosylase deficient mice, mice deficient in subsequent steps of base excision repair (pol β , AP endonuclease, Xrcc1 and ligase I knockout mice) are embryonic lethal. It is unclear whether the embryonic lethality of these mice is due to the accumulation of toxic intermediates, whether BER is essential during development or whether these proteins are also involved in other pathways.

Clinical Relevance

MYH ► Polymorphisms

Polymorphic variants of enzymes involved in base excision repair have been linked with cancer predisposition. Inherited defects of the DNA glycosylase gene *MYH* cause a predisposition to multiple colorectal adenomas and colorectal cancer (5). Individuals with MYH gene mutation are not very efficient at removing A incorporated opposite 8-oxoG and therefore they have an increased frequency of G:C to T:A transversion mutations. Furthermore there has been a polymorphism in an ►intron sequence of the *MYH* gene resulting in alternative splicing of the transcript and reduced synthesis of the MYH protein.

OGG1 Polymorphisms

Polymorphisms of the OGG1 gene have been associated with increased lung and esophageal cancer. The Cys326 allele of the human *OGG1* gene was less capable than the Ser326 allele at suppressing the spontaneous mutation frequency of a *mutM mutY E. coli* strain suggesting that different variants might have different repair activities.

Alzheimer's disease is linked to oxidative stress and reduced OGG1 activity has been observed in cells from Alzheimer's patients. Furthermore, reduced AP endonuclease activity has been observed in brain tissue from amyotrophic lateral sclerosis disease suggesting that polymorphic variants in base excision repair enzymes might play a role in degenerative diseases.

XRCC1 Polymorphisms

The Trp194 variant of the *XRCC1* gene has been associated with reduced risk for lung and breast cancer whereas Gln399 may be associated with increased risk for solid tumors like breast and lung cancer. There are also some studies that correlate the presence of the Gln399 allele with reduced risk for bladder and non-melanoma skin cancer and some studies that do not find any correlation between Gln399 and cancer risk. It remains to be seen what role polymorphic variants at ►codon 399 play in cancer development (6).

Basement Membrane (BM)

Definition

Basement membrane (BM) is a specialised form of extracellular matrix. Ultrastructurally, it can be identified as a dense, about 100–250 nm thick, structure on the basal side of epithelial and endothelial cells, and surrounding Schwann, muscle and fat cells. The subepithelial BM is composed of specialised molecules, Type IV collagen, several laminin isoforms, heparan-sulfate proteoglycan and nidogen, which organise into a complex three dimensional structure. These molecules are tissue and age-specific; they modulate epithelial cell behaviour (proliferation, differentiation, migration) through their binding to cellular integrin receptors. Mutations in the genes encoding laminin isoforms are responsible of pathologies (epidermolysis bullosa, muscular dystrophy). Abnormal synthesis or degradation of BM molecules is involved in tumor progression and invasion.

Base-Pairs (bp)

Definition

Base pairs are pairs of nucleotide bases that constitute a fundamental unit of the DNA double helix. Base-pairs are formed with either adenine (A) and guanine (G), or thymine (T) and cytosine (C) as purine or pyrimidine bases, respectively. The complementary bases A and T, or G and C are connected by hydrogen bonds in the DNA double helix.

Basic Helix-Loop-Helix

Definition

Basic Helix-Loop-Helix (bHLH) is a structural motif that mediates protein-protein interaction in transcription factor dimers that bind to the DNA with their basic domain. It is characterized by two alpha-helices separated by a loop. The helices mediate dimerization, and the adjacent basic region is required for DNA binding.

Basic Helix-Loop-Helix Transcription Factors

Definition

Basic Helix-Loop-Helix (bHLH) transcription factors are characterized by the basic helix-loop-helix structural motif, which consists of two alpha-helices separated by a loop. The helices mediate dimerization, and the adjacent basic region is required for DNA binding. These genes are positive or negative regulators of cell fate commitment, by controlling the Notch signalling in adjacent cells.

► [Leukemia](#)

Bcl-2/Bcl-xL

Definition

Bcl-2 and its homolog Bcl-xL are members of a large evolutionarily conserved protein family (the Bcl-2 family) of regulators of apoptosis. The Bcl-2 family members contain at least one of the so-called Bcl-2 homology (BH) domains 1 to 4, originally defined in Bcl-2. Dependent on their BH domain architecture, Bcl2 family members exert pro-or anti-apoptotic properties. Bcl-2 and BclxL inhibit apoptosis by preventing the release of proapoptotic factors from mitochondria.

The term bicistronic refers to an mRNA molecule that encodes two proteins.

- ▶ Transposons

Bijvoet Difference

Definition

Bijvoet pairs are Bragg reflections that are space group-symmetry equivalents to the two members of a Friedel pair, which holds that they have equal amplitude and opposite phase (Friedel pair $|F(hkl)| = |F(-hkl)|$, $\varphi(hkl) = -\varphi(-hkl)$).

They have been measured for the same wavelength. The difference in the measured amplitude of a Bijvoet pair is called a Bijvoet difference. The Bijvoet difference $\Delta F_{\text{Bijvoet}} = |F_{\text{obs}}(\lambda_i, hkl)| - |F_{\text{obs}}(\lambda_i, -hkl)|$ is maximal when measured at λ_{peak} , with maximum fluorescence. A complete dataset of anomalous reflections comprises of all Bijvoet reflection pairs.

► [MAD Phasing](#)

Bile Acids

Definition

Bile acids are oxidation products of cholesterol, with the enzyme cholesterol 7 α -hydrolase as a rate limiting step in their synthesis. In humans, cholic acid (the most abundant) and chenodeoxycholic acid are the most important bile acids. They function in the gut to facilitate solubilization and disposal of cholesterol.

Binary GAL4-Expression System

The GAL4 system is a method for directed gene expression that can be used to misexpress genes in specific cell types, or tissues, at different times of development. This system relies on the generation of transgenic lines that carry ‘activator’ or ‘effector’ constructs. Activator lines express the yeast transcription factor, GAL4, under the control of a desired promoter, whereas effector lines contain DNA-binding motifs for GAL4-(UAS) linked to the gene of interest.

Binding Affinity

Definition

Binding affinity comprises of all energetic effects that are responsible for the binding of two molecules, e.g. a ligand and a receptor. In general, the ligand and the receptor are dissolved in water. Thus, the binding process occurs in aqueous solution, and water molecules are highly involved in the binding process.

► [Structure-Based Drug Design](#)

Binding Isotherm

Definition

Binding isotherm refers to the dependence of the population of unbound molecules and complex in

association-dissociation equilibrium on the total concentrations of the interacting molecular components.

Biochemical Engineering of Glycoproteins

RÜDIGER HORSTKORTE

Institute for Biochemistry and Molecular Biology,
Charité, Berlin, Germany
ruediger.horstkorte@charite.de

Definition

During recent years the human ► **genome** project has produced an enormous quantity of data. This flood of information has been further increased by the development and extended use of ► **DNA chip** technologies. There has been parallel progress in the analysis of the proteome, in particular through improvements in analytical methods.

The main goal of biochemical engineering in the life sciences is to use the enzymatic machinery of cells to achieve the chemical synthesis of novel biomolecules. Such engineered biomolecules may have novel properties and are potentially useful in both science and medicine. The challenge facing biochemical engineering is to obviate the limited potential of the gene by supplying non-DNA-coded products for basic research and industrial production. The present account focuses on the production of novel ► **glycoproteins** by biochemical engineering and outlines some potential applications of this methodology in medicine.

Characteristics

Glycosylation and Sialylation

► **Glycosylation of Proteins** represents the most common posttranslational modification of proteins. ► **Glycans** of glycoproteins are synthesized in the

► **Golgi apparatus** by specific glycosyltransferases, which attach nucleotide-activated ► **monosaccharides** to specific sugar residues of glycoproteins. Although these glycans have a common core structure (Fig. 1) the combination of different monosaccharides and different linkage-types allows the cell to create an enormous number of different structures. Note that the terminal monosaccharide of most glycoproteins is a ► **sialic acid**.

Sialic acids represent a family of aminosugars with over 40 members. ► **N-Acetylneuraminic acid** is the most prominent sialic acid in eukaryotes. Different sialic acids possess different highly specific recognition and binding properties for cellular receptors. This structural and functional diversity of sialic acid is exploited by viruses, bacteria and toxins and by the sialoglycoproteins and sialoglycolipids involved in cell-cell recognition.

Biosynthesis of Sialic Acid and Biochemical Engineering of Glycoproteins

The physiological precursor of all sialic acids is ► **N-acetyl-D-mannosamine** (ManNAc) (Fig. 2). It has been shown recently that synthetic *N*-acyl-modified D-mannosamines can be taken up by cells and efficiently metabolized to the respective *N*-acyl-modified neuraminic acids *in vitro* and *in vivo* (3). *N*-acyl-modified D-mannosamines successfully employed in this way include *N*-propanoyl- (ManNProp),

Biochemical Engineering of Glycoproteins.

Figure 1 Typical structure of a glycan from a glycoprotein. The common core structure of all glycoproteins is indicated. GlcNAc, N-acetylglucosamine; Man, mannose; Gal, galactose; Sia, sialic acid.

Biochemical Engineering of Glycoproteins. Figure 2 Biosynthesis of sialic acid. The biosynthesis of sialic acid starts in the cytosol. Activation occurs in the nucleus, whereas glycoproteins are built in the Golgi. Finished glycoconjugates are expressed on the cell surface. The structure of the precursor of all sialic acids, N-acetylmannosamine is shown. Its N-acyl side chain, the target of biochemical engineering, is marked in red.

N-butanoyl- (ManNBut)-, *N*-pentanoyl- (ManNPent), *N*-hexanoyl- (ManNHex), *N*-crotonyl- (ManNCrot), *N*-levulinoyl- (ManNLev), *N*-glycolyl- (ManNGc) and *N*-azidoacetyl D-mannosamine (ManNAc-azido) (Fig. 3). All these synthetic, unnatural sialic acid precursors are metabolized by the promiscuous sialic acid biosynthetic pathway in the cytosol and are incorporated into cell surface sialoglycoconjugates where, depending on the cell type, they replace 10–85% of normal, physiological sialic acids (for review, see 4). This method of introducing novel, unphysiological sialic acids into cellular glycoconjugates has been termed biochemical engineering of the side chain of sialic acid.

Application of the above mentioned synthetic sialic acid precursors to different biological systems has revealed important and unexpected functions of the *N*-acyl side chain of sialic acids. Furthermore, the introduction of chemically reactive ketone and azido groups into cell surface glycoconjugates using the respective *N*-acyl-modified sialic acid precursors, offers a variety of applications including the generation of artificial cellular receptors for viral gene delivery (6). Novel sialic acid precursors have enabled studies on sialic acid modifications on the surface of living cells

and have improved our understanding of carbohydrate receptors in their native environment. Biochemical engineering therefore provides new tools for studying the biological relevance of sialic acid and for exploiting it as a tag for therapeutic and diagnostic applications.

Clinical Relevance

Engineering of Cell Surface Sialic Acid Interferes with Virus Infections

Recognition of and binding to an appropriate receptor on the surface of the host cell by a virus is the first step of viral infection. Despite the ubiquity of sialic acid on the cell surface, sialylated oligosaccharides are an essential receptor component for many animal viruses from different virus families, such as influenza A and C viruses, Newcastle disease virus and cardioviruses as well as murine and primate polyomaviruses. When 18–64% of the sialic acids on host cells were biochemically engineered by treatment with the respective analogues (usually ManNProp), binding and/or infection by different primate polyomaviruses, which depend on cell surface sialic acids for entry, were markedly altered (5). For human polyomavirus BK the elongation of the *N*-acyl side chain by one methylene group (from *N*-acetyl to *N*-propanoyl) resulted in up to 7-fold

Biochemical Engineering of Glycoproteins. Figure 3 Biochemical engineering. The common precursor and the final sialic acid are shown. The structural differences between the physiological, natural acetyl side chains (Ac) and all engineered analogues are indicated.

enhancement of infection, whereas further elongation to *N*-pentanoyl drastically reduced infection. Binding and infection by the African green monkey B-lymphotropic papovavirus were decreased about 5-fold and more than 10-fold respectively, by incorporation of the *N*-propanoyl side chain. In contrast, the ▶sialidase-independent infection of closely related simian virus 40 was, as expected, unaffected (5).

Immunotargeting of Tumor Cells Expressing Unnatural Polysialic Acids

Immunotargeting of tumor cells by creating vaccines based on cancer-specific cell surface glycoconjugate antigens has long been proposed, but many tumors fail to express unique markers. Polysialylation, e.g. alpha 2–8 linked polysialic acid sequences located on the outer chains of an N-linked oligosaccharide, is a unique and functionally important property of the neural cell adhesion molecule. Its expression is regulated during embryogenesis, with maximal expression in the perinatal phase and restriction in the adult nervous system to plastic regions. However, over-expression of polysialic acid is found on a number of cancers, including small cell lung carcinomas and Wilms tumors, and is thought to promote tumor cell metastasis. Using ManNProp, Jennings and co-workers successfully generated polysialic acid containing *N*-propanoylneuraminic acid. Since a monoclonal antibody to polyNeuProp is available (13D9; 8), this

biochemically engineered polysialic acid expressed on leukemic tumors can be used for an antibody-mediated cell killing. Furthermore, in an *in vivo* study this antibody effectively controlled metastasis of a solid tumor model in mice, which had been given ManNProp. Bertozzi and coworkers have demonstrated that even ManNLev is incorporated into poly sialic acid. Using ManNLev, it is possible to introduce reactive ketone groups onto cell surfaces; this also offers novel possibilities for specifically attacking polysialylated tumor cells. The same group reported recently that ManNBut is a potent inhibitor of polysialylation (7). Application of ManNBut resulted in biosynthesis of the expected *N*-acyl-modified sialic acid (*N*-butanoylneuraminic acid), but this biochemically-engineered sialic acid seems to induce termination of polysialylation. Recent data suggest that biochemically engineered sialic acids specifically inhibit the polysialyltransferase II (2). Future work will have to address the applicability of these strategies to the targeting of polysialic acid-expressing human cancers and assess the potential adverse effects of biochemical engineering.

Activation of Human T-lymphocytes by ManProp

Sialic acids are implicated in the ▶differentiation and maturation of lymphocytes. Preliminary studies revealed that application of ManProp leads to an incorporation of *N*-propanoylneuraminic acid into human T-cells. These biochemically engineered T-cells

show several hallmarks of activation, including proliferation, secretion of interleukin-2 and the expression of the IL-2-receptor α -chain. This stimulation is dose-dependent and in the same range as that observed with the commonly used toxic plant lectins, concanavalin A or wheat germ agglutinin. ManNProp, however, did not induce cytotoxicity, even at high concentrations. The ManNProp-induced stimulation is accompanied by an increase in the peptidase-activity of CD26, a costimulator of lymphocytes. In agreement with this, an incorporation of N-propanoylneuraminic acid into CD26 was observed.

N-Acyl-modified Sialic Acids Stimulate Neuronal Cells Stimulation of Glia Cells

Modified sialic acids have striking biological consequences for glia cells of the mammalian central nervous system. Application of ManNProp to primary glial cells in culture leads to an expression of N-propanoylneuraminic acid in glycoproteins on the cell **▶membrane** (10). This biochemical engineering of the N-acyl side chain of sialic acid stimulated the proliferation of astrocytes and microglia *in vitro*. Furthermore, oligodendrocytes showed increased signs of a non-mature cell stage when ManNProp was applied. Mature oligodendrocytes are the myelin-forming cells in the central nervous system. They develop from oligodendrocyte progenitor cells, which can be immunologically identified by their expression of specific ganglioside-**▶epitopes**, such as the A2B5-epitope. This A2B5 epitope is regarded as a specific marker for a subset of rat oligodendrocyte progenitor cells. Application of ManNProp leads to a dramatic increase in A2B5-expression *in vitro*. Since the A2B5 epitope is considered to be a functional marker of cells of the early oligodendrocyte lineage, ManNProp has to be considered as a potent regulator of the lineage progression of oligodendrocytes at early stages of their development. Only oligodendrocyte progenitor cells and not mature oligodendrocytes are proliferative and migratory. These properties play an important role not only during development but also in the regeneration of the adult nervous system, since they develop constitutively into myelin-forming cells *in vitro* and *in vivo*. Oligodendrocytes are functionally impaired in a number of severe neurological diseases. The most important disease is the loss of oligodendrocytes followed by demyelination in multiple sclerosis. These results underline the important role of biochemically-engineered sialic acid in neural development and regeneration. The molecular mechanism underlying the stimulation of oligodendrocytes might depend on signal transduction events. The incorporation of N-propanoylneuraminic acid, followed by the application of GABA, leads to calcium oscillations in oligodendrocytes. It has been proposed

that biochemical engineering of the N-acyl side chain of sialic acid in conjunction with the activation of GABA-receptors, which are sialylated glycoproteins, modulates, e.g. increases, the intracellular calcium concentration in oligodendrocytes. The prolonged increase in intracellular calcium concentration after calcium oscillations could be responsible for the occurrence of A2B5-positive oligodendrocyte precursor cells.

Further data underlining the potency of biochemically-engineered sialic acid in myelination have been reported by Schnaar and coworkers. They used ManNGcPA as a synthetic precursor and demonstrated the conversion of neuronal sialic acids from N-acetyl- to N-glycolylneuraminic acid. The result was an inhibition of the binding of myelin-associated glycoprotein (MAG) to neuronal cells. MAG is expressed on myelin in the central nervous system and is known to be a potent inhibitor of neurite regrowth after nerve damage. This inhibitory capacity is mediated by the interaction of oligodendrocyte-expressed MAG with gangliosides of **▶neurons**, since MAG is a sialic acid-binding molecule of the siglec family. Thus, a means of interfering with MAG binding to nerve cells might enhance the possibility of post-traumatic nerve regeneration.

In this context it should be noted that in human lung fibroblast cultures also contact inhibition-regulated cell growth is influenced by chemically modified N-acyl mannosamines. By treatment of these cells with ManNProp, ManNBut or ManNPent for 7 days the density-dependent inhibition of growth is abolished.

These examples hopefully demonstrate the potency of synthetic D-mannosamines as therapeutic agents in nerve regeneration.

Stimulation of Neurons

Rat PC12-cells have been widely used as a standard system for the study of neurite outgrowth. These cells respond to nerve growth factor (**▶NGF**) by extending neurites *via* a ras-dependent pathway.

PC12 cells were cultured in the presence of suboptimal concentrations of NGF on poly-D-lysine, collagen I or laminin. The best neurite outgrowth was observed on laminin. In the presence of ManNProp, PC12-cells extended up to over 60% longer neurites on laminin compared to control cultures in the absence of ManNProp. This stimulation of neurite outgrowth was concentration-dependent (1). Furthermore, re-establishment of the perforant pathway was stimulated in brain slices. In addition, several cytosolic proteins with regulatory functions that are differentially expressed after treatment with ManNProp were identified. Since sialic acid is the only monosaccharide activated in the nucleus, we hypothesize that transcription is modulated by the unnatural CMP-N-propanoylneuraminic acid and that sialic acid activation might serve as

a general tool for regulating cellular functions, such as neurite outgrowth (1). This indicates the fundamental role of sialic acids in general and especially the role of the N-acyl side chain of the biochemically engineered sialic acid in neurite outgrowth.

Stability of Glycoproteins Is Increased after Incorporation of *N*-acyl-modified Sialic Acids

The biological ▶half-life time of many glycoproteins is regulated *via* terminal sialic acids. We found that the half-life of the highly sialylated CEACAM1, a member of the ▶immunoglobulin superfamily, is increased by more than 50% by replacement of the N-acetylneuraminic acid by the novel, engineered N-propanoylneuraminic acid. This demonstrates that biochemical engineering not only modulates the structure of cell surface sialic acids, but that biochemical engineering also influences biological stability of defined glycoproteins. Some of the observed effects of ManNProp on cells might be explained by the prolonged expression of specific cell surface receptors.

Biogerontology

Definition

Biogerontology is a branch of biomedical research aimed at finding the biological determinants of ageing, based on different biological models. These models range from lower organisms like *C. Elegans* to *in vitro* models based on human cells, like the model of

stress-induced premature senescence. It also considers cross-sectional or longitudinal studies of human populations including the very old (centenarians (>100) and supercentenarians (>110)).

Bioinformatics

Definition

Bioinformatics comprises of a broad area of computational methods that try to handle, store, retrieve, and analyze information about biological systems. Starting with the sequence information on the genetic code and gene products, bioinformatics allows the mining and prediction of properties of biomolecules. Furthermore, bioinformatics provides tools to compare biomolecules and to predict how their function could be modified, e.g. by docking ligands into binding pockets or forming protein/protein complexes.

Definition

Biological membranes are the basis for highly defined and separated functional units such as a cell and its subcellular compartments. The cell membrane, or plasma membrane, resembles the external boundary of every cell, separating the cytoplasm from the surrounding environment and strictly regulating in- and out-put of material and information. In animal cells, this separation is established by the plasma membrane alone, while in other eukaryotic cells (e.g. plant and yeast cells) and prokaryotic cells (bacteria) an additional cell wall serves as the outermost boundary, providing primarily mechanical support. Eukaryotic

cells contain in addition numerous subcellular membranes that divide the cytoplasm into multiple compartments (organelles), thereby allowing different functions to occur efficiently and simultaneously in different parts of the cell. Among these functions are nutrient and ion transport, oxidative and photosynthetic phosphorylations, signal transduction and electrical excitability.

Almost all biological membranes are organized as bilayers consisting of two leaflets, which are structurally formed by phospholipids. Depending on the (sub) cellular membrane, both leaflets may harbor also other classes of lipids including glycolipids and sterols. Proteins with specific functions important for the structure and stability of membranes as well as for cell homeostasis span (integral membrane proteins), loosely bind to the bilayer (peripheral membrane proteins) or are covalently linked to a fatty acid or a lipid molecule that is embedded in the membrane (lipid-anchored proteins). Biological membranes are highly dynamic structures as regards rotational, lateral and transversal motions of the components within the membrane. In addition, many membrane systems are capable of extruding membrane domains in the form of vesicles and of incorporating vesicles by ► [fusion](#), processes that provide for intracellular transport and secretion and that are consequently central to cell growth and proliferation.

Characteristics

Lipid Composition

The primary building blocks of most membranes are glycerolipids which consist of a glycerol backbone, two fatty acid chains and a polar head group at the *sn*-3 position (Fig. 1) (1, 2). The fatty acid chains are attached to the *sn*-1 (usually saturated, 16 or 18 carbons) and *sn*-2 (usually (poly)unsaturated, 18–20 carbons) positions of glycerol by ester or ether linkages, and they vary widely in length, branching, and degree of unsaturation. The major subclass of glycerolipids and the most important class in mammalian cells are the phospholipids (or phosphoglycerides). Their polar head group consists of a phosphate residue which is (except for phosphatidic acid, PA) esterified by an alcohol such as choline (to form phosphatidylcholine, PC), ethanolamine (phosphatidylethanolamine, PE), serine (phosphatidylserine, PS) or inositol (phosphatidylinositol, PI). The glycosylglycerolipids are another important subclass, in which the *sn*-3 position of glycerol is linked glycosidically to a carbohydrate, e.g. galactose. Sphingolipids constitute a second important lipid class in eukaryotic cells, where they compose 10–20% of the total lipid. The lipid moiety consists of a sphingoid base, which is an amino alcohol (usually of 18 carbons) and a (usually saturated) fatty acid chain

Biological Membranes. Figure 1 Biological membranes are mainly formed from three different classes of lipids. Phosphatidic acids (PA), phosphatidylcholines (PC), and phosphatidylinositols (PI) are examples of glycerolipids derived from glycerol. The fatty acid at the *sn*-1 position has a saturated chain with 16 or 18 carbon atoms. At the *sn*-2 position, the fatty acid is generally longer (at least 18 carbon atoms) and is unsaturated, with one or more *cis* double bonds. Sphingomyelins (SM) and glucosylceramides (GlcCer) are examples of sphingolipids derived from sphingosine. Typically, the amide-linked fatty acyl chains in sphingolipids are long (up to 24 carbons), saturated and often α -hydroxylated. Cholesterol is an abundant sterol in animal membranes. All lipids that are shown in the pictures are amphipathic molecules. The polar head groups are highlighted with blue, glycerol in the glycerol lipids with red and the sphingoid base in the sphingolipids with green.

linked *via* an amide linkage. Sphingolipids are richer in longer fatty acids (22–24 carbons) than glycerolipids and thereby tend to form thicker bilayers. The type of head group attached leads to their classification into sphingomyelins (phosphocholine or phosphoethanolamine head group), cerebrosides (head groups are sugar residues) and gangliosides (oligosaccharides with at least one sialic acid residue). The third class of membrane lipids found in eukaryotes are sterols. The most abundant sterol in animal membranes is cholesterol. It is essential for the properties of biological membranes and is, on the other hand, a precursor for steroid hormones.

In eukaryotes, membrane lipid composition varies dramatically between organelles (1). For example, plasma membranes are typically enriched in sphingolipids, PS and sterols, while the endoplasmic reticulum is depleted in these lipids (Fig. 2). Several lipids exist in

minor amounts. However, they often serve important biological functions and may be localized in specific (sub)cellular membranes. For example, the amount of glycolipids in the plasma membrane is typically about 5% of total lipid. In the apical membrane of polarized cells, however, they are greatly enriched, supporting the stability of the membrane. Likewise, the myelin shells of neuronal axons consist for the most part of sphingomyelin and gangliosides amount to 6% of the brain lipids. Cardiolipin, a diphosphatidylglycerol, is enriched in the inner mitochondrial membrane (~20%), but rare in other membranes. Although the membrane concentration of PIs is comparatively low, e.g. less than 10% in the plasma membrane, these lipids play an essential role in signal transduction. In gram-negative bacteria, the lipid and protein composition of the cell wall membrane (outer membrane) is very different from that of the plasma membrane (inner

Biological Membranes. Figure 2 Cellular membranes contain unique sets of proteins and differ in their lipid compositions and transbilayer lipid distributions in spite of extensive bi-directional membrane trafficking. For example, eukaryotic plasma membranes (PM) are typically enriched in sphingolipids, cholesterol and phosphatidylserine and display transbilayer lipid asymmetry, while the endoplasmic reticulum (ER) is depleted in those lipids and shows a symmetric lipid distribution. In addition, cellular membranes display a lateral heterogeneous organization by the clustering of specific lipids into highly condensed domains (termed lipid rafts). Lipid rafts in the plasma membrane outer leaflet are composed of cholesterol, sphingolipids and phospholipids with saturated fatty acyl chains (indicated as straight lines in lipid tails) while the inner leaflet contains domains of unknown lipid composition. Various domains of different composition may occur within a monolayer and domains in both monolayers may colocalize (gray bilayer). A variety of proteins partition into lipid rafts (gray bilayer), e.g. glycosylphosphatidylinositol-anchored proteins (GPI) and transmembrane proteins (TM3 in contrast to TM1 and TM2). PC, phosphatidylcholine; PE, phosphatidylethanolamine; PS, phosphatidylserine; SM, sphingomyelin; Chol, cholesterol; GL, glycolipid.

membrane). For example, the outer leaflet of the cell wall membrane of *E. coli* harbors solely lipopolysaccharides while the inner leaflet is enriched in PE.

Protein Composition

Biological membranes contain between 20% and 80% (w/w) proteins (1). They are of broad functional variety covering substance exchange and transport (pores, channels, transporters), biochemical reactions including energy perception and conversion (enzymes), signal transduction, immunoreaction, endo- and exocytosis and cell-cell interaction. In addition, membrane proteins may serve to support the stability of membranes (membrane skeleton) and to establish a lateral and transversal heterogeneous organization. Membrane proteins are either anchored to the membrane surface (peripheral membrane proteins) *via* hydrophobic or electrostatic interaction, covalently linked to a fatty acid or to a lipid molecule that is embedded in the membrane (lipid-anchored proteins; e.g. ►GPI proteins) or span the hydrophobic part of the membrane (integral membrane proteins). Integral membrane proteins may cross the membrane several times, for example G-protein linked receptors, ion channels and ATP-dependent transporters. The

transmembrane domains are usually α -helices, but in some cases, such as porins, also β -strands. Membrane protein activity often requires homo- or hetero-oligomerization of proteins. The majority of proteins that are secreted or embedded in the plasma membrane are modified by carbohydrate attachment and called glycoproteins. Glycoproteins on cell surfaces are important for communication between cells, cell adhesion, maintaining cell structure and self-recognition by the immune system.

Molecular Interactions

Biological membranes are typically organized in bilayers (3). The formation of this lamellar structure by lipids does not require energy and is an entropic process driven by so-called hydrophobic force (1). However, maintenance of a specific lipid composition and an asymmetric distribution of lipids between leaflets (see below) requires energy consumption. Non-bilayer organization of lipids as hexagonal structures has been observed in model membranes, depending on the lipid composition and the characteristic shape of lipids as well as other factors, e.g. interaction with cations and temperature. Formation of local non-bilayer structures, which are very likely of transient occurrence, has also

been detected in biological membranes. The significance of these structures is not well understood. They have been suggested to be involved in fusion of biological membranes.

Lateral Organization of Biological Membranes

In model membranes of homogenous lipid composition, lipids can adopt different phases depending on the lipid as well as on various factors like temperature, pressure and ionic strength. For example, the liquid-disordered (or fluid) phase transforms into the ordered gel phase on lowering the temperature, a phase transition. Membranes of lipid mixtures do not usually exhibit phase transitions (1). Typically, biological membranes with several hundred chemically different lipids are in the fluid state. Nevertheless, the degree of interaction and of miscibility of different kinds of lipids leads spontaneously to formation of separate lateral domains of different lipid composition with striking similarities to phases described in model membranes. Most prominent are so-called **rafts** which are found in the plasma membrane and probably also in subcellular membranes of eukaryotic cells (Fig. 2). These domains are essentially enriched in phospholipids carrying long saturated fatty acid residues, sphingolipids and cholesterol and resemble a specific interaction between these lipids (3, 4). Rafts are in a liquid-ordered state in which the lipids are ordered but retain their free rotational and lateral diffusion. The size and stability of these domains are not clear. Dimensions between a few molecules and 300 nm and half times between nsec and sec have been reported. Membrane proteins may selectively redistribute into and enrich in rafts. Apart from redistribution into these domains, non-random lateral distribution of proteins is achieved by other phenomena such as protein oligomerization or interaction with peripheral proteins (membrane skeleton) on the cytoplasmic leaflet. Furthermore, membrane proteins may become depleted in membrane regions of high curvature/bending.

Specific protein-lipid interactions are another factor leading to lateral heterogeneous lipid arrangement. These interactions induce an enrichment of selected lipid species in the immediate vicinity of membrane proteins, forming a lipid shell.

The so-called tight junctions separating the plasma membrane of polarized cells (e.g. epithelial cells) into an apical and a basolateral domain are a characteristic example of protein-mediated membrane domain formation. The two domains differ with respect to protein and lipid composition.

Transversal Distribution of Lipids

Numerous eukaryotic cell types exhibit a non-random, asymmetric distribution of phospholipids across their

plasma membranes and probably also in the late Golgi and endosomal compartments (Fig. 2) (2). For example, cerebrosides, gangliosides and sphingomyelins are found only in the exoplasmic leaflet of the plasma membrane. The enrichment of sphingolipids on the cell surface not only plays an important structural role in protecting cells but is also essential for intercellular recognition and signal transduction. For most mammalian cells, the exoplasmic leaflet of the plasma membrane is especially rich in PC, providing a rather inert surface essential for stability and barrier function, whereas the inner leaflet is rich in the amino phospholipids PS and PE, lipids which promote membrane-membrane interactions and fusion.

Dynamics

Lipid bilayers are two-dimensional fluids, since membrane lipids and many proteins can easily move within the plane of a membrane leaflet (1, 3). In the case of lipids, this lateral diffusion is very rapid; the lateral diffusion coefficient (the area over which a molecule moves in 1 sec) is about 10^{-7} to 10^{-8} cm²/sec, being slightly lower for liquid-ordered domains. Furthermore, individual lipid molecules rotate very rapidly along their head-to-tail axis with a characteristic time of 10^{-7} sec, and display molecular vibrations with a characteristic time of 10^{-14} sec. Membrane proteins can also move laterally within the membrane. Their lateral diffusion is about two orders of magnitude slower and depends on their size, degree of oligomerization and interaction with peripheral proteins as well as on the physical state of the surrounding lipid phase (for example, entrapment in rafts). Lipids can move between the two leaflets of the membrane bilayer, a process termed transverse diffusion or flip-flop (2). Neutral lipids such as diacylglycerol and charged lipids such as free fatty acids, phosphatidic acid or phosphatidylglycerol in their protonated form can move from one leaflet to the other in seconds or minutes. By contrast, phospholipids with polar head groups and glycolipids with bulky hydrophilic carbohydrate moieties flip spontaneously only slowly across a lipid bilayer, displaying half-times of hours to days depending on the size and charge of the head group. Cholesterol is embedded in the membrane with its polar OH group facing the aqueous phase and the acyl chain pointing towards the bilayer center. Experimental evidence supports rapid flip-flop of cholesterol in PC membranes, red cell membranes and, presumably, in most other cellular membranes.

Regulatory Mechanisms

For the specific function of each biological membrane, distinct sets of lipids and proteins are essential. In many cases, structure, organization and activity of membrane

proteins depend on the presence of specific lipids. In eukaryotes, a selective transport of lipids and proteins between organelles is the central process in the organization of membrane compartments (2). This process is mainly mediated by the budding of transport vesicles from a donor compartment followed by the vectorial trafficking to and fusion with an acceptor compartment. Apart from differences in protein and lipid composition, the various organellar membranes display striking differences in the leaflet distribution and transbilayer movement of their lipids (Figs. 2, 3). For example, the endoplasmic reticulum is the principal site of membrane assembly in eukaryotes and in this aspect similar to the plasma membrane in prokaryotes. Lipid synthesis in these membranes is an asymmetric process that results in the insertion of new lipids into the cytoplasmic leaflet. To ensure balanced growth and thus stability of the membrane, half of the newly synthesized lipids must flip to the opposing leaflet. This process is facilitated by so-called ►flippases, membrane proteins that catalyze a transverse diffusion

of most, if not all, lipid classes in both directions and function independently of metabolic energy (2). The situation is different for the plasma membrane of eukaryotes where flip-flop of phospholipids is constrained and ATP-dependent transporters maintain an asymmetric lipid distribution by moving specific lipids towards (►P-type ATPase family members) (5) or away from (►ABC transporters) the cytosolic leaflet (6). The maintenance of the nonrandom lipid distribution across the plasma membrane is important for cellular functions. Changes in this arrangement generally trigger a physiological event such as the nucleation of coagulation cascades on the surface of activated platelets or the phagocytic clearance of apoptotic cells by macrophages. Local changes in transbilayer ►lipid asymmetry caused by local lipid metabolism, transbilayer movement or domain formation are crucial for processes such as membrane budding and fusion, where membrane curvature plays an important role. Furthermore, the lateral organization of lipids, especially cholesterol and sphingolipids, into

Biological Membranes. Figure 3 Specific proteins (flippases) involved in lipid transbilayer movement are embedded in biological membranes. The activity of these proteins may be unspecific or highly selective (e.g. for the head-group of phospholipids). In the endoplasmic reticulum (ER), bi-directional flippases facilitate rapid flip-flop of lipids and allow them to equilibrate between the two membrane leaflets independently of ATP. This system is unable to accumulate a given lipid in one leaflet, thereby promoting a symmetric lipid distribution across the bilayer. In contrast, flip-flop of phospholipids across the plasma membrane (PM) is constrained owing to high levels of cholesterol and sphingolipids and/or the absence of constitutive bi-directional flippases. Thus, ATP-dependent flippases can maintain an asymmetric lipid distribution by moving specific lipids towards (P-type ATPase family members) or away from the cytosolic leaflet (ABC transporters). Cellular activation triggered by cytosolic calcium can collapse the lipid asymmetry by the transient activity of an ATP-independent scramblase.

rafts has consequences for the recruitment and concentration of proteins, regulation of protein-protein interactions within the membrane and cell signaling functions. Since rafts have also been reported for subcellular membranes, these domains may provide a molecular basis for sorting lipids and proteins into specific vesicular pathways.

Biomarker

Definition

A biomarker is a biomolecule-based diagnostic marker for a disease, or certain disease stage.

- Mass Spectrometry: SELDI
- Proteomics in Human-Pathogen Interactions

Biomimetic Ligands

Definition

Biomimetic ligands are synthetic protein ligands that mimic natural ligand-protein interactions.

- Affinity Chromatography and *In Vitro* Binding (Beads)

Biopanning

Definition

Biopanning is the procedure of selecting binding partners from phage display libraries. In this affinity-driven selection procedure, specific binders against a target of choice are enriched from a phage display library during consecutive cycles of incubation, washing, amplification and re-selection of bound phage. Multiple rounds of selection are necessary to enrich specifically binding phage particles over a general background of unspecific sticky phage.

- Protein Interaction Analysis: Phage Display

Biopharmaceuticals

Definition

Biopharmaceuticals, biologics and biologicals are synonyms that refer to natural biomolecules that are used in medical therapy and are produced biotechnologically in host organisms or cells. Many biopharmaceuticals are identical to molecules of the human body, e.g. interferon. The largest class of biopharmaceuticals are antibodies.

- Affinity Chromatography and *In Vitro* Binding (Beads)

Biosensors

Definition

Biosensors are detection systems that use reactions that are performed or mediated by biological materials (enzymes, antibodies, cells) to detect different substances. The reaction is generally measured as an electrical, thermal or optical signal.

- Monoclonal Antibodies

Bipartite NLS

Definition

Bipartite NLS (Nuclear Localization Signal) designates a specific sequence within a protein that is responsible for the translocation into the cell nucleus, composed of

two interdependent clusters of basic amino acids separated by a spacer region of 10–12 amino acids.

Synonyms

Manic depression

Definition

Bipolar affective disorder, also termed “manic depression”, is characterized by an alternation in mood between two poles, mania and depression. This alternation can be rapid, taking place within hours or days, or the episodes of illness may occur at longer intervals, separated by months or years.

The mood in the depressed phase is sad and despondent. Other characteristic features are loss of drive, slowness of thought, feelings of guilt and loss of interest in life. These features are typically accompanied by appetite and sleep disturbance. In contrast, the manic phase is characterized by an expansion of mood, with exaggerated estimation of ability, increased drive, rapid thoughts and speech. Marked irritability is another frequent feature of the manic phase.

The modern classification system DSM IV (1) distinguishes between bipolar I and bipolar II disorder, and the distinction is based on the severity of the manic symptoms. Bipolar I disorder has clear manic symptoms and may include delusions. Bipolar II disorder has less distinct symptomatology, so called hypomanic symptoms. In cases where only depressive symptoms are found, the diagnosis of unipolar depression is applied. The depressive symptoms of unipolar depression and the depressive phases of bipolar disorder

cannot be distinguished clinically. However, course of disease, treatment and formal genetic findings suggest that unipolar depression and bipolar disorder should be considered as separate illnesses.

Characteristics

Bipolar affective disorder is a serious and common illness. The lifetime prevalence of bipolar I disorder is 0.5–1%, and the suicide rate for affected persons is approximately 10–15%. Despite intensive research, the cause of the disorder remains obscure. Thus, although some effective medications are available, treatment remains incomplete at this time.

Formal Genetic Studies

A substantial contribution of genetic factors to the development of bipolar disorder has been suggested through a large number of formal genetic studies (5).

Family Studies

All completed family studies to date, using standard diagnostic methods, have shown that first-degree relatives of patients with bipolar I disorder have an increased risk of developing a bipolar disorder. The relative risk for first-degree relatives is approximately 7. These studies also show that the first-degree relatives have an increased risk of developing unipolar depression. The risk is approximately doubled. It is not possible in individual cases to determine if the prevailing depressive illness is related to the familial genetic loading with bipolar disorder, as unipolar depression is very common in the general population, with a life time prevalence of 5–10%. There are estimations that 70% of unipolar cases among relatives of bipolar patients share a common genetic background. In these families it is noted that unipolar depression occurs twice as commonly in women as in men, while the risk for bipolar disorder is equal for both sexes. The same sex ratio is observed in the general population. Other disorders that are observed in relatives of patients with bipolar I disorder are bipolar II disorder and schizoaffective disorder, so that, as with unipolar disorder, there is a suspicion of overlapping aetiology.

Twin Studies

The ►concordance rate for bipolar disorder for monozygotic twins is on average 50% in comparison with the rate for dizygotic twins, which is approximately 10%. If unipolar disorder is considered, the concordance rate is approximately 80%. The extent of heritability, that is the extent to which genetic individual differences contribute to individual differences in phenotype, is 60–80%.

Adoption Studies

There has only been one adoption study to date from which meaningful conclusions can be drawn concerning

bipolar disorder (6). This identified increased morbidity rates for affective disorders in biological parents of bipolar patients, compared to adoptive parents of affected children and to a control group of adoptive parents of non-affected children.

Specificity of the Genetic Contribution

The fact that schizoaffective disorder is also found in the relatives of bipolar patients may suggest an aetiological overlap with schizophrenia spectrum disorders. Bipolar patients are frequently observed to have co-morbidity with other psychiatric disorders. Early onset disorders have been associated with attention deficit hyperactivity disorder and conduct disorder, while later onset illness has been associated with substance misuse. This observed co-morbidity might be a sign of ►pleiotropic gene effects.

Cellular and Molecular Regulation

The biological mechanisms responsible for the development of bipolar disorder remain largely unknown. Biological psychiatric research has proposed a multitude of possible mechanisms, including a disturbance of neurotransmitters, intracellular transduction or neuroendocrine regulation. Whether these mechanisms are genuinely implicated, and to what extent they are involved, is still unclear. The advantage of the molecular genetic approach is that the identification of vulnerability genes reveals causal factors. This will allow understanding of the function of a given gene product, and gradually reveal the functional context which ultimately produces the clinical phenotypes.

►Candidate Gene Studies

The number of published studies on candidate genes for bipolar disorder is large, and a simple interpretation of the findings is difficult. Many candidate gene studies have the disadvantage of small sample sizes and the lack of a systematic approach for the investigation of specific candidate genes (e.g. low number of investigated polymorphisms and insufficient knowledge of haplotype structure). Furthermore, there are theoretically a multitude of biological mechanisms that could be responsible for the illness, and therefore there are a large number of potential candidate genes to be examined. When a candidate gene is in a chromosomal region, which has been shown to have linkage with the disorder, it naturally has a higher plausibility.

Amongst the most discussed candidate genes are the *serotonin transporter gene (5-HTT)*, the *catechol-O-methyl-transferase gene (COMT)*, and the *brain-derived neurotrophic factor gene (BDNF)* (4). On account of the inconsistency of reported findings, no judgement can be made at this time.

Linkage Studies

The linkage study approach is carried out to localize disposition genes to specific chromosomal regions. Since the mid 1980s, linkage studies in bipolar disorder have been carried out with the help of genetic markers. The value of the first studies lay less in their results than in the insights they gave into the methodological and conceptual weaknesses of transferring the classical approach of linkage studies for monogenic disorders to complex genetic disorders. This understanding gave impetus to the further development of the linkage method, in particular the creation of assumption-free analysis methods using large samples of “nucleus families”, that is families with a minimum of an affected sib-pair and their parents. In recent years these methods have enabled the localisation of chromosomal regions which have a high probability of containing genes which contribute to bipolar disorder: 4p16, 4q35, 8q24, 10q25-q26, 12q23-24, 13q32-q33, 18p11.2-cen, 18q21-q23, 21q22 and 22q12-q13. Although all these chromosomal loci have been found by two or more independent research groups, no locus has been consistently replicated by all of the groups. This reflects on the one hand the high degree of locus heterogeneity and on the other the variability of studies with regard to their phenotype definition, sample sizes and the type and density of genetic markers used.

In recent years two large meta-analyses of all published genome-wide linkage studies have been conducted (2, 7). Since the original studies were not uniform with regard to a number of methodological issues (e.g. diagnostic criteria, genetic markers), by integrating the results the ►meta-analyses had to accept a degree of loss of information. A specific advantage of such meta-analyses, however, lies in their sensitivity for genes with a relatively small but widespread contribution to the development of the illness. These genes may remain undetected in an individual study but may be detectable if results from a large number of studies are combined. It is therefore not surprising that the meta-analyses, in addition to the confirmation of previously implicated loci, also suggested new loci (9p22-p21, 10q11-q22, and 14q24-q32). Interestingly, for some of the chromosomal regions suggested by the meta-analyses, linkage has also been reported with schizophrenia. Since there is a possible aetiological overlap between bipolar disorder and schizophrenia, the genes that have been identified for schizophrenia in these regions are excellent candidate genes for bipolar disorder. Using this strategy, the G72/G30 locus (chr. 13q33) has recently been associated with bipolar disorder. The responsible gene has not yet, however, been unequivocally identified.

Clinical Relevance

Phenotypic Heterogeneity

The results to date of linkage studies suggest that the contribution of an individual gene to the aetiology of bipolar affective disorder is low to moderate. With complex genetic illnesses there has been a series of examples where characteristic illness phenotypes have been helpful in defining aetiologically more homogeneous sub-types. In bipolar affective disorder the following features have been proposed for homogenisation: age at onset, presence of psychotic symptoms, rapid cycling, response to lithium and co-morbidity with other psychiatric disorders (3). The inclusion of these parameters is only in its initial stages within the context of linkage studies. Future studies will consider these parameters in more detail.

The Need for Large Samples

For genes with small to moderate effects, the search for genes is highly reliant on the size of the samples. This relates to both association and linkage studies, particularly in the latter, where small family numbers can dramatically reduce statistical power. Several collaborative efforts to collect large samples are under way. Retrospective meta-analyses, such as the above-mentioned studies, have the disadvantage that the original studies are often not comparable in terms of phenotype definition, selection of genetic markers and so forth, which results in considerable information loss. Prospective collaborative studies, in principle, will be better able to identify genes with small to moderate effects.

The Potential of Isolate Populations

In isolated populations it is hoped that, through founder effects, the contribution of individual genes might be larger and easier to detect. There is, however, no unanimous opinion regarding which population size and history are most appropriate for use in gene identification. In bipolar disorder, genome-wide linkage studies have been conducted in families drawn from isolated populations such as the Old-Order-Amish, the Finns, Central Valley Costa Rican families and families from the Quebec region of Canada. Despite promising linkage findings, this approach has not yet identified a gene. In isolated populations, the ►linkage disequilibrium can extend over a large genomic region, which could be unfavourable for the detection of genes.

Gene-environment Interaction

Better understanding of the interaction between genes and environment may rest with identification of illness genes. The mode of gene-environment interaction is still unknown. It is possible that many gene-environment

interactions are based on additive effects, though more complex interactions are also possible since data from family and twin studies suggest that genetic factors also influence the susceptibility and the tendency for exposure to environmental factors.

Bispecific Antibodies

Definition

Bispecific antibodies react with two different antigens. All natural antibodies only react with one antigen, because both antigen-binding fragments have the same amino acid composition. Bispecific antibodies can be produced by biochemical, cell fusion or recombinant methods.

►Monoclonal Antibodies

Bithorax Complex

Definition

Bithorax complex (BX-C) designates the cluster of homeotic genes that specify the identities of posterior segments in *Drosophila Melanogaster*.

►Homeodomain Transcription Factors

BLAST

Definition

BLAST stands for Basic Local Alignment Search Tool, a program for searching biosequence databases, designed to identify the classification and potential homologs for a given sequence. Different versions allow DNA or protein sequences as input, as well as DNA or protein databases. This tool is maintained by the National Center for Biotechnology Information (NCBI). BLAST locates paths of regional similarity instead of calculating the best overall alignment using gaps. The program then uses a scoring matrix to rank these matches as positive, negative or zero. If the initial match is scored highly, the search is expanded in both directions until the ranking score falls off.

Blastocyst

Definition

The blastocyst is a multicellular early embryo (approximately 3.5 days post fertilization in mouse) in which the cells destined to form the developing fetus have not yet differentiated into discrete cell types. A blastocyst consists of a hollow ball of trophoblast cells, surrounding a fluid-filled cavity, and an inner cell mass (which is composed of pluripotent stem cells). Gene-modified mice are generated by injection of blastocysts with gene-modified embryonic stem cells.

Bloom Syndrome

EBERHARD PASSARGE

Institute of Human Genetics, University Clinic Essen,
Essen, Germany

eberhard.passarge@uni-essen.de

Definition

Bloom syndrome (►MIM 210900) is a human hereditary disease. It was first described by a dermatologist in New York, David Bloom (1954), under the title “Congenital telangiectatic erythema resembling lupus erythematoses in dwarfs” (1). It is one of a group of disorders characterized by signs of genomic and ►chromosomal instability, an increased rate of ►somatic mutations and an increased risk of developing different types of malignancies. Bloom syndrome can be classified as a ►DNA helicase-deficiency disorder that results from mutations in the *BLM* gene, which encodes a ►DNA helicase of the RecQ type.

Characteristics

Bloom syndrome is unique among human hereditary diseases as it combines clinical features that occur individually in other disorders, but here together result in a rather specific clinical and cellular phenotype. The main clinical features are (1) striking pre- and postnatal growth retardation, (2) a characteristic configuration of the face and head, including facial skin manifestations in most patients, (3) variable, unspecific immune deficiency resulting in increased susceptibility to infections, mainly of the broncho-pulmonary system, (4) areas of hyper- and hypo-pigmentation of the skin, (5) absence of mental retardation, but development of a behavioral pattern of reduced attention span with learning and memory deficits, (6) increased risk of developing various types of malignancies throughout life, often with multiple independent primary tumors at

different ages, (7) hypersensitivity to DNA-damaging chemicals *in vivo* and *in vitro*, (8) male infertility, (9) feeding difficulties in infancy and early childhood, followed by lack of appetite in adults and (10) diabetes mellitus type 1 and type 2 in about 17% of patients over the age of 20. A spontaneous ten-fold increase in the rate of ►sister chromatid exchanges (SCE) in metaphases derived from cultured lymphocytes serves as a specific diagnostic test.

- Data Base:

The Bloom Syndrome Registry has provided a comprehensive database for Bloom syndrome (2, 3, 4, 5).

- Inheritance pattern:

autosomal recessive. No clinical or cellular manifestations in heterozygotes.

- Gene Locus:

on the long arm of chromosome 15 at region 2, band 6.1 (15q26.1).

- Genetic Heterogeneity:

No other gene locus known, but considerable allelic heterogeneity demonstrated by molecular gene mutation analysis.

- Population Genetics:

A characteristic ►founder mutation occurs in populations of ►Ashkenazi Jewish origin with a heterozygote frequency of about 1 in 107 and linkage disequilibrium with linked polymorphic microsatellite loci. The estimated heterozygote frequency in non-Jewish populations is about 1 in 300; parental consanguinity is increased in non-Jewish populations. Bloom syndrome has been observed in different populations of European ancestry, including Latin American countries and in Japan.

- Mouse model:

Homozygous knockout mice (*Blm*^{-/-}) are not viable and die at 13.5 days of embryogenesis (6).

Cellular and Molecular Regulation

Cellular Phenotype

Cultured cells from homozygotes *BLM*^{-/-} grow poorly. Lymphocytes transform with reduced efficiency. Lymphoblastoid cell lines are difficult to establish and require considerably more time than normal cells. Cultured fibroblasts have an extended doubling time and occasionally form anaphase bridges. DNA excision repair is normal.

Metaphase Chromosomes

A high rate of breaks in one or both chromatids is visible in about 30–40% of metaphases. Reunion of homologous chromosomes, evident as characteristic quadriradial figures, occurs in about 1–3% of metaphases. Dicentric chromosomes, acentric fragments

and premature chromosome condensations can be observed in a few percent of cells.

Sister Chromatid Exchanges (SCEs)

An about ten-fold spontaneously increased rate of sister chromatid exchanges is the diagnostic hallmark of Bloom syndrome. It is the only disease with this cellular phenotype, which serves as a specific diagnostic test.

Occasionally in certain patients a few individual metaphases show a normal SCE pattern. This is interpreted as a reversion to the normal phenotype as a result of somatic intragenic recombination when the underlying mutations are ►**allozygous**, i.e., at different sites in the *BLM* gene (compound heterozygous state). This observation was instrumental in identifying the gene (7).

Increased Rate of Somatic Mutations

Bloom syndrome is the prototype of a human mutator phenotype. Somatic mutation occurs at an increased rate in all tissues tested. Direct evidence has been obtained by studying the following loci in lymphocytes from affected persons: HGRT, glycophorin A, MN blood type, HLA (5).

Identification of the Bloom Gene *BLM*

The gene is localized on 15q26.1. It was identified by a novel variant of ►**homozygosity mapping** called somatic crossover point (SCP) mapping (7). This was based on five lymphoblastoid cell lines from *bona fide* patients with a normal rate of SCE. German and

colleagues argued that the reversion to a normal rate of SCEs was the result of intragenic recombination, which rendered the cell involved heterozygous and thereby normalized the rate of SCEs. The objective was to identify the region (the *BLM* region) between the most proximal polymorphous marker locus (in the direction of the centromere) that was constitutionally heterozygous, but had become homozygous in the cell lines with low SCE and the region with loci that always were homozygous and therefore were not subject to Bloom-related intragenic recombination. In this region of 250 kb between marker loci D15S1108 (proximal) and D15S127 (distal), a 4437-bp cDNA sequence was found containing an open reading frame encoding a 1417-amino acid protein. This hybridized to single-copy genomic sequences spanning about 100 kb of genomic DNA. A 4.5-bp transcript was identified from total RNAs prepared from different human cells proliferating *in vitro*.

Structure of the *BLM* Gene

The *BLM* cDNA contains 7 motifs present in most DNA and RNA helicases. From this, and sequence homology observed in cDNA, it can be deduced that the gene encodes a DNA helicase that belongs to the RecQ family of DNA/RNA helicases (see below).

Mutations

The Bloom Syndrome Registry (3, 5) contains 64 different mutations scattered throughout the gene, identified in 124 of 134 affected persons (Table 1). Eighteen mutations were recurrent in unrelated

Bloom Syndrome. Table 1 Summary of Mutations reported in Bloom syndrome, in a sample of 133 patients*

Observation	Number of patients in which mutation found
Mutations present	124
Unique mutations:	64
Amino acid substitutions	10
Small deletions/insertions	21
Nonsense mutations	20
Splice site mutations	9
Deletions of one exon or more	4
Total number of protein truncating mutations	54
Missense mutations	10
Recurrent mutations	18
No mutation	9

* Data reported by German & Ellis, 2002 (4)

persons. Most common are nonsense mutations resulting in truncated protein (21 small insertions/deletions, 20 resulting in a premature stop codon, 10 substitutions in conserved regions, 9 splice site mutations, 4 deletions of a whole exon or more and 10 missense substitutions (of these 5 in a helicase domain). A unique mutation occurs in persons of Ashkenazi Jewish origin, a 6-bp deletion/7-bp insertion in exon 10 at nucleotide 2281 (*BLM*^{Ash}). The next most common mutation allele is C1933T, which results in an exchange of a glycine (Q) for a stop codon (X) at amino acid 645 (Q645X).

Homology of the BLM Protein

Homology comparison of amino acid sequence data bases established that the 1417-amino acid protein encoded by the *BLM* gene belongs to the ▶*RecQ* helicases, a subfamily of DExH box-containing DNA and RNA helicases (5). These occur in such diverse organisms as *E. coli*, yeast (*S. cerevisiae*, *S. pombe*), *Drosophila melanogaster*, *Xenopus laevis* and *Homo sapiens*. In humans, five helicases of this type are known, BLM (1417 amino acids), WRN (1432 amino acids), RECQL4 (1208 amino acids), RECQL (649 amino acids) and RECQL5 (410, 435 and 991 amino acids owing to three RNA splice variants) (6). Of these, three are known to be related to human genetic disorders, BLM in Bloom syndrome, WRN in Werner syndrome (MIM 277700) and RECQL4 in Rothmund-Thomson syndrome (MIM 268400).

Molecular Biology of the BLM Protein

Antibodies to an N-terminal part of BLM raised in rabbits make it appear to be identical to a protein of 180 kD identified by western blot analysis of fibroblast, lymphoblastoid and HeLa cells that is absent in all Bloom syndrome cell lines homozygous for a premature translation-termination mutation (3). Presumably this protein is the *BLM* gene product. This protein is present in the nucleus of all proliferating cells, except those homozygous for the *BLM* mutation. This corresponds to the presence of a nuclear localization signal in the last 100 amino acids of the BLM protein. BLM is present in the nucleus in two types of distribution, as fine granular speckles in varying local concentrations and as bright, punctate foci. The latter have been identified as ▶*PLM* nuclear bodies (reviewed in 5). At metaphase, the BLM protein becomes homogeneously and diffusely distributed throughout the cytoplasm (8). This reorganization correlates with ▶*ATM*-dependent phosphorylation. BLM interacts with RAD51 in the yeast two-hybrid system suggesting that BLM participates in recombination-coupled repair of double strand breaks.

In meiosis BLM is present near paired chromosomes in the zygotene and leptotene stages. This suggests that

lack of functional BLM protein interferes with meiotic prophase and chromosome pairing. This may be the basis of the clinically observed lack of spermatogenesis and male infertility (reviewed in 3).

Clinical Relevance

The various clinical features of Bloom syndrome have been reviewed in detail elsewhere (2, 3, 4, 5). Therefore, only the main features will be mentioned here.

Growth Retardation

This is a constant feature that can be considered as obligatory. The mean birth weight is 1800–1900 g at normal gestation. Growth is below the third percentile throughout childhood until an average adult height of about 140–150 cm is reached. No adult patient has been taller than 160 cm. The prepubertal growth spurt does not take place. Growth retardation is the most frequent cause of seeking medical advice.

Craniofacial Phenotype

Until early adulthood patients can be easily recognized by their narrow face and skull (dolichocephaly) (Fig. 1). Later in life this may become less obvious, up to point that the diagnosis cannot be entered based on the facial phenotype (own unpublished observations).

Bloom Syndrome. Figure 1 The clinical and the chromosomal phenotype in Bloom syndrome. The upper row shows three different patients with the characteristic facial phenotype. Below are part of a metaphase with a high rate of sister chromatids in Bloom syndrome (left) and a normal metaphase (right). (Figure from E. Passarge, *Color Atlas of Genetics*, 2nd ed., Thieme Medical Publishers, Stuttgart-New York, 2001).

Skin Manifestations

Most patients develop a sun-sensitive telangiectatic erythema during their second or third year of life. This may be the chief complaint in some patients. Eyelids, ears and the dorsal side of their hands may be involved, but no other parts of the body even when exposed to sun. A few patients do not manifest skin lesions or show just some reddening.

Immune Deficiency

Reduced levels of immunoglobulins are common albeit variable. Common infections, mainly of the bronchopulmonary system, the ears and the gastrointestinal system occur more often and are more prolonged than in unaffected children. In some cases they may be life threatening. Response to vaccinations is usually normal, but immunity to repeat infections is reduced.

Feeding difficulties

This is a common complaint. Vomiting, regurgitation and esophageal reflux are frequent signs. In addition, lack of appetite is a constant feature. A number of patients had to be fed by gastric tube.

Hyper- and Hypo-pigmented Areas of the Skin

This is a medically unimportant, but diagnostically typical sign. The areas of hyper- or hypo-pigmentation range from a few millimeters to decimeters in size are irregularly shaped and range from a few to a dozen or more areas. We interpret them as signs of somatic recombination involving pigmentary skin cells.

Predisposition to Cancer

This is the most impressive feature of Bloom syndrome. In the most recent assessment (5) no fewer than 90 malignant tumors arose in 70 patients. In 13, two or more primary tumors developed. The most common types of cancer are leukemias of different types, lymphomas (Burkitt and others) and carcinomas of the gastrointestinal tract, stomach, naso-oro-pharynx and esophagus, breast and other organs. The mean age at the diagnosis of a malignancy is 24.7 years (range 2–48 years). ► **Cancer** is the documented cause of death in 50 of 60 deceased persons in the Registry. In addition to leukemias, a myelodysplastic syndrome has been diagnosed in 14 registered persons between the ages of 4 and 39 (mean age 22.8). The precise reasons for the remarkably high prevalence of malignancies in Bloom syndrome have not been established. ► **Genomic instability** resulting from a deficient DNA helicase and the increased rate of somatic mutations are assumed to be important factors.

Hypersensitivity to DNA-Damaging Chemicals

Cells homozygous for a mutation in the *BLM* gene are highly sensitive to DNA-damaging agents. This needs

to be considered when initiating chemotherapy in a patient with cancer. The bone marrow is especially vulnerable. Single agent chemotherapy in a dose reduced to about 50% compared to the usual dose should be employed initially.

Male Infertility

Mild to moderate hypogonadism is present at puberty and thereafter. Puberty occurs at about the normal time. Adult males have been observed to be infertile. The testes are small and lack of spermatogenesis has been documented. Females may have reduced fertility. Four women with Bloom syndrome have borne a normal baby.

Diabetes Mellitus

In recent years an increased rate of diabetes mellitus has been observed in Bloom syndrome in about 17% of adult patients. Both insulin-dependent and non-insulin-dependent types have occurred. The basis for this observation is not known.

Diagnosis

Diagnosis is clinically based on the typical history and phenotype. Increased SCE in metaphases of cultured lymphocytes is diagnostic. Diagnostic mutational analysis is usually not necessary.

Management

Management is by diagnostic and genetic counseling. No regular diagnostic hematological evaluation in children, but parental awareness of the increased rate of leukemia and lymphoma is recommended. Adult patients benefit from regular examinations for adenocarcinoma of the gastrointestinal tract, breast and other organs.

► Chromosomal Instability Syndromes

Acknowledgement

I thank Dr. James L. German III. and Dr. Maureen Sanz, New York, for pleasant cooperation.

Boc Chemistry

Definition

Boc chemistry is a peptide synthesis strategy in which the tert-butylmethoxycarbonyl group (t-Boc group) is used as a temporary protecting group for the N-terminus. The t-Boc group is cleaved under acidic conditions. Trifluoroacetic acid is mainly used for this purpose.

Bone and Cartilage

CHRISTINE HARTMANN

Research Institute for Molecular Pathology, Vienna, Austria

hartmann@imp.univie.ac.at

Definition

Bone is a highly specialized form of connective tissue, with a mineralized ►extracellular matrix (ECM), which confers rigidity and stability on the skeletal elements of higher vertebrates while still maintaining some degree of elasticity. In addition to its supportive function, bone is also the major source for inorganic ions, being actively involved in calcium ►homeostasis, and furthermore, the ►bone marrow is the main hematopoietic organ during ►postnatal life. Cartilage is also a specialized form of resilient, flexible connective tissue, which consists of one major cell type, the chondrocyte. Three different types of cartilage can be distinguished, hyaline-, fibro- and elastic-cartilages, based on their ECM and fiber arrangements. Hyaline cartilage is found in the trachea, nose, the growth plate and epiphysis of the long bones during postnatal growth and in the embryonic skeleton. Fibro-cartilage is found in the ►intervertebral discs and

joints, while elastic cartilage is found in the external ear and the ►[epiglottis](#).

Bones of the vertebrate skeleton are formed by two processes, membranous and endochondral ossification. The flat bones in the skull are formed by membranous ossification, whereby ►[neural crest](#)-derived, mesenchymal cells aggregate and directly differentiate into ►[osteoblasts](#). Most of bones within the vertebrate skeleton are formed by endochondral ossification, starting with a cartilaginous template, which ultimately will be replaced by bone. This process begins during embryonic development with the condensation of mesenchymal cells. Cells in the center of these aggregates will become ►[prechondrogenic](#) and will subsequently differentiate into chondrocytes, while cells at the periphery will go on to form the so-called ►[perichondrium](#). In order for the final replacement by bone to occur, chondrocytes have to undergo a well-controlled maturation program proceeding from proliferating chondrocytes, through prehypertrophic, to finally ►[hypertrophied](#) chondrocytes, which will gradually be removed and replaced by bone. The replacement of the hypertrophied, ►[calcified](#) region by bone is coupled with the entry of blood vessels into this region. Subsequently, this sequential process of chondrocyte proliferation, ►[hypertrophy](#) and replacement by osteoblasts becomes organized in the growth plates at the metaphyseal regions near each end of the growing bone, which regulate longitudinal growth of the skeleton until their disappearance at the end of puberty in humans (Fig. 1). The perichondrium adjacent to hypertrophic chondrocytes differentiates into a structure known as ►[periosteum](#). The innermost periosteal cells adjacent to the region of hypertrophic chondrocytes differentiate into osteoblasts, which secrete a bone matrix (►[osteoid](#)) that becomes progressively calcified, forming a membranous bone collar around the ►[diaphysis](#) (shaft region) of the skeletal element (1).

Characteristics

Bone is a complex, living tissue consisting of four different cell types, the ►[bone lining cells](#), osteoblasts, ►[osteocytes](#), and ►[osteoclasts](#). The ECM of bone is rich in type I collagen (Col1a1, Col1a2) and the tissue is heavily vascularized. Bone cells are of different origins; bone lining cells, osteoblasts and osteocytes are mesenchymal in origin, while the osteoclasts are derived from the hematopoietic lineage. Osteoblasts secrete the osteoid, which in its immature form, called woven bone, is characterized by irregular bundles and randomly oriented collagen fibers and is only weakly mineralized. Woven bone ultimately gets remodeled into lamellar bone, with a highly organized fiber structure and extensive mineralization. The shaft of

Bone and Cartilage. Figure 1 (a) Schematic drawing of the distal part of a long bone, indicating the different regions such as articular cartilage (red), secondary ossification center, growth plate (blue) and trabeculation (primary and secondary spongiosa). (b) Hematoxylin/eosin stained section of a growth plate region from a mouse humerus at birth, displaying the different zones of chondrocytes (proliferating, prehypertrophic, and hypertrophic).

endochondral-derived skeletal elements is surrounded by a thick layer of cortical bone, giving the bone its stability. Cortical bone is formed by osteoblasts originating from the periosteum through ►[appositional growth](#), while the trabecular bone, also known as

spongy bone or cancellous bone, found within the bone shaft is formed by a remodeling of calcified, hypertrophied cartilage, involving osteoblasts and osteoclasts.

The different skeletal disorders can be classified into metabolic (can be hereditary or acquired) and congenital and hereditary diseases and they can affect either bone or cartilage (2). Common bone diseases associated with a reduction in bone density are ►osteoporosis and ►osteopenia, which are due to an imbalance in bone remodeling, whereby osteoblasts produce less bone than the amount resorbed by osteoclasts. Osteoporosis is an age-related bone disease, associated with high fracture risk, due to the decreased bone mass. Metabolic bone diseases resulting from vitamin D deficiency are rickets in infants and growing children and ►osteomalacia in adults, due to insufficient mineralization of the bone. Von Recklinghausen's disease and osteitis fibrosa cystica are metabolic bone disorders due to hyperparathyroidism resulting in a diffuse or focal resorptive loss and fibrous replacement of bone, due to an excess of osteoclastic over osteoblastic activity caused by an over-production of ►parathyroid hormone (PTH).

Patients with ►osteopetrosis (hereditary disorder) have too high a bone mass, caused by an impairment in the differentiation of osteoclasts and/or their function. The inherited congenital bone disease, ►osteogenesis imperfecta (brittle-bone disease), is due to mutations in extracellular matrix proteins such as the type I collagen genes, resulting in structural or secretion abnormalities, affecting osteoid production and remodeling of woven into lamellar bone.

Cartilage on the other hand is ►avascular tissue and consists of chondrocytes secreting an ECM, which is rich in proteoglycans, sulfated mucopolysaccharides and type II ►collagens (Col2a1). When chondrocytes hypertrophy, they become vacuolated, produce type X collagen (Col10a1) and their matrix eventually becomes calcified. Chondrocytes, like osteoblasts, are of mesenchymal origin. Achondroplasia is an inherited ►congenital ►autosomal dominant disorder of the skeleton, characterized by a unique form of dwarfism and bone deformity resulting in a disproportionate shortness of the extremities relative to the trunk. Certain point ►mutations in one of the fibroblast growth factor receptor genes (FGFR3), leading to a constitutive activation of the receptor, cause achondroplasia. Disorders affecting the cartilage are generally referred to as chondrodysplasias, affect various segments of the bones, such as the metaphysis and ►epiphysis and can be associated with growth factors, their receptors or transcription factors. Furthermore, mutations in genes encoding components of the ECM often lead to skeletal disorders (3).

Molecular Interactions

Endochondral skeletogenesis starts with the aggregation of mesenchymal cells. The formation of these early aggregates is dependent on changes in cell adhesion properties and is under the control of positive and negative signals leading to the formation of the prechondrogenic condensations. Cells within this region express the transcription factor Sox9, which is absolutely required for the differentiation of condensed mesenchymal cells into chondrocytes. ►Haploinsufficiency of Sox9 in humans is associated with the severe skeletal dysmorphology syndrome, campomelic dysplasia. Sox9 controls the expression of chondrocyte-specific marker genes, such as aggrecan and members of the collagen family (Col2a1, Col9a2, Col11a2), as well as of two other Sox-gene family members, L-Sox5 and Sox6, which are also required for chondrocyte differentiation. Proliferation of non-hypertrophic chondrocytes within the cartilage elements is under the control of a number of signaling molecules, including members of the fibroblast growth factor family (FGFs), ►bone morphogenetic proteins (BMPs), Indian hedgehog (Ihh) and the Wntless/int-gene family (WNT). In addition, two other locally produced peptides have been shown to control chondrocyte proliferation, C-type natriuretic peptide (CNP) and parathyroid-hormone-related peptide (PTHrP). FGFs are negative regulators of chondrocyte proliferation, with probably Fgf18 as the preferred ligand of FGFR3 signaling through the ►transcription factor STAT1 leading to an up-regulation of the cell-cycle inhibitor p21. Ihh acts as a positive regulator of chondrocyte proliferation regulating CyclinD1 expression. BMPs have been shown to stimulate chondrocyte proliferation, while other members of the TGF- β superfamily such as TGF- β 1 can have a negative effect on proliferation; it is so far unclear how these distinct effects on proliferation are achieved. It is also unclear how CNP affects cell proliferation on the molecular level.

Regulation of chondrocyte proliferation is coupled to a control of differentiation rate. Experiments with ►transgenic animals have revealed that some WNTs (Wnt5a and Wnt5b) differentially control the expression of cell-cycle regulators such as the negative regulator p130/Rb2 and the positive regulator CyclinD1, thereby controlling the progression of cells from the proliferative to the non-proliferative state (4). Similarly PTHrP signaling also controls the progression of proliferating to non-proliferating chondrocytes. Signaling through its receptor PPR, a serpentine receptor interacting with heterotrimeric G-proteins, it positively affects proliferation of chondrocytes through adenylate cyclase-cAMP-mediated activation of protein ►kinase A (PKA), leading to a transcriptional up-regulation of positive regulators of the cell-cycle such

as CyclinA and CyclinD1, mediated through transcription factors of the CREB/ATF and AP-1 family. In contrast, activation of the phospholipase C (PLC) branch of PPR intracellular signaling is probably involved in dampening the cAMP/PKA effect on proliferation and promoting chondrocyte differentiation (5).

A number of transcription factors have been shown to be essential within the osteoblast lineage, such as Cbfa1/Runx2 which acts upstream of the ►zinc-finger transcription factor Osterix in osteoblast differentiation. Patients ►heterozygous for mutations in Cbfa1/Runx have cleidocranial dysplasia (CCD) syndrome, in which only bones formed through intramembranous ossification are affected. Cbfa1/Runx2 has also been shown to be required for osteoblast function. Loss-of-function studies in mice have further revealed that the homeobox-containing proteins Dlx5, Msx1, Msx2 and Bapx1/Nkx3.2 are involved in osteoblast differentiation. In addition, a signaling pathway has been identified which seems to only affect osteoblast proliferation, but not differentiation and might act independently of Cbfa1/Runx2. This signaling pathway requires the LDL-receptor-related-protein 5 (LRP5), which is ubiquitously expressed. Inactivating mutations in the human gene lead to the osteoporosis-pseudoglioma syndrome, while activating mutations result in a high-bone mass syndrome. Since LRP5 can also act as a co-receptor for Wnt proteins, these

findings suggest that Wnt-signaling is controlling peri- and post-natal osteoblast proliferation.

Osteoclasts differentiate from hematopoietic stem cells and share a common precursor with macrophages (monocyte-macrophage lineage). During development mononucleated precursors enter the mesenchyme surrounding the skeletal elements, divide and differentiate into tartrate-resistant acid phosphatase (TRAP-) positive cells that migrate together with endothelial cells through the nascent bone collar, invading the calcified cartilage where they fuse into multinucleated, fully functional osteoclasts. They require the transcription factor PU.1 for differentiation early within the macrophage lineage specification and c-Fos a member of the AP-1 transcription factor family for the specification of osteoclast precursors *versus* macrophages (Fig. 2).

Regulatory Mechanisms

In order to coordinate skeletal growth during development (embryonic and postnatal), a variety of factors are employed, which have been shown to regulate proliferation and differentiation. These include locally produced cytokines and growth factors during embryonic development and circulating hormones regulating post-natal growth. In addition, other factors such as nutritional intake and mechanical influences regulate growth and ►morphogenesis of the skeleton. Coordination between

Bone and Cartilage. Figure 2 Summary of the molecular mechanisms and regulation of osteoblastogenesis and osteoclastogenesis from stem cells to functional osteoblasts and osteoclasts. The particular molecules presumably acting at the different stages during precursor proliferation and differentiation are depicted: transcription factors involved in these steps are colored blue. Abbreviations (for factors not mentioned in the text): AP, alkaline phosphatase; CTR, calcitonin receptor; CA-II, carbonic anhydrase II; CIC-7, chloride channel-7; Mi, microphthalmia transcription factor; TRAF6, TNF receptor associated factor 6.

maturation of chondrocytes, ►osteoblastogenesis, and blood vessel invasion is particularly important during embryonic development for proper skeletogenesis. One of the central molecules coordinating these processes is *Ihh*. *Ihh* is expressed in a subpopulation of chondrocytes, the prehypertrophic chondrocytes. As mentioned above, it controls chondrocyte proliferation, but also their maturation, by regulating the progression from the proliferative to the non-proliferative, hypertrophic state. The latter is achieved *via* *Ihh*-dependent regulation of PTHrP expression levels in the articular region. *Ihh* signaling is further required for the induction of osteoblast progenitor differentiation from mesenchymal cells within the adjacent perichondrium/periosteum. The transcription factor *Cbfa1/Runx2*, which is absolutely required for osteoblastogenesis, is under the control of *Ihh* signaling in the periosteum. *Cbfa1/Runx2*, however, is also playing a role in chondrocyte maturation. In *Cbfa1/Runx2* mutant mice, hypertrophic chondrocytes are absent from several, but not all, skeletal elements and constitutive expression of *Cbfa1/Runx2* in non-hypertrophic chondrocytes induces their differentiation into hypertrophic chondrocytes; in addition, *Cbfa1* induces the expression of *Ihh*. Thus regulatory loops exist between *Cbfa1* and *Ihh* in chondrocytes and *Ihh*-signaling and *Cbfa1* in osteoblast precursors. *Cbfa1/Runx2* is further necessary for vascular invasion of the hypertrophic region, a function, which is independent of its role in regulating differentiation of hypertrophic chondrocytes. Attraction of blood vessels into the hypertrophic region is achieved *via* a *Cbfa1/Runx2* mediated up-regulation of the expression of vascular-endothelial growth factor (VEGF) within the hypertrophic chondrocytes. Thus, the *Ihh*/PTHrP regulatory loop controls the rate of chondrocyte progression at the level of proliferative to non-proliferative prehypertrophic chondrocytes, while *Cbfa1/Runx2* controls the level of *Ihh* expression and the progression from prehypertrophic to hypertrophic chondrocytes. In addition, *Cbfa1/Runx2* controls the process of blood vessel invasion *via* regulation of VEGF. *Ihh*-signaling, on the other hand, controls directly or indirectly the expression of *Cbfa1/Runx2* in osteoblast progenitors thereby coordinating the onset of bone formation with the status of chondrocyte maturation. However, additional modulators on post-transcriptional and post-translational levels are required, since *Ihh* as well as *Cbfa1/Runx2* expression precedes the appearance of functional osteoblasts. One of these modulators is probably Osterix, which is required downstream of *Cbfa1/Runx2* in osteoblastogenesis (1).

Regulatory mechanisms also exist between osteoblasts and osteoclasts ensuring bone homeostasis in healthy individuals. Osteoblasts secrete factors controlling the

differentiation of osteoclasts, such as macrophage colony-stimulating factor (M-CSF), required for the induction of osteoclast differentiation from the monocyte-macrophage lineage. Together with M-CSF, a second factor expressed by osteoblasts and stromal cells, the membrane-associated protein, receptor activator of nuclear factor κ B ligand (RANKL), a member of the tumor necrosis factor (TNF)-ligand family, is required for osteoclast differentiation. Osteoclasts express the counterpart RANK, a TNF receptor family member. Signaling through RANK leads to activation of nuclear factor κ B (NF- κ B) and c-Jun N-terminal protein kinase (JNK). In mature osteoclasts RANKL/RANK interaction is required for bone resorbing activity. The fine-tuning of the system is achieved by the fact that osteoblasts/stromal cells also express a soluble decoy receptor of RANKL, osteoprotegerin (OPG), which functions as an inhibitory factor of ►osteoclastogenesis. In summary osteoblasts/stromal cells produce stimulators and inhibitors of osteoclastogenesis (Fig. 2).

Bone Disease and Skeletal Disorders, Genetics

STEFAN MUNDLOS

Institute for Medical Genetics, Charité-University Medicine Berlin, Berlin, Germany
stefan.mundlos@charite.de

Definition

The skeleton is an extremely complex organ that fulfills multiple functions in the vertebrate body. It consists of

more than 230 individual elements, many of them connected by joints allowing movement through muscle contraction. Furthermore, the skeleton harbors the bone marrow, the primary source for hematopoietic progenitor cells and is the body's largest resource for calcium. Cells within the skeleton create the entire longitudinal growth generated during an individual's life. Even in adult life, the skeleton is an active organ that is constantly being remodeled. Giving the complexity of the system it is not surprising that a large number of genes are involved in the molecular control of growth and maintenance of the skeleton. Accordingly, genetic disorders of the skeleton are frequent and comprise a large group of genetically heterogeneous and clinically distinct conditions. The skeleton can be affected as part of a complex malformation syndrome or the genetic defect may affect solely the skeleton. In the latter case, the condition will be called a primary skeletal disease. Traditionally, these conditions have been subdivided into ►**dysostoses**, defined as malformations of individual bones or groups of bones or ►**osteochondrodysplasias** defined as disorders of chondro-osseous tissue. More recently, disorders of bone maintenance have been added that affect bone turn over and consequently result in too much or too little bone.

Characteristics

The clinical manifestations of skeletal disorders range from neonatal lethality to only mild growth retardation or even normal growth in late onset conditions. Their clinical diversity makes them often difficult to diagnose. Many attempts have thus been made to facilitate diagnosis by delineating single entities or groups of diseases. On the basis of clinical, radiological and molecular features, a group of experts created a taxonomy that has been called "Nosology" (1). Recent advances that were made in understanding the molecular pathology of these disorders were incorporated into this classification. However, the merging of clinical and molecular data to create a comprehensive picture of this disease group proved to be difficult. While the molecular data help to understand pathogenetic mechanisms and, in addition, have been extremely instrumental in grouping diseases into larger "families", they have been less helpful in the respective clinical aspects. Some conditions that have a common molecular origin have little in common clinically. Mutations in *FGFR3*, for example, can result in such diverse conditions as lethal ►**thanatophoric dysplasia**, ►**achondroplasia**, a condition characterized by moderate to severe growth retardation or ►**hypochondroplasia**, which is frequently only associated with borderline small stature. Thus, clinical and genetic data are often difficult to merge.

Based on clinical, embryological and molecular findings we have proposed classifying skeletal disorders into a) conditions that have defects in bone patterning, b) conditions with defects in early formation of cartilage/bone, c) conditions with abnormal growth and d) conditions with abnormal bone homeostasis (2).

Abnormal Patterning

Patterning genes control the overall body plan (ground plan) of the skeleton, i.e. the number, size and gestalt of individual skeletal elements. In spite of our increasing knowledge about developmental mechanisms *per se*, how skeletal pattern is established is still largely a mystery. Much of what we know comes from gene inactivation studies in the mouse or the study of rare human genetic conditions. Human skeletal malformations can generally be considered to be deficiencies of embryonic patterning that can be subdivided into defects involving the craniofacial, the axial or the limb skeletons.

Most of the craniofacial bones are of neural crest origin. Accordingly, many of the craniofacial dysostoses include abnormalities in migration and/or differentiation of cranial neural crest cells. Waardenburg syndrome, for example, is characterized by deafness and pigmentation anomalies in variable combination with skeletal anomalies and is caused by mutations in the *PAX3* gene coding for a transcription factor involved in cell migration of muscle and neural crest progenitors. A multitude of other gene defects are associated with craniofacial malformation. Principles and details of craniofacial development have been discussed in detail elsewhere (for review, see (3)).

The axial skeleton, consisting of vertebrae and ribs, originates from the ►**somites**, transient organizational structures located at both sides of the embryonic body (4). Upon patterning signals from the ►**notochord**, cells from the somite differentiate and migrate to form the ►**sclerotome**. Four adjacent sclerotome compartments eventually fuse to form a single vertebra and the corresponding ribs. Defects of the axial skeleton occur frequently in association with other malformations, but those that primarily affect the axial skeleton are rare and are summarized under the term spondylocostal dysostoses. Such conditions can be caused by mutations in *DLL3*, which is part of the notch-delta pathway, involved in somite boundary formation.

The appendicular skeleton has its origin in mesenchymal cells located in the lateral plate mesoderm. Localization of limb bud outgrowth is determined by the axial Hox gene code. Outgrowth of the limb bud depends on expression of members of the fibroblast growth factor (FGF) family in the apical ectodermal ridge (►**AER**), an anatomical structure located at the

very tip of the bud. Once the bud is formed, the differentiation of each cell is controlled by a three-dimensional coordinate system consisting of signals that define the dorsoventral, proximodistal and anteroposterior axes. Subsequently, the various tissues of the limb are laid down in a proximodistal sequence, i.e. first the humerus, then the radius and ulna and finally the digits (5). Defects in the AER result in truncations or the ►split-hand-foot phenotype, as caused by mutations in the transcription factor p63 or by deletion on chromosome 7q encompassing the DLX5/DLX6 genes. Defects of the anteroposterior axis frequently involve the ►hedgehog pathway and result in polydactyly, as seen in Greig syndrome (mutations in GLI3), Townes Brooks syndrome (SALL1) or triphalangeal thumb-polysyndactyly syndrome (regulatory mutations of SHH). Defects in ►HOX genes result in digit hypoplasia (hand-foot-genital syndrome, mutations in HOXA13) or in central synpolydactyly (Fig. 1) (mutations in HOXD13). Other phenotypes involve deficiencies of the radial or the ulnar ray. Hypoplasia of the thumb and/or the radius can be observed in Holt-Oram syndrome, which is caused by mutations in TBX5. Ulnar ray deficiencies, on the other hand, are part of the ulna-mammary syndrome phenotype caused by mutations in TBX3. Tbx genes play important roles in the specification of the upper vs. the lower limb and in the initial limb outgrowth.

Abnormal Formation of Bone/Cartilage

After cells have received their positional information through patterning genes, they migrate and condense to form the skeletal ►anlage. Within the condensation, they differentiate into either ►chondrocytes that form cartilage or ►osteoblasts that form bone. Cartilage formation is controlled by the transcription factor Sox9 and two other members of the family, Sox5 and Sox6. Without Sox9 no cartilage forms. Mutations in SOX9, on the other hand, cause campomelic dysplasia, a commonly lethal condition characterized by severe osteochondrodysplasia, bowed femura and hypoplastic scapulae. The ►transforming growth factor β family (TGF β) consisting of bone morphogenetic proteins (►BMPs) and their receptors plays essential roles in the formation of the early condensations. Mutations in GDF5, a member of the BMP family and in its receptor, BMPRII, cause ►brachydactyly (shortening of the digits, absence of individual phalanges) type C and type A2, respectively. Although bone and cartilage may originate from a common progenitor cell, their further differentiation is regulated separately. The protein Runx2 (Runt-related transcription factor 2; also called Cbfa1) has been shown to be essential for osteoblast differentiation. Without Runx2, no bone is formed. Mutations in RUNX2 result in ►cleidocranial dysplasia, a condition characterized by absent/hypoplastic

Bone Disease and Skeletal Disorders, Genetics.
Figure 1 Hand of individual with synpolydactyly caused by a mutation in HOXD13.

clavicles, ossification defects in the skull and abnormalities of tooth formation.

Abnormal Growth

Growth of the long bones is generated *via* a mechanism called ►endochondral bone formation. In contrast to the growth of the flat bones of the skull that grow by appositional growth (►desmal ossification), endochondral bone formation works *via* the transformation of a transient cartilaginous template into bone. Central to this process is the formation of a ►growth plate, a highly organized structure within the cartilaginous part of the growing bone that constantly produces new cartilage through cell proliferation, cell differentiation and matrix production. The newly produced cartilage calcifies and is then removed by ►osteoclasts and replaced by bone. A schematic of the growth plate architecture is given in Fig. 2.

The integrity of the extracellular matrix is essential to growth plate function. Accordingly, many defects in cartilaginous matrix constituents result in abnormal growth plate function and, consequently, in short stature. Collagen type II, probably the most important component of cartilaginous matrix, is mutated in spondyloepiphyseal dysplasia (SED) congenita, a condition characterized by severe dwarfism, flat

Bone Disease and Skeletal Disorders, Genetics. Figure 2 Schematic of growth plate architecture. The growth plate is a highly organized structure that continuously produces new cartilage through the proliferation, matrix production and differentiation of chondrocytes. During this process, chondrocytes differentiate from small resting cells with little proliferation to proliferating cells and finally become hypertrophic. Hypertrophic chondrocytes produce a specific extracellular matrix that subsequently is removed by osteoclasts and replaced by bone. The different zones of chondrocyte differentiation are shown on the right, the cell types on the left hand side.

vertebrae, precocious arthropathy and eye involvement (myopia). A more severe form of mutation in COL2A1 results in ▶**achondrogenesis** type II, a neonatally lethal chondrodysplasia with highly abnormal cartilage, severely delayed ossification and very short limbs (Fig. 3). Mutations in other collagens that connect type II collagen with the surrounding matrix, such as collagen types IX and XI give rise to milder phenotypes such as multiple epiphyseal dysplasia (MED) and ▶**Stickler syndrome**, respectively. Another form of MED and pseudoachondroplasia, a condition characterized by a short limb dwarfism with body proportions resembling those of achondroplasia but with a normal facies, are caused by mutations in cartilage oligomeric matrix protein (COMP). COMP interacts with collagens type I, II, III, and IX and connects them with the cartilaginous proteoglycans. Proteoglycans are highly sulfated, a process that involves several enzymatic steps as well as active transport of sulfur into the cell through the sulfate transporter DTDST. Mutations in

DTDST result in a spectrum of diseases including lethal achondrogenesis type 2, ▶**atelosteogenesis** type 2, ▶**diastrophic dysplasia** and a milder, recessive form of MED. Diastrophic dysplasia, the condition in which the transporter was first identified, is a severe dwarfing condition characterized by multiple joint contractures (club feet frequently), proximally set, hypermobile thumbs, cystic masses at the external ears, cleft palate and scoliosis.

The major matrix component of bone is collagen type I, encoded by two genes, COL1A1 and COL1A2. Mutations in this collagen result in a spectrum of conditions collectively termed ▶**osteogenesis imperfecta** (OI) or brittle bones disease. The hallmark of these conditions is an extreme bone fragility and ▶**osteoporosis**. Based on clinical and radiological findings, four major subtypes have been delineated. Type 2 OI is the most severe and lethal form. Multiple fractures already occur *in utero* and the bones are very thin (ribs), or extremely short and crushed (Fig. 4). OI

Bone Disease and Skeletal Disorders, Genetics.

Figure 3 X-ray of a fetus with achondrogenesis type II and a mutation in COL2A1. Note complete lack of ossification of vertebrae and very small long bones with cup shaped ends.

Bone Disease and Skeletal Disorders, Genetics.

Figure 4 X-ray of a fetus with osteogenesis imperfecta type II and a mutation in COL1A1. Note very thin ribs with multiple fractures, very short limbs with bowing and signs of multiple fractures and inefficient healing.

type 3 patients survive but frequently become wheelchair bound due to recurrent fractures and bone deformities. Type 4 OI shows moderate deformity, short stature and dentinogenesis imperfecta. OI type 1 is the mildest form characterized by blue sclerae, normal teeth, near normal stature and recurrent fractures that heal without deformities. OI types 2–4 are caused by point mutations in either of the collagen type I genes, usually affecting one of the repetitive glycines within the triple helical domain of the molecule. This disrupts the correct folding of the helix resulting in the degradation of normal chains as well, hence the severe phenotype. There is no clear phenotype/genotype correlation. OI type 1 is caused by nonsense mutations resulting in loss of one COL1 allele.

Growth of the cartilaginous template depends on proliferation and differentiation of chondrocytes. During their differentiation fate chondrocytes change from small round cells in the resting zone to flat stacked cells

in the columnar zone, and finally become hypertrophic before they are removed by osteoclasts. This differentiation process is highly regulated and depends on the interaction of multiple signaling pathways. One major pathway involves the hedgehog/parathyroid hormone (PTH)-related peptide (PTHrP) pathway. Indian hedgehog (Ihh), which is expressed by pre-[hypertrophic chondrocytes](#), controls cell proliferation and the differentiation into hypertrophic cells. Ihh regulates the expression of PTHrP *via* its receptor patched and the transcription factor Gli. Mutations in IHH result in a generalized skeletal dysplasia, acrocapitofemoral dysplasia and brachydactyly type A1, which can also be associated with short stature. Homozygous loss of function mutations of PPR, the receptor for PTHrP/PTH, result in Blomstrand chondrodysplasia, a severe, often lethal dysplasia with severely shortened tubular bones and an accelerated bone maturation. In contrast, dominant activating mutations of this receptor result in Jansen type

Bone Disease and Skeletal Disorders, Genetics. Figure 5 X-ray of a fetus with thanatophoric dysplasia type I and a mutation in the FGFR3 gene. Note narrow thorax, flattening of the vertebral bodies, also shown in the lateral view in (B), abnormal pelvic bones, short and bowed long bones (arrow shows bowing of femur).

metaphyseal dysplasia. Patients suffer from severe growth retardation, generalized demineralization, rachitiform changes and enlargement of the metaphyses. Another important pathway in the growth plate involves FGF signaling molecules and their receptors, the FGFRs. FGFs control multiple functions but most importantly appear to influence proliferation and differentiation. Mutations in the FGFR3 gene cause achondroplasia, a common form of dwarfism with disproportionately short limbs, a large head and a characteristic facies. The mutations lead to an activation of the receptor resulting in ligand independent signaling. Other mutations in FGFR3 that result in more or less activation result in more severe, lethal phenotypes (thanatophoric dysplasia) (Fig. 5), or milder phenotypes (hypochondrogenesis).

Defects in Homeostasis

Bone, although it appears rather static, is in fact a very active tissue. Our bones are constantly remodeled to adjust to the continually changing mechanical and

metabolic needs. It is important that the overall bone mass and bone structure is preserved in this process in order not to lose bone or to gain too much bone. This steady state is achieved through a concerted action of bone producing osteoblasts and bone removing osteoclasts. Any imbalance of this intricate system will result in bone loss and thus osteoporosis or too much bone as in ▶osteopetrosis. The RANKL/OPG system has recently been shown to be a major regulator of the osteoblast-osteoclast crosstalk. Recessive juvenile Paget disease is caused by mutations in the OPG encoding gene TNFSRF11B. This hereditary form resembles adult Paget disease showing hyperactive osteoclasts and excessive bone formation. Mutations in the RANK signaling peptide, which lead to intracellular accumulation and self-stimulation of the receptor, result in familial expansile osteolysis.

Inactivation of osteoclast function, on the other hand, leads to excessive bone formation and, in severe cases, to a solid bone without bone marrow. Mutations in the gene for cathepsin k, an acidic protease secreted by the

osteoclast, result in the sclerosing bone disorder pycnodysostosis. Strong acidification of the osteoblast absorption lacunae is needed to degrade the matrix components of bone with proteases such as cathepsin and to dissolve the hydroxyapatite of bone. Acidification is accomplished *via* proton pumps. Mutations in *TCIRG1*, which encodes a subunit of the osteoclast's proton pump, result in recessive, malignant osteopetrosis. A very similar phenotype is caused by mutations in a chloride channel, *CLCN7*, which transports chloride ions in parallel to the protons pumped into the resorption lacunae. Dominant missense mutation in the same gene may cause dominant osteopetrosis type 2, a late onset high bone density phenotype.

Cellular and Molecular Regulation

As outlined above, skeletal patterning and growth is determined by an extremely complex set of signaling pathways involving a multitude of genes. One emerging picture is that mutations within the same gene frequently result in clinically distinct conditions. However, a close look at the phenotype reveals overlapping, common features that are unique to these mutations. Such common features have previously been identified on purely clinical grounds and have been called “disease families”. The more recent molecular data support this concept and link the common phenotype to a specific molecular pathway. Such “disease families” frequently cover a whole spectrum of conditions. For example, thanatophoric dysplasia, achondroplasia and hypochondroplasia have, in spite of their completely different clinical outcome (see above), a common radiological pattern. This common feature results from activating mutations in *FGFR3*, which lead to an arrest of chondrocyte proliferation and differentiation. The difference in severity correlates with the degree of *FGFR3* activation, i.e. thanatophoric dysplasia has the strongest activation and hypochondroplasia the weakest. A similar spectrum of conditions results from mutations in the sulfate transporter *DTDST*. Complete inactivation results in the most severe, lethal phenotype (achondrogenesis type 2), whereas diastrophic dysplasia (severe dwarfism) and recessive MED correspond to partial function. Similar disease spectrums can be observed in the collagen type 1 (OI) and the collagen type 2 (SED congenita) related conditions.

In certain cases overlapping or even identical phenotypes can be observed even if the mutation occurs in a different gene. Such a phenotypic copy may be produced by pure chance, for example because the number of phenotypes that can be produced is limited or because the mutations affect genes that are closely linked in a common molecular pathway. Examples are the polydactyly phenotypes caused by perturbations of the hedgehog pathway.

Clinical Relevance

Although individually rare, disorders of the skeleton are of high clinical relevance because of their overall frequency. The clinical severity differs from minor handicaps to death in the neonatal period. In surviving patients, secondary complications of skeletal deformity and manifestations in extraskeletal organs add to the burden of disease. Genetic factors are important determinators of more common diseases such as osteoporosis and osteoarthritis. Osteoporotic fractures, for example, are a major healthcare problem in Europe. Understanding the molecular and genetic regulators of bone development and maintenance will help to understand these conditions better and to finally establish effective therapies.

Bragg's Law

Definition

Bragg's law depicts the mathematical relationship ($n\lambda = 2d \sin \theta$) that relates the spacing d of a diffraction grating, the wavelength λ of diffracted light, the order n of the reflected wave, and the diffraction angle θ . In a three dimensional crystal, the grating spacing for first order ($n = 1$) reflections corresponds to the spacing between Miller planes.

Definition

The brain develops from the rostral end of the ► [neural tube](#) and is thus continuous with the spinal cord, which evolves from its caudal portion. Although no sharp border exists between these two parts of the central nervous system (CNS), in vertebrates the brain may be defined as the part of the CNS enclosed in the cartilaginous or bony cranium. Here, the general organization of the spinal cord (gray matter ► [neurons](#) located in the center surrounded by ascending and descending fibers of white matter) is no longer maintained. Gray matter develops at the surface as well as in the deep regions of the brain and fiber tracts develop to interconnect different brain areas and transfer information to and from the periphery. The morphogenesis of the brain is initiated by the development of embryonic vesicles (Fig. 1, Table 1), which further differentiate into the rhombencephalon (hindbrain), mesencephalon (midbrain) and prosencephalon (forebrain). The last consists of the central diencephalon containing the hypothalamus, thalamus and pineal gland (epithalamus) and the telencephalon, i.e. the cerebral hemispheres covered by the cerebral cortex. As evolution continues, the cerebral cortex massively expands through the multidirectional growth of the telencephalic lobes (frontal, parietal, occipital and temporal, Fig. 2a, b, c) and gyrencephalisation, i.e. the development of sulci and gyri in monkeys and man.

Brain. Figure 1 Schematic drawing of the embryonic vesicles.

Brain. Table 1 Overview of the derivatives of the embryonic vesicles (compare Fig.1/2)

Embryonic vesicle	Derivative	Prominent structures	Derivatives of the neural tube's central canal
Paired prosencephalic vesicles (forebrain vesicles)	Telencephalon	Hemispheres/Cortex: Frontal, parietal, occipital, temporal lobe, hippocampus, amigdala subcortical nuclei (basal ganglia): Nucl. caudatus, Putamen, Pallidum	I.+II. Ventricle
	Diencephalon	Hypothalamus, Thalamus, Epiphysis (pineal gland)	III. Ventricle
Unpaired mesencephalic vesicle (midbrain vesicle)	Mesencephalon	Colliculi, substantia nigra, Central gray	Aqueduct
Unpaired rhombencephalic vesicle (hindbrain vesicle)	Metencephalon	Pons, Cerebellum	IV. Ventricle
	Myelencephalon	Medulla oblongata	Central canal of the cord

The direction in which the lobes grow is reflected in the form of the ventricles, which are the continuous derivatives of the neural tube's central canal (Fig. 2b). As a result of the massive expansion of the telencephalic lobes in man, the midbrain and upper hindbrain (i.e. the cerebellum) are completely covered by the hemispheres (Fig. 2c).

Functionally, the brain integrates sensory input from the spinal cord and afferent portions of the cranial nerves, controls motor activity and analyses visual, acoustic, gustatory and olfactory information. The integration of all the afferent information provides a picture of the world outside and the position of the body therein. Changes in the environment or sudden contact with

objects may be responded to by reflexive loops which do not require – or which occur in the absence of – consciousness. In addition, regulation of homeostasis (e.g. breathing, food intake and digestion, blood pressure), circadian rhythms and the ovarian cycle occur subconsciously *via* the autonomic nervous system and hormonal pathways controlled within the CNS. Upon conscious reflection on the situation in the world, purposeful acts can be planned and performed in the absence of actual environmental stimuli. Consciousness appears to require the thalamus of the diencephalon and the cortex of the telencephalon, yet such issues are difficult to address experimentally. The question as to whether an individual's responses to cognitive and

Brain. Figure 2 (a) Development of the telencephalon. The frontal lobe is distinguished from the temporal lobe by the lateral fissure, the parietal from the occipital lobe by the parieto-occipital sulcus and the occipital from the temporal lobe by the calcarine sulcus. The insula, a region involved in the processing of acoustic information, is completely covered by the temporal lobe due to its rostral expansion. The central sulcus distinguishes motor areas (precentral region) from sensory areas (postcentral region). (b) The growth of the lobes during the brain's morphogenesis is reflected in the form of the lateral ventricle, which follows their expansion. Its ventral horn is located within the frontal lobe, the corpus in the parietal lobe, the dorsal horn in the occipital lobe and the inferior horn in the temporal lobe. A subcortical nucleus, the caudate nucleus, is similarly formed by the U-turn of the hemisphere's expansion. (c) The final form of the brain; the lobes (upper panel) and parts of the brain are labeled with regard to their origin from the vesicles (lower panel). (From: Zilles&Rekämper, Funktionelle Neuroanatomie, Springer 1998)

social tasks occur autonomously or are controlled by a responsible “self” remains open.

Characteristics

Topography

Meninges

The brain is enclosed by the cranium and enveloped by the meninges. Their outer layer, the dura mater (pachymeninx), consists of compact collagenous tissue covering the inner skull. From there, massive membranes, the falx cerebri and tentorium cerebri, separate the inner space of the skull into three compartments, one for each hemisphere and one for the cerebellum (Fig. 3). The leptomeninx consists of two layers of soft connective tissue, the arachnoid, which is attached to the dura and follows the bony surface of the inner skull and the pia mater, which is attached to the surface of the brain. The subarachnoid space between the two is filled with cerebrospinal fluid (CSF). This fluid is produced by the choroid plexus of the ventricles, which are connected to the subarachnoid space *via* three holes, the unpaired apertura mediana (Magendi, Fig. 4) and the paired aperturæ laterales (Luschke), all located at the caudal end of the cerebellum. One can thus picture the brain filled

with and “swimming” in the CSF, an important feature protecting this vital organ from damage induced by head trauma.

Vessels

The subarachnoid space also harbors the larger veins and arteries. Disruption of the latter thus leads to subarachnoid bleeding. Blood reaches the brain *via* four arteries, two internal carotid arteries and two vertebral arteries forming the basilar artery. These two systems are interconnected *via* small vessels building the arterial circle of Willis. Because of this interconnection, slow occlusion of one vessel, e.g. due to arteriosclerosis, can be compensated by the others. Blood drainage occurs *via* cervical and spinal veins and the venous sinus located within the dura mater (marked blue in Fig. 3). Disruption of the veins connecting the brain and these sinuses leads to subdural bleeding. A common reason for this kind of lesion is the shaking of infants (by their parents). Arterial pulsation leads to changes in the pressure within the CSF, which drives blood flow within the veins. Intravenous pressure depends mainly on hydrostatic pressure and, therefore, on the position of the head. In a reclining position this pressure is about 0 mmHg; in a standing

Brain. Figure 3 The dura separates three compartments, two for the hemispheres separated by the falx and one for the cerebellum separated by the tentorium. This keeps the brain in position, thereby avoiding damage during rapid movements. On the other hand, swelling of the brain can lead to injuries due to squeezing under the falx or tentorium. The brainstem passes through the small hole indicated by the arrow, where it is often damaged during edema or bleeding. The sinuses of the dura are labeled in blue.

position it is negative. Since cervical, facial and intracranial veins have no valves, blood can flow in both inside-out and outside-in directions. Thus, infectious agents can be transmitted from the face to the inside of the skull, where they may produce severe neurological problems. Increased intracranial pressure as occurs, for example, as a result of tumors, hinders venous drainage, thereby causing severe secondary damage. Moreover, parts of the brain may be squeezed under the falx and tentorium (Fig. 3) under these conditions. This points to a general problem in neurology/neuropathology; due to the limited space within the skull, even minor expansion of the tissue and thus swellings or tumors that are benign *per se*, easily produce life-threatening conditions.

Blood-Brain Barrier

The blood compartment and central nervous parenchyma are separated by a tissue barrier provided by the endothelial cells of CNS vessels. These cells are interconnected by ►tight junctions and – in contrast to those in most other regions of the body – are not fenestrated. Thus, diffusion of hydrophilic substances from blood to brain is inhibited in order to maintain homeostasis within the brain, a crucial prerequisite for proper neural transmission. Therefore, peripherally administered drugs (e.g. antibiotics) often do not reach the central nervous system, an important problem in neuropharmacology. In addition to this mechanical barrier, there is also a functional barrier for leukocytes, limiting their access to the CNS and their operations once inside the tissue. The highly differentiated networks apparently require special protection to keep inflammation-induced cell loss to a minimum, since post-mitotic neurons can hardly be replaced. As a result, many antigens, e.g. deriving from viruses, which are

readily eliminated elsewhere in the body, are tolerated within the CNS. From an evolutionary point of view, the persistence, for example, of the varicella-zoster virus illustrates that such tolerance is less detrimental for the individual than the elimination of all infected neurons.

Embryology/Morphogenesis

The brain differentiates from four embryonic vesicles. An overview of the general morphogenesis is provided in Figs. 1, 2. Table 1 gives an overview of the respective derived structures of the adult brain.

The Adult Brain of Man

An overview of the most important structures is provided in Figs. 2c, 4, 5.

A simplified overview of structures and their function is provided in Table 2.

Functional Histology of the Brain

Central nervous tissue consists of neurons, ►glia, ependyma and a complex intercellular matrix.

Neurons

The morphology (shape and size) of neurons is extremely heterogeneous. Generally, they consist of a soma containing the ►nucleus, ►dendrites and an ►axon. Axons and dendrites are also referred to as neurites. Neurons are connected to each other at the ►synapse. The terminal of the axon forms the presynaptic part, while the postsynaptic part may be located at dendrites, the soma or the axon of the target neuron. Some neurons exhibit a pyramidal shape about 70 µm in size, others are round and no larger than 10 µm. In some regions, most

Brain. Figure 4 Overview of the adult brain from the lateral (upper panel) and medial (lower panel) perspectives. Some important areas, sulci and gyri are labeled. (From: Zilles&Rekämper, Funktionelle Neuroanatomie, Springer 1998)

prominently within the cortex of the telencephalon and cerebellum, neurons are located in separate layers of cells that are organized parallel to the cortical surface. In other regions, e.g. the brainstem of the mesencephalon and metencephalon, neurons are located in groups or columns forming specialized nuclei rather than layers. Lesion experiments and circumscribed pathologies have helped clarify the connectivity and function of many such nuclei and cortical areas.

The axons (synonym: fibers) of neurons may terminate at other neurons (their axon, dendrite or soma) or leave the CNS to innervate (smooth) muscle cells outside the skull. Axon endings often divide into collaterals and may therefore build synapses with many other structures. Target neurons may be located within the same region from which the axon derives or be located far away. Intrinsic fibers remain within one region (e.g. one particular gyrus), associational fibers connect areas

of the same hemisphere and commissural fibers terminate in the contralateral hemisphere. A prominent structure of commissural fibers is the corpus callosum (Fig. 2 a, c; Fig. 4). Particularly long fibers reach from the cortex down to the spinal cord, where they control motor functions. Bundles of many axons projecting from one region to another form circumscribed fiber tracts. In cross-sections of the brain, accumulations of neurons are the gray matter, while areas containing fiber tracts are visible as white matter to the naked eye. The white color of fiber tracts is due to the insulation of axons with myelin-containing fatty acids. Functionally, connections between certain neuronal populations form circuits related to particular operations. Knowledge of the step-by-step integration of information/response along such neuronal circuits allows localization of a lesion on the basis of given symptoms (topology).

Brain. Table 2 Overview of brain structures and their function

Structure	Function
Prosencephalon	
-Telencephalon	
Cortex	Sensory perception Motor control Consciousness
Basal ganglia: (Ncl. caudatus, Pallidum, Putamen, Claustrum)	Motor control Programmed movements
Hippocampus	Short-term memory Spatial orientation
Amygdala	Control of emotions Connection of memory with emotion Autonomous reactions
-Diencephalon	
Hypothalamus/Hypophysis	Regulation of hormonal pathways
Thalamus	Relay to the cortex, "Gate to consciousness"
Epithalamus (pineal gland)	"Biological clock"
Mesencephalon	
Superior colliculi of the tectum	Visual relay
Inferior colliculi of the tectum	Auditory relay
Substantia nigra	Motor control
Central gray	Perception of pain
Rhombencephalon	
Pons/Medulla oblongata	Relay for fiber tracts to and from the spinal cord; Regulation of vital functions including breathing
Cerebellum	Coordination and balance

given neuron is integrated in a binary way in that it generates an AP in neurons or not. There is, however, also information encoded in the frequency of firing. In addition, input from a given region may, although not providing enough stimuli to induce continuous APs, sensitize neuronal populations so that they easily generate APs in response to input from other regions. In that sense, EPSPs induced by a given system are not necessarily "wasted" if they alone do not reach the threshold for AP generation. Once generated at the initial segment of the axon, APs spread along the axon up to its terminal, where they may induce the release of vesicles filled with neurotransmitters into the synaptic cleft. These transmitters then bind to specific receptors at the postsynaptic membrane of the target neurons, where they induce an EPSP (excitatory transmitters) or an IPSP (inhibitory transmitters) by opening certain ion channels. Thus, within the synapse, electrical information (AP) is transformed to chemical information (transmitter

release), in turn inducing electrical changes (IPSP/EPSP) at the membrane of the next neuron in the network.

Some transmitters can be taken up by the presynaptic membrane and recycled or cleaved shortly after they have been released, while others exhibit long-term effects at the postsynaptic membrane. The former are called "classical" neurotransmitters (e.g. glutamate, GABA, serotonin, acetylcholine) while the latter have been termed co-transmitters (e.g. NPY, substance P). There is, however, no sharp borderline between the two. Interfering with cleavage, re-uptake and binding of neurotransmitters to their receptors are important targets in neuropharmacology.

A single neuron produces and secretes one classical neurotransmitter into the synaptic cleft, and is therefore termed glutamatergic, dopaminergic, cholinergic, etc., but receives input *via* many different transmitters for which it possesses the appropriate receptors at the postsynaptic membrane. A good example is the

α -motoneuron, the axon that innervates muscles in the periphery. This task is regulated by many cortical, subcortical and intrinsic (spinal) systems which all terminate, often *via* local interneurons, at the α -motoneuron, using different transmitters with opposite effects. Once this neuron is excited to generate APs, there is no physiological way to hold back contraction of those muscle cells innervated by its axon. The baseline generation of APs by motoneurons innervating a given muscle leads to a certain degree of tension, which, for example, may be important for withstanding gravity. Only the coordinated excitation of the neurons innervating a single muscle leads to visible contraction. The fact that the reader can move his little finger at his command demonstrates that it is possible to induce coordinated APs in the appropriate motoneurons at will and it is known that cortical activities induce this act *via* corticospinal projections. However, if the same reader puts the finger into boiling water, sensory input will induce a spinal reflex of coordinated movements withdrawing the finger before she/he can even think about what may be the proper response to rescue the finger from serious harm. Up to a certain point, however, it is possible to suppress this reflexive response if desired, but not beyond the point of AP generation in the motoneuron. This simple example shows that different, discernable systems terminate on the same groups of neurons, here the motoneuron. At the cognitive level, it is not only input from the eye that generates conscious pictures of the environment in the cortex. Similar pictures can be summoned with closed eyes using pure imagination. In like manner, many people are capable of imaging even complex pieces of music simply by inducing the respective activity within the cortex. Thus, while environmental stimuli still lead to uniform neuronal reactions, the human brain can also purposefully trigger some of these reactions in the absence of the corresponding stimuli.

Brain-Derived Neurotrophic Factor

► BDNF

Branchial Arches

Definition

Branchial arches are embryonic structures that contribute cells to various organs including skeletal and muscle elements of the face.

► Muscle Development

BRCA

Definition

BRCA is a gene for early-onset familial breast and ovarian cancer, which is a tumor suppressor gene located on chromosome 17q12-21. Mutations in that gene are responsible for breast cancer.

► Breast Cancer

BRCA1

Definition

Mutations in the BRCA1 (Breast Cancer Susceptibility Gene 1) gene are responsible for 45% of the cases of inherited breast cancer and over 80% of inherited breast and ovarian cancer cases.

► Chromosomal Instability Syndromes

BRCA2

Definition

Mutations in the BRCA2 (Breast Cancer Susceptibility Gene 2) gene are responsible for some forms of inherited breast cancer.

► [Chromosomal Instability Syndromes](#)

BRCT Domain

Definition

BRCT domain is an autonomously folding protein module of about 95 amino acids, first identified in the C-terminal region of the ► [BRCA1](#) tumor suppressor protein. However, it has also been found in a wide range of proteins involved in DNA replication, repair and checkpoint functions.

Synonym

Breast Carcinoma

Definition

Breast cancer (breast carcinoma) is the most frequent cancer of women. It is a group of malignant epithelial tumors that develop in the mammary gland and subsequently metastasize to regional lymph nodes and to distant organs, ultimately leading to the death of the patients.

Characteristics

General Features

Human breast carcinomas arise, through malignant transformation, from the lining epithelium of the peripheral ducts (commonly the ► [terminal ductal-lobular unit](#)) of the female and, much more rarely, the male mammary gland (1). The malignant, indefinitely proliferating epithelial tumor cells first spread within ducts and/or acini (*in situ* stage) and subsequently invade the interstitial connective and fatty tissue of the breast (invasive stage). Macroscopically, this typically results in the appearance of a firm nodular, often stellate tumor mass. Later on, carcinoma cells may infiltrate adjacent tissues such as skin and pectoral (thorax wall) muscle. If invasion of local lymphatic vessels occurs, tumor cells drift into regional (mostly the axillary) lymph nodes, giving rise to lymph node metastases. The invasion of small blood vessels opens the way to hematogenous systemic metastases in distant organs, such as the lungs, liver, brain, adrenal glands and bones. Death of the patients is essentially due to the unlimited growth of these distant metastases.

Types of Breast Carcinoma

Breast cancer is no single disease; instead, a variety of histological types of breast carcinoma can be distinguished (1). The most frequent type (~75%) is invasive (infiltrating) ductal carcinoma, not otherwise specified (NOS) (Fig. 1). This type is itself heterogeneous, comprising a spectrum of morphological variants and different ► [grades of malignancy](#) [increasing from well (G1) through moderately (G2) to poorly differentiated (G3)]. Generally, the invasive tumor cells form coherent epithelial structures such as tubules, cords and sheets (Fig. 1a). The second most frequent type (~10%) is invasive lobular carcinoma (Fig. 2). Here, the tumor cells show little coherence and infiltrate in a markedly dispersed fashion in single-cell files and individual cells (Fig. 2a). Various rare types of breast cancer include, among others, tubular, mucinous, papillary and medullary breast carcinoma. These rare types behave less aggressively than the two common types.

Breast Cancer. Figure 1 Invasive ductal carcinoma of the breast, poorly differentiated (G3): (a) Hematoxylin & eosin staining, showing solid cords of atypical tumor cells with pleiomorphic nuclei and mitoses (arrows). (b-e) Immunohistochemical stainings (paraffin sections; antigen retrieval by microwave oven heating), the detected antigen being visualized by brown color based on 3,3'-diaminobenzidine (DAB). (b) Strong complete membrane staining of the carcinoma cells for HER-2 protein, indicating HER-2 over-expression (the *HER-2* gene was amplified in this case). (c) Detection of proliferating tumor cells by nuclear staining for Ki-67, here revealing a proliferation index of 20%. (d) Clear-cut staining of tumor cell nuclei for p53, suggesting a *p53* gene mutation with resulting increased stability and nuclear accumulation of the p53 protein. (e) Preserved expression of E-cadherin with uniform staining of the intracellular borders. Magnification: x 220.

Histological Carcinogenesis

Concerning the development of invasive ductal carcinoma NOS, transformed cells first proliferate and expand for shorter or longer periods of time longitudinally within the intact ductal tree. This first stage is called ductal carcinoma *in situ* (DCIS) or intraductal

carcinoma (1). DCIS cell clones that have acquired invasive properties, may break through the ductal basement membrane and subsequently invade the surrounding tissue. Thereby, the second stage is reached, i.e. invasive ductal carcinoma.

Breast Cancer. Figure 2 Invasive lobular carcinoma of the breast, moderately differentiated (G2): (a) Hematoxylin & eosin staining showing the typical histomorphology with diffusely infiltrating single-cell files of tumor cells and dispersed tumor cells. Note a preserved normal mammary gland duct (D) included within the tumor tissue. (b,c) Immunohistochemical stainings (paraffin sections; antigen retrieval by microwave oven heating), the detected antigen being visualized by brown color based on DAB. (b) Strong nuclear staining for the estrogen receptor (ER) in most tumor cells, a typical finding in invasive lobular carcinoma. (c) Completely negative reaction of the tumor cells for E-cadherin, contrasting with the positive staining of two small residual normal ducts (D). Magnification: x 220.

As to the lobular type of carcinoma, early *in situ* growth of tumor cells involves the small ductules of mammary gland lobules, giving rise to lobular carcinoma *in situ* (LCIS) [also called lobular neoplasia or lobular intraepithelial neoplasia (LIN)] (1). Later, LCIS may proceed to invasive lobular carcinoma. LCIS thus represents a (nonobligatory) precursor lesion.

Invasive breast carcinomas in general are characterized by invasive and destructive growth, the induction of stromal connective tissue, often with pronounced desmoplasia, and the formation of new intra-tumoral blood vessels (►angiogenesis). As the clinically decisive steps of progression, invasive breast carcinomas give rise to lymphogenous and hematogenous metastases (see above). It has been recognized more recently that already in the early stages, single cells may detach from the primary tumor and disseminate in the body, notably in the bone marrow; however, most of these cells remain dormant.

Molecular Interactions and Regulatory Mechanisms

Molecular Carcinogenesis of Breast Cancer

Although there is ample evidence for the involvement of endocrinological and reproductive factors including sex hormones, a specific etiologic agent causing breast cancer has not yet been identified. This hampers the fight against this fatal disease, the incidence of which is still rising. Nevertheless, quite abundant knowledge on the molecular biology of breast cancer has accumulated. As holds for most other types of cancer, molecular carcinogenesis in the breast is based on genetic changes that breast epithelial cells undergo, involving the activation of ►oncogenes and the inactivation of ►tumor suppressor genes. The most important of them relevant to breast cancer will be summarized in the following section. First, a special biological feature of normal breast epithelium and many breast carcinomas, i.e. their sex hormone dependency, will be discussed.

Steroid Hormone Receptors

About two third of breast carcinomas express the ►estrogen receptor (ER) (1, 2). This is a transcription factor of the nuclear receptor superfamily, which is activated by its ligand, estrogen and then binds to certain genes containing estrogen responsive elements (EREs), activating their transcription. ER thus exerts various effects, notably the proliferation of mammary epithelial and carcinoma cells. The main ER is ER α encoded by *ESR1* (certain breast tumors express a second type of ER, ER β). Immunohistochemistry of ER-positive breast carcinomas reveals nuclear staining of variable proportions of tumor cells (Fig. 2b). ER-positive breast carcinomas behave less aggressively than ER-negative ones. Correspondingly, well/moderately differentiated invasive ductal carcinomas (grades

G1/G2) are more frequently ER-positive than poorly differentiated carcinomas (G3). Absence of ER expression in breast cancer cells has been associated with DNA methylation of the *ESR1* promoter. The great majority of invasive lobular carcinomas is ER-positive (Fig. 2b). Importantly, ER-positive tumors respond to treatment with the anti-estrogen substance, tamoxifen, making the determination of the ER status an obligatory diagnostic procedure for breast carcinomas. In the presence of a functional ER, breast carcinoma cells may also express the ER target gene encoding the ►progesterone receptor (PR), a transcription factor of the same superfamily (with two isoforms, PR-A and PR-B) stimulated by progestins.

Oncogenes

HER2

HER2 (also called ErbB2/neu; 185 kD), one of the four members of the EGFR family of transmembrane glycoprotein receptors possessing intracellular tyrosine kinase activity, is over-expressed in ~25% of invasive ductal breast carcinomas, usually due to amplification of the *HER2* gene on chromosome 17q12 (1, 3, 4). In these cases, it is an important oncogene. HER2 has no ligand of its own, but after binding of a ligand (such as EGF or TGF- α) to one of the other EGFR types, HER2 forms a heterodimer with the latter, upon which the intracellular tyrosine kinase domains are phosphorylated. This activates signaling cascades, in particular the ►PI3K pathway and the ►MAPK pathway, ultimately resulting in cell-cycle progression and increased proliferation.

Over-expression of HER2 shows some preference for poorly differentiated and ER-negative invasive ductal breast carcinomas. In tumor tissue specimens, HER2 protein over-expression can be analyzed by immunohistochemistry (Fig. 1b) and *HER2* gene amplification by fluorescence *in situ* hybridization (FISH). This is clinically important, since the group of patients with HER2-over-expressing breast carcinomas have reduced survival but respond to treatment with a humanized monoclonal antibody [trastuzumab (Herceptin)] targeted against the HER2 protein.

Epidermal Growth Factor Receptor (EGFR)

The prototype of the EGFR family of receptors, the ►epidermal growth factor receptor (EGFR) (ErbB1, ►HER1; 170 kD), is – as another oncogene – over-expressed in some breast carcinomas (associated with ER negativity), although its gene is not usually amplified (3, 4). This appears to be a factor conferring poor prognosis. There are also other mechanisms of EGFR deregulation in breast cancer, including activating gene mutation. After ligand-induced homo- or hetero-dimerization of EGFR, intracellular signaling

proceeds mainly through the MAPK pathway, resulting in increased cellular proliferation. Specific targeted therapies are in development.

Akt

►Akt (protein kinase B) (2, 4, 5) is part of the PI3K signaling pathway that may be activated by HER2 (see above). Akt is commonly activated in breast carcinomas, providing cell survival signals required for tumor progression thus suppressing apoptosis and is probably involved in mechanisms of resistance against therapeutic agents. Moreover, Akt may functionally inactivate the tumor suppressor gene product ►BRCA1.

c-Myc and Telomerase

►c-Myc is a nuclear protein (62 kD) and transcription factor involved in cell proliferation, apoptosis, and cellular transformation (1, 2, 5). The *MYC* gene on chromosome 8q24 is a mammary oncogene and amplified in ~20% of breast cancers, being correlated with ER negativity and worse prognosis. Among the target genes transactivated by c-Myc is human ►telomerase reverse transcriptase (hTERT), the catalytic subunit of telomerase (2, 6). This enzyme complex is essential for the unlimited proliferation and immortal state of cancer cells. Thus, c-Myc over-expression seems to be an important factor for increased telomerase activity in such cells. As regards breast cancer, telomerase is activated in most tumors and high levels of hTERT have been shown to be associated with worse prognosis in an independent manner.

Cyclin D1

►Cyclin D1 (1) plays an important role in progression of the cell cycle from the G1 phase to the S phase, contributing to phosphorylation of the ►retinoblastoma (Rb) protein. Its gene on chromosome 11q13, *CCND1*, is amplified in 15–20% of breast cancers, which is strongly associated with ER positivity. Over-expression of cyclin D1 is more frequent in invasive lobular carcinomas as compared to invasive ductal carcinomas. Data on the prognostic significance of cyclin D1 in breast cancer are still controversial.

Ki-67

Ki-67 (3, 7) is a unique, large nuclear protein (395 kD) whose expression is tightly connected to the proliferative status of cells: It is specifically expressed in the G₁, S, G₂, and M phase of the cell-cycle but absent in resting cells of the G₀ phase. Although, surprisingly, its physiologic function is not yet clear, it is widely used as a proliferation marker to determine the growth fraction of tissues and tumors. In breast cancer (Fig. 1c), Ki-67 has been extensively studied; a high Ki-67 fraction is an independent indicator of poor prognosis.

Tumor Suppressor Genes

p53

p53 is a nuclear transcription factor of 53 kD encoded by *TP53* on chromosome 17p13 and, upon DNA damage, may induce cell-cycle arrest or apoptosis (1, 2). *TP53* is extremely important in tumor biology and is the most commonly mutated tumor suppressor gene in sporadic breast cancer. *TP53* mutations are found in 20–25% of breast cancers and are mostly inactivating missense mutations accompanied by loss of the wild type allele. The mutated p53 protein is usually abnormally stable and thus can easily be detected in the tumor cell nuclei by immunohistochemistry (Fig. 1d). Mutations of *TP53* in breast carcinomas are associated with aggressive histopathological features and poor survival of the patients.

Rb 1-inducible coiled-coil 1 (*RB1CC1*)

For the ►retinoblastoma gene *RBI*, the classical tumor suppressor gene, no mutations have been observed in primary breast cancers. However, the *RB1CC1* gene, coding for retinoblastoma 1-inducible coiled-coil 1 (*RB1CC1*) (1), an important activator of *RBI*, has been described to be mutated in 20% of such tumors, in this manner still producing inactivation of the retinoblastoma pathway. The tumor suppressor gene *RB1CC1* is located on chromosome 8q11; its product represents a transcription factor localized in the nucleus.

PTEN

The *PTEN* tumor suppressor gene (on chromosome 10q23) (2) encodes for PTEN protein, which inhibits the activation of Akt (see Akt). Loss of PTEN due to gene mutation thus results in unopposed cell survival signals. *PTEN* is frequently mutated in sporadic breast cancer; its germline mutation causes Cowden's syndrome predisposing to breast cancer.

BRCA1

►*BRCA1* is a rather large protein of 220 kD with a predominantly nuclear localization and cell-cycle-dependent expression (5). It is encoded by *BRCA1* (on chromosome 17q12-21). The multiple functions of *BRCA1* include inhibition of cell proliferation, DNA damage-induced cell-cycle arrest at the G2/M checkpoint and DNA repair. It inhibits the activity of the mammary oncogene c-Myc. *BRCA1* is the most commonly mutated gene in the small group of hereditary (familial) breast cancers (comprising 5–10% of all breast cancer cases). *BRCA1* mutations are usually frame-shift mutations resulting in truncated *BRCA1* proteins. The resulting tumors are peculiar; they often have high nuclear grade, are exceptionally highly proliferative, are ER and PR negative, lack HER2 over-expression, show a high frequency of *TP53* mutations and often present histological features of the

medullary type of breast carcinoma, but the prognosis for these patients is probably no worse than that for women with sporadic breast cancer. Notably, this tumor suppressor gene also plays a role in sporadic breast cancer, since 30–40% of such tumors, in particular poorly differentiated ones, show decreased *BRCA1* expression caused by different mechanisms.

BRCA2

The ►*BRCA2* gene on chromosome 13q12 is the second most frequently mutated gene in hereditary breast cancer (5). The *BRCA2* protein is very large (380 kD) and localized in the nucleus. Its expression is cell-cycle-dependent and co-regulated with that of *BRCA1* and the two proteins have overlapping functions, e.g. in DNA repair. In particular, *BRCA2* is involved in the repair of DNA double strand breaks during the S phase; consequently, the loss of this tumor suppressor gene leads to chromosomal instability, promoting malignant transformation. Breast carcinomas arising on the basis of *BRCA2* mutations are usually ER positive.

Maspin

Maspin (42 kD) is a serine protease inhibitor (serpin) with various tumor-suppressing functions (3, 8). Its expression is down-regulated during breast cancer progression by gene silencing.

E-Cadherin

E-Cadherin is the prototype of the ►cadherin family of calcium-dependent homophilic cell-cell adhesion proteins and one hallmark of epithelial differentiation (9). It is a transmembrane glycoprotein of 120 kD localized in intercellular ►adherens junctions. In malignant epithelial tumors, its role as a potent invasion suppressor molecule has been demonstrated in various experimental systems.

As to E-cadherin's role in breast cancer (8, 9, 10), the situation differs between ductal and lobular carcinomas. Invasive ductal carcinomas show either preserved (Fig. 1e) or heterogeneously reduced E-cadherin expression. Reduced expression, which may be due to promoter hypermethylation of the E-cadherin gene (*CDH1*) and the presence of repressing transcription factors such as the zinc finger transcription factor Snail, is correlated with a higher degree of malignancy and poor prognosis. The down-regulation of E-cadherin expression in some invasive ductal carcinomas may be transient, since there may be strong re-expression in corresponding metastases.

In contrast, the majority of invasive lobular carcinomas characteristically exhibit inactivating mutations of one allele of the *CDH1* gene on chromosome 16q22.1, mostly truncating, together with loss of heterozygosity of the wild type allele (9). Immunohistochemically,

most of these tumors are completely E-cadherin negative (Fig. 2c) (9, 10). This is most probably correlated with the conspicuously diffuse and dissociated infiltrative growth pattern of invasive lobular carcinomas. Since E-cadherin is already absent in the precursor stage, LCIS (see above), its loss appears to be an early event during tumor development, with E-cadherin exerting a genuine tumor suppressor role. E-cadherin immunostaining may be used for diagnostic differentiation between ductal and lobular breast carcinomas. An E-cadherin-associated cytoplasmic plaque protein of adherens junctions, β -catenin, which in certain tumors has an oncogenic function, is usually also absent in invasive lobular breast cancers.

Molecular Mechanisms of Progression of Breast Carcinoma

After malignant transformation and acquisition of indefinite cell proliferation, further progression of breast carcinoma involves tissue invasion, induction of mesenchymal stroma, and metastasis. These processes are based on various molecular mechanisms (including e.g. E-cadherin as invasion suppressor; see E-Cadherin).

Invasion and Metastasis – Role of Proteases

An essential step for invasive growth and metastasis is proteolytic degradation of extracellular matrix components, including those of basement membranes of epithelia and blood vessels, thus opening up the way for invading tumor cells. Various proteases are involved in breast cancer invasion. Cathepsin D (2, 8) is a lysosomal aspartyl endoprotease belonging to the pepsin family. Its expression is regulated by estrogen. Its multiple functions include not only matrix degradation but also promotion of mitoses and tumor growth. The level of cathepsin D produced by breast cancers is correlated with poor prognosis. Another proteolytic system very important for breast cancer invasion and prognosis is the serine protease urokinase plasminogen activator (uPA) (2, 8), its receptor [uPAR (CD87)] and its inhibitor (PAI-1). uPA activates plasminogen to produce plasmin; it again has multiple functions. Associated with the cell surface, uPA-uPAR confers pericellular proteolytic activity and promotes the invasive and metastatic capacity of tumor cells. There is a strong correlation between high concentrations of uPA and PAI-1 in breast cancer tissue and poor prognoses for the patients. A third group of proteinases highly relevant in breast cancer are the **▶matrix metalloproteinases** (MMPs), a family of zinc-dependent endopeptidases (2, 8). MMPs degrade basement membranes and interstitial matrix but also have roles in tumor growth and angiogenesis. High levels of MMP-2 (collagenase type IV) and MMP-11 (stromelysin-3) have been found to correlate with poor prognosis.

There are specific tissue inhibitors of MMPs (TIMPs). Attempts are being made to develop targeted therapies with specific MMP inhibition but they have not yet succeeded.

Stroma Induction and Angiogenesis

The stromal compartment containing myofibroblasts and blood vessels also plays an important role in the biology of breast cancer. Macrophages stimulated by cytokines such as granulocyte-macrophage colony stimulating factor (GM-CSF) produce growth factors such as transforming growth factor- β 1 (TGF- β 1) which stimulates collagen-synthesizing myofibroblasts. This results in remodeling of the extracellular matrix and the formation of a reactive desmoplastic stroma, which, particularly in breast cancer, may be excessive. *Vice versa*, stromal fibroblasts promote tumor growth. In parallel, angiogenic factors, in particular vascular endothelial growth factor-A (**▶VEGF-A**), secreted by tumor and stroma cells induce the new formation of tumor-supplying blood vessels (3). VEGF-A stimulates endothelial cells by binding to the receptor tyrosine kinase VEGFR2/KDR. Effective anti-angiogenic therapies are not yet available.

Various Breast Cancer Antigens

Breast cancer cells, although rarely producing lactation-associated molecules, may express certain differentiation-related antigens with more or less tissue specificity for the mammary gland. Such antigens may serve as histological and/or serological tumor markers. Among these, gross cystic disease fluid protein-15 (GCDFP-15), a major glycoprotein of 15 kD present in breast cyst fluid, has been established as a useful histological marker for breast origin of unclear carcinoma metastases. Except for a few other rare tumor types expressing GCDFP-15, its expression is specific for breast carcinomas (about two thirds of cases being positive). Mammaglobin, a 10 kD glycoprotein of the uteroglobin family, is a relatively mammary-specific differentiation marker of still unknown function (3, 11). Its expression is associated with a less aggressive breast cancer phenotype. RT-PCR tests for mammaglobin mRNA may detect disseminated breast cancer cells in lymph node, bone marrow and blood specimens. MUC-1, a mucin-like transmembrane glycoprotein of high molecular weight recognized by monoclonal antibody CA15-3, is widely used as a serological marker for monitoring breast cancer progression; whether MUC-1 might serve as an immunotherapeutic target still remains to be clarified.

Cytokeratins are a large family of cytoskeletal (**▶intermediate filament**) proteins of epithelial cells, which are expressed in cell type and differentiation dependent patterns. Most breast carcinomas exhibit a simple (luminal) epithelial-type pattern consisting of

CK7, CK8, CK18 and CK19. A small proportion (15%–20%) of invasive ductal carcinomas reveals a bimodal pattern with additional, mostly focal expression of basal-cell markers CK5, CK14 and/or CK17 (12). This tumor group is characterized by aggressive behavior and poor clinical outcome and appears to be distinct, since it corresponds to the basal-like subgroup as identified by cDNA microarray profiling (see below).

Gene Expression Profiles

The novel technique of cDNA ►microarrays, allowing the simultaneous expression analysis of thousands of genes, has been applied to breast carcinomas (1, 2, 13). Although these studies are still limited, five tumor subtypes could be delineated on the basis of distinct mRNA patterns (13). Among these, a basal-like subgroup, with expression of basal cell-typical cytokeratins (12), showed a particularly poor prognosis. In contrast, a luminal-like subgroup was characterized by a good prognosis. It appears that gene expression profiling is a highly powerful method for predicting disease outcome and may be a potential approach to reach the important goal of individualizing breast cancer therapy. To what extent this expensive technique will become clinical routine remains, however, to be seen in the future.

Breast Cancer Resistance Protein

Definition

Breast cancer resistance protein (BCRP), alias Mitoxantrone-resistance protein (MXR), alias ABC transporter in placenta (ABCP), alias ABCG2, belongs to the ABC transporter family, subfamily ABCG (4q22). It is an integral membrane protein of 655 amino acids acting dimerized as an energydependent drug efflux pump responsible for decreased drug accumulation in multi-drug resistant cells.

Definition

Caenorhabditis elegans (*C. elegans*) is a small, free-living nematode found commonly in many parts of the world. It is 1 mm long and has a life cycle of 3–4 days at 20°C. *C. elegans* is a bacteriovore and feeds mainly on *Escherichia coli* under laboratory conditions. It exists as two sexes, as hermaphrodites and males. The hermaphrodite produces both sperm and oocytes and reproduces by self-fertilisation. Spontaneous males are very rare and occur at a frequency of 10^{-3} to 10^{-4} . During its reproductive life span, a hermaphrodite lays around 300 eggs. This number is controlled since

sperm is the limiting factor during self-fertilisation. Freshly hatched eggs undergo four larval stages (L1–L4), punctuated by moults. The adult arising after the fourth larval moult is reproductively mature for about four days and lives for an additional ten days.

Characteristics

The success of the worm as a model system in modern biology lies in its easy amenability under laboratory conditions and its simple anatomical architecture. *C. elegans* is made up of a relatively small number of cells and the cell lineage is invariant, that is, it is identical from individual to individual. Specifically, the adult hermaphrodite has 959 cells and the adult male has 1031 cells. The development of all of these cells is known and can be studied by differential interference contrast (DIC) microscopy. Pioneering work during early phases of *C. elegans* research led to the complete description of the cell lineage and the determination of the connectivity of the nervous system (1). To test functional aspects of the cell lineage and potential cell-cell interactions two approaches are used. First, by laser microbeam irradiation, individuals cells can be deleted from living animals and the consequences of these “cell ablations” be investigated during the further development of the individual. Second, mutants can be obtained following chemical mutagenesis or exposure to ionising radiation (2). *C. elegans* possesses six linkage groups (5 autosomes and 1 sex chromosome) with each linkage group having a genetic size of 50 cM. The physical size of the genome is 100 Mb. Together, the small genome size, the rapid generation time, the invariant cell lineage and the ability to generate mutants made *C. elegans* a popular model system for developmental genetics.

Further research in *C. elegans* focussed on getting a molecular understanding of the vast diversity of mutants isolated in various genetic screens. These studies were accelerated by the development of two major technologies; first the production of a ▶cosmid physical map by the *C. elegans* genome project and second the development of an effective transformation system (3). The physical map was constructed by ▶fingerprinting clones from a cosmid library. Gaps in the cosmid library were covered by the ▶yeast artificial chromosome (YAC) library. In addition, an ▶expressed sequence tag (EST) library was created to support the

identification of genes. Transgenic animals can easily be obtained by injecting all sorts of DNA into the syncytial gonad of gravid females. In a standard assay, 50–100 transgenic lines can be obtained by injecting 10–20 animals.

Genome Sequence

C. elegans was the first metazoan genome to be sequenced completely (4). The 100 Mb sequence comprised 2527 cosmids, 257 YACs and 113 fosmids. Genome sequencing revealed that at first sight the genome looks remarkably uniform. The GC content is 36% and remains essentially unchanged across all chromosomes. As of 1st July 2003, the genome contains the surprisingly high number of 20,621 predicted **▶open reading frames** (ORF). Gene predictions in *C. elegans* are done *ab initio* using the Gene Finder algorithm (<http://ftp.genome.washington.edu/cgi-bin/GeneFinder>). Sequence analyses indicated that centres of chromosomes have lower recombination frequencies and a higher gene density than chromosomal arms. The X chromosome has more genes than any of the autosomes. The chromosomal arms have a prevalence of **▶tandem repeats** and **▶pseudogenes** indicating that these regions are highly evolving.

Another unique feature of *C. elegans* and some other nematodes is that several genes are organised in polycistronic units called **▶operons**. Such operons are resolved by polyadenylation and **▶trans-splicing**, with the first gene in the operon receiving the spliced leader sequence 1 (SL1) and the downstream genes receiving either SL1 or a spliced leader of another family of leader sequences. Recent studies suggest the existence of around 1000 operons in *C. elegans*. It should be noted however, that genes within one operon are mostly unrelated in function and that the evolutionary origin of *C. elegans* operons and trans splicing remains a mystery. Information on all of the predicted ORFs and the complete annotated genome is stored in a centralized database known as WormBase (<http://www.wormbase.org/>).

Functional Genomics

Less than 5% of the 20,621 predicted ORFs have been characterised by conventional genetic or biochemical tools. To revisit the information that was generated by the genome sequence, high throughput functional genomic approaches are being carried out. These approaches are based upon the generation of loss of function phenotypes, analysis of expression profiles and protein-protein interactions.

Large-scale Generation of Loss-of-function Phenotypes by RNA Mediated Interference (RNAi)

The discovery that treatment of individuals with single or double stranded RNA of a gene could result in a

mutant phenocopy was a revolution in exploring gene function (5). The advantage that this technique provided over conventional mutagenesis screens was the speed with which one could relate sequence information to gene function. Gene knockdown by **▶RNAi** can be administered by several ways, injecting into the gonad of the worm, soaking the worm in the RNA solution or feeding the worm with dsRNA-expressing bacteria. The phenotype can be observed not just in the injected mother but also in the progeny of the treated worms.

With the completion of the genome sequence of *C. elegans*, a large-scale systematic RNAi analysis of 16,757 ORFs (87% of the total gene complement of *C. elegans*) has recently been carried out. 1721 (10.3%) of the genes analysed gave a detectable phenotype ranging from non-viable (lethals and steriles) to viable (growth and post-embryonic) phenotypes. Among the detectable phenotypes, the most common RNAi phenotype was embryonic lethality (5.5%). 92% of the observed phenotypes corresponded to the genetic mutant phenotype if known. An added benefit of this large-scale approach is the availability of a bacterial strain library of the entire genome complement.

Gene Expression Profiling

A way of complementing the genome wide RNAi analysis is to examine gene expression patterns on a global scale. A whole genome microarray of more than 17,000 ORFs has been developed. Different experiments utilising several different parameters such as growth conditions, developmental stages and mutants have been performed to obtain a global analysis of gene expression. Such a correlation reveals an **▶expression landscape** with several 'gene mountains' showing similar expression profiles (6). Each mountain contains sets of highly correlated genes with the mountain altitude representing the total number of genes present in the mountain and the mountain width denoting the overall level of correlation of all the genes present in that mountain. *In silico* microarray data are supported by *in situ* hybridization of a non-redundant EST dataset of *C. elegans* providing useful information on cells and tissues in which genes are expressed.

Protein – Protein Interaction Screens

Once an ORF is identified and characterized using genetic and/or RNAi approaches, one can study the nature of the protein encoded by the gene and its potential interactors. Large-scale **▶yeast two-hybrid analysis** allows determination of genome wide protein interactions that may provide valuable insight into protein function. To test the conceptual and functional feasibility of such a method, interactions of key proteins involved in vulva development were used as an example. 29 proteins were chosen and a matrix experiment was performed to identify the already known interactors.

50% (6/11 interactions) of the interactions already known in the literature were detected.

Comparative Nematode Genomics

To complement the *C. elegans* genome sequence, a draft genome sequence of *C. briggsae* has been released. This free-living soil nematode belongs to the same genus as *C. elegans* and has diverged from *C. elegans* ~50–150 million years ago. The *C. briggsae* genome has been estimated to be around 108 Mb, approximately, 8 Mb more than *C. elegans*. Comparison of segments from the two species reveals conservation of gene order making cloning by synteny easier. It also strengthens gene and exon predictions often providing candidate regulatory elements based on sequence similarities between *C. elegans* and *C. briggsae* in upstream and intronic regions. The coding regions between the two species are more similar than the non-coding regions. At a more global level, comparisons of genome sequence between *C. elegans* and *C. briggsae* suggest a rearrangement rate of 0.4–1.0 breakages/Mb/million years.

Nematode Diversity

Nematodes were treated as a minor phylum and originally classified as pseudocoelomates. Recent evidence indicates a close relationship between nematodes and arthropods in a newly suggested monophyletic taxon named Ecdysozoa. Nematodes inhabit nearly all ecosystems and are numerically abundant with over millions of animals per square meter. Although the number of described species is only ~20,000, estimates suggest that there are over 10 million different nematode species. They exist either, as free-living, parasitic or aquatic forms. Molecular data from several nematodes have been applied at a phylogenetic level, revealing a depth and diversity in many groups of these nematodes. The molecular phylogeny provides landmarks across the nematode phylum from a target gene of interest in *C. elegans* to socio economic aspects of a parasitic nematode.

Clinical Relevance

The annotated genome sequence was the dawn of a new era in the clinical relevance of the worm. The discovery of several genes in the worm having human homologues is beginning to make an impact on our understanding of human disease genes. It also proves that *C. elegans* can now be used as a model to study several human diseases, such as cancer, neurodegeneration, infectious diseases and physiological disorders. Sequence analysis of the worm genome suggested that 42% of human disease genes have orthologues in *C. elegans*. Identifying the human homologue in the worm and knocking it down using ►‘reverse genetics’ is a useful way of understanding the function of this

gene. In the long run, the functional analysis of orthologous genes in *C. elegans* makes it possible to understand the mechanisms of human disease with the added advantage of suggesting novel approaches in drug discovery. Given the several functional genomic approaches in *C. elegans* outlined above, one can identify candidate modifier genes and study their nature of action. Another aspect of nematode research is the biology of parasitic nematodes. Amongst the parasitic nematodes, many species affect humans or other vertebrates and agriculture worldwide. For example, *Onchocerca volvulus* a parasitic nematode, is the causative agent of river blindness, one of the most harmful human diseases. In order to ascertain the molecular nature of parasitism, numerous EST sequencing projects have been initiated. At present, 33 different nematode species are being sequenced (7). The partial genomic information from these projects reveals information that can lead to the development of novel control strategies and anti-nematode drugs.

C2H2 Zinc Finger Gene

Definition

C2H2 zinc finger genes comprise of a subfamily of one of the largest human gene families, the zinc finger gene family, which plays an important role in the regulation of transcription. They contain a C2H2 ►zinc finger, a small protein domain with a helical region that binds to the major groove of the DNA. The structure is held

together by a zinc atom bound to two cysteines and two histidines, from which the name is derived. In the (Cys)₂(His)₂ type of zinc finger genes, there is a highly conserved consensus sequence TGEKPYX (X representing any amino acid) between adjacent zinc finger motifs.

CAAX-Box

Definition

The CAAX-box indicates the amino acid sequence cysteine – aliphatic amino acid – aliphatic amino acid – any amino acid at the C-terminus of proteins. Proteins with a CAAX-box are modified at the cysteine with isoprene-groups via a thioether linkage. Generally, a farnesyl-group (C 15) is transferred to the protein unless leucine is present at position X, which results in modification with the more hydrophobic geranyl-geranyl moiety (C 20). Two different enzymes, designated farnesyl- and geranylgeranyltransferase I, catalyze these reactions. The amino acids AAX are then cleaved by an endoproteinase, and the resulting carboxyl group of the cysteine residue is methylated. Rab-proteins, a large family of small G-proteins involved in vesicular transport, contain the C-terminal sequence CC or CXC. They are geranylgeranylated at both cysteine residues by yet another enzyme, geranylgeranyl-transferase II.

► [Fatty Acid Acylation of Proteins](#)

► [Protein Prenylation](#)

Definition

A cadherin was identified as a calcium-dependent cell-cell [adhesion molecule](#). A mature cadherin polypeptide is a type I transmembrane protein composed of three domains, an extracellular domain, a transmembrane domain and a cytoplasmic domain. The extracellular domain is composed of five repetitive sequences – the cadherin repeat or EC (extracellular) domain. Basically, each repeat has conserved sequences like PE, LDRE, DxDND and DxD, some of which have been implicated in calcium binding. Over 20 different cadherin subtypes have been found in a single vertebrate species. The cytoplasmic domain of cadherin is conserved among these subtypes and interacts with catenins through the carboxy terminal half domain as discussed below. This catenin-binding domain is required for the normal function of cadherins. The presence of the cadherin motifs in the extracellular domain and the catenin-binding site in the cytoplasmic domain serve as defining characteristics of cadherins (known as “classic” cadherins when using a more precise classification; see below). On the basis of specific amino acid sequences in the cytoplasmic domain, cadherins can be divided into two subfamilies, type I and type II cadherins. Type I cadherins comprise E-, N-, P- and R-cadherins, which were named according to the organ or tissue in which they were first identified (epithelial, neural, placental and retinal, respectively). Many type II cadherins were identified by the cloning of molecules with the cadherin repeats, and were named using a number system representing the chronological order of their discovery, in which the

CADASIL

Definition

CADASIL (cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy) is

discovery of cadherin-5 predates that of cadherin-6, and so on. Type I cadherins are also represented as numbered cadherins; E-cadherin may be represented as cadherin-1, N-cadherin as cadherin-2, P-cadherin as cadherin-3 and R-cadherin as cadherin-4.

A large number of molecules have been reported that have cadherin repeats in an extracellular domain, but without a catenin-binding site in the cytoplasmic domain. These molecules are collectively called non-classic cadherins. In this respect, the cadherins discussed within this essay are classic cadherins. Non-classic cadherins include a variety of molecules. Major subfamilies are desmosomal cadherins, Fats, protocadherins and Flamingos/Celsrs. These non-classic cadherins display variation in the number of the cadherin repeats and cytoplasmic sequences. Desmosomal cadherins consist of desmogleins and desmocollins, whose cytoplasmic tails have some similarity with those of classic cadherins. These proteins are responsible for adhesion and anchorage to cytoskeletons in a specialized cell-cell junction: the ►desmosome (see below). Fat is a large cadherin with 34 cadherin repeats in the extracellular domain. This protein was first identified as a tumor-suppressor gene in *Drosophila*, and is involved in cell proliferation and maintenance of epithelial structure. Flamingos/Celsrs are also large cadherins that are characterized by a 7-pass transmembrane domain. These proteins are involved in the control of planar polarity and patterning of dendrites. The physiological functions of other non-classic cadherins, including whether these molecules function as cell adhesion molecules, have not been elucidated. The cadherins on which we will concentrate in this short essay are classic cadherins.

Characteristics

Major characteristics of cadherins include calcium dependency and the exhibition of strong cell adhesion activity, cytoskeletal interactions and cell adhesion specificity. In the absence of calcium, cadherins do not function as cell adhesion molecules and are sensitive to trypsin digestion. Cadherins mediate strong cell-cell adhesion when in the presence of calcium. As a consequence, cadherin-positive cells are seldom dissociated into single cells from cell aggregates, even under high shearing force. This strong cell adhesion activity is dependent on an interaction between the cadherin and the actin-based ►cytoskeleton at the proper temperature, and is thought to play a fundamental role in tissue formation and maintenance. Dysfunction of cadherins is believed to be one of the major causes facilitating ►cancer invasion and metastasis. Adhesion specificity is another characteristic property of cadherins. For example, E-cadherin-positive and P-cadherin-positive cells aggregate separately when mixed. Since different cadherin

subtypes are expressed in different tissues, cadherins are thought to play crucial roles in cell-type specific selective adhesions.

Molecular Interactions

A single cadherin repeat (EC domain) consists of about 110 amino acids and forms a barrel-like structure. It has been shown that 3 Ca^{2+} are bound at each interdomain boundary of the first four cadherin repeats. The tandem array of barrels is flexible when the concentration of Ca^{2+} is low, but rigid when the concentration of Ca^{2+} is high. It has also been suggested that two cadherin molecules form a homodimer in the presence of Ca^{2+} . The structural changes caused by the Ca^{2+} interaction seem to be necessary for cadherin to function as a cell adhesion molecule. The conformational change of cadherin in the presence of calcium also protects certain subtypes of cadherins from degradation by trypsin. Cadherin-mediated cell-cell adhesion is basically homophilic; the extracellular domain of cadherin molecules binds to that of other cadherin molecules on neighboring cell surfaces. Various analyses of crystal structure have so far yielded three models that attempt

Cadherins. Figure 1 Schematic drawing of cadherin-mediated cell-cell adhesion. (a) Cell-cell adhesion is mediated by the cell adhesion molecule cadherin (yellow or red bars). Different cadherins, yellow cadherins and red cadherins, may have different adhesion specificities. Cells expressing different cadherins preferentially form different colonies. (b) The cell adhesion molecule cadherin is a transmembrane protein. Ca^{2+} is required for the proper conformation of the extracellular domain, which is directly responsible for cell-cell adhesion. Cadherin forms a complex with several cytoplasmic components, collectively called catenins. β -catenin and p120ctn might regulate the adhesion activity of cadherins. α -catenin is involved mainly in cadherin-cytoskeleton interactions.

to explain the trans-interaction of cadherin extracellular domains. As these models vary in specific details, the molecular mechanisms of cadherin trans-interactions remain elusive.

Cadherin forms a relatively stable complex with α -catenin and **▶ β -catenin** (or plakoglobin) through its catenin-binding site in the cytoplasmic domain. β -catenin and plakoglobin are highly homologous proteins and belong to the armadillo family of molecules. β -catenin and plakoglobin bind directly to the catenin-binding site of cadherin and the amino terminal domain of α -catenin to establish a connection between these proteins. α -catenin has a weak homology with vinculin, and binds to various actin-binding proteins, such as vinculin, α -actinin, ZO-1 and actin itself. The interaction with actin-based cytoskeletons through α -catenin is essential for cadherins to function as strong cell adhesion molecules. Other armadillo family proteins interact directly with cadherins, including p120-catenin (p120ctn) and delta-catenin, but do so at the juxtamembrane domain of the cadherin that is situated at the N-terminal position of the catenin-binding site. These proteins are not required for the basic adhesive function of cadherins, but may be necessary for cadherin stability and other regulatory processes involved in cell adhesion.

Regulatory Mechanisms

The spatial and temporal expression of cadherin subtypes is strictly regulated during animal morphogenesis, during which adhesion specificity of cadherin subtypes might play an important role. It was reported recently that the transcription of E-cadherin is directly repressed by several transcription regulators, including snail, slug, ZEB-1/deltaEF1, ZEB-2/SIP-1 and E47. These E-cadherin repressors may be involved in **▶epithelial-mesenchymal transitions** during embryonic development and tumor progression.

Cadherin expression is also under post-transcriptional regulation. Cadherin molecules are synthesized as a precursor molecule with a pro sequence at the amino terminus. This sequence is removed prior to arrival at the plasma membrane, to form a mature cadherin. E-cadherin displaying a mutation that prevents the removal of this pro sequence fails to function as a cell adhesion molecule. It has also been reported that a specific cleavage, endocytosis and recycling mediated by various proteins, including presenilin-1, HAKAI, protein kinase C and Rac1, are involved in the regulation of mature cadherin expression. The physiological functions of such regulation have not been elucidated. On the other hand, the expression of β -catenin is post-transcriptionally regulated using the ubiquitin-proteasome system. This regulation is required, not for cadherin-mediated cell adhesion, but for the **▶Wnt signaling pathway**, which plays a

fundamental role in cell fate decisions and patterning of embryos. β -catenin that has not associated with cadherins is effectively degraded and absent from the cytoplasm and nucleus when a Wnt signal is absent. Wnt signals prevent this ubiquitination and degradation, causing the accumulation of β -catenin in the cytoplasm. Stabilized β -catenin finally translocates into the nucleus with the LEF/TCF transcription factor to activate LEF/TCF target genes.

Cadherin-mediated adhesion is regulated by intracellular signals in an 'inside out' direction. It has also been suggested that cadherins transduce signals in the reverse direction. Many **▶kinases**, including EGFR and src, and phosphatases, such as PTP μ and PTP κ , are localized at cadherin-based adhesion sites. Many reports indicate that major targets of kinases and phosphatases are the tyrosine residues of β -catenin and p120ctn. It is generally believed that phosphorylation of β -catenin and p120ctn affect cell adhesion activity. On the other hand, cadherin-mediated adhesion is involved in the activation of a signaling pathway through phosphorylation mechanisms. It has been reported that the AKT/MAPK pathway and the PI3-kinase/Akt cascade could be activated by cadherin-mediated cell adhesion. "The contact inhibition" of cell movement or cell growth is a well-accepted concept in the field of cell biology. Although the 'outside-in' signals mediated by cadherins are a good candidate for signals involved in this concept, little experimental evidence exists at the moment to associate cadherins with the contact inhibition of cell movement and growth.

Rho small GTPases are other strong candidates for regulators of cadherin-mediated cell adhesion. There is much evidence indicating that Rac1, cdc42 and RhoA types of GTPases affect cadherin function through the regulation of cadherin accumulation or cadherin-catenin complex formation. Furthermore, the activity of these small GTPases is modulated by cadherin-mediated cell adhesion or p120ctn. Since Rho small GTPases are involved in various dynamic cellular processes, such as cell motility, these proteins might regulate the balance between adhesive and motile cellular phenotypes.

Cadherin is essential for the formation of a highly specialized cell-cell junction, the **▶adherens junction** (AJ). The Ig-superfamily adhesion molecule nectin and its associated protein afadin have been shown to be components of the AJ. This adhesion system works cooperatively with the cadherin system to form AJs in certain cellular contexts. Three specialized cell-cell junctions, **▶tight junctions** (TJs), AJs and **▶desmosomes**, form junctional complexes at the apical edge of cell-cell boundaries in epithelial cells. The epithelial AJ is highly developed and is called the zonula adherens. Anti-E-cadherin antibodies not only disrupt AJs, but

also perturb the organization of TJs, indicating that cadherin-mediated cell adhesion regulates the formation of other junctions in epithelial cells. In fact, the dysfunction of the cadherin adhesion system, which occurs in many tumor cells, is correlated with the loss of junctional complexes and epithelial integrity. Recent studies have demonstrated that cadherins are also involved in regulation of synaptic junctions.

Definition

► *C. elegans* is a small free-living soil nematode that has become an important model organism of intense

investigation. Complete descriptions of its development, nervous system and genome provide a unique platform to launch functional genomic studies of evolutionarily conserved genes, pathways and processes from worm to human.

Characteristics Features

Pioneered by Brenner as a genetic system in the 1960s, *C. elegans* was chosen in large part because of its small size (1 mm), rapid generation time (3.5 days) and ease of cultivation on an *E. coli* lawn. Moreover, stocks can be frozen in liquid nitrogen for years. Because of its clarity, cell constancy (959 somatic cells) and invariant development, the fate of every cell has been traced in entirety by Sulston, Horvitz and co-workers, forming a complete and precise framework for detailed biological exploration. Indeed, Sulston, Horvitz and Brenner were awarded the 2002 Nobel Prize in Medicine for their efforts.

Despite a simple anatomy, *C. elegans* has several major organ systems: a nervous system comprised of sensory neurons and motor circuits that control behavior, body muscle for movement, a pharynx for food ingestion and body fluid transport, an intestine for digestion and metabolic control, gonads and associated structures for reproduction, an excretory system and epidermis for fluid balance and barrier protection. Notably, the anatomy is described down to the ultrastructural level. In particular, with only 302 neurons, the entire hermaphrodite nervous system, including every synaptic connection and gap junction, has been reconstructed from serial electron micrographs, providing neural network models for behavioral studies.

Genetics

C. elegans has 5 pairs of autosomes and the sex (X) chromosome. Two X's specify the hermaphrodite sex, one X, the male. Because laboratory stocks are inbred, homozygous, and of single origin, powerful isogenic comparisons are possible. Self-fertilizing hermaphrodites produce broods of about 300 progeny. Self-fertilization greatly facilitates large-scale genetic screens, since a homozygous colony can be derived from a single worm, while mating with males permits markers to be crossed between strains. Basic forward genetic techniques such as chemical mutagenesis, complementation tests and gene mapping by morphological markers were established early on, followed by advanced techniques such as transgenesis, mosaic analysis, transposon insertion mutagenesis, balancer and deletion chromosomes, snp mapping, ►positional cloning and ►reverse genetics (below). Genes are described by a three letter name, usually an acronym for the mutant phenotype or function, followed by a

gene number and the allele in parenthesis (e.g. *unc-5* (*e53*), uncoordinated mutant gene 5, allele *e53*).

Genomics

C. elegans is a highly developed genomic organism. Extensive web-based bioinformatic development and central data archives are supported by Wormbase (www.wormbase.org) and nematode related links are found at <http://elegans.swmed.edu/>. The entire genome is cloned into overlapping cosmids and yeast artificial chromosomes (Sanger Center, UK) and ordered into a contiguous physical map. Because of its relatively small genome (97 megabases, 1/30 human), and dense physical and genetic map, *C. elegans* became the first metazoan whose genome was decoded (1), a collaborative effort between the Sanger Center (UK) and Washington University Genome Center (US). The catalog contains over 19427 predicted genes, about half that of human. Approximately, 36% of them are conserved with vertebrates.

cDNAs encoding most genes are available as expressed sequence tags (Yuji Kohara, National Institute of Genetics, Mishima) or full length cDNAs (Marc Vidal, Orfome project, Harvard). ▶**Expression profile** studies have been carried out using Affymetrix technology, cDNA or exon rich gene arrays, as well as serial analysis of gene expression. Such studies have included expression profiles describing temporal development and ▶**aging**, dauer formation, germline and sex-specific genes, muscle specific genes and pharyngeal organogenesis. One of the most promising approaches includes comparisons among the hundreds of array experiments, which suggest clusters of coexpressed genes visualized as “▶**expression mountains**” (2). ▶**Yeast two-hybrid** screens to identify protein-protein interactions were first employed systematically to study whole pathways such as vulval development, DNA damage and repair and germline expressed genes, an approach now being scaled up to build a comprehensive genome-wide ▶**interaction map** (3).

The ability to deduce gene function starting with a known gene, known as reverse genetics, has been achieved on a genome-wide scale by RNA mediated inhibition (RNAi, see below). In addition, the Gene Knockout Consortium systematically searches for deletions in a particular gene of interest by screening mutant pools of DNA by PCR. A library containing random insertion of transposons serves as another source of mutants as well as polymorphic markers for high-density mapping. Gene expression patterns are being documented systematically using *in situ* cDNA hybridization as well as promoter fusions to β -galactosidase and ▶**green fluorescent protein** (Fig. 1). Comparisons to the recently acquired sequence of *C. briggsae*, a related species, is proving

***Caenorhabditis elegans* as a Model Organism for Functional Genomics. Figure 1** A worm expressing green fluorescent protein (GFP) fused to DAF-9/cytochrome P450, which regulates *C. elegans* life span.

important for understanding evolution of genes and their regulatory regions.

Clinical Relevance

C. elegans is a mainstay model organism for fundamental pathway discovery, as well as a ▶**disease model** for analysis of clinically relevant gene function. Some areas of inquiry include organogenesis, muscle structure and physiology, neural development, ▶**synaptogenesis**, behavior, body patterning, ▶**developmental timing**, cell signaling, endocrine regulation, innate immunity, pathogenesis, sex determination and aging (4). Fundamental problems in developmental cell biology, such as cell-cycle, cell death, migration and fusion, cell polarity, spindle and chromosome dynamics, secretion, endo/exocytosis, extracellular matrix and cell-cell junctions have also been studied in *C. elegans*. Here we highlight a few prominent examples where *C. elegans* has led the way.

Programmed Cell Death

Elucidation of the *C. elegans* cell lineage shows that 131 cells are destined to undergo ▶**programmed cell death** at stereotyped times and positions. Notably, the first cell death mutants in any metazoan were isolated in the worm and genetic ▶**epistasis** experiments revealed a pathway that selects this fate. Included in this pathway are transcription factors that specify cell death (CES-1, CES-2, TRA-1), proteases that execute

cell death (e.g. ►CED-3/caspase) and their regulators (CED-4/Apaf1, EGL-1/BH3 and CED-9/Bcl2), as well as genes involved in cell corpse engulfment (CED-1/SREC scavenger receptor, CED-2/CrkII, CED-5/DOCK 180, CED-6/GULP adaptor, CED-7/ABCA1 transporter, CED-10/Rac1 GTPase, CED-12/Elmo1). Furthermore, cell death in the germline was shown to be sensitive to radiation damage and linked to CEP-1/p53 mediated pathways. Importantly, work in flies and mammalian systems demonstrated that the apoptotic machinery is evolutionarily conserved. Thus, mechanistic insights gleaned from work in the nematode have broadened our understanding of some cancers in which aberrant cells fail to undergo ►apoptosis, of autoimmunity where removal of autoreactive clones has gone awry and of neurodegenerative diseases and stroke where massive cell death leads to organismal demise. Finally such studies have revealed how programmed cell death plays an intimate part in development.

Neurobiology

Brenner identified numerous behavioral mutants that affected the nervous system in early genetic screens. Among them were a set of genes that guide the migrations of neuroblasts and growth cones, identifying the first true ►axon guidance cues in metazoans. ►UNC-6 is a homolog of the vertebrate netrin, which both attracts and repels axonal outgrowth in the floorplate. This secreted protein is proposed to polymerize in the extracellular matrix, providing graded cues for its receptors, UNC-40 and UNC-5. UNC-40 transmembrane receptor is a DCC (deleted in colorectal cancer) homolog, which alone mediates attraction to netrin sources, but together with coreceptor UNC-5 mediates repulsion. Other molecules involved in axon guidance and cell migration conserved across taxa include ephrins (EFN-1-4) and the eph receptor (VAB-1), semaphorins (SMP-1, SMP-2, MAB-20) and their receptors plexin (PLX-1) and neuropilin, as well as *slit* (SLT-1) and its cognate receptor round about (SAX-3). Molecules such as these are important for understanding neural development and regeneration.

Finally, numerous molecules involved in synaptogenesis (e.g. SYD-2/alpha liprin, UNC-104/KIF1 kinesin) and synaptic function (e.g. UNC-13/MUNC13, DGK-1/diacylglycerol kinase, SNT-1/synaptotagmin, SNB-1/synaptobrevin), have been intensely studied in the worm and have vertebrate counterparts performing similar functions. The use of green fluorescent protein (GFP) reporters to monitor neural structure and function, actually first pioneered in the worm, has facilitated the discovery of genes central to these pathways. Conceivably, mental retardation in humans

could be associated with mutational loss of such molecules.

RNAi and MicroRNAs

One of the most surprising findings first discovered in *C. elegans* is that double stranded RNA of a particular gene acts as a potent and specific inhibitor of gene function, known as RNA mediated inhibition (RNAi). In the worm, double stranded RNA is injected, soaked in or ingested and spreads systemically throughout the organism. Double stranded RNAs are cleaved into 21-mer fragments, called siRNAs, by the enzyme Dicer. Once incorporated into the RNA induced silencing complex, the antisense RNAi then serves as a template for mRNA degradation leading to loss of gene function. Remarkably, this technique works in mammalian cell culture and even in live mice. Surely, RNAi will prove to be an important therapeutic innovation and revolutionize high throughput analysis of gene function in higher organisms.

Indeed, RNAi has greatly accelerated functional genomics in the worm. Worms fed RNAi from 16757 genes gave rise to basic embryonic and larval phenotypes in 10.3% of the cases (5). Interestingly, such studies divulge unexpected aspects of chromosomal architecture, such as the relative dearth of essential genes on the X chromosome. Genome-wide screens for genes influencing ►fat metabolism, spindle dynamics, genome stability, ►cell migration, ►cell division, ►axon guidance, life span and other processes promise to illuminate numerous areas of biology. A particularly powerful approach combines ►microarray or yeast two-hybrid data with functional RNAi screens. In this way, many germline specific transcripts have been assigned functional roles in meiosis and chromosome dynamics. Similarly, yeast two-hybrid interactors of known DNA repair components have led to the discovery of new genes that influence the damage response.

Interestingly, the endogenous RNAi machinery in the worm is employed to translationally regulate a number of genes in the heterochronic pathway, which controls developmental timing. Initially discovered in the worm, ►lin-4 and let-7 ►microRNAs are 21–22 nucleotide long molecules that base pair imperfectly with the 3'UTRs of several genes, down-regulating their translation. Subsequently, it was discovered that scores of such genes exist not only in the worm but also in mammalian genomes. Remarkably, clear human orthologs to *lin-4* and *let-7* are among them. The function of these tiny RNAs is just beginning to unfold but already they are suggested to be involved in several diseases and syndromes. In addition, the role of the endogenous RNAi machinery in metazoan gene silencing is just beginning to emerge.

Aging and Life Span Regulation

A fascinating area of research spawned by findings in *C. elegans* is the biology of aging and longevity. Single gene mutations were found in *age-1*/PI3 kinase and

daf-2/insulin/IGF receptor mutants, that double or triple nematode life span, with little compromise in the fertility, vitality or metabolism of the organism. The molecular identity of these genes and similar mutants,

reveal insulin/IGF-signaling components as central regulators of longevity. While up-regulated insulin signaling is pro-aging, modest inhibition of the pathway leads to animals that are stress resistant and long lived. Longevity depends entirely on ►DAF-16, a FOXO forkhead transcription factor. Remarkably, recent work in fly and mouse indicate that reduced insulin/IGF signaling also extends life span. In addition, molecular dissection of this pathway in the worm has identified pivotal molecules, such as DAF-18/PTEN and DAF-16/FOXO, previously unknown to be involved in insulin signal transduction, illuminating disease states such as ►diabetes. Another endocrine pathway that influences life span is nuclear hormone receptor signaling. In particular, DAF-9/CYP450 produces a lipophilic hormone that regulates the life extending properties of nuclear receptor DAF-12 (Fig. 1). Currently over 50 genes modulate *C. elegans* life span and include components involved in mitochondrial function, eating behavior, thermotolerance and heat shock, checkpoint control, germline maturation, gene silencing and endocrine systems. Moreover, expression profiling and bioinformatic approaches to identify DAF-16 targets have uncovered genes that incrementally shorten or extend life span. Genome-wide screens using RNAi have also yielded a plethora of molecules, which by unknown mechanisms modestly influence life span. It will be interesting to understand which amongst them play a similar role in humans.

Prospectus

Future work will utilize high throughput functional analysis of genes by RNAi or other systematic methods, integrated with expression profiles and proteomic approaches, to elucidate gene interaction networks (3). From a clinical perspective, as new disease genes are unveiled, *C. elegans* will help elucidate their function as a simple genetic disease model. Already orthologs of several important disease loci have been identified and are being studied (Table 1). The primary challenge will be to clarify the relationship from gene, pathway and mutant phenotype to the relevant physiology in human.

Definition

► [Immunoglobulins](#) raised against non-self molecules are key-players in the vertebrates' adaptive immune response. An elicited antibody associates with its cognate ► [antigen](#) with high ► [affinity](#) and specificity. The IgG are the most abundant antibodies in the peripheral blood and it has been well established that they are invariably composed of two heavy chains and two light chains (Fig. 1). The heavy and light chains contain four and two domains, respectively. The first domain of both the light and heavy chain is more variable in sequence (referred to as ► [VH](#) and ► [VL](#)) than the remaining domains and the paired VH and VL domains form the antigen-binding site. The discovery in *Camelidae* (dromedaries, camels and llamas) of naturally occurring IgG molecules consisting of heavy chains only and lacking light chains was totally unexpected (Fig. 1). These so-called ► [heavy-chain antibodies](#) (HCAbs) are functional in antigen binding (4). However since the homo-dimeric HCAbs lack a light chain and thus a VL, the antigen is bound by only one single domain, the ► [VHH](#) (VHH is the abbreviation of variable domain of the heavy chain of HCAbs). A VHH can easily be cloned and expressed in bacteria or yeasts to yield high amounts of soluble protein. Such a single-domain antibody format (VHH) has a MW of only 15 kD, which is at most half the size of the intact antigen-binding site of a conventional antibody, the ► [VH-VL pair](#). The VHHs possess a number of biophysical and biochemical properties that offer instrumental advantages over the antigen-binding fragments of conventional antibodies (i.e. the paired VH and VL) for their versatile usage in functional genomics.

Characteristics

General Characteristics and Properties of VHH

The VHHs possess a number of 'hallmark' amino acid substitutions that distinguish them from the conventional variable domain of the heavy chain of conventional antibodies (VH). These hallmarks are all located at the side of the domain that corresponds to the

Camel as a Model for Functional Genomics.

Figure 1 Schematic representation of a conventional antibody, a heavy-chain antibody of camelids and the VHH antibody fragment derived from such a heavy-chain antibody (from top to bottom). The heavy chains are in dark grey, the light chains are in light grey. The variable domains of the chains are represented as cylinders, the constant domains are represented by cubes.

VL-binding site of a VH (4). The nature of the VHH hallmark substitutions renders this area much more hydrophilic, probably leading to an enhanced solubility of the isolated domain.

The HCAb presence in serum of ►**camelids**, in conjunction with the possibility of immunizing these animals, allows for a straightforward cloning and selection procedure and for the production of an antigen-binding unit consisting of a single-domain only, the VHH (4). Hence, a technology is available to obtain *in vivo* matured antigen binders in a single domain format. To this end, a dromedary (or a llama) is first immunized with low amounts of antigen (50 µg), or a mixture of purified antigens. The peripheral blood ►**lymphocytes** are isolated to extract mRNA, which is used in an RT-PCR with VHH-specific primers to amplify the *VHH* genes. The *VHH* gene fragments are then ligated in a phage display vector and an 'immune' library is created from which potent antigen binders can be selected.

With this technology at hand, we have already selected over 100 binders against some 20–25 different antigens. The chosen *VHHs* are recloned in an expression vector behind a signal sequence to direct the VHH into the ►**periplasm** of bacteria and with a histidine tag used for purification by immobilised metal

affinity chromatography. After a further gel filtration we routinely obtain pure VHH at yields of 5–10 mg/l of culture in shaking flasks. This yield is on average 10× higher than most VH-VL constructs, and even higher yields have been reported when VHH expression was carried out in yeast under fermentation conditions.

The VHH domains are highly soluble, they can be brought to concentrations of 10–20 mg/ml without any sign of aggregation. The VHH tested so far are remarkably stable, e.g. they resist a one week incubation at 37°C and some of them can be heated to 90°C without loss of antigen binding activity (4). This feature might be correlated with the frequent occurrence of an extra disulfide bond between the antigen binding loops.

The VHH isolated from the immunised libraries are highly specific for the target antigen and do not cross-react with other, non-related antigens. The interaction between the VHH and its cognate antigen occurs with affinities in the nanomolar range, an affinity that is similar to that obtained for the best VH-VL pairs. The crystal structure of more than a dozen have been determined, creating a large structural database on how these binders interact structurally with their cognate antigen.

Surprisingly, many of the camelid VHHs directed against enzymes act as competitive inhibitors (4). This will definitely be an asset for provoking an immunomodulation (see further). This feature is probably related to the VHH's small size and especially to its small footprint on the associated antigen.

Although not of high priority in functional proteomics, the VHH possess two additional properties that might become important for subsequent applications. First, the low complexity of the antigen-binding site of VHHs consisting of only three loops (instead of 6 loops in VH-VL pairs) offers particular advantages over classical antibodies in designing novel inhibitors or cell receptor blockers. Secondly, the large sequence identity shared by VHH and human VH predicts a negligible ►**immunogenic** reaction against the VHH when administered to humans.

VHHs Against the Proteome

During the immunisation of a camelid, the B-cells producing antigen-specific HCAbs are enriched in the pool of antibody producing cells, and might even reach 1% of the population. Moreover, it is possible to immunise with a complex mixture of antigens, possibly even the whole proteome and to raise an immune response to each antigen or at least to the majority of the antigens. The cloned VHH repertoire of such an immunised camelid might be an ideal source to retrieve *in vivo* matured, high-affinity binders against any antigen of the proteome. This approach is quite feasible since the cloning of 10⁸ individual *VHHs* amplified from 10⁸–10⁹

B-cells should yield 10^8 different VHH sequences, each of which might be directed against a different epitope. It is unlikely that this might be achieved after immunising a mouse or rabbit because the *VH* and *VL* gene fragments of the 10^8 conventional antibodies will be amplified separately and assembled randomly in the subsequent step to arrive at 10^{16} possible *VH-VL* constructs. Only a fraction of this can be transformed in bacteria as a result of transformation efficiency limitations. In addition, starting from a large naïve library might turn out to be inefficient as well, because binders retrieved from such libraries are frequently of too low an affinity for subsequent applications.

Camelid VHH as Probe in Protein ► Biochips

Antibody-based assays are among the most commonly used diagnostic tools. In addition, the use of antibodies is ever expanding to detect and purify bio-molecules in complex samples. The introduction of phage-displayed antibodies and antibody engineering resulted in greater flexibility in assay and probe design. The generation of a panel of highly stable, antigen-specific binders that can be directionally immobilised at a high density on the sensor layer opens great opportunities in novel diagnostic tools and proteome research (1).

The incorporation of the camel single domain antibody fragments, in conjunction with their small size, high specificity and high k_{on} rates for the antigen allows the detection of low analyte concentrations (in the range of ng/ml). The robust behaviour of the camel VHH probe increases the lifetime of the biosensor.

Coupling the various antigen binders, obtained from our proteome immunisation technology, side by side in a micro-array should in principle allow the simultaneous detection of multiple antigens from the proteome present in various cell-types. The outcome of this protein profiling provides the basic information to identify new targets for therapy to be developed in the near future.

Camelid VHH for Immuno-targeting and Immuno-modulation

After unveiling a new gene it will be necessary to find out the function of its encoded product. Determination of the cell-types that express this gene and the localisation of the gene product and identifying its interacting partners are crucial steps in the target validation process.

The nucleotide-based micro-array is a perfect tool to investigate the gene expression profile, however, it might be substituted by antibody-based micro-arrays (see above).

For years, labelled antibodies have been used to determine the localisation of the antigen. The strictly monomeric nature of the VHH, and its free C-end located at the opposite side of the paratope within

the domain make it easy to tether tags (e.g. green fluorescent protein, hexahistidine, or another VHH to generate bispecific constructs...) by genetic fusion. These immuno-conjugates are well expressed, soluble and retain full antigen binding activity rendering them suitable for immuno-targeting. The VHH coupled by chemical means to paramagnetic beads and mixed with a protein cell extract should enable the capturing of the antigen together with its interacting partners. With the help of a magnet, the interacting protein complex can then be isolated for further identification.

In addition, the unique preference of a VHH to interact with cavities on the surface of the antigen and the likelihood that the catalytic sites of enzymes are within such cavities often make VHHs competitive enzyme inhibitors. Therefore, besides targeting the antigen, the introduction of a VHH inside cells might decrease and even knockout the function of the target. Such an immuno-modulation by the ectopic expression of *VHH* genes might become a powerful technique to manipulate cellular metabolism, signal transduction or pathogen infectivity. Proof of the principle has been given by the intracellular expression and proper folding of VHHs in eukaryotic cells (intracellular immunization) leading to interference with biological processes that take place inside such cells (3).

Camelid VHH as Crystallisation Aids

Now that most genes of the genome have been identified, there will be a desire to determine the structure of all gene products by crystallography or NMR. Both of these techniques require highly concentrated samples of pure protein. Keeping these proteins soluble at high concentration and the crystallisation of flexible proteins or membrane proteins for high-resolution structural studies remain challenging because of the non-uniformity in folding and the amphipathic surface of the molecules, respectively. Embedded in the membrane bilayer, the surfaces of the protein in contact with the acyl chains of the phospholipids are hydrophobic, whereas the polar surfaces of the protein are exposed to the polar head groups of the lipids and to the aqueous environment. Because many membrane proteins contain exposed hydrophobic areas, a strategy to increase the probability of getting well-ordered crystals consists in covering the hydrophobic areas by specifically bound antibodies. This association might increase the solubility of the antigen, and fix the flexible proteins in a suitable conformation for crystallisation (2).

Monovalent recombinant antibody fragments such as *VH-VL* pairs and especially the rigid VHH should be suitable crystallisation aids. The VHHs can be first used to purify the antigens by affinity chromatography and can later be added in a 1:1 stoichiometry to

stabilize the antigen by forming a tight complex, in which hydrophobic patches of the antigen are shielded or flexible protein subdomains are stabilized. Several VHH-antigen complexes, including unstable antigens, have already been crystallised and their structure solved by molecular replacements.

Clinical Relevance

Microarrays or biochips provide an efficient way to obtain a global molecular perspective of human disease. DNA micro-arrays have been used extensively to generate transcriptional fingerprints of cancer. More recently, high-throughput techniques to study proteins have also been developed. Protein-based micro-arrays containing labelled antigens or antibodies offer the ability to study protein-protein interactions, identify biomarkers and study the humoral response to cancer.

However, the role of a VHH could go well beyond the target validation step, since many *in vivo* diagnostic and therapeutic molecules are derived from antibodies. The high degree of sequence identity between a VHH and a human VH and the minimal immunogenicity of a VHH suggest that the selected VHH used for target validation could easily be readapted into a diagnostic or therapeutic compound. Moreover, the VHH might create special opportunities for fast and reliable *in vivo* diagnosis at an early stage of the disease. The ideal cancer-imaging agent should deliver an amount of label sufficient to detect the smallest metastases against a low level of non-specific background signal. The minimal sized VHH based imaging agents would represent a valuable imaging tool. The rapid distribution of VHH over the whole organism, the superior potential in tissue penetration of minimal-sized VHH, combined with high affinity target binding and fast clearance of excess VHH from the circulation, represent the ideal basis for imaging purposes.

The employment of single domain antibodies as crystallisation aids will boost the process of crystallisation and structure determination of flexible and membrane proteins. The structural information about these antigens will be a valuable resource in drug design.

Cancer

Definition

Cancer is the name given to a disease characterized by the accumulation of cells, causing the formation of a tumor, which is always fatal when untreated and is therefore called malignant. Cancer may originate from almost every tissue in the body; it grows into neighboring tissues and organs and in half of the cases forms distant metastases. Benign tumors differ from cancers because they remain confined to the tissue of origin and are easily removed. The development of tumors involves frequent mutations in genes termed "oncogenes and tumorsuppressor genes". Cells in highly malignant human tumors often bear five to seven mutations. Many mutations afflict genes that regulate the cell cycle directly or have activities upon cell division. Thus, tumorigenic cells become insensitive to growth factors, replicate their DNA content more than once per cell cycle, and typically have more

than one centrosome per cell. The cancer cells have the ability to escape from destruction by the immune system.

Definition

Invasion and Metastasis as Markers of ► **Cancer Malignancy**

Cancer is a disease of those cellular activities that are essential for the development and the maintenance of the organism, namely growth, ► **differentiation**, tissue integrity and ectopic ► **apoptosis** (Fig. 1) (3). Loss of growth control leads to accumulation of cells producing a tumour. Loss of tissue integrity and ectopic survival marks the difference between benign non-invasive tumours and malignant invasive ones. Loss of differentiation is found in invasive tumours and in their non-invasive precursors. Invasion is characterized by the presence, i.e. survival and eventual growth, of cells in tissues different from their tissue of origin, implying their penetration through the ► **basement membrane** tissue barrier, e.g. epithelial cells in the stroma. Metastasis is characterized by the growth of cells in organs distant from the organ of origin (secondary site), e.g. breast cancer cells in the bone and colon cancer cells in the liver (Fig. 1). To form metastases, cancer cells need to be transported by the lymph and blood circulation.

Characteristics

Bioassays for Invasion and Metastasis

Various *in vivo* and *in vitro* assays have been used to analyse cellular and molecular mechanisms of invasion and metastasis. Some assays aim at a close mimic of the

Cancer Invasion and Metastasis: Cellular, Molecular and Clinical Aspects.

Figure 1 The multi-step invasion process of metastasis. Consecutive steps are: invasion from the primary tumour through the basement membrane into the surrounding tissue; intravasation; transport through the blood circulation; extravasation; survival and growth at a secondary site. Molecular crosstalks take place between cancer cells, host cells, extracellular matrix elements and environmental factors. Cancer cells are represented in grey and host cells in white. Thick arrows indicate transformation. Thin arrows indicate direction of movement. Gradients of chemokines (C), growth factors (G), pro-invasive and motility factors (M), proteases (P) point at their respective receptors at the cell surface (black dots). $\alpha\beta$, integrins; B, bacteria; BM, basement membrane; CAD, Ca^{2+} -dependent cadherins; En, endothelial cells; Ep, epithelium; F, fibroblast; H, hepatocyte; IgCAM, Ca^{2+} -independent immunoglobulin cell adhesion molecules; K, Kupffer cell; L, leukocyte; MF, myofibroblast; SD, space of Disse; St, stroma; VL, vascular lumen.

natural situation; others are limited to one invasion- or metastasis-associated cellular ► **phenotype**. Invasion is frequently accompanied by the transition from an epithelial differentiation towards a mesenchymal one, a phenomenon called ► **EMT** (4). In brief, when cells pass through a bare filter in a two-compartment chamber *in vitro*, their activity is called ► **migration**; when the filter is covered by a layer of ► **extracellular matrix**, it is called invasion. When cells produce

colonies in the lungs, liver or bone after subcutaneous or intravenous injection into syngeneic or immunosuppressed mice, they are called metastatic. ▶ **Transgenic** animals, comprising mice, fish, flies and worms are valuable tools in the analysis of invasion and metastasis.

Invasion and Metastasis is not Unique to Cancer

Invasion and metastasis, as defined above, are also observed in diseases caused by microorganisms, during embryonic development and in adults when leukocytes leave the bone marrow and home to various organs (3). Microorganisms invade the cells lining the alimentary and the respiratory tracts, where they cause enteritis and bronchitis; they eventually metastasise to distant organs such as the heart and the brain, where they cause endocarditis and meningitis.

Molecular Interactions

▶ Tumour Promoter and ▶ Suppressor Genes

Abnormal activation and inactivation of promoter and suppressor genes respectively are the cause of cancer (3). Loss of genes that are implicated in DNA repair will increase the risk of alteration in all genes that are sensitive to mutation and so influence the acquisition of invasion and metastasis in a non specific manner. Examples of invasion- and metastasis-specific genes altered in human cancer, as well as the criteria by which they were recognized are shown in Table 1A and 1B. Only for a minority of these genes do we understand the mechanisms by which the proteins they encode determine the invasive and metastatic phenotype. For example, the kinase *MKK4* is a metastasis suppressor because it restricts growth of cancer cells at the secondary site. Sometimes the abnormal expressions of promoter and suppressor gene products make the cells responsive to pro-invasive factors present in the tumour micro-environment (2). For example, a background of Ras activation makes the cells invasive upon loss of regulators of cell polarity or upon contact with cytokines such as TGF- β . The same pro-invasive molecules may emerge through various genomic alterations. For example, enhanced transcription of the pro-invasive matrix metalloprotease MMP7 may result from oncogenic mutation of ▶ **β -catenin** or of the ▶ **adenomatosis polyposis coli (APC)** gene. Several genomic changes are usually needed for the development of an individual tumour and its acquisition of invasiveness and metastasis. DNA micro array-based gene expression profiling of cancers as compared to their precursors reveals hundreds of differences in mRNAs and proteins. This multiplicity may be explained by the fact that the product of the oncogene controls the expression of many other genes. For example, the enhancer of zeste homolog 2 (EZH2) stimulates invasion and metastasis because it changes

the balance between suppressors and promoters through modulation of multiple genes. It is a matter of debate whether metastasis genes are already activated or inactivated in earlier stages of tumour development or only in later stages.

Regulatory Mechanisms Proteomes of Invasive Cells

Several ▶ **protein families** play a role in invasion and metastasis. Some of these proteins are the products of promoter or suppressor genes (Table 1A, B), others are targets of the proteins encoded by these genes. For example, when the tumour suppressor ▶ **Von Hippel Lindau (VHL)** protein is mutated, the DNA-binding hypoxia inducing transcription factor (HIF) fails to be degraded; this leads to the constitutive activation of the CXCR4 gene encoding a ▶ **receptor** for a motility factor that attracts metastatic cells. The members of these protein families emerged as key players in distinct activities of invasive cells. Cadherins and Ig-CAMs are crucial for homotypic and heterotypic ▶ **cell-cell adhesion**, respectively counteracting primary invasion and stimulating metastasis (1); their activity should not, however, be solely considered as mechanistic, since they participate extensively in ▶ **signal transduction** through their linkage with cytoplasmic components. Moreover, cadherins may undergo ▶ **ectodomain shedding** and their soluble fragments may regulate invasion. Integrin receptors and their extracellular matrix protein ligands regulate cell-matrix adhesion and de-adhesion mechanistically as well as inside-out and outside-in signalling, i.e. from the cell to the matrix and vice versa (5). This interaction has a dual function, arresting cells in the matrix and assisting migration. Motility factors and their receptors stimulate the locomotory machinery of the cancer cells and guide them through the invasion pathways (5). Proteases break down the extracellular matrix, paving the way for invaders. They may also release pro-invasive factors from the cell surface as well as from the extracellular matrix. Proteases act in cascades, with inactive precursors being activated by other proteases and active proteases being neutralized by specific inhibitors. Most normal cells are ▶ **anchorage dependent** for survival; when they are released from their substrate or when they arrive in an alien environment they go into ▶ **apoptosis**. Invasive cancer cells escape from apoptosis through activation of growth and survival pathways, as well as inactivation of death pathways. The role of the abovementioned proteins is not limited to single categories of cellular activities as they participate in integrated invasion programs. They all form multi-protein complexes, most of which establish networks together with other complexes. Remarkably, the same protein, e.g. β -catenin, may serve as an invasion-suppressor in one complex, e.g. the E-cadherin/catenin complex, and as

(A1) The genomic change is present in invasive (metastatic) lesions or their precursors and not in benign lesions or normal precursor tissues of a given tumour type; (A2) more rigorously, invasive and benign areas are obtained by micro-dissection and quantitative PCR from the same tumour. (B) The genomic change marks the difference between invasive and noninvasive variants of a cell line derived from the same tissue (same genetic background as evidenced by DNA profiling). (C) Transfection of cells with sense or anti-sense cDNA or siRNA causes conversion of the invasive (metastatic) phenotype. (D) Transgenic animals expressing or silencing the gene of interest in a specific tissue develop tumours with different invasive (metastatic) behaviour. To distinguish between invasion genes and metastasis genes, models are needed showing conversion from non-invasive towards invasive, non metastatic and from invasive, non metastatic to metastatic. I & M, the invasive and metastatic phenotypes conveyed by the genomic alteration have not been distinguished from one another; I, invasion but not metastasis; M, metastasis is conveyed upon an invasion-positive tumour. Gene names are according to UCL/HGNC/HUGO Human gene nomenclature databases.

an invasion-promoter in another complex, e.g. the APC/GSK-3 β complex. The networks constitute the positive and negative invasion signalling pathways (3). Such pathways are understood in terms of invasion factors binding to specific receptors that mediate transduction of the signal to stimulate or inhibit the cellular activities implicated in invasion and metastasis. Pivotal in the signal transduction are [small GTPases](#) of the Rho family that modulate assembly/disassembly of the [actin cytoskeleton](#) and as a consequence cell migration. Note that different types of tumours may use different invasion pathways and that even the same tumour may change invasion pathways following alterations of the context. This is realized in a versatile manner as the participant proteins can be modulated at multiple levels affecting their structure and their localization; examples are transcriptional modulation, proteolysis, [phosphorylation](#) and dephosphorylation and glycosylation. Taken together, this profusion of

regulatory systems permits cancer cells to invade following various strategies.

The Tumour Ecosystem

In the first issue of the Lancet (1889), Paget launched the "seed" and "soil" hypothesis, which is still valid today: the development of metastases results from the interaction between the cancer cells (the "seed") and the organ environment (the "soil"). Malignant tumours are not just a collection of cancer cells. In most of them, about half of the population consists of host cells that moved into the tumour from immediate or distant sites and all of which participate in invasion (2). Remarkably, these host cells show characteristics of invasive cells. When cancer cells lack oxygen, they produce vascular endothelial growth factors (VEFG) that attract blood- and lymph vessels to the tumour, a process called angiogenesis. Cancer cells produce cytokines, e.g. TGF- β , that cause the transition from stromal

fibroblasts into myofibroblasts, producing pro-invasive factors such as SF/HGF and tenascin C. Cancer cells release ►[chemokines](#) that attract white blood cells that release proteases, so paving the way for cancer cell invasion through a passive countercurrent mechanism. Considering this mutual cross talk between cancer cells and host cells, one may rightly ask the question who is invading whom (Fig. 1).

It is still not yet clear whether cancer cells spread to most organs and selectively grow as a consequence of the molecular conversation with the host or spread selectively to organs as a consequence of molecular attractants recognizing markers on the cancer cell and grow there. It has recently been found that not only host cells but also bacteria may participate in the production of pro-invasive factors. Taken together the recent observations confirm Paget's hypothesis and provide a molecular basis for it.

Host Defence Against Invasion and Metastasis

Metastasis is an inefficient process, as only a few of the cells that enter the circulation will ultimately form metastases. Such cells may remain dormant for several years and then form "late" metastases, well documented in the bone for breast cancer and in the liver for ocular melanoma. It is not clear whether inflammatory or immunological reactions target specifically metastatic cells and in this way are responsible for tumour ►[dormancy](#). Escape of cancer cells expressing tumour specific antigens from the defence mechanism has been shown through loss of ►[HLA](#) class I molecules that are needed for recognition by the immune effector cells or through a cancer cell-mediated anergic state of immune effector cells.

Medical Applications

Invasion and metastasis are the major determinants of tumour ►[prognosis](#). For most cancers, prognosis is based on staging according to depth of invasion and on grading according to degree of differentiation. It is the aim of adjuvant chemotherapy to destroy small nests of metastatic cells that remain after primary surgery and radiotherapy. The actual staging and grading is, however, not refined enough to spot those patients that bear such nests and are, therefore, good candidates for adjuvant therapy. The consequence is that many patients are treated with toxic agents without any benefit, for the simple reason that there are no cancer cells left. One of the expectations of molecular oncology is that the presence of metastasis will be predicted with high probability from the characterization of individual primary cancers, so that toxic treatment can be avoided. Moreover, a better molecular understanding of the mechanisms of invasion and metastasis might lead to new, more efficient and less

toxic treatment strategies. Here, the major obstacle to be overcome is the cancer cells' capability to reprogram their mechanisms of invasion and metastasis.

- ▶ RNA Capping

Capacitation

Definition

Capacitation describes the final maturation of sperm in the female reproductive tract that enables sperm to bind to eggs and undergo the acrosome reaction.

- ▶ Mammalian Fertilization

Cap-Dependent /Cap-Independent Translation

Definition

Cap-dependent/Cap-independent translation refers to protein synthesis using only capped mRNAs or uncapped as templates, respectively.

- ▶ RNA Capping

Capillary Electrophoresis

Definition

Capillary electrophoresis is a method for electrophoretic separation of biomolecules, or other large molecules, in (fused silica) capillaries with an inner diameter of 50–100 μm and 30–80 cm in length. The capillaries are filled with gel-material and electrophoresis buffer. Molecules such as DNA are separated by high voltage (5–30 kV). The use of a high voltage gradient (200–1000 V/cm) results in significantly faster electrophoresis than conventional gel electrophoresis in flat gels (about five times shorter). This is possible due to rapid heat dissipation of the capillary.

Synonyms

Control of protein synthesis

Definition

Translational control is defined as a change in the rate or efficiency of translation of one or more [mRNAs](#) per unit of time (1). The rate of protein synthesis is determined by (i) the amount of mRNAs present, (ii) the activity of the protein synthesis machinery, (iii) the abundance of [ribosomes](#) and (iv) the rate of peptide chain elongation. Therefore, changes in any of these factors may limit the rate of protein synthesis and thus regulate overall protein synthesis.

Characteristics

Translational control is the final step in a complex network of regulatory processes involved in the control of gene expression. In the process of translation the genetic information carried in the molecule of mRNA is converted into protein. This process takes place in three stages – initiation, elongation and termination. Although all three stages are targets of regulatory mechanisms, in most cases it is the initiation of

translation that is the rate-limiting step. This is probably due to the fact that it is more efficient to control the onset of a biological process rather than to interrupt it later and deal with the consequences of aberrant protein synthesis (1). Since translation is the last step in the flow of the genetic information, regulation at this level also allows for an immediate and rapid response to changes in physiological conditions without the involvement of mRNA synthesis and transport.

Cap-Dependent Initiation of Translation

The initiation of translation in a eukaryotic cell involves the recognition of mRNA by a specific subset of eukaryotic initiation factors (eIF) followed by recruitment of the ribosome, recognition of the initiation codon AUG and initiation of protein synthesis (Fig. 1). This mechanism is known as the scanning model (2). Because of the compartmentalization of the eukaryotic cell, the translation is spatially and temporally separated from mRNA synthesis (►transcription). Following mRNA synthesis in the ►nucleus, an m⁷G-cap structure is added on the 5' terminus and a poly(A) tail on the 3' terminus of the mRNA. The mRNA is further processed by ►splicing to remove non-coding introns before it is exported into the cytoplasm as a messenger ribonucleoprotein (►mRNP) complex (3). Once in the cytoplasm the m⁷G-cap structure is specifically recognized by cap-binding protein eIF4E, which is part of a larger multiprotein complex called eIF4F. eIF4F consists of eIF4E (cap binding protein), eIF4G (a scaffold protein) and eIF4A (an RNA helicase). The binding of eIF4F to mRNA commits the translation machinery to the translation of that mRNA by facilitating the binding of the 40S ribosomal subunit carrying the initiator methionine-►tRNA to the mRNA. Once the 40S subunit of the ribosome is bound to the mRNA it "scans" in the 5'–3' direction until an initiation codon is encountered. The 40S ribosomal subunit then stably binds at the initiation codon and is joined by a 60S subunit to form an 80S ribosome that commences protein synthesis.

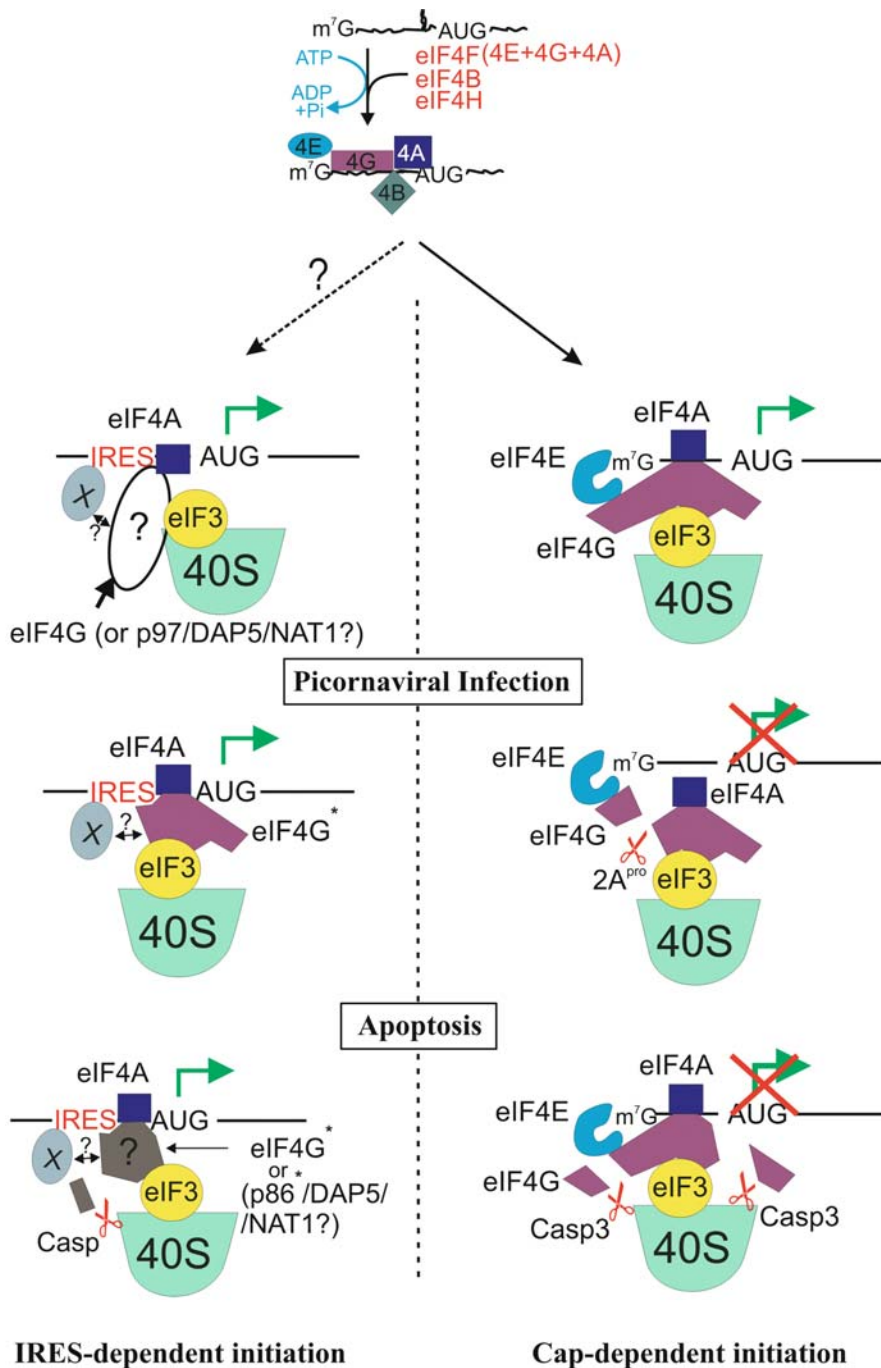

The rate of translation for a given mRNA is controlled by both RNA structural elements and protein factors. eIF4F is a key factor in selecting mRNA for translation and its activity is regulated by several mechanisms. (i) The affinity of the cap-binding complex is regulated by the phosphorylation of eIF4E and eIF4G, (ii) a group of proteins called 4E-BPs bind to eIF4E and prevent its association with eIF4G (the binding of eIF4E and 4E-BPs is also regulated by phosphorylation) and (iii) proteins that are structurally related to eIF4G such as PAIP and p97/DAP5/NAT1 can compete with eIF4G and thus regulate the affinity of eIF4F for mRNA. In addition, global protein synthesis can be controlled by regulating the formation of the ternary complex by changing the phosphorylation status of

eIF2 by four distinct ►protein kinases HRI, PERK, PKR and GCN2 (3). In addition to proteins, the binding efficiency of a given mRNA is affected by the length and secondary structure of the 5' ►UTR and placement of the initiation codon. The 5' UTR is a region between the cap structure and the initiating codon and is typically 50–70 nucleotides long with low degree of secondary structure. Extensive secondary structure within the 5' UTR is thought to be refractory to efficient translation. Indeed, the RNA helicase activity of the eIF4A subunit of eIF4F aided by eIF4B and eIF4H serves to melt the secondary structures in the 5' UTR and to allow binding of the 40S ribosome to RNA. The placement and type of the initiation codon also determine the efficiency of translation initiation. Most initiation in mammalian cells occurs at the AUG initiation codon, although other codons such as GUG, UUG or CUG are sometimes used. In addition, the initiation codon is often found in the favorable sequence context (Kozak sequence) with purines at positions –3 and +4. Deviation from this surrounding sequence may result in the ribosome scanning through and initiating at a different AUG in a more favorable context.

Cap-independent Initiation of Translation

Since eukaryotic translation machinery utilizes cap structure, the binding of the ribosome necessarily occurs at the 5' terminus of the mRNA. However, there exists an exemption to this rule. Some cellular mRNA transcripts and viral RNAs are translated by an internal ribosome entry (IRES) mechanism that is independent of the cap structure (4). The genomic RNA of ►RNA viruses is naturally uncapped and yet translated efficiently. In addition, during viral infection of cells by some members of the *Picornaviridae*, *Flaviridae* and retrovirus families, host protein synthesis is shut off to compromise the host anti-viral response. These viruses produce a protease that cleaves the eIF4E-binding domain from eIF4G so that it is unable to bind to the mRNA cap binding protein eIF4E (Fig. 1). The cleavage of eIF4G disables cellular translation but still allows the viral mRNA to be translated through a cap-independent mechanism using an IRES for translation initiation. Interestingly, the truncated form of eIF4G can stimulate translation of some of the viral RNAs containing an IRES. By this effective and clever mechanism the virus hijacks the cellular translation machinery, allowing the virus to maintain high levels of viral protein synthesis.

The IRES element is a specific regulatory sequence that is found in the 5' UTR of RNA and mediates translational initiation by directly recruiting and binding ribosomes, thus allowing for cap-independent translation. In addition to viral RNA, IRES elements are found in a limited but growing number of cellular

Cap-Independent Translational Control. Figure 1 Mechanisms of cap-dependent (right) and IRES-dependent (left) control of translation initiation. Conditions and initiation factors thought to favor one mode of translation initiation over the other under normal conditions (top), picornaviral infection (middle) and apoptosis (bottom) are shown. For clarity only eukaryotic initiation factors (eIF) pertinent to this essay are indicated. The cap-binding protein eIF4E (blue) recognizes and binds to the 5' m⁷GpppX cap structure. The capped end of the mRNA is bridged with the 40S ribosomal subunit (light blue) by an adapter molecule eIF4G (purple). The binding of eIF4G to the 40S subunit is facilitated by eIF3 (yellow). eIF4A (dark blue) is an RNA-dependent ATPase and RNA helicase involved in the unwinding of the secondary structure of the 5' UTR. Individual components of the translation machinery are not drawn to scale. Factor X represents a putative IRES-binding protein(s) that has been suggested by several laboratories to be involved in internal initiation. Asterisks denote initiation factors proteolytically modified (indicated by scissors) by viral protease (2A^{pro}), caspase 3 (Casp3) or other caspases (Casp).

mRNAs (Table 1). Interestingly, these mRNAs include growth factors, [▶oncogenes](#) and genes that are critically involved in the regulation of [▶apoptosis](#). There is no structural or sequence homology among cellular IRES elements so their discovery remains largely experimental. In addition, the mechanism by which IRES elements recruit ribosomes is not clear. The experimental evidence indicates that the IRES translation requires the canonical initiation factors as well as auxiliary cellular proteins. However, the IRES-mediated translation escapes many of the control mechanisms that regulate cap-dependent translation and was therefore proposed to be critical

for selective translation of mRNAs under physiological conditions, such as apoptosis, hypoxia, amino acid starvation or cell-cycle or during viral infection, when translation of most cellular mRNAs is compromised (5, 6). The regulation of cellular IRES translation is only poorly understood. The best-characterized mechanism so far is the regulation of IRES translation during apoptosis, where it was shown that the ►caspases cleave eIF4G and p97/DAP5/NAT1, resulting in the inhibition of cellular cap-dependent translation. The caspase-generated fragments of eIF4G and p97/DAP5/NAT1 however, selectively drive the translation of Apaf-1 and p97/DAP5/NAT1, presumably to enforce the commitment of cells to die.

Clinical Relevance

Since translation plays such a critical role in the control of gene expression it is not surprising that aberrant translational control correlates with many human pathologies. Increased levels of eIF4E and eIF4G were found in a broad spectrum of transformed cell lines and primary cancers. Furthermore, over-expression of eIF4E, eIF4G and some other initiation factors causes ►malignant transformation, presumably by allowing indiscriminate translation of cellular mRNAs. The accumulated data suggests that over-expression of eIF4E could be used as a valuable prognostic marker in breast cancers. Abnormal IRES translation also correlates with several human disorders. A point mutation in the IRES element of connexin 32 leads to a remarkable inhibition of connexin 32 translation and is found in some patients with ►Charcot-Marie-Tooth disease, a neurodegenerative disorder. Similarly, a point mutation in the IRES of an oncogene, c-Myc, found in patients with multiple myeloma resulted in a significant increase in c-Myc protein levels. Finally, many human viral pathogens depend on IRES function for translation of their proteins. For example, mutations in the IRES element of hepatitis C virus were found to correlate with increased virulence; conversely the attenuated neurovirulence of the Sabin strain of poliovirus used for vaccination is caused by a single nucleotide change in its IRES.

Cardiac Signaling: Cellular, Molecular and Clinical Aspects

MICHAEL GOTTHARDT, KATY RADDATZ
MDC, Berlin, Germany
gotthardt@mdc-berlin.de

Definition

The cardiovascular system distributes oxygen and nutrients in the organism according to the demands of the environment. The required short- and long-term adjustments depend on a complex system of signal transduction pathways that integrate biochemical and biomechanical cues to regulate cardiac growth and function (Fig. 1). The same signaling pathways that are essential for normal cardiac function mediate changes that accompany heart disease e.g. the hypertrophic gene response in ► [cardiomyopathy](#) or ► [apoptosis](#) in ► [myocardial infarction](#). Considerable effort has been put into elucidating these pathways as a basis for developing novel therapeutic strategies.

Overall the responses of the ► [cardiomyocyte](#) to diverse stimuli such as exercise, hormonal or pharmacological stimulation and hemodynamic overload are surprisingly uniform. A growing number of cardiac signaling pathways have been characterized, which include ► [G-protein](#) signaling pathways, the mitogen activated protein kinase (► [MAPK](#)) pathways, calcium signaling, protein kinase C, calcineurin, ► [AKT](#) and many others. Most of these pathways are interconnected and operate in concert to regulate growth, differentiation, cell death and the generation of active and passive forces in the ► [sarcomere](#). A summary of proteins involved in the various pathways is provided in Table 1.

Cardiac Signaling: Cellular, Molecular and Clinical Aspects. Figure 1 Signal transduction in the cardiomyocyte. Mechanical and biochemical signals (input layer) are communicated through the action on transmembrane or intracellular receptors. In the cytoplasm multiple signal transduction pathways, such as G-protein coupled receptor signaling, Akt/PKB signaling, mitogen activated protein kinase (MAPK) cascades and the Jak/Stat pathway integrate these signals to affect gene expression. Ultimately changes in gene expression help adjust the number of cardiomyocytes (growth and apoptosis) and their function (differentiation, contractility, and elasticity) to the needs of the organism. Heart disease is accompanied, and in part caused by, deregulation of cardiac signaling cascades that leads to excessive hypertrophy, dilation, and impaired ventricular function. Kinases are depicted in green, phosphatases in red, adaptor proteins in yellow, G-proteins and their regulators in orange, and transcription factors in blue. Arrows indicate stimulation (pointed) or inhibition (blunted). For abbreviations used also refer to table 1. SR, sarcoplasmic reticulum; ROS, reactive oxygen species; GPR, G-protein coupled receptor; RSTK, receptor serine/threonine kinase; RTK, receptor tyrosine kinase; CR, cytokine receptor; PIP, phospho-inositol-phosphate; IP₃, inositol phosphate; DAG, di-acylglycerol; Ca, calcium.

Characteristics

Cardiac Function

The cardiomyocyte has to perform the daunting task of producing sufficient energy for muscle contraction and ion homeostasis, turn over its protein content in less than three weeks and relay signals to adjust to environmental cues, while contracting at more than 60 beats per minute. These functions coexist and are mediated and regulated through signaling pathways that crosstalk, utilizing shared components, as exemplified for the calcium ion: Calcium is not only essential to develop the action potential, but also to develop active force (contraction of the heart in

►systole), to modulate the elastic properties (filling of the heart in ►diastole), to mediate the ►hypertrophy signal and to regulate glucose metabolism (through activation of phosphorylase kinase). These functions can only coexist through compartmentalization and rapid movement of calcium within the cell.

Not only can a single molecule cause a plethora of changes in the cardiomyocyte – conversely a number of pathways can converge on a common response such as the hypertrophic gene response, which can be activated through beta-adrenergic signaling, growth factors, cytokines, hormones and stretch. If these biochemical or mechanical stimuli persist for extended periods of

Cardiac Signaling: Cellular, Molecular and Clinical Aspects. Table 1 Proteins involved in cardiac signaling

Hormones, vasoactive peptides and catecholamines	Growth factor signaling
AT-II, angiotensin-II	4E-BP, eukaryotic initiation factor-binding protein
ET-1, endothelin-1	Akt, oncogene =PKB, protein kinase B
T3, 3,5,3'-triiodo-L-thyronine	ATF2, Activating transcription factor2
T4, L-thyroxine	Cdc42, homologous to yeast cell division cycle gene 42
NO, nitrogen oxide	c-Jun, oncogene "ju-nana" = 17 from avian sarcoma virus 17
epinephrine	ELK1, oncogene, ETS-domain protein
norepinephrine	ERK, extracellular signal regulated kinase;
acetylcholine	ERK1= p44; ERK2 =p42
Cytokines	ETS, E twenty-six
CT-1, cardiotrophin-1	Fyn, Src-family tyrosine kinase
IL, interleukin	GAP, GTPase activating protein
TNF, tumor necrosis factor	GEF, guanine nucleotide exchange factor
Growth factors and receptors	Grb, growth factor receptor bound protein
EGF, epidermal growth factor	GSK3, glycogen synthase kinase 3
FGF, fibroblast growth factor	HSP27, heat shock protein, 27 kDa
FGFR, FGF receptor	IRS, insulin receptor substrate
IGF, insulin-like growth factor	JNK, c-Jun N-terminal kinase
IGFR, IGF receptor	MAP, microtubule associated protein
PDGF, platelet-derived growth factor	MAPK, mitogen activated protein kinase
TGF β , transforming growth factor β	MAPKAPK, MAPK activated protein kinase
G-protein signaling	MAPKK, MAPK kinase
AC, adenylate cyclase	MAPKKK, MAPKK kinase
CaM, calmodulin	MEF2, mads box transcription enhancer factor 2
CaMK, calcium/calmodulin-dependent protein kinase	MEK, Map/Erk kinase
cAMP, cyclic adenosine monophosphate	MEKK, MEK kinase
CREB, cAMP responsive element-binding protein	MKP, MAP kinase phosphatase
CBP, CREB binding protein	mTOR, mammalian target of rapamycin
DAG, 1,2-diacylglycerol	NFAT, nuclear factor of activated T cells
G-protein, heterotrimeric guanine nucleotide-binding protein	p38=RK, reactivating kinase
GPR, G-protein-coupled receptor	p70S6K, p70 ribosomal protein S6 kinase
IP3, inositol-1,4,5-trisphosphate	PI3K, phosphoinositide 3-kinase
PA, phosphatidic acid	PLD, phospholipase-D
PI, phosphatidylinositol	PP2A, protein phosphatase 2A
PIP2, phosphatidylinositol-4,5-bisphosphate	Rac, a member of the Ras superfamily
PKA, protein kinase-A	Raf, a MAPKKK

Cardiac Signaling: Cellular, Molecular and Clinical Aspects. Table 1 Proteins involved in cardiac signaling (Continued)

Hormones, vasoactive peptides and catecholamines	Growth factor signaling
PKC, protein kinase-C	Ral, Ras-related protein
PLC, phospholipase-C	Ras, a monomeric GTPase (p21)
	Rho, Ras homologous
	RSTK, receptor serine/threonine kinase
	RTK, receptor tyrosine kinase
	SAPK, stress-activated protein kinase (JNK)
Cytokine signaling	SH domain, Src homology domain
CR, cytokine receptor	Shc, SH2-domain containing adaptor protein
gp130, membrane glycoprotein 130	Sos, mammalian homologues of Son-of-sevenless (a GEF)
gp130R, membrane glycoprotein receptor	Src, derived from the Rous sarcoma virus oncoprotein
JAK, Janus kinase	TAK1, TGF β activated kinase 1
LIF, leukemia inhibitory factor	
STAT, signal transducer and activator of transcription	
Apoptosis	
BAD, Bcl2-antagonist of cell death	
Stretch signaling	
GMEB, glucocorticoid modulatory element binding protein	
MLP, muscle LIM protein	
MURF, muscle specific ring finger protein	
Hormone signaling	
TBP, T3 binding protein	
TR, T3 receptor	

time, signaling pathways required for the adaptation of cardiac function have the potential to produce cardiac decompensation.

Signal Transduction

Biochemical and biomechanical signals are processed through transmembrane receptors and ion-channels (input layer, Fig. 1). In the cytoplasm and nucleus, the incoming signals are amplified and relayed through an intricate network of signaling molecules (signal-processing layer). Through changes in gene expression, the fate (differentiation, apoptosis) and function (growth, contractility, elasticity) of the cardiomyocyte are altered (output layer).

Signal transduction can lead to effects that are short-term (posttranslational modifications such as

phosphorylation), intermediate (changes in gene expression, alternative splicing), or long-term (adaptation through structural changes and changes in cell number). Regulation of signal transduction itself usually involves short-term changes such as translocation of proteins to the nucleus, redistribution of calcium between cytoplasm and **sarcoplasmic reticulum**, and changes in activity through phosphorylation or exchange of cofactors such as GDP for GTP.

Molecular Interactions

Biochemical Signals

G-Protein Coupled Receptors

►Catecholamines and ►vasoactive peptides exert their signaling functions through binding to the G-protein coupled seven-transmembrane-spanning domain receptors.

In the cardiovascular system there are three classes of **►G-protein coupled receptors**. The β -adrenergic receptor (β AR) is stimulated by epinephrine and norepinephrine and coupled to $G_{\alpha s}$. Beta-adrenergic signaling leads to increased heart rate and myocardial contractility. The second class comprises the cholinergic receptors, which are activated by acetylcholine and coupled to $G_{\alpha i}$, thus counteracting the stimulatory signals relayed through $G_{\alpha s}$. The third class includes angiotensin II, endothelin and α -adrenergic receptors, which are coupled primarily to $G_{\alpha q}$. They are less important in cardiac function but play a major role in the cardiac hypertrophic gene responses to pathological stimuli.

Growth Factor Signaling

Peptide growth factors such as TGF β (transforming growth factor β), FGF (fibroblast growth factor), and IGF (insulin-like growth factors) have been shown to play an important role in the hypertrophic gene response of cardiomyocytes. A common feature of these growth factor signaling pathways is ligand induced dimerization and cross-phosphorylation of their receptors, stimulation of MAP kinase and PI $_3$ kinase pathways to regulate cell growth, cell division, differentiation and apoptosis.

TGF β binds to three different receptors. Type-I and -II are receptor serine/threonine kinases (RSTK). Ligand binding to the type-II receptor leads to heterodimerization with the type-I receptor. Subsequently type-II receptor phosphorylates the type-I receptor, which transmits the signal to TAK1 (TGF β -activated kinase). TAK1 directly activates MEKK and leads to JNK and/or p38 activation (Fig. 1). For Type-III TGF-receptors no signaling function has been described so far.

FGF binds to a transmembrane receptor with intracellular tyrosine kinase activity (RTK). After ligand induced dimerization and cross-phosphorylation, the phospho-tyrosine residues serve as high-affinity binding sites for a number of intracellular signaling proteins which contain SH2 and **►SH3 domains**. Insulin-like growth factors (IGF) I and II promote cellular proliferation and/or differentiation through binding to a heterotetrameric receptor with tyrosine kinase activity. Ligand binding leads to phosphorylation of the catalytic receptor domains, which in turn phosphorylate insulin receptor substrates (IRS 1 and 2) on multiple tyrosines. IRS serves as a docking site for **►SH2 domain**-containing proteins such as PIK, Fyn, and Shc, resulting in Grb2, Sos and Ras activation.

Cytokine Signaling

►Cytokines are signaling molecules that act as local mediators in cell-cell communication, such as colony-stimulating factors, **►interferons**, and **►interleukins**. Ligands such as cardiotrophin, a member of the **►IL-6**

family and leukemia inhibitory factor (LIF) can induce cardiac hypertrophy or regulate energy metabolism.

Cardiotrophin 1 interacts with the gp130 receptor and the low affinity leukemia inhibitor factor receptor (LIFR). Ligand binding to the gp130-LIFR complex results in phosphorylation of associated Janus kinase signaling factor, which in turn phosphorylates the gp130 receptor, generating a docking site for SH2 domain-containing proteins (Shc, STAT). Thus the cytokine receptors are able to signal *via* several downstream pathways. The family of signal transducers and activators of transcription (STAT) are SH2 domain-containing factors that are phosphorylated by gp130. Activated STATs form homo- and heterodimers, translocate to the nucleus and bind response elements to induce transcription. Gp130 and/or LIFR activation has also been shown to induce MAPK signaling through activated Ras. In addition gp130 activation leads to PIK activation by a mechanism involving Jak1-mediated phosphorylation.

Hormone Signaling

The thyroid hormone is associated with several cardiovascular disorders. In **►hyperthyroidism**, heart rate, contractility, ejection fraction and coronary blood flow are increased, while peripheral vascular resistance is reduced. The active thyroid hormone is 3,5,3'-triiodo-L-thyronine (T3) which is formed by deiodination of L-thyroxine (T4) in the periphery. About 0.3% of serum T3 is in a free form, which can be taken up by the cells by an energy dependent process. The translocation of T3 into the nucleus is still unclear although different cytosolic T3 binding proteins (TBP) have been identified. The nuclear T3 receptor (TR) belongs to the superfamily of hormone responsive nuclear transcription factors. There are two TR genes with two alternative splice products per gene (TR α_1 , TR α_2 , TR β_1 , TR β_2). Cardiomyocytes express TR α_1 , TR α_2 (down-regulated by T3) and TR β_1 (upregulated by T3). T3 furthermore regulates expression of several proteins involved in muscle contraction (e.g. actin and myosin heavy chain) and Ca $^{2+}$ -handling (α_2 , α_3 and β subunit of the **►sarcolemmal** Na-K-ATPase) as well as markers of hypertrophy such as ANF. In addition it has been shown that T3 represses PKC α and PKC ϵ activity in **►neonatal** and PKC ϵ in the adult rat.

Biomechanical Signals

The Stretch Signal

Stretch leaves a mark on the subsequent contraction of cardiomyocytes, which enables the heart to adjust the ejection of blood in systole to the filling of the ventricle in diastole.

So far, it is largely unknown how the stretch signal is sensed and transmitted, but the giant elastic protein titin has been proposed to play a critical role in the process:

Not only do titin's elastic subdomains unfold according to the mechanical forces applied, but furthermore a plethora of titin binding proteins are related to signal transduction through their domain structure and/or translocation to the nucleus upon the application of stretch. Titin forms a continuous filament overlapping at the z-disc and m-line of the sarcomere. It contains a kinase domain, with a binding site for the ring-finger protein MURF-1 in close proximity. MURF-1 can translocate to the nucleus and bind the transcription factor GMEB-1. Titin's N-terminus has been implicated in sensing stretch through the titin binding protein MLP, although the mechanism remains elusive.

Stress

Deformation of the cardiomyocyte during contraction represents a mechanical stress for the cellular structures and induces several responses that modify cardiac rate and rhythm. Acute mechanical stress depolarizes the cell membrane and shortens the duration of the action potential by activation of mechano-sensitive ion channels including K^+ , Cl^- , Na^+ and Ca^{2+} channels. So far, it is largely unknown how the signal is relayed, but it has been shown that stretch activates PKC and AT-II and that both lead to an activation of Raf-1 and MAPK-signaling pathways.

Environmental stress can also be transmitted through proteins expressed in response to injury, such as the cytokines TNF or IL-1 and the cytoprotective factors bradykinin or NO. Stress in response to increased mechanical load is signaled in part through TGF β and angiotensin II. Overall these pathways work to either delimit injury through up-regulation of cytoprotective factors, or to induce tissue repair, when cytoprotection is insufficient to prevent apoptosis. The nature and coordination of these signaling pathways is only poorly understood.

Regulatory Mechanisms

G-Protein Signaling Pathways

All heterotrimeric **G-proteins** consist of $G\alpha$ and $G\beta\gamma$ subunits. Agonist occupation of a membrane-bound receptor leads to an exchange of GDP for GTP on the $G\alpha$ subunit and dissociation of $G\alpha$ from $G\beta\gamma$. The ratio of GTP bound active to GDP bound inactive state determines signal strength. Accordingly the G-protein signal is modulated by proteins that facilitate the exchange of GDP to GTP (such as the guanine nucleotide exchange factors (rhoGEF) or that increase hydrolysis of GTP to GDP (**GTPase** activating proteins – GAPs).

The $G\alpha$ and $G\beta\gamma$ subunits modulate the activity of different downstream signaling effectors – $G\alpha$ works through the adenylate cyclase and PKA to modulate the stretch signal, while the $G\beta\gamma$ subunit activates PLC and PKC linking to the growth factor signal transduction pathways (Fig. 1). Both pathways converge on

adjusting calcium levels. PKA phosphorylates a number of intracellular protein targets at serine and threonine residues e.g. **L-type calcium channels**, **phospholamban** (modulator of the sarcoplasmic reticulum associated ATP-dependent Ca^{2+} -pump), titin's elastic N2B domain and modulatory proteins associated with the contractile apparatus such as troponin I. Activation of PKA targets increases the intracellular Ca^{2+} -level, myocardial contractility and rate of relaxation. Increased Ca^{2+} concentrations in turn affect several Ca^{2+} -dependent proteins, such as calmodulin and calcineurin. In addition PKA phosphorylates G-protein coupled receptors (e.g. the β -adrenergic receptor), resulting in partial uncoupling and desensitization of receptors for further agonist stimulation.

Ras/MAPK Signaling

The oncogene ras is a low molecular weight GTPase that is activated by **G-protein-coupled receptors** (GPCR), receptor tyrosine kinases (RTK), Janus kinase 1 (**JAK**) or an increase in intracellular Ca^{2+} . Ras activation results in GDP to GTP exchange and activation of numerous effector proteins, Raf-1, PI $_3$ K, small GTPase Ral proteins, PKC and all three MAPK signaling branches. Ral promotes activation of PLD which catalyses the hydrolysis of phosphatidylcholine to phosphatidic acid (PA) and choline. PA is then further metabolized to 1,2-diacylglycerol (DAG), an activator of PKC. In addition Ral activates **cdc42** and **Rac-1**, two members of the **Rho family** of small GTPases. Both have been implicated in the regulation of the actin **cytoskeleton** and have been shown to stimulate two MAP kinases, p38 and **JNK/SAPK**.

Mitogen-activated protein kinase signaling pathways (**MAPK**) are activated in cardiomyocytes by G-protein-coupled receptors (GPRs), receptor tyrosine kinases (RTKs), transforming growth factor beta-receptor (TGFR), protein kinase C (PKC), calcium or stress stimuli. The upstream events result in the activation of Map/Erk kinase kinase (MEKK), which leads to the activation of Map/Erk kinase (MEK) factors and in turn to activation of the three terminal MAPK effectors, c-Jun NH2-terminal kinases (JNK1/2/3), extracellular signal-regulated kinases 1 and 2 (ERK1 and 2) and p38. The three mammalian MAPK families are defined by their distinct phosphorylation motifs, *Thr-Glu-Tyr* for **ERKs**, *Thr-Phe-Tyr* for the JNKs and *Thr-Gly-Tyr* for the p38. They activate various nuclear and extranuclear substrates by phosphorylation at serine and threonine residues. Extranuclear substrates of ERK comprise microtubule-associated proteins (MAP1, 2, 4 and **tau-protein**), which mediate **microtubule** rearrangements and changes in cell morphology.

Nuclear substrates of ERK and JNK include the ternary complex factor Elk-1 and the transcription factor

ANF2. ANF2 can heterodimerize with c-Jun, an additional substrate of JNK, to activate gene expression through the cAMP response element (Cre).

Downstream targets of p38 are the transcription factors MEF2, ATF-2 and ELK-1 as well as the cytoplasmic protein MAPKAPK2, which phosphorylates HSP27 and might protect cells against ►oxidative stress and apoptosis.

PI3K/Akt/GSK-3-Signaling

The serine threonine kinase ►Akt/PKB, plays a central role in diverse cellular processes, including glucose metabolism, proliferation and apoptosis. It mediates many events downstream of receptor tyrosine kinases (RTK), such as the IGF-1 receptor, ►Janus kinase (JAK-1), Ras and ►G-protein-coupled receptors (GPR) that induce the accumulation of phosphatidylinositol-triphosphates (PI3P) by the phosphoinositide 3-kinase (PI3K). Akt controls cell growth through mTor (mammalian target of rapamycin), which activates translation through p70S6 kinase and the translation initiation factor 4EBP1/eIF4E. In addition Akt also directly phosphorylates the proapoptotic protein BAD and glycogen synthase kinase 3 (GSK-3), thereby inhibiting their activity.

Ca²⁺-Signaling

Ca²⁺ is essential in cardiac electrical activity and is a direct activator of the myofilaments that cause contraction. Local calcium levels in microdomains within the cell are crucial to enable signaling function, while the electrical demands on the cardiomyocyte cause rapid changes in total cytoplasmic Ca²⁺ levels. Ca²⁺ influx and release from the sarcoplasmic reticulum (SR) is modulated after adrenergic stimulation through PKA. Accelerated relaxation is mediated by phosphorylation of phospholamban and troponin, which leads to increased Ca²⁺ reuptake and dissociation from the myofilament. Ca²⁺ reuptake is mediated by four pathways, sarcoplasmic Ca²⁺-ATPase, sarcolemmal Na⁺/Ca²⁺ exchange, sarcolemmal Ca²⁺-ATPase or the mitochondrial Ca²⁺ uniport. Elevated sarcoplasmic Ca²⁺ stores increase the developed contraction.

Ca²⁺ channels are regulated by stretch, receptors, membrane potential and internal Ca²⁺ stores. After activation, Ca²⁺ signals can act locally or recruit other channels to activate processes through a global increase in Ca²⁺. Since high levels of Ca²⁺ are toxic, the signal is modulated in amplitude or frequency. Different pathways can respond according to the duration or frequency of the Ca²⁺ signal, such as calmodulin dependent kinase II (CaMK) or induction of the serine-threonine phosphatase calcineurin, which in turn dephosphorylates members of the NFAT-transcription factor family or calmodulin dependent kinase II

(CaMK). Multiple Ras exchange factors and GTPase activating proteins are regulated by Ca²⁺ through CaMKII. Thus Ca²⁺ microdomains can influence growth through crosstalk with the ERK/MAPK pathway.

Medical Applications

►Heart disease is the main cause of death in industrialized nations. Patients with impaired cardiac function from various causes have benefited from treatment with drugs that interfere with signal transduction to counteract hypertrophy and improve remodeling of the heart muscle.

►Beta-blockers inhibit beta-adrenergic signaling and help improve cardiac performance by decreasing heart rate, thus improving ventricular filling. Additionally they reduce myocardial oxygen demand. Similar effects are obtained with Ca²⁺-channel blockers, such as verapamil, which do not impair responsiveness to sympathetic stimulation and help maintain blood pressure.

Angiotensin converting enzyme ►(ACE) inhibitors are used to treat congestive cardiac failure. Their anti-hypertrophic and anti-apoptotic action is mediated by increased bradykinin signaling and inhibition of myocardial renin-angiotensin-aldosterone system. The underlying mechanisms are still under investigation and include attenuation of PKC translocation to prevent down-regulation of Ca²⁺ cycling and activation of ERK signaling.

Cardiac signal transduction can also mediate the side effects of drug therapy such as the cardiotoxicity of the erbB2 receptor antibody (Trastuzumab/Herceptin). Understanding cardiac signaling, such as the ErbB2 signaling pathway in adult cardiomyocytes might help develop strategies to alleviate the cardiotoxic effects of Trastuzumab treatment, allowing for safer treatment of cancers over-expressing erbB2.

Cardiochip

CHOONG-CHIN LIEW

Harvard Medical School, Boston, MA, USA

cliew@rics.bwh.harvard.edu

Synonyms

Cardiovascular microarray; Cardiovascular DNA chip

Definition

The Cardiochip is a customized human cardiovascular gene-specific DNA-based [▶microarray](#), constructed in-house at our institution from genes derived from clones of our heart [▶cDNA](#) library. The Cardiochip enables us to review gene expression profiles for the study of cardiac growth and development, as well as study the progression of cardiovascular diseases. Such information may be utilized to develop specific molecular portraits of individual diseases and disease subtypes, to monitor disease progression at the molecular level, for diagnostic and prognostic purposes, to assess potential drug candidates or to investigate drug responses.

Rationale for the Cardiochip

Each living organ and organ system is associated with a set of genes that are involved in maintaining and regulating its function. The heart cells, for example, include cardiomyocytes, smooth muscle cells, endothelial cells, conduction cells for maintaining cardiac rhythm, neuroendocrine cells and other cell types; specific genes are associated with each of these cell types. Thus, transcripts derived from the cells of the heart represent the genes of the entire cardiovascular system. Our human heart [▶cDNA libraries](#) are representative of gene transcription in the heart tissues and thus of mRNA populations of all the genes of the cardiovascular system. Since the Cardiochip is based on our heart tissue specific library and the cDNA library, the chip provides a window for the study of the function, development and diseases of the cardiovascular system.

Cardiac specific genes are first expressed during embryonic development and function to control and regulate that development in a cell appropriate fashion. Embryonic heart cell genes signal stem cells to differentiate and to develop mature cells (i.e., cardiac myocytes) with a cardiac-specific structure. Cardiac myocytes divide during embryogenesis but lose their ability to divide soon after birth. Subsequent cardiac cell growth is achieved by an increase in cell size (hypertrophy), during maturation and later by accommodating fibroblasts when the heart is damaged during disease processes.

Microarray technology such as the Cardiochip tracks tissue specific gene expression at all stages of development and disease; thus, the technology can be used to characterize gene expression at various stages of disease. Microarray-based portraits of cardiovascular gene expression enable cardiovascular diseases to be compared at the gene level, using “snapshots” of different diseases or of the same disease over time.

Characteristics

We constructed our flexible, tissue-specific cDNA based “Cardiochip” microarray in-house at the Cardiovascular Genome Unit of Brigham and Women’s Hospital, Harvard Medical School. (1) We used PCR products generated from our comprehensive collection of cardiovascular [▶expressed sequence tags](#) (EST) derived from human fetal and adult heart, familial hypertrophic cardiomyopathic tissue and vascular cDNA libraries. After [▶BLAST](#) sequence similarity searching, we compiled the non-redundant Cardiochip which comprises to date, 10,848 spots. Of these spots, 2761 (25%) are known genes, 3406 (31.4%) are matched ESTs, 4489 (41.4%) are unmatched novel ESTs, and 192 (1.8%) are bacterial clones (for quality control purposes).

We have conducted a number of [▶hybridization](#) studies using the Cardiochip. This technique involves extracting RNA from the tissue of interest. The RNA probe is then color-coded (or “labeled”) using fluorescence technology and subsequently hybridized onto the chip. Hybridization capitalizes on the phenomenon that DNA of genes of interest recognize and bind complementarily to corresponding DNA on the microarray chip. After labeling and hybridization is complete, color images of the bound genes can be derived from each chip. These images allow convenient visualization of differential gene expression; they are also used to generate a quantitative measure for each gene’s expression level that can be used for statistical data analysis. These microarray results may be verified, either one gene at a time or in a high-throughput capacity, using real-time RT-PCR. Identifying up- or down-regulated genes may also provide insight into gene “pathways”, where certain genes trigger the expression of other genes in order to attain a disease state.

Our preliminary Cardiochip study compared samples of failing heart tissue (obtained at the end stage of hypertrophic cardiomyopathy) with normal heart tissue. (1) We identified 38 key transcripts among which were genes previously suspected to be involved in heart failure as well as several novel, previously uncharacterized genes. In a later study, we utilized the Cardiochip to explore end-stage dilated cardiomyopathy (2). We found more than 100 genes consistently differentially expressed in dilated cardiomyopathy as

compared to normal samples. Atrial natriuretic peptide was highly up-regulated in dilated cardiomyopathy samples, confirming its pivotal role as a marker of cardiac stress. In addition, numerous sarcomeric and cytoskeletal proteins, stress response proteins and transcription/translation regulators were up-regulated in dilated cardiomyopathy. Cell signaling channel and mediator proteins were prominently down-regulated, especially those involved in calcium signaling. Intriguingly, we also found several novel expressed sequence tags identified as differentially regulated. Such tags may represent key genes in the pathophysiology of heart failure. We have also developed gene expression profiles comparing dilated and hypertrophic cardiomyopathy, and identified several genes differentially expressed between these two diseases. (3) Most recently, we used the Cardiochip to determine that cardiovascular related genes form a distinctive cluster in the chromosome structure (4). A current study in progress is the characterization of the genetic profile of Chagas disease, a form of cardiomyopathy prevalent in Latin America; preliminary results indicate an up-regulation in chemokine- and cytokine-related immune genes, consistent with the established knowledge regarding the disease.

Clinical Relevance

Understanding the genetic basis of highly complex, multifactorial cardiovascular diseases is a major challenge. Many genes and gene pathways remain to be elucidated before we are able to convincingly map out the molecular mechanisms driving such diseases as hypertension, heart failure, atherosclerosis and other conditions.

Microarray technology is facilitating our exploration of complex cardiovascular diseases. The use of the Cardiochip and similar microarrays in cardiovascular medicine has been favorably reviewed (5, 6). Applied to the cardiovascular system, microarray technology has made it possible to carry out large-scale global gene expression profiles. Thousands of genes can be compared simultaneously, rather than one by one, and microarray technology distinguishes genes that are expressed and genes that are not. Such gene snapshots of disease samples can be compared with normal samples to indicate which genes are specifically up- or down-regulated; similarly, different cardiovascular diseases can be compared with one another to discover disease-specific differential gene expression. This type of information is essential for characterizing diseases at a molecular (as opposed to a histological or clinical) level. With the development of the Cardiochip and related microarray technologies, we now have genomic tools wherewith we can examine the genetic changes that

distinguish different stages of heart failure or any other heart condition (7). Further use of microarray technology should lead to clues about gene function, gene pathways and the identification of novel genes. Differing molecular disease portraits allow for the diagnosis of disease subtypes; using the Cardiochip, this information may be used to identify the molecular changes that occur in the cardiovascular system at different clinical stages of disease or drug response. Recent research has focused on further refinement to Cardiochip and other microarray systems (8). For instance, microarray studies have relied on tissue samples in the past. However, disease tissue is not always readily obtainable, especially in the case of heart disease. Thus, our laboratory and other groups are beginning to establish blood RNA-based microarray systems as alternatives to tissue-based systems for disease diagnosis and prognosis (9-11).

Casein Kinase I

Definition

Casein kinase I (CKI) represents a large family of ► [serine-threonine kinases](#) that are implicated in a variety of cellular functions and processes. CKI exists in multiple forms in mammalian tissues and is present in the nucleus, cytosol, plasma membrane and microsomes. CKIs prime β -catenin for phosphorylation by glycogen synthase kinase-3 (GSK3). It also binds and phosphorylates multiple other pathway components.

► [Wnt/Beta-Catenin Signaling Pathway](#)

Casein Kinase II

Definition

Casein Kinase II (CKII) are serine-threonine kinases that bind and phosphorylate ► [Dvl \(Dishevelled\)](#) in *Drosophila*. In vertebrates it has multiple roles in the Wnt pathway and phosphorylates multiple pathway components.

► [Wnt/Beta-Catenin Signaling Pathway](#)

Caspase

Definition

Caspases are cysteine proteases that facilitate ► [apoptosis](#) by cleaving a growing number of cellular targets. Caspases are synthesized as inactive zymogens that are proteolytically processed to produce mature, active proteases. In addition, caspases are arranged into a cascade, such that the upstream caspases (initiator caspases, such as caspase-9) activate downstream caspases

(effector caspases, such as caspase-3). Caspases also have apoptosis independent functions, e.g. in T-cell proliferation or IL1 maturation.

Definition

Rapid developing technologies that involve several types of functional RNA have received increasing attention as possible approaches to gene therapy. The functional RNAs, such as ▶ antisense RNAs, ▶ ribozymes and ▶ small interfering RNAs (siRNAs), inactivate genes in a sequence-specific manner at the mRNA level. ▶ RNA aptamers, namely, RNAs that can bind to proteins, have also been used to modulate gene function at the protein level. Selective modulation of gene expression is very important not only for the elucidation of the biological functions of individual genes but also for the phenotypic analysis of genes in living cells. In addition, functional RNAs have been tested for their ability to target specific disease-related genes in efforts to combat human diseases. With the accumulation of vast amounts of data from genome sequencing, potential targets for functional RNAs are rapidly being identified and validated and RNA-based systems that attack such targets are being evaluated in clinical trials. This essay focuses on recent advances that have been made with two types of functional RNA, ribozymes and siRNAs, as efforts continue to exploit them as therapeutic agents that will be useful in a clinical setting.

Characteristics

Application of Ribozymes

Ribozymes have been successfully employed to suppress the expression of disease-related genes in cultured cells and tissues and in living organisms. Ribozymes that cleave their substrates “*in trans*”, such as ▶ hammerhead and ▶ hairpin ribozymes, can cleave target RNAs specifically after they have bound to their substrate RNAs *via* base-pairing interactions (Fig. 1). Such ribozymes can target and cleave their respective substrates repeatedly, acting as authentic catalysts. Synthetic nuclease-resistant ribozymes have been evaluated in clinical trials. One such ribozyme is ANGIOZYME, which is directed against the transcript of the *Flt-1* gene, which encodes the high-affinity

Catalytic RNAs. Figure 1 Secondary structures of a hammerhead ribozyme (a) and a hairpin ribozyme (b). The polyX corresponds to the sequence that is complementary to the target RNA. These ribozymes can cleave any RNA substrate that contains an NUH triple, where N is any nucleotide and H is A, C or U in the case of the hammerhead ribozyme, or GUC in the case of the hairpin ribozyme.

receptor (VEGF-R1) for vascular endothelial growth factor (VEGF) (1). Since VEGF is involved in angiogenesis, namely, the formation of new blood vessels, it is required for the sustained growth of tumor. VEGF appears to be a promising target for therapeutic antagonists such as ribozymes. In mice, ANGIOZYME efficiently and dose-dependently inhibits the metastasis of colorectal cancer to the liver. This ribozyme was tested in patients with advanced malignancy.

Although synthetic ribozymes can inhibit the expression of specific genes, their application over long periods of time is severely restricted in living cells or organisms. To overcome this limitation, numerous viral and non-viral vectors have been developed for the stable expression of ribozymes. In such cases, strong and constitutively active **▶promoters** are employed to control the expression of each ribozyme. The **▶RNA polymerase III** (pol III) system has proved to be useful in this context since (i) large numbers of extra sequences are not required for appropriate transcription and termination and (ii) levels of expression are higher than those obtained with the **▶RNA polymerase II** (pol II) system. One of the specific pol III systems involves the promoter of genes for tRNAs. Hairpin ribozymes produced under the control of the promoter of the human gene for tRNA^{Val} efficiently inhibit the replication of various strains of HIV-1 in cells in culture (2). In addition, **▶hammerhead ribozymes** transcribed from the human tRNA^{Val} promoter have been used to confirm the roles of **▶p300** and **▶CBP**, which are

transcriptional co-activators, in retinoic acid-induced differentiation, cell-cycle arrest and apoptosis of embryonal carcinoma cells (3).

The promoter of the human gene for tRNA^{Val} has been also used for the production of a dimeric ribozyme known as the **▶maxizyme**. The maxizyme is an allosterically controllable ribozyme that has cleavage activity only in the presence of its specific target sequence. Thus, a maxizyme can be designed such that its activity is evident only, for example, in the presence of an abnormal RNA sequence, such as the junction sequence of the chimeric mRNA generated by the *BCR/ABL* rearrangement. This rearrangement is the molecular equivalent of the Philadelphia chromosome that arises from the reciprocal chromosomal translocation t(9;22)(q34;q11). Chronic myelogenous leukemia (CML) is a clonal myeloproliferative disorder of hematopoietic stem cells that is associated with the Philadelphia chromosome. Appropriate targeting of the chimeric *BCR/ABL* fusion would kill tumor cells specifically, while normal cells would remain unaffected. A maxizyme directed against the junction sequence of *BCR/ABL* did, indeed, disrupt the chimeric transcript specifically without affecting the normal *BCR* and *ABL* transcripts in murine cells. Furthermore, the maxizyme efficiently killed BV173 cells, which were derived from a patient with leukemia who carried the Philadelphia chromosome. The potential utility of the maxizyme in the treatment of CML has also been assessed in a murine model of

CML. All mice, without exception, that had been injected with cells from a patient with CML died of diffuse leukemia within 13 weeks. By contrast, all mice remained disease-free when the CML cells that were injected had been treated with the maxizyme prior to injection. These results suggest that maxizyme technology might provide a useful approach to the treatment of CML (4).

In addition to the potential utility of ribozymes in a clinical setting, combinatorial ribozyme libraries are useful for the identification of genes that are associated with specific phenotypes in mammalian cells. Several reports have described systems for screening for novel functional or disease-related genes using ribozymes with randomized binding arms. For example, a library of hammerhead ribozymes with randomized binding arms allowed the identification of certain genes that are involved in the migration of cells that is an essential feature of ►metastasis, one of most serious problems in cancer therapy (5). A line of highly invasive cancer cells, HT1080 fibrosarcoma cells, normally migrates toward a chemoattractant. However, after treatment with the library of randomized ribozymes, some of the cells did not migrate toward the chemoattractant. Sequencing of the randomized regions of the ribozymes that were then isolated from the nonmigrating cells and a search for the sequences in databases allowed the rapid identification of genes that are likely to play a role in metastasis. Two ribozymes directed against the transcript of *ROCK1*, one of the genes that regulate the ►actin cytoskeleton, were found among 924 positive ribozyme clones obtained in such an experiment. These two ribozymes inhibited the migration and invasion by invasive HT1080 cells almost completely without any effect on the proliferation of the cells. Similar experiments with a library of ribozymes with randomized binding arms have also allowed identification of genes involved in ►Fas- and ►TNF α -mediated apoptosis and cell invasion. Such ribozyme technologies are powerful tools for the development of gene-inactivating reagents of therapeutic importance and for the rapid identification of disease-related genes.

RNAi – a Brief Description

RNA interference (RNAi) has emerged as another novel tool for the silencing of gene expression in animals and plants. In this phenomenon, double-stranded RNA (dsRNA) induces the sequence-specific degradation of a cognate mRNA. In mammalian cells, RNAi with long dsRNAs was first described in mouse embryonal carcinoma cells and embryonic stem cells. However, long dsRNAs (of more than 30 bp) also induce non-specific responses as a result of inhibitory effects on protein synthesis and the degradation of mRNA in mammalian somatic cells.

Tuschl and coworkers demonstrated that 21-nucleotide (21-nt) synthetic RNA duplexes with 2-nt 3' overhangs, defined as small interfering RNAs (siRNAs), specifically suppressed the expression of endogenous genes in mammalian cells (6). It became apparent subsequently that siRNAs are associated with a multicomponent nuclease, the ►RNAi-induced silencing complex (RISC) and that they guide this enzyme so that it can catalyze the sequence-specific degradation of the cognate mRNA (Fig. 2).

Successful experiments with synthetic siRNAs were followed by the development of several vector-based systems for the expression of siRNA that could also induce RNAi in mammalian cells. This technical advance not only allowed the long-term expression of silencing effects *in vivo* but also opened the door to the therapeutic application using vector-mediated RNAi.

Clinical Relevance

Clinical Application of RNAi

The phenomenon of siRNA-mediated gene silencing *in vivo* is extremely powerful and sequence-specific. Thus, RNAi technology clearly has significant potential for application in a clinical setting. Indeed, considerable progress has been made in assessing the potential utility of RNAi that is directed against specific pathogenic genes (Table 1).

Studies of the potential utility of siRNAs as anti-viral agents have already shown that synthetic and vector-based siRNAs can inhibit the replication of HIV-1 at several stages of infection, including the very early stage. Moreover, infection by HIV-1 was blocked by targeting either viral genes or host genes that are involved in viral infection or proliferation. RNAi technology has also been applied to the evaluation of drugs against hepatitis C virus (HCV) using an HCV-replication system that supports the replication of the virus, but not the production of infectious virions. siRNAs directed against HCV RNA efficiently eliminated replicating HCV RNA from human hepatoma cells. Furthermore, siRNAs targeted to the 5'-untranslated region (5'UTR) of HCV suppressed HCV replication by 80% at a relatively low dose of siRNAs. Vector-based siRNAs also significantly suppressed the replication of HCV. Nonetheless, most RNA viruses can become resistant to single-drug therapies because they can mutate rapidly. Thus, for example, siRNAs directed against the poliovirus genome failed to prevent production of viruses completely because of the rapid mutation of this virus. Multidrug and multitarget strategies will have to be developed as effective methods for preventing viral proliferation.

The potential utility of RNAi in cancer therapy is also being examined. Most human tumors have multiple mutations that include dominant mutations in oncogenes or tumor suppressor genes. For example, tumor

Catalytic RNAs. Figure 2 A model for RNAi. The RNase III-related endonuclease, known as Dicer, cleaves dsRNA into siRNAs. Subsequently, siRNAs associate with the RISC, and then this enzyme catalyzes the sequence-specific degradation of target mRNA.

cells with mutated genes for p53 can proliferate at abnormally high rates. p53 is a transcription factor that plays a crucial role in the maintenance of cell-cycle arrest at the G1 phase after DNA damage. The *RAS* genes (*K-RAS*, *H-RAS* and *N-RAS*) encode guanine nucleotide-binding proteins that interact with the inner

plasma membrane and transduce external signals to the interior of the cell. *RAS* genes are frequently mutated in some human cancers, in particular, pancreatic and colon carcinomas. Single base-pair mutations that affect the functions of the *p53* or *RAS* genes occur frequently during oncogenesis. RNAi can specifically

Catalytic RNAs. Table 1 Examples of the application of siRNA, targeted against transcripts of genes related to infectious diseases or cancer

Virus or disease	Target gene or protein	Cell line	Source of cells	Type of siRNA	Phenotype

Catalytic RNAs. Table 1 Examples of the application of siRNA, targeted against transcripts of genes related to infectious diseases or cancer (Continued)

Virus or disease	Target gene or protein	Cell line	Source of cells	Type of siRNA	Phenotype
Breast cancer	<i>p53</i>	MCF-7	Mammary adenocarcinoma	Non-viral vector	Suppression of G1 arrest
Pancreatic cancer	K-RAS V12	CAPAN-1	Human pancreatic carcinoma	Retroviral vector	Suppression of tumorigenicity
Colon cancer	K-ras	SW480	Human colon carcinoma	Non-viral vector	Suppression of proliferation
Prostate cancer	Zeste homolog2 (EZH2)	RWPE	Prostate carcinoma	Synthetic siRNA	G2/M arrest
Prostate cancer	Fatty acid synthase	LNCap	Prostate carcinoma	Synthetic siRNA	Suppression of cell proliferation
Liver cancer	<i>cyclin E</i>	Hep3B, HepG2	Hepatocellular carcinoma	Synthetic siRNA	Suppression of cell proliferation
Angiogenesis	VEGF	cJ4	Rat fibrosarcoma	Synthetic siRNA	Suppression of TSP1 resistance
Colon cancer	hTERT, hTR	HCT-15	Colon carcinoma	Synthetic siRNA	Suppression of telomerase activity
CML	<i>bcr/abl</i>	K562	Chronic myeloid leukemia	Synthetic siRNA	Suppression of bcr/abl

inhibit the expression of *p53* or *RAS* genes with single point mutations, without affecting the wild type genes. In attempts to combat leukemia, siRNAs directed against *BCR/ABL* mRNA specifically disrupted the expression of the chimeric gene but did not affect the expression of normal *BCR* and *ABL* genes in cultured cells. The development of other siRNAs might lead to effective treatments for other cancers. For example, it was reported that siRNAs can inhibit telomerase activity in human cancer cells. ▶ **Telomerase** activity protects cells from senescence and might be an important target for anti-cancer drugs. siRNAs, targeted to either human telomerase reverse transcriptase (hTERT) or to human telomerase RNA (hTR), have been shown to reduce telomerase activity in carcinomas and sarcomas.

Successful RNAi has been demonstrated not only in cultured mammalian cells but also in mice. For example, when siRNA that was designed to target a gene for luciferase was introduced into mice that expressed luciferase, by the rapid injection in a large volume of physiological solution into the tail vein, levels of expression of luciferase were suppressed by 80–90% in the liver, spleen, lung, kidney and pancreas. Delivered by the same technique, siRNAs designed to target the NS5B region of HCV suppressed the expression of luciferase in mice that harbored a gene

for luciferase fused to the NS5B of HCV. Viral and non-viral vectors should also be useful in a clinical context.

Future Applications

Recent advances have shown that RNA-based technologies have obvious and significant potential in the treatment of patients with malignant disorders. Ribozymes are now being developed not only as potential therapeutic agents but also as tools for the identification of genes involved in certain diseases, such as certain cancers. In addition, RNAi technology now allows researchers to modulate gene expression more easily and, thus, to clarify and identify the role of known and unknown genes. The recent discovery of yet another new class of RNAs, micro-RNAs (miRNAs), suggests that they too hold great promise as future therapeutic agents. miRNAs are small non-coding RNAs of 18–25 nt in length. Numerous miRNAs have been found in animals and plants. Some act as repressors of their target mRNAs at the translational level. Such repression requires the presence of partially complementary sequences in the 3'-untranslated regions (UTRs) of the target mRNAs. It was reported that miRNA-23 participates in the retinoic acid-induced neuronal differentiation of NT2 cells, which are human embryonal carcinoma (EC) cells (7). miRNA-23 is expressed in differentiated NT2 cells

and promotes neuronal differentiation *via* regulation of the expression of Hes1, which is a negative regulator of the differentiation of NT2 cells. These results suggest that it might even be possible to regulate the differentiation of stem cells exogenously by introducing appropriate miRNAs. This technology suggests that, in the future, it might be feasible to engineer the phenotypes of certain cells and tissues, in addition to preventing the unchecked proliferation of malignant cells.

cDNA

Definition

cDNA (complementary DNA) is a DNA that is copied from an RNA molecule with the help of the enzyme “reverse transcriptase”, and therefore does not contain any introns that are present in genomic DNA. In contrast to the unstable and single stranded RNA, the cDNA is chemically more stable and can be easily manipulated (e.g. cloning, sequencing).

Cell Cycle Checkpoints

Definition

Cell cycle checkpoints refer to mechanisms that monitor cell cycle progression and prevent premature entry into the next phase of the cell cycle. In general, activation of cell cycle checkpoints leads to the arrest of cell cycle progression in the presence of damaged DNA. If repair is successful, cell cycle proceeds. In cases where the repair fails, the cell undergoes apoptosis or becomes tumorigenic (cancer).

Definition

The cell division cycle describes the ordered sequence of events that cells undergo in order to duplicate. Cell divisions are not only required for producing the approximately 10^{14} cells that make up an adult human being, starting from a single fertilized egg, but also during adulthood, when many cell types need to be continuously replaced. Appropriate control over the cell-cycle is critical in order to produce the appropriate number of cells in every tissue and to secure the error-free propagation of the genome. Major tasks to be accomplished during the cell cycle are the precise duplication of the genome (DNA) and its accurate segregation (in the form of chromosomes) into the two daughter cells. In eukaryotic cells, the duplication and segregation of the genome usually occur as two discrete and non-overlapping processes; DNA replication occurs during ▶S phase (S for synthesis) and chromosome segregation during ▶M phase (M for mitosis). M and S phases are separated by two gap phases, termed G1 and G2. This basic outline of the cell-cycle and the molecular wiring of its controls have been highly conserved during eukaryotic evolution, but individual cell types and species may exhibit significant variations in the temporal and spatial choreography of cell-cycle events. Cell-cycle control relies not only on transcriptional and translational regulation but also, to a large extent, on posttranslational mechanisms, primarily phosphorylation and the proteolytic degradation of key regulatory proteins. Surveillance mechanisms, so called checkpoint controls, assure the proper order and completion of cell-cycle events. Internal or external signals also control the transitions between the cell-cycle and a state of quiescence. Deregulation of the cell-cycle may result in aberrant responses to mitogenic stimulation and/or the destabilization of the genome and thus give rise to cancer and other hyperproliferative disorders.

Characteristics

Most somatic cells in an adult organism exist in a non-dividing, resting state (G0). However, stem cells enter the cell-cycle as required for tissue homeostasis and some resting cells can also be re-activated to replace cells that have been lost due to injury or cell death. Most cells exit the cell-cycle from early ►G1 phase, but exit from ►G2 phase also occurs (e.g. with certain epidermal cells). Arguably the most spectacular stage of the cell-cycle is M phase, when chromosome segregation (mitosis) and cell division (cytokinesis) occur. Proliferating human cells in culture usually undergo M phase in about 1 h, whereas ►interphase occupies about 17–24 h. Interphase, the time between one M phase and the next, thus consists of G1 phase, S phase and G2 phase.

G1 Phase

During G1 phase, cells grow in size. Moreover, they choose during early G1 between continued division or withdrawal from the cell-cycle. Cells may exit into ►G0 phase if unfavorable conditions prevail, or if they receive anti-mitogenic signals from other cells. Cells in G0 remain biochemically active but undergo no DNA synthesis or cell divisions. They may be prompted to re-enter the cell-cycle (G1 phase) by appropriate mitogenic stimulation. In the presence of favorable conditions and mitogenic stimuli, cells proceed through the cycle. A point of no return exists in G1 phase where cells become committed to undergo a complete round of cell division, even if unfavorable signals subsequently prevail. This checkpoint in G1 of animal cells was termed the restriction point (R-point; equivalent to Start in yeast) and divides the G1 phase into early G1 (when cells are responsive to growth or differentiation signals) and late G1 (after commitment to cell division, when cells prepare for DNA replication).

S Phase

Both the genome and the ►centrosome (the microtubule organizing center of animal cells) need to be duplicated exactly once per cell-cycle. In mammalian cells, DNA replication and duplication of the centrioles (short cylinders of microtubules that lie at the center of the centrosome), take place during S phase. Both events are coordinated by the cell-cycle control system. This system regulates the expression of enzymes required for DNA synthesis; it activates origins of replication at the beginning of S phase and prevents the reinitiation of DNA synthesis (and centriole re-duplication) at later stages of the cell-cycle.

G2 Phase

The G2 phase separates S phase from M phase. It can provide additional time for growth before cells enter mitosis. Checkpoint controls during G2 phase can

arrest the cell-cycle if DNA has been damaged or if not all DNA has been replicated.

M Phase

During M phase, sister ►chromatids, representing duplicated and connected strands of DNA that were originally generated during S phase, are separated and segregated. Moreover, in tight temporal and spatial coordination with the segregation of the duplicated genome, cytokinesis, the actual process of cell division takes place. Each daughter cell thus receives an exact copy of the genome, one centrosome and similar shares of other cytoplasmic organelles and macromolecules. Mitosis in vertebrate cells is usually subdivided into five stages. In the first stage, prophase, replicated chromosomes undergo condensation, the duplicated centrosomes migrate apart and spindle assembly begins (Fig. 1). Breakdown of the nuclear envelope then marks the beginning of prometaphase and sister chromatids can thus be captured by spindle microtubules. (The ►mitotic spindle is a bipolar microtubule array that serves to segregate attached sister chromatids to opposite poles. This requires that two microtubule bundles, emanating from opposite poles of the spindle, attach to ►kinetochores, proteinaceous complexes assembled at the so-called centromeres of the sister chromatids). Prometaphase ends when all sister chromatids are properly bound to the spindle and have migrated to its center, the metaphase plate. During metaphase the sister chromatids remain aligned on the spindle. A signal to separate sister chromatids then initiates anaphase and mitotic exit. Importantly, this signal is delayed by the spindle checkpoint until all chromosomes have undergone bipolar attachment. In anaphase the sister chromosomes are pulled to opposite poles of the spindle (anaphase A) and the spindle poles themselves move further apart (anaphase B). Finally, in telophase, the spindle disassembles and the nuclear envelope reforms around the decondensing chromosomes.

Temporally overlapping with exit from mitosis, cells proceed through cytokinesis. Animal cells form a cleavage furrow with the help of a contractile ring (composed of actin bundles and myosin II) that gradually pulls their membranes inwards. Membrane depositions then allow the cell surface to grow and the final separation (abscission) of two newborn daughter cells occurs.

Specialized Cell-Cycles

Even though the basic outline of the cell-cycle described above is used by most eukaryotic cells, there are important variations from this scheme. Most notable is ►meiosis, the process by which diploid parental cells give rise to haploid germ cells. In this case, a single round of DNA replication is followed by

Cell Cycle – Overview. Figure 1 Cell division seen under the fluorescence microscope: Dramatic changes in cell architecture occur as cells (here human osteosarcoma U2OS cells) enter mitosis. DNA (blue, stained with Hoechst) condenses, the centrosomes (orange, highlighted with an antibody against γ -tubulin) move apart and microtubules (green, detected by an antibody against α -tubulin) reorganize to form the mitotic spindle. From left to right: interphase; prophase; prometaphase; anaphase and cytokinesis. (Courtesy of Elena Nigg)

two sequential divisions. During meiosis I, the homologous chromosomes pair and segregate from each other. Sister chromatids then separate during meiosis II, which resembles mitosis in somatic cells. Another deviation of the canonical cell-cycle is seen during endoreduplication (e.g. in salivary glands of insects) when multiple rounds of DNA replication occur without intervening M phases. Finally, in the embryonic cell-cycles of some species, G1 and G2 phases are largely suppressed, so that the fast alternation of S and M phases results in extremely rapid divisions.

Regulatory Mechanisms

To ensure that cell-cycle events are triggered in the correct order and only once per cycle, a complex regulatory network governs all major cell-cycle transitions. Moreover, surveillance mechanisms monitor the completion and accuracy of cell-cycle events. When irregularities are detected (e.g. DNA damage, incomplete DNA replication, incorrect chromosome attachment to the spindle), these surveillance mechanisms block cell-cycle progression at specific times and are thus referred to as checkpoints.

Cell-cycle control is to a large extent based on a combination of regulated protein synthesis, phosphorylation and proteolysis. These mechanisms are interdependent in that phosphorylation controls the machinery regulating synthesis and degradation, and conversely, many enzymes involved in phosphorylation are controlled by synthesis and degradation. Together, these mechanisms assure the unidirectional progression through the cell-cycle. Irreversibility is brought about by positive feedback loops and protein destruction.

Principles

Kinases and Phosphatases

At the center of cell-cycle control are the protein kinases of the **cyclin-dependent kinase (CDK)** family. The most prominent members of this family function in cell-cycle control (CDK1, 2, 4 and 6) and CDK activation (CDK7), others control basal transcription by RNA polymerase II (e.g. CDK7,8 and 9) as well as migration and differentiation of post mitotic neurons (CDK5). As indicated by their name, activation of the inactive CDK requires binding of a positive regulatory subunit called cyclin. Several cyclins are typically expressed at specific stages of the cell cycle (Fig. 2). These cyclins are usually classified as G1, G1/S, S and M phase cyclins.

The catalytic activity of CDKs is controlled by distinct mechanisms. In addition to cyclin binding, these include activating and inhibitory phosphorylations and binding of CDK inhibitory proteins. Inhibitory phosphorylation of CDK1 by specific kinases (Wee1, Myt1) and activating dephosphorylation by the Cdc25C phosphatase are especially important at the onset of mitosis. During interphase, the binding of members of two families of CDK inhibitors (**CKIs**) plays a key regulatory role especially during the G1/S transition.

In their function as master regulators of the cell cycle, CDKs are supported and controlled by additional protein kinases. Some of these kinases are implicated in the regulation (both positive and negative) of CDK activity. In turn, some of these non-CDK kinases (as well as phosphatases) are under the control of CDKs. For example, Cdc7 cooperates with Cdk2 during replication and Polo-like kinases (Plks)

Cell Cycle – Overview. Figure 2 The cell cycle. Key regulatory proteins are indicated next to the position of the cell cycle where they are active. Cyclin dependent kinase complexes are shown in green and E3 ubiquitin ligases are shown in red. The red bar in G₁ phase represents the restriction point.

and Aurora kinases play central roles, along with Cdk1, in regulating the progression through mitosis.

Synthesis and Proteolysis

Periodic expression of most cell-cycle regulatory proteins relies on a balance between their synthesis and their destruction. In most cases, regulation of synthesis depends on transcriptional mechanisms. This frequently involves activation of transcription factor complexes or inactivation of repressors, processes that can in turn be regulated by phosphorylation.

Some cell-cycle regulatory proteins are relatively stable during most phases of the cell-cycle but become unstable at other specific times. Destruction of these proteins frequently involves attachment of poly-ubiquitin chains and subsequent degradation by the proteasome. Key determinants conferring specificity for degradation are ubiquitin ligases. Of this family of enzymes, two sub-families play a central role in the proteolysis of cell-cycle regulators. At the G₁/S transition, ubiquitin ligases belonging to the ►SCF sub-family target CKIs, G₁ cyclins and other substrates for proteolysis. SCF complexes (SCF stands for Skp1,

Cullin and F-box protein) contain three core subunits (Skp1, Cul1 and Rbx1) and one interchangeable subunit known as F-box protein. Each F-box protein targets a subset of substrates for destruction. Substrate recognition frequently requires prior modification by phosphorylation.

The second class of ubiquitin ligases important for cell cycle control is the ►APC/C complex (APC/C stands for anaphase-promoting complex/cyclosome). Proteolysis initiated by APC is required for the metaphase to anaphase transition. In contrast to SCF, APC function does not require phosphorylation of the substrate but activation of the APC core enzyme. At least two different activating subunits, termed Cdc20 and Cdh1, associate consecutively with APC and control its activity from the metaphase/anaphase transition (Cdc20) until late G₁ phase (Cdh1).

Subcellular Localization

The function of several cell-cycle regulatory proteins is also controlled at the level of their localization. Some cyclins, for instance, shuttle between the nucleus and the cytoplasm. Import into and export from the nucleus

usually depend on specific signal sequences, termed NLS (nuclear localization sequence) and NES (nuclear export signal), respectively. The functionality of these signals during the cell cycle can be subject to regulation by phosphorylation/dephosphorylation and/or interactions with other proteins.

Cell-Cycle Concepts

The G₁/S Transition and the Retinoblastoma Protein (pRb) Pathway

The decision as to whether to continue proliferation or exit from the cell-cycle is made during G₁ phase. Upon passage through a specific point in G₁, called the restriction point (R-point), cells become insensitive to lack of growth factors or differentiation signals (Fig. 3). In contrast to normal cells, most cancer cells appear to have lost R-point control. At the molecular level, R-point passage was proposed to depend on a short-lived protein, whose synthesis would be sensitive to growth factors. D-type cyclins meet this criterion. Through their association with CDKs, and in concert with cyclin E, they indeed control the G₁/S transition. The major substrate of the CDKs that are activated by D-type cyclins is the **retinoblastoma protein** (pRb). This tumor suppressor gene product becomes increasingly phosphorylated at multiple sites during G₁ progression. When hypophosphorylated, pRb binds transcription factors, notably members of the E2F family, and recruits them into a repressor complex. Mitogenic stimulation leads to activation of cyclin D/CDK4 or 6. Cyclin D dependent initial

phosphorylation of pRb then leads to release of transcriptional repression and activation of the cyclin E promoter. The cyclin E/CDK2 kinase is initially kept inactive by CDK inhibitor proteins of the Cip/Kip family. Destruction of these inhibitors allows the kinase to further phosphorylate pRb, leading to further activation of E2F-mediated transcription. As a result, genes are expressed that encode proteins required for DNA synthesis, inactivation of APC/C, and further progression through the cell-cycle. These genes include cyclin A and CDK1.

DNA damage signaling activates transcription by the p53 tumor suppressor. Among the proteins induced by p53 is the CDK inhibitor p21. This inhibitor inactivates cyclin E/CDK2 and prevents the hyperphosphorylation of pRb, thereby leading to cell-cycle arrest. Thus, DNA damage inhibits the G₁/S transition, in part through the pRb pathway. Components of the p53 and the pRb pathways are among the most frequently mutated proteins in human cancer.

A Single Round of DNA Replication

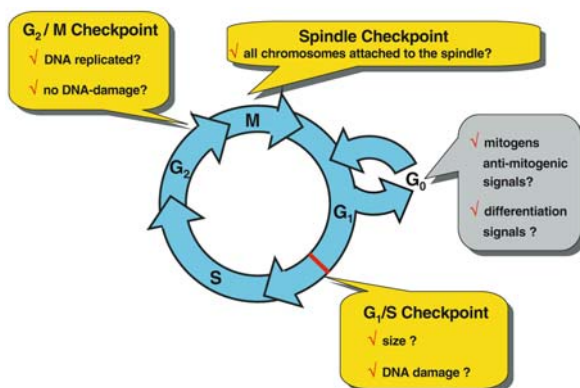

DNA replication initiates at origins of replication. The assembly and activity of the replication machinery at origins is controlled by several kinases, including CDKs. CDK activity is first required for the activation of origins and later prevents reinitiation of replication during late S, G₂ and M phases. During these latter stages, active CDKs inhibit the formation of pre-replication complexes and thus prevent “licensing” of DNA for replication.

The G₂/M Transition

The G₂/M checkpoint arrests cells prior to entry into mitosis if DNA is unreplicated or damaged. Damage signaling involves several kinases that up-regulate Wee1 and Myt1 and inhibit Cdc25C. This prevents the activation CDK1, which is required for entry into mitosis. DNA damage signaling also activates p53, which induces transcription of proteins such as p21, GADD45 and 14-3-3 and, moreover, inhibits the mitotic Plk1 kinase. In the absence of checkpoint signaling, both CDK1 and Plk1 become activated and a positive feedback loop supports maximal activation of CDK1/cyclin B.

The Spindle Assembly Checkpoint and Exit from Mitosis

A key checkpoint prevents sister chromatid separation until all chromosomes are properly attached to the mitotic spindle. Bipolar attachment of microtubules to kinetochores generates tension. Both attachment and/or tension can be monitored. Even a single unattached kinetochore activates the checkpoint and prevents the metaphase to anaphase transition. After all chromosomes are properly aligned on the spindle, the APC/C is activated by Cdc20 and triggers proteolysis of a

Cell Cycle – Overview. Figure 3 Cell cycle checkpoints. Negative signals from incomplete earlier cell cycle events or damage signals can provoke cell cycle arrest at specific points called checkpoints (yellow). External signals (grey) like lack of growth factors or differentiation signals may lead to withdrawal from the cell cycle into the G₀ phase. After transition through the restriction point, indicated by a red bar, cells become insensitive to growth factors and differentiation signals and committed to one round of cell division.

subset of proteins, notably cyclins and the anaphase-inhibitor securin. Destruction of securin activates separase, a protease that cleaves cohesion proteins, allowing the separation of sister chromatids. In parallel, the progressive inactivation of Cdk1, due to cyclin destruction, initiates mitotic exit. Finally, chromosome segregation has to be coordinated in time and space with the formation of a cleavage furrow (Fig. 1). The error-free segregation of complete sets of chromosomes in every cell division is essential to prevent the onset of chromosomal instability, a hallmark of human cancers.

Definition

Cell division is the process by which a cell separates itself into two parts (infrequently more parts) to generate two genetically equal daughter cells.

Characteristics

The physical division of cells is a requirement of natural growth in unicellular organisms as much as in complex organisms. In order to multiply a cell needs to duplicate its own composition, cytoplasmic organelles and genetic material. Only then will cell division proceed by separation of the nucleus (► [mitosis](#)) and cytoplasm (► [cytokinesis](#)). This process is restricted to somatic cells, since germ cells form four haploid cells out of one diploid cell (► [meiosis](#)). In normal somatic cells, division occurs as part of a complete cell-cycle (“cell division cycle”). Moreover, the decision for cytokinesis and mitosis are linked to the cell-cycle at several stages. This limits ► [centrosome](#) amplification and DNA replication to once per cell-cycle. In all organisms cell division is highly regulated. Molecules required for the regulation of this process are often highly conserved in evolution. During development of metazoans cell division may occur symmetrically or asymmetrically. The orchestrated events leading to cell division are important contributors to human diseases, specifically ► [cancer](#), if de-regulated.

Plant cells differ significantly from animal cells. Plant cells lack certain structures such as centrosomes. On the other hand, plant cells have specialized structures such as specific cytoskeletal structures, phragmoplasts and unique microtubule associated proteins. These differences lead to subtle differences in cell division. To describe cell division and its dependence on proper execution of mitosis and cytokinesis, we will focus on details in animal cells.

Mitosis and Cytokinesis

Mitosis has long been recognized to occur in stages. These stages are inter-, pro-, meta-, ana- and telo-phase and are microscopically distinguishable (Fig. 1). Directly after chromosomal DNA replication (in the S phase of the cell-cycle) interphase marks the beginning of mitosis. ► [Chromosomes](#), with their sister ► [chromatids](#), are discrete but not visible. Centrioles are now being replicated into two small daughter centrioles.

Cell Division. Figure 1 Mitosis and its stages.

Early prophase is marked by centrosome movements towards opposite sides of the cell. Now, the chromosomes are visible and the nuclear membrane breakdown begins. In late prophase condensation of chromosomes is finished. Structurally each chromosome contains two chromatids attached by a centromere. Specific spindle fibers (►mitotic spindle) are built. These consist of microtubules and are made inside the cell in a region close to the centrosomes. While the centrosomes move towards the opposite poles, some of the fibers contact the other pole. In addition the fibers contact chromatids and attach to the kinetochores. In metaphase the chromosomes orient themselves in one plane, which is sometimes called the equator of the cell. It is not until anaphase that the two sister chromatids are separated. Now two separated chromosomes are present, each containing a centromere. The spindle fibers connect each centromere to one pole. The separated chromosomes begin to move towards the poles. Telophase is characterized by the formation of new membranes. These form to build new nuclei around the chromosomes, which now uncoil again and thus become less visible. The spindle fibers disappear and microtubules are depolymerized. Cytokinesis is nearly complete. Throughout this process, both centrioles at the poles have grown. Finally, both descendants have a full-sized centriole. Only after the end of cytokinesis can both new cells enter another cell-cycle.

Regulatory Mechanisms

The molecules required for cell division, are believed to be under the control of a complex network of “cyclins”, kinases and inhibitors. These periodically expressed molecules are active at discrete stages of the cell division cycle but mainly act in the ►checkpoints of the cell-cycle. At any of these points cell division may be

halted, potentially corrected or proceed. The core of the molecules acting in the cell-cycle and checkpoints are dimers consisting of a catalytic and a kinase molecule, a cyclin and its “cyclin dependent kinase” (CDK). These complexes are themselves under the control of secondary modifications (like phosphorylation and ubiquitination). As part of the cell-cycle these events may lead to an increase in gene expression, intracellular translocation, protein degradation, nuclear envelope breakdown, DNA replication, chromosome separation and lastly to cell division.

Sometimes cytokinesis is viewed as the last stage of mitosis. Mitotic events regulate the location of the future cleavage plane through an unknown mechanism. It is known, that a contractile ring of actin and myosin constricts the cell during cytokinesis. This contractile ring and future cleavage will develop where the chromosomes line up during metaphase. It is still unclear which components of the mitotic machinery predict where the contractile ring will assemble. Analyses in sea urchin embryos suggest that the two ►asters, not the spindle itself, are critical for the prospective cleavage plane. These astral microtubules may signal to cortical regions, activating the polymerization of actin and myosin, which form the contractile ring where the cleavage furrow later starts. Since the signal has yet to be identified, it has been hypothesized that the cyclin dependent kinase CDC2 may be responsible. This kinase is not only activated throughout the relevant phases of the cell-cycle but is known to have a number of important substrates including myosin. CDC2 induced phosphorylation can promote the assembly of myosin filaments. Therefore, down-regulation of CDC2 is required for mitotic exit. This example serves to illustrate how cytokinesis may be linked to the cell-cycle.

Cell Division Concepts

Cell Division in Development

As exemplified in the early development of *Drosophila melanogaster*, cell division may be altered to fit the needs of speedy growth; for a short time nuclear growth is uncoupled from cell division. During early development of this fruit fly, nuclear division occurs through 13 rapid and synchronized rounds in the fertilized egg. Within this shared cytoplasm all nuclear divisions occur in short cycles. DNA synthesis alternates with mitosis without distinguishable interphases. This unusual stage of development is termed the “syncytial blastoderm”. After another round of duplication, the bulk of the nuclei migrate to the cortex of the embryo. Then, cellular walls emerge that divide the embryo into individual cells. At this stage, the “cellular blastoderm”, cell division gradually lengthens including a gap-phase. There is strong evidence to suggest that sequential destruction of mitotic cyclins by the

► **anaphase-promoting complex (APC/C)** may be important. In post-blastoderm embryos, cyclins A and B are degraded prior to the metaphase/anaphase, at the transition and during anaphase. It seems that, cyclin A degradation is required to disjoin sister chromatids. In addition, cyclin B degradation is required for cytokinesis and stable kinetochore-spindle attachments during anaphase. Stabilized cyclin B is able to block cytokinesis completely during early divisions. Conversely, homozygous *cyclin B* mutant embryos have an advanced onset of cytokinesis during early development. Cyclin B seems to act partly through a Rho-GEF, which is also required for initiation of cytokinesis. Lastly, cytokinesis in early and late *Drosophila* embryos depends on regulation by mitotic cyclin degradation. This is an example of tight-knit interaction between regulators of cell division with an active role in development.

Aberrant Cell Division Leads to Cancer

Molecular analysis of human cancer revealed that the genome of tumor cells usually acquires a number of mutations. In many cases these mutations are harbored within specific classes of genes. These genes that were later shown to be responsible for the initiation of the tumors were called “oncogenes and tumor suppressors” (among these genes some have viral counterparts, viral oncogenesis). Most mutations are inflicted upon genes that regulate the cell-cycle directly or have an activity upon cell division. As a consequence of these mutations, tumorigenic cells are insensitive to growth factors, replicate their DNA content more than once per cell-cycle and have typical aberrant ► **mitotic figures** or more than one centrosome per cell. Cells in highly malignant tumors often bear five to seven mutations. Not surprisingly, cells in such tumors are able to execute cell division in an uncontrollable fashion. Recent findings suggest a new group of molecules that link cytokinesis, chromosome segregation and tumorigenesis. The ► **serine/threonine kinases** Aurora are a family with three members in mammals. All Aurora genes map to loci frequently altered in human tumors. The proteins differ in their activities, timings and localizations. Aurora A is implicated in centrosome maturation and spindle assembly, whereas Aurora B has been proposed to regulate chromosome condensation, cohesion and segregation as well as kinetochore assembly and control of ► **spindle check-points**. In the case of Aurora A direct evidence suggests it to be a cancer susceptibility gene. Ectopic expression of Aurora A can transform rodent cells. More importantly, over-expression yields tetraploid cells. These cells display numerous extra centrosomes. Usually, additional numbers of centrosomes are recognized at the spindle checkpoint. Thus a cell division failure leads here to centrosome over-duplication, which finally produces

cellular aneuploidy. The resistance of some tumors to chemotherapeutic agents may partly be explained by similar failure in their mitotic spindle checkpoint.

Specialized Cell Division: Asymmetry

In specific cases cell division establishes two unequal descendants. Often this asymmetry is based on the polarity within the dividing cell. The establishment of polarity is considered to be the basis of differentiation and cellular diversity in higher organisms. Examples are embryonic stem cells (ES-cells) and specialized sheets of cells (including epithelial and neuronal cells) in nematodes.

In embryonic stem cells (ES-cells) there is a fine balance between symmetric and ► **asymmetric cell division**. In ES-cells symmetrical division occurs as part of their unlimited proliferative capacity. Self-renewal is a hallmark of stem cells. Only upon differentiation does unequal distribution of specific factors create two unequal descendants, one committed cell with a restricted fate and another progenitor cell with unlimited self-renewal potential. This asymmetrical division of an isotropic cell (in all directions completely symmetrical) is a rather unusual behavior. A number of mechanisms or specific factors may regulate this specific cell division in ES-cells. These potentially involve the generation of cell polarity within the cell, the orientation of the mitotic spindle and the segregation of differentiation or stem cell determinants into the two daughter cells. All these mechanisms have been likened to the establishment of polarity and epithelial-mesenchymal transition in the embryo. Molecules like APC, dynein-dynactin, PKC ζ , actin and myosins are currently under scrutiny for potential roles in this process.

In a genetic screen of the nematode ► *Caenorhabditis elegans*, defects in the axis determination of the early embryo were observed. The underlying defects were attributed to mutation of the PAR molecules. This family of proteins is now reckoned to be important for the planar polarity of a variety of cells in many organisms. In *C. elegans* in response to fertilization, PAR3, PAR6 and PKC become localized to the posterior pole of the zygote. Thus, PAR proteins polarize the embryo. The function of the PAR protein is also required to position and rotate the spindles along the anterior-posterior axis of the embryo. Again PAR3, PAR6 and PKC are important to tether the posterior centrosome close to the cortex (thereby forcing its change in shape). This action is believed to originate from asymmetric forces applied by the astral microtubules. Cortical forces applied to these microtubules in turn are controlled by PAR action. Apart from its interaction with PKC, PAR is also downstream of and dependent on CDC42, another link to cell polarity and asymmetrical cell division.

Cell Division Cycle 42 Protein

► CDC42

Cell Lineage Specification

Definition

Cell lineage specification refers to the process by which signals direct a multipotent cell (capable of entering a number of differentiation programmes) towards a particular tissue fate.

► Somitogenesis

Cell Membrane

► Biological Membranes

► Cell Polarity

Cell Migration

Synonyms

Cell Motility

Definition

Cell migration is a highly integrated multistep cellular process involving the active movement of individual cells or cell sheets. Migration (motility) is important throughout whole life of an organism. During gastrulation, large groups of cells migrate collectively as sheets to form the resulting three-layer embryo. Later on in embryonic development, cells (for example the neural crest cells) migrate from various epithelial layers to target locations, where they then differentiate to form the specialized cells that make up different tissues and organs. In the adult organism, cell migration governs tissue repair and regeneration (during the renewal of skin and intestine, new epithelial cells migrate up from the basal layer and the crypts, respectively). Migration is also crucial for immune surveillance, in which leukocytes from the circulation migrate into the surrounding tissue to destroy invading microorganisms and infected cells and to clear debris. Migration contributes to several important pathological processes, including vascular disease, osteoporosis, chronic inflammatory diseases such as rheumatoid arthritis and multiple sclerosis, cancer metastasis, and mental retardation.

Cell migration is initiated by chemical signals (► chemokines, ► growth factors, signals from the ► extracellular matrix), that via cell surface receptors initiate a complex cascade of events, including the activation of ► G proteins or ► tyrosine kinases, the production of PI (3,4)P₂/PIP₃, and the stimulation of Rho family proteins.

In general, cell migration can be described as a cyclic process involving cell polarization, adhesion and traction of the cell, and detachment of the cell rear. In response to a migration-promoting agent (chemotactic agents like chemokines) the cell starts to polarize and extend protrusions in the direction of migration. These protrusions can be large, broad lamellipodia or spike-like filopodia. Their formation is usually driven by actin polymerization. Rho family proteins are central regulators of actin and adhesion organization and thereby control the formation of lamellipodia and filopodia. ► Cdc42 also contributes to cell polarization by mediating reorientation of the microtubule organizing center (MTOC) toward the cell front, inducing the growth of microtubules and release of vesicles into this region. Adhesion molecules, like integrins, are activated by PI3Ks, PKCs, and/or Rap via talin, and they stabilize the protrusion via structural connections to the actin filaments. These adhesion sites then serve as traction sites. While the cell moves forward over them, these contacts are broken up at the cell rear and the cell can detach. The disassembly of adhesions is controlled by pathways that include FAK, ERK, Src, and the protease calpain, as well as microtubule dynamics.

Retraction at the rear requires Rho kinase and is a myosin-dependent process.

Definition

Cell polarity is a fundamental property of eukaryotic cells and refers to the polarized organization of the ▶ cell membrane with associated proteins, as well as to the polarized arrangement of the ▶ cytoskeleton and organelles within the ▶ cytoplasm and to the vectorial transport of ▶ secretory vesicles. Some types of neurons are highly polarized cells harboring elaborate dendritic extensions (▶ dendrites) at the postsynaptic side and ▶ axonal outgrowths at the presynaptic side. Similarly, epithelial cells are organized along a cellular axis that extends from the apical side facing an external lumen to the basal side facing either the ▶ extracellular matrix or adjacent cells. In addition to this apical-basal axis of polarity, epithelial cells are often oriented within the plane of the tissue along a proximal-distal axis, which is referred to as “tissue polarity” or “planar polarity”.

Genetic studies (performed mainly in the genetic model organisms *Caenorhabditis elegans* and *Drosophila melanogaster*) along with biochemical and tissue culture experiments have identified a set of genes that are essential for establishing apical-basal and “planar polarity” within epithelial cells. Some of these genes are also required for neuronal cell polarity. Cell polarity

genes regulate diverse biological processes including cell and tissue morphogenesis, ▶ cell migration, and organ morphogenesis. Moreover, the polarized state of neuronal and epithelial cells is a prerequisite for the physiological functions of mature tissues. Examples of these functions include the directional transport of nutrients through the gut ▶ epithelium, the secretion or reabsorption of ions and solutes in epithelia of glands and kidney ducts and the correct establishment of neuronal connectivity. The failure to establish or maintain cell polarity causes abnormal cellular functions and can result in disease. This chapter reviews the molecular mechanisms that lead to the establishment of apical-basal cell polarity in vertebrate epithelial cells and gives an overview of related human disorders.

Characteristics

The correct establishment and maintenance of cell polarity begins with the correct formation of an ▶ apical junctional complex that initiates ▶ cell adhesion and controls the creation of different membrane compartments. Next, apical and basolateral membrane domains are supported by sorting and targeting mechanisms for membrane material and proteins. The latter process requires that the cytoskeletal tracks used for vesicle trafficking are oriented towards cellular cues that propagate the maintenance of cell polarity.

The Formation of the Apical Junctional Complex

Evidence from tissue culture systems indicates that the initial spatial cues for the establishment of epithelial cell polarity are generated at the cell surface by cell-cell contacts or cell-extracellular matrix (ECM) contacts. Cell adhesion is mainly mediated by E-cadherin, a member of the Ca^{2+} -dependent ▶ cadherin superfamily of ▶ adhesion molecules, and nectins. On the future basal side, cell-ECM adhesion is mediated by the integrin superfamily of adhesion receptors. Cell adhesion initiates the restricted localization of basolateral membrane proteins whereas cell-ECM adhesion is required for organizing the apical-basal axis of polarity (reviewed in 1).

The apical junctional complex comprises several protein complexes, each assembled around a membrane protein linked to several submembraneous scaffolding proteins (2, 3). Many of the proteins involved contain the PSD-95/Discs large (Dlg)/ZO-1 (PDZ) protein-binding domain and establish links with the ▶ actin or ▶ microtubule cytoskeleton. The principal players within the apical junctional complex are the cadherin/catenins, the Par6/atypical protein kinase C (aPKC) and the Crumbs (Crb)/ Stardust (Sdt)/Pals-1 protein complexes. The latter two complexes localize to the subapical region of the membrane and are required to define the apical character of the cell membrane. A fourth protein complex formed by the

proteins Scribble (Scrib), Dlg and Lethal giant larvae (Lgl) appears to define basolateral membrane character. Genetic and biochemical studies have demonstrated that these proteins act in a regulatory pathway that is essential for the establishment of apical and basolateral membrane domains. However, the biochemical mechanisms responsible for the ►genetic interactions are currently not known.

On an ultrastructural level, the formation of the apical junctional complex results in the establishment of circumferential apical-lateral ►adherens junction (AJ) belts. The AJ is comprised of the E-cadherin/catenin cell adhesion system and is associated with an apical ►microfilament ring that regulates cell shape. In addition to mediating cell adhesion, the AJ is essential for the coordinated movement of epithelial tissues. Moreover, ►tight junctions (TJ) form in close proximity just apical to the AJ. In vertebrates, the TJ presents an important morphological difference between epithelial and non-epithelial cells. The TJ provides the most apical cell-cell junction and acts as a selective permeability barrier restricting paracellular diffusion across the epithelium. In addition, the TJ forms an intracellular fence against lateral diffusion of membrane proteins and lipids, thereby contributing to the maintenance of apical-basal polarity. The mechanisms by which non-epithelial cells that lack the TJ maintain a highly polarized surface are currently unknown. TJ function is dependent on transmembrane proteins including claudins, occludin and the junctional adhesion molecule (JAM). Currently, there are no ►animal models for these TJ genes.

Several human diseases have been linked to genes involved in the establishment of the apical junctional complex. These diseases fall into two classes.

- The first class includes several malignant tumors of an epithelial origin. Some of these tumors are associated with a down-regulation of E-cadherin. Loss or down-regulation of E-cadherin causes the breakdown of tissue integrity and epithelial barrier function and can result in inappropriate cell motility. Similarly, β -catenin has been implicated in tumorigenesis, possibly due to a role as a component of the ►Wnt signaling pathway. ►Peutz-Jeghers Syndrome (PJS) is an autosomal dominant disorder characterized by the development of multiple gastrointestinal hamartomatous polyps (benign epithelial and stromal overgrowth). Subsequently, a high percentage of PJS patients will develop malignant tumors at an early age. PJS is caused by mutations in the *Lkb1/Par4* gene that encodes a serine/threonine ►kinase required for the establishment of cell polarity (4, 5).
- The second class of diseases is comprised of several diseases that affect tissue integrity and result in

epithelial degenerations or malformations. This class includes retinitis pigmentosa (RP) type 12 that is caused by loss-of-function mutations in *crbl1* (6). RP is characterized by the progressive degeneration of the ►photoreceptor cells associated with disrupted AJ and results in severe visual impairment. Since a wide range of phenotypes can be observed in patients with mutations in *crbl1*, the ►genetic background may modulate the ►expressivity of the symptoms. Mutations in the *nectin-1* gene resulting in truncated forms of the protein are responsible for the cleft lip/-palate-ectodermal dysplasia syndrome. Whether the nectin adhesion complex is essential for the establishment and maintenance of adherens junctions is unclear.

Polarized Secretion and Protein Targeting

The best evidence for the involvement of vesicle targeting during cell polarization comes from studies in cultured epithelial cells. According to these studies, both endocytic and transcytotic pathways are utilized for membrane protein sorting. In addition, membrane proteins synthesized *de novo* go through the ►Golgi into the ►trans-Golgi network (TGN), where they are directly sorted as basolateral or apical membrane proteins. Apical targeting of proteins appears to require the assembly of membrane proteins onto ►lipid rafts. The glycosylphosphatidylinositol (GPI) domain present in several apical membrane proteins is sufficient for direct apical sorting. Similarly, basolateral sorting signals are present in the cytoplasmic tails of several proteins. PDZ domain-containing proteins have been shown to play a key role in protein targeting. The PDZ domain facilitates binding of the carboxy-terminus of transmembrane proteins with cellular signaling complexes.

The correct delivery of transport vesicles into different membrane domains requires ►SNAREs (soluble *N*-ethylmaleimide-sensitive factor attachment protein receptors) on the target membrane (►t-SNARE) and on the vesicular membrane (►v-SNARE). In epithelial cells, apical membranes contain the t-SNARE syntaxin-3 and basolateral membranes the t-SNARE syntaxin-4. Blocking their function disrupts vesicle delivery. Little is known about the mechanisms that lead to the polarized distribution of the t-SNAREs. The proper maintenance of apical syntaxin-3 is dependent on microtubules, as their disruption causes syntaxin-3 to mislocalize to the lateral membrane. Consequently, apical proteins are mistargeted into the lateral membrane.

An essential prerequisite for polarized sorting is the organization of the ►cytoskeleton. Both actin and microtubule cytoskeletons have been implicated in vesicle transport and polarized sorting mechanisms. The actin cytoskeleton may be involved in the short-range delivery of vesicles to the membrane whereas microtubules may function in long-range transport of

Cell Polarity. Table 1

Human gene	Protein structure (domains)	<i>Drosophila</i> homolog mutant phenotype	Mouse homolog mutant phenotype	Molecular function	Disease
occludin	Transmembrane (TM)	No homolog reported	occludin: Development	Cell adhesion, paracellular barrier	Unknown

(Status: 2003)

vesicles to distinct membrane domains. In epithelial cells, a cortical meshwork of actin filaments is associated with each membrane domain and there is a tight apical actin belt at the AJ. The dynamics of actin reorganization/polymerization (during cellular morphogenesis and cell adhesion) are regulated by the Rho-family of small GTPases ([►Cdc42](#), Rho and Rac1), the Arp2/3 complex and several regulators of actin dynamics including the [►Wiskott-Aldrich syndrome protein](#) (WASP). The distribution of lateral membrane proteins is controlled by membrane scaffolds containing ankyrin and spectrins cross-linked with actin. Microtubules are organized along the apical-basal axis with their plus ends at the basal pole. Minus-end

(dyneins) and plus-end (kinesins) directed [►motor proteins](#) appear to be involved in vesicle transport. The small GTPase Cdc42 has some role in basolateral targeting of transport vesicles. Similarly, the basolateral determinant Lgl has been found to bind the t-SNARE syntaxin-4. Although, the function of Lgl in basolateral targeting has not been directly tested, it is possible that Lgl may be involved in regulating the delivery of transport vesicles containing basolateral proteins. The incorrect sorting of membrane proteins can cause loss of the polarized surface distribution and can affect cell polarity with pathological consequences. Most of the defects currently known in humans are due to mutations in sorting signals or defective [►endocytosis/](#)

►**transcytosis** that result in inappropriate protein localization. Examples include the mistargeting of the low-density lipoprotein receptor (LDLR) in ►**familial hypercholesterolemia** and the inhibition of endocytosis of the amiloride-sensitive epithelial Na⁺-channel in a hereditary form of arterial hypertension.

Regulatory Mechanisms

Many pathologies display defective cell polarity. However, the loss of cell polarity in most diseases may only be secondary to physiological changes or cell/tissue damage. Only a few examples of monogenetic diseases (►**Monogenic Disorder/Monogenic**) are currently known in which ►**apical junctional complex** proteins, components of the polarized ►**sorting** machinery or regulators of ►**cytoskeletal** assembly have been implicated. More insight into the potential involvement of these cell biological processes in disease formation has been gained through work in various animal models (Table 1).

The protein complexes assembled at the ►**apical junctional complex** have primarily two functions: 1) as mechanical components that link neighboring cells with each other and control the connection between membrane proteins and the ►**cytoskeleton** and 2) as signaling components for the regulation of multiple cellular functions. Therefore, most pathologies caused by defects in ►**apical junction complex** proteins may be caused by divergent molecular mechanisms as exemplified during tumor formation. Many ►**epithelial** malignant tumors are characterized by the inactivation of the E-cadherin/catenins ►**cell adhesion** system, breakdown of the ►**basement membrane** (which facilitates the inappropriate motility of cells) and misregulation of proliferation. Experiments carried out in *Drosophila melanogaster* have shown that the invasive behavior of epithelial malignant tumor cells requires the loss of apical junctional complex proteins (which may cause a failure in the assembly or maintenance of basement membrane components) and misregulated expression of ►**oncogenes** (leading to increased proliferation). In addition, malignant cells may increase the turnover of basement membrane components through the release of ►**proteases** and may therefore be more sensitive to already reduced basement membrane assembly. Tumor progression may also be associated with defective signaling as seen with the ►**Wnt-signaling pathway** component β -catenin that binds to the transcription factor LEF-1/TCF and regulates gene expression. The stability of β -catenin is regulated via another binding partner, Adenomatous polyposis coli (Apc), which is mutated in ►**familial adenomatous polyposis**.

Clinical Relevance

Currently, only a small number of human diseases have been directly linked to defects in components of the cell

polarity machinery. However, a large number of genes required for cell polarity have been identified through studies in animal models whose ►**mutant phenotypes** suggest a possible involvement in human diseases. Therefore, increased ►**genotyping** and mapping projects of candidate genes within human patient populations will continue to uncover additional disease genes. Further studies in model organisms are required to provide better insight into the relationship between cell polarity and disease and, ultimately, to allow for the development of new therapies.

Definition and Characteristics

The concept of cellular senescence was first established by Leonard Hayflick in the 1960s from the seminal observations he made on the growth behaviour of ►fibroblasts obtained from human embryos (1). Hayflick observed that once explanted and maintained under standard laboratory tissue culture conditions, the fibroblast cultures could be expanded for only a limited number of passages, after which the cells ceased dividing and there was no net gain in cell number. Hayflick reasoned that this terminal non-proliferative state resulted from an intrinsic feature of the cells and named it senescence. Although it was first observed and remains best characterised in fibroblasts, senescence has been described in many different cell types, including T lymphocytes, epithelial cells, macrophages

and glial cells among others. Senescence occurs after a fixed number of cell divisions for each species and cell type, this number being around 70–80 for human fibroblasts. Senescent fibroblasts display a number of morphological and molecular features and a specific gene expression profile that distinguishes senescence from other non-proliferative states such as ►quiescence (2, 3). One of the most distinctive features of senescent fibroblasts is their change in cell shape from thin, elongated cells to a characteristic flat, enlarged morphology, frequently with multiple nuclei per cell. Senescent cells also display a characteristic beta-galactosidase enzymatic activity at neutral pH, named senescent-associated beta Gal activity or SA-beta Gal, which is absent from actively dividing pre-senescent cells or quiescent cells. Although viable and metabolically active, senescent cells have lost their ability to respond to mitogens, as evidenced by the lack of induction of early genes by serum. Entry into senescence is typically accompanied by changes in chromatin organisation and a defined gene expression program (2). Among the changes in gene expression associated with senescence, the up-regulation of several negative cell-cycle regulator proteins, such as the ►cdk inhibitors p16INK4a and p21CIP1 or the ►p53 regulator ARF, together with the down-regulation of cyclins should be mentioned. The expression of gene products involved in cell-extracellular matrix interactions, such as metalloproteases or collagen, and proteins related to inflammation, such as interleukin-1, is also altered in senescent cells.

Regulatory Mechanisms

Senescence can be triggered by several types of stimuli (2, 3, 4, 5, 6, 7). The primary mechanism responsible for the onset of senescence in primary human fibroblasts is ►telomere dysfunction. Telomeres are the DNA-protein structures located at the ends of eukaryotic chromosomes and consist of tandem repeats of short sequences (TTAGGG in mammals). The number of repeats and therefore the telomeric length is variable between species, being around 10 kb in human germ cells. Telomeres act as protective structures preserving chromosome integrity. As a consequence of the semi-replicative nature of eukaryotic DNA replication, each round of DNA synthesis results in the loss of telomeric sequences at the end of the chromosomes. In the absence of a telomere maintenance mechanism, telomeres suffer progressive shortening at each cell division until a critically short telomeric length is reached. The protective action of telomeres also requires the formation of an appropriate structure, dictated by the length of the telomeric DNA and the participation of specific telomeric proteins. The lack of telomere integrity appears to be the signal that triggers the onset of senescence in human fibroblasts.

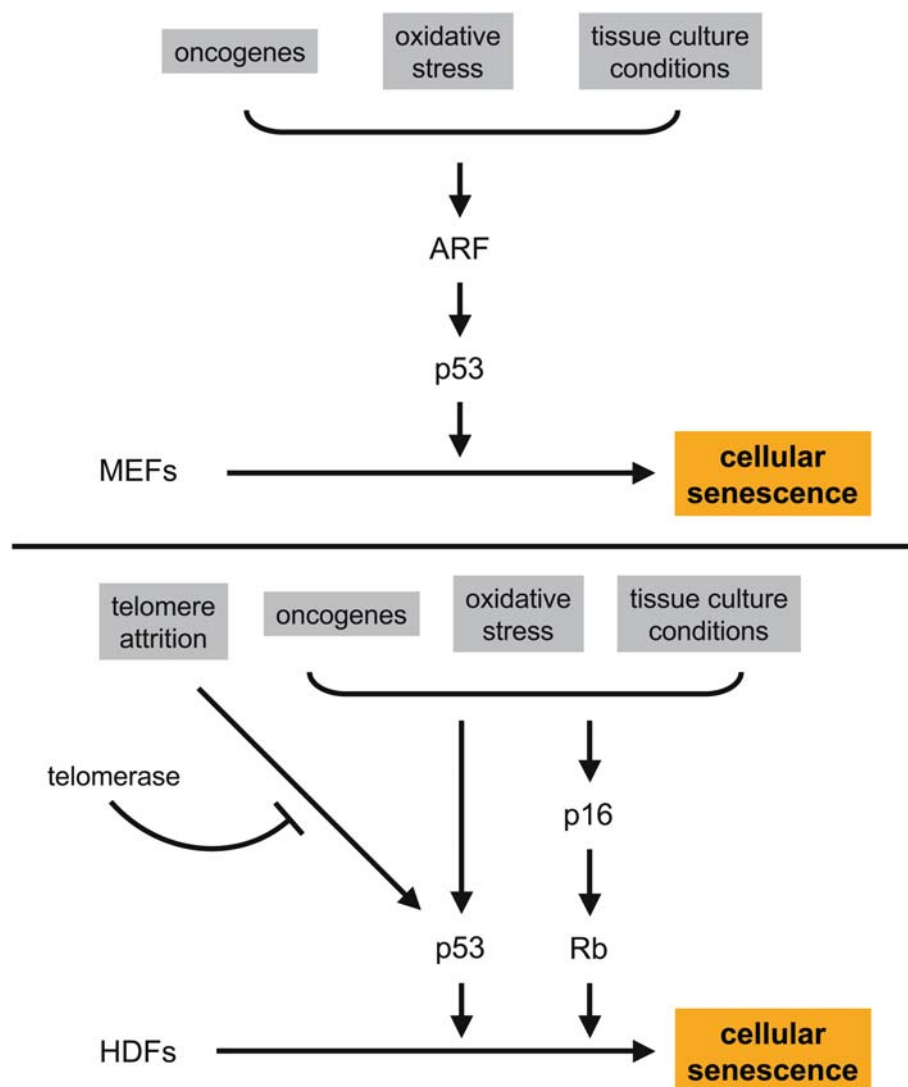

The importance of telomere erosion in the onset of senescence is revealed by studies using the enzyme telomerase. ▶**Telomerase** is a ribonucleoprotein that elongates telomeres using the telomeric repeats as templates and thus maintains telomere length. Human primary fibroblasts do not normally show telomerase activity. When telomerase is ectopically expressed in these cells, telomere erosion is prevented and this results in a significant extension of their normal life span.

Telomere exhaustion is not the only signal capable of triggering senescence in primary fibroblasts. Several other different stimuli are capable of causing a non-proliferative state indistinguishable from senescence before telomere exhaustion (5, 6). These stimuli include oxidative stress, exposure to DNA damaging agents, chronic expression of activated oncogenes and growth under suboptimal conditions. Senescence caused by these stimuli has been variedly referred to as stress-induced premature senescence (SIPS), oncogene-induced premature senescence (for oncogenes) or stress or aberrant signalling-induced senescence (Stasis), whereas the term replicative senescence tends to be used to describe exclusively telomere-dependent senescence (7). In an attempt to unify the concept of senescence, the term cellular senescence is normally used to include all types of senescence, irrespective of the initiating signal. The current view is that all the above-described stimuli, ranging from growth on plastic dishes to telomere shortening are interpreted by the cell as “stress” signals that ultimately activate an anti-stress response mechanism that leads to a cessation of active division (Fig. 1) (5, 6). The importance of telomere-dependent and independent pathways to senescence varies between cell types and species (7). For instance, mouse embryonic fibroblasts (▶**MEFs**) have very long telomeres and express telomerase. However, they stop dividing and enter senescence after a short number of divisions under normal tissue culture conditions. This form of telomere-independent senescence is an example of stress-induced senescence, triggered by the abnormal environment conditions caused by standard tissue culture practice and can be bypassed by changing culture conditions including oxygen level or mitogen supply. Similarly, some human epithelial cells suffer a senescent arrest well before telomere exhaustion, which again can be avoided by growing these cells in more favourable conditions. The stringency of the senescence program determines the different rates at which a particular cell type can be immortalised in culture. MEFs, where senescence is controlled by a relatively simple genetic pathway, undergo ▶**immortalisation** spontaneously in culture at a low but measurable rate. In contrast, immortalisation of human fibroblasts, which requires several concurrent genetic alterations, is an extremely rare event under standard culture conditions.

Interestingly, all forms of senescence ultimately activate a similar molecular machinery (2, 7). Different forms of stress-induced senescence impinge in the cellular pathways controlled by the tumour suppressors ▶**Rb** and ▶**p53**, most frequently through the action of the products of the ▶**INK4a/ARF** locus, the cdk-inhibitor p16INK4a and the p53 regulator ARF (p14ARF in humans and p19ARF in the mouse). In MEFs, senescence triggered by accumulation of cell divisions in culture is mainly mediated by the ARF protein, which in turn activates p53. Similarly, oncogene-induced senescence triggered by the activated form of the Ras oncogene is also mediated by ARF and p53 in this cell type. In agreement with this, MEFs genetically deficient for ARF or p53 do not undergo senescence upon continued culture or after exposure to the Ras oncogene. In other cell types, p16 plays the main role as sensor of stress. This is the case in some human epithelial cells or mouse macrophages, where inactivation of p16 is sufficient to extend their life span. Telomere-dependent senescence also feeds into similar molecular pathways. Telomeres act as protective structures of chromosome ends, and critically short or unprotected telomeres are probably interpreted by the cell as a DNA damage signal that ultimately activates the p53 pathway.

Cellular Senescence, Cancer, and Ageing

Cellular senescence has been extensively characterised as a phenomenon in ▶**primary cells** grown under laboratory conditions. How this phenomenon can be extrapolated to the behaviour of normal cells in living organisms and in particular its possible implication in cancer or ageing has been a matter of intense investigation. It has been assumed that cellular senescence in culture is a reflection of the limited proliferative potential of normal cells in the organism. Escape from senescence is a prerequisite for oncogenic ▶**transformation** of primary cells in the laboratory. It has been proposed that senescence acts as a tumour suppressor mechanism in living organisms (2, 3). Although, in theory, a cell could give rise to a tumour before exhausting its normal lifespan, the existence of high levels of ▶**apoptosis** and the selection of malignant clones in the early stages of tumorigenesis mean that bypassing the lifespan limit established by senescence is necessary for tumour formation. In support of this view, the genes that play important roles in the control of senescence are frequently mutated in tumours. This is clearly the case for the p53 tumour suppressor and the two products of the INK4a/ARF locus. It can be speculated that in the progression from normal to tumoral, cells experience stress situations similar to the ones studied *in vitro*, such as excessive mitogenic signalling, abnormal oxygen levels or DNA damage. These stress situations

Cellular Senescence. Figure 1 A schematic representation of the regulatory pathways that contribute to the onset of cellular senescence in human and murine primary cells. *MEFs*: Mouse Embryo Fibroblasts, *HDFs*: Human Diploid Fibroblasts.

would activate the senescence checkpoint and impede the formation of tumours by cells carrying potentially oncogenic alterations. Disabling of the senescence response by mutation of its regulators would then facilitate tumour formation. This model is supported by the observation that chemotherapeutic treatments that result in DNA damage can induce in living organisms a cell-cycle arrest reminiscent of senescence with the appearance of senescence-specific markers, such as SA-beta Gal staining.

Maintenance of telomere length is required for the continued growth of tumour cells. Although most normal tissues in the adult do not express telomerase, most tumour cells activate telomere-elongating mechanisms, implicating either *de novo* expression of

telomerase or poorly defined alternative mechanisms. Inhibition of telomerase in tumour cells has been proposed as a possible antitumour therapy. However, the potential use of this approach to restrain uncontrolled growth of tumour cells might have undesirable side effects. Inhibition of telomerase can result in critically short telomeres that in turn can provoke chromosomal instability in the target cells, which might have deleterious effects outweighing the beneficial antiproliferative effects.

The possible contribution of the senescence program to organismal ageing is more controversial. Several hypotheses have been put forward but a definitive proof for a link between senescence and ageing *in vivo* is still needed (2). Firstly, the Bmi protein, a known

regulator of senescence, has been shown to have an important role in the control of proliferation of stem cells in some tissues, mediated in part by the regulation of senescence effectors such as p16 or ARF. Based on this observation, it has been proposed that senescence plays an important role in the control of self renewal of stem cells *in vivo* and accordingly the depletion of the pool of stem cells that normally occurs during ageing could be due to the onset of senescence in these cells. Secondly, as mentioned above, senescent cells typically display alterations in gene products involved in the interaction between cells and the extracellular matrix and it has been speculated that these senescence-associated changes could contribute to the disruption of tissue organisation in ageing organisms. This must be weighed against the lack of conclusive evidence showing that senescent cells are more abundant in ageing organisms, although this observation is made difficult by the reduced number of senescent-specific markers available. Finally, based on the premature ageing phenotype described for some mouse models with over-expression of p53, it has been argued that premature ageing could be a consequence of reinforced tumour suppression and senescence. However, this view is not supported by other models and the possible connection between cellular senescence and organismal ageing remains to be firmly established.

CENPs

Definition

This acronym identifies a group of six centromere proteins that are required for various functions, for example, for the attachment of microtubules to chromosomes.

► **Centromeres**

Central Element

Definition

Central element refers to a thin proteinaceous fibril that is present in the central region of the ► **synaptonemal complex**. This structure unites homologous chromosomes during the prophase of meiosis.

► **Meiosis and Meiotic Recombination**

Centromere

WILLIAM R. BRINKLEY, SCOTT SLATTERY
Department of Molecular and Cellular Biology, Baylor College of Medicine, Houston, Texas, USA
brinkley@bcm.tmc.edu

Synonyms

The older literature contains up to 27 different terms for the centromere, including the use of “kinetochore” as a synonym. Most of these alternate names have been abandoned and current studies in molecular genetics and cell biology clearly identify centromeres and kinetochores as structurally and functionally distinct components.

Definition

The centromere is a specialized site on a chromosome that directs the segregation of chromosomes to daughter cells during ► **cell division** (mitosis). The goal of mitosis is to divide and partition the genome equally by distributing one copy of each chromosome to the nucleus of each daughter cell and centromeres play a key role in this process.

The centromere appears only once on each chromosome. It can be identified microscopically within a prominent constriction (► **primary constriction**) along the chromosome's length. The centromere can assume one of three possible positions, near the tip of the chromosomes (► **telocentric chromosomes**), in the middle of the chromosome, with arms of equal length flanking the centromere (► **metacentric chromosomes**) or near one end of the chromosome, with arms of unequal length flanking the centromere (► **acrocentric chromosomes**).

The centromere consists of a discrete DNA-protein complex that assembles the ► **kinetochore** (1), a plate-like structure located on the outer surface of the centromere that connects the chromosome to ► **spindle**

microtubules. The kinetochore is composed of multiple centromere proteins (►CENPs) that associate with centromere DNA on one surface and attach to microtubules on the other. Microtubules, in conjunction with certain ►motor proteins of the kinetochore, provide the force needed to split duplicated chromosomes apart and move them to opposing ►mitotic spindle poles, where they are enclosed within the nucleus of each new daughter cell at the end of mitosis.

Characteristics

The centromere functions to organize and direct the assembly of the kinetochore at the primary constriction of the chromosome. Each centromere assembles two ►sister kinetochores, one on each half of the duplicated chromosome (►chromatid), that face opposite poles of the mitotic spindle. The kinetochore is a sophisticated motile device that couples chromosomes to spindle microtubules enabling one copy in a set of duplicated chromosomes to be pulled to each spindle pole and partitioned into the nucleus of daughter cells. In addition to supplying force and motility, some kinetochore proteins function in cell signaling as ►checkpoints to regulate mitosis and chromosome movements (2).

Centromere DNA

Each chromosome is composed of a single linear DNA duplex, associated with nuclear proteins forming a basic 30-nanometer ►chromatin fiber, which is folded and compacted into the chromosome arms. DNA in the centromere (cenDNA) is continuous with the DNA of the chromosome arms. CenDNA differs from the DNA in the chromosome arms, however, because it has a unique nucleotide sequence composition, it remains condensed (►heterochromatin) and it is genetically silent. The size and sequence composition of cenDNA varies in different organisms, ranging in complexity from 124 ►base pairs (bp) in budding yeast, to 40–100 kilobase (kb) pairs in fission yeast, to 0.5–5 megabase (mb) pairs in humans. Human cenDNA belongs to a family of DNA known as alpha satellite or ►alphoid DNA. Alphoid DNA consists of repeating units of 171 bp arranged in tandem arrays of 1,500 to 30,000 copies. The sequence of nucleotides within the cenDNA of higher plants and animals, unlike that of budding yeasts, does not appear to specify the location, organization or function of the centromeres. Instead, their centromere location and function is determined largely, if not exclusively, by ►epigenetic determinants thought to be specific CENPs (2, 3).

Centromere/Kinetochore Proteins

The kinetochore is a multi-protein complex that is bound to cenDNA. The table in Fig. 1 lists known

centromere/kinetochore proteins along with symbols depicting their approximate localization within five centromere sub-domains, as diagrammed in Fig. 1. The sub-domains represent five specialized zones of the centromere, the corona, a layer of fibrous loops that extend out from the outer plate, an inner plate adjacent to the underlying heterochromatin and the pairing domain that connects the two sister kinetochores as illustrated in Fig. 1. Of the seven groups of proteins in the centromere, some, such as CENPA, are constitutive and remain at the centromere throughout the life cycle of the cell. Others, such as motors and mitotic checkpoint proteins, are facultative and appear transiently at the kinetochore to regulate specific functions required for movement and progression of mitosis (4).

Chromosome Movements

The kinetochore must be physically tethered to spindle microtubules to enable the complex movements necessary to align chromosomes on a mitotic spindle and segregate them to the nuclei of daughter cells. Spindle microtubules are long, hollow tubules with a slow growing (minus) end, attached to poles at opposite ends of the spindle and a fast growing (plus) end, attached to the kinetochores facing each pole. In the budding yeast, a single spindle microtubule attaches to a discrete point at the centromere. In human chromosomes, bundles of microtubules attach to the trilaminar kinetochore plates located on opposite sides of the centromere (Fig. 1).

Cells in mitosis progress through five stages, including ►prophase, ►prometaphase, ►metaphase, ►anaphase and ►telophase. At the end of prophase, the ►nuclear envelope breaks down, releasing chromosomes into the cytoplasm. As chromosomes maneuver to the cell equator during prometaphase (►congressional movement) and align on the metaphase plate, sister kinetochores on each side of the centromere attach to spindle microtubules extending from opposite poles, thereby subjecting chromatids to equal force in opposing directions. Subsequently, the chromatids split apart and the kinetochores pull the chromosomes to opposite poles (►anaphase movement) (5).

Regulatory Functions

For many years, the centromere and its associated kinetochores were thought to function as passive “handles” that spindle microtubules grasp to pull microtubules along the mitotic spindle. More recent studies have discovered a remarkable set of kinetochore proteins that form a complex signaling circuitry for regulating chromosome movement (2, 3) and progression through mitosis. As shown in the diagram in Fig. 1, a group of proteins known as checkpoint proteins are strategically located along the outer face of

Centromere. Figure 1 (a) Acrocentric chromosome from the muntjac deer with the centromere (green) located in the primary constriction between the long arm and short arm (red). The centromere proteins are stained with a specific antibody directed against CENPs A, B, and C (green). (b) Electron micrograph of muntjac deer chromosome showing prominent inner and outer kinetochore plates and corona. (c) Triple-stained chromosome showing proteins (green) on sister kinetochores. DNA in the chromosome arms is stained blue. (d) Diagram of the centromere/kinetochore showing the 5 sub-domains of the centromere. The colored symbols depict the approximate localization of various known kinetochore proteins. Two microtubules have attached to one sister kinetochore with the plus ends, associated with the corona and various anchoring and motor proteins, found at the splayed ends. The minus ends of the microtubules are directed toward the spindle poles (not shown). The table below lists currently known centromere-associated proteins of human chromosomes. Symbols correspond to the sub-domain localization of groups of proteins within the centromere/kinetochore. (Fig. 1a–c are reproduced from Van Hooser, AA. 2001. Specification of kinetochore-forming chromatin by unique nucleosome structure [Ph.D. dissertation]. Houston (TX): Graduate School of Biomedical Sciences, Baylor College of Medicine.)

the kinetochore, in sub-domains 1–3. ►**Checkpoint** proteins are enzyme complexes that modify protein substrates by inserting phosphate groups at specific sites to regulate their functions. As chromosomes align on the metaphase plate, a “wait anaphase” checkpoint prevents further progression, assuring that all chromosomes are properly aligned and fully attached to spindle microtubules extending from opposite poles. When alignment is complete and equal pole-directed forces are exerted on opposing sets of sister kinetochores, a second checkpoint “switch” signals the chromatids to split apart and move to opposite poles. This regulation achieves proper segregation and corrects any improper orientation of chromosomes, thus assuring equal partitioning of the genome. When checkpoints are abrogated or fail, however, errors in chromosome segregation occur that may lead to serious genetic disorders.

Clinical Relevance

Unequal distribution of chromosomes to the nuclei of daughter cells can produce altered genomes in cells characteristic of a number of serious human diseases. Normal mitosis leads to the perpetuation of a balanced ►**diploid genome** in which each nucleus contains 46 chromosomes. Errors in mitosis can lead to an imbalanced genome – a condition known as ►**aneuploidy**. Aneuploidy has numerous causes. Defective centromeres can interfere with normal chromosome splitting and chromosome segregation in mitosis. Premature chromosome separation can also lead to genomic imbalance. A centromere defect can cause chromosomes to lag behind and be excluded from the nucleus. Mutations in checkpoint proteins in the centromere can prevent chromosomes from splitting apart at anaphase, a process known as ►**nondisjunction**. Chromosome breakage and translocations can produce a condition in which chromosomes contain more than a single copy of the centromere, producing dicentric or tricentric chromosomes that fail to divide and segregate properly. Defects in chromosome structure and distribution can also arise when ►**neo-centromeres** form on chromosomes. Numerical disorders involving human sex chromosomes include the 47XXY condition in Klinefelter's syndrome and 45X in Turner's syndrome. ►**Downs syndrome** results from duplication of ►**chromosome 21**. Aneuploidy is also associated with most forms of human cancer.

Centrosome

Definition

The vertebrate centrosome, also called the “microtubule-organizing center”, consists of two barrel-shaped centrioles. These are made up of nine triplets of short microtubules embedded within a so-called pericentriolar matrix. The two centrioles are arranged such that one is perpendicular to the other. Centrosomes influence a variety of processes: organelle transport, cell shape, polarity and motility. Centrosomes are vital for proper execution of mitosis and control spindle bipolarity, spindle positioning and cytokinesis. They serve as nucleation points for microtubular polymerisation and constrain the lattice structure of a microtubule to 13 protofilaments. Thus, in animal cells, the centrosome is the major microtubule organizing center (MTOC).

Centrosome Cycle

Definition

Throughout the cell cycle centrosomes undergo a series of morphological changes. These discrete events are called centrosome cycle (also termed growth cycle of the centrosome). In higher organisms it consists of a duplication, maturation, separation and centrosome disorientation phase. Centrosome duplication and segregation is strictly coordinated with the duplication and segregation of the genome.

Charged Coupled Device (CCD) Camera

Definition

Charged coupled device (CCD) camera designates a video camera, in which a charged coupled device (CCD) is used as a two-dimensional light detector. A CCD is a light-sensitive silicon chip containing a two-dimensional array of light sensitive elements. The single elements represent photodiodes, where the produced photoelectrons are collected in potential wells, which are the picture elements ("pixels") of the CCD. CCDs show an extremely linear response to the light irradiance, and can collect the charges for long exposure times. Scientific grade CCDs feature extremely low dark currents and high quantum efficiencies for the photon-to-charge conversion process. The main source of noise in CCD images is produced by the charge readout. The noise level is related to the readout speed, i.e. the digitization rate. Therefore, scientific grade CCDs are often read out with speeds below the video standard, and are then designated as slow-scan CCDs.

Chemokine Receptors

RICHARD HORUK

Department of Immunology, Berlex Biosciences,
Richmond, CA, USA
horuk@pacbell.net

Definition

Chemokine receptors are members of the GPCR superfamily (1). Synonyms are chemoattractant receptors, chemokine receptors, ►G-protein coupled receptors.

At the latest count well over 850 members of this G-protein coupled receptor (GPCR) superfamily have been identified and classified into families (2). Six CXC, ten CC and one CX3C and XC chemokine receptors have been cloned so far (3). Receptor binding initiates a cascade of intracellular events mediated by the receptor associated heterotrimeric G proteins. These G-protein subunits trigger various effector enzymes, which leads to the activation not only of chemotaxis but also to a wide range of functions in different leukocytes, such as an increase in the respiratory burst, degranulation, phagocytosis and lipid mediator synthesis (4).

Characteristics

Chemokines belong to a large family of small, chemotactic cytokines characterized by a distinctive pattern of four conserved cysteine residues (5). They are divided into two major (CXC and CC) and two minor (C and CX3C) groups dependent on the number and spacing of the first two conserved cysteine residues. Although originally identified on the basis of their ability to regulate the trafficking of immune cells, the biological role of chemokines goes well beyond this simple description of their function as chemoattractants, and they have been shown to be

involved in a number of biological processes, including growth regulation, hematopoiesis, embryologic development, angiogenesis and HIV-1 infection (6) (Fig. 1). Chemokines have been shown to be associated with a number of autoimmune diseases including multiple sclerosis, rheumatoid arthritis, atherosclerosis, dermatitis, organ transplant rejection, etc. (7). Evidence, reviewed below, is mounting that chemokines may play a major role in the pathophysiology of these diseases and thus chemokine receptor antagonists could prove to be useful therapeutics in treating these and other proinflammatory diseases.

Chemokine Receptors

Although leukocytes continue to be the major site of expression of chemokine receptors, several studies have recently demonstrated chemokine receptor expression on neurons in the CNS. A number of

chemokine receptors including CXCR2, CXCR4, CCR1, CCR5 and DARC have been demonstrated in either adult or in fetal brain. Not only were these receptors present on the cell surface but they were also functional. Clearly the role of these receptors on CNS neurons must be very different from their role on immune cells. Given that human astrocytes can be stimulated with cytokines to tend to up-regulate the expression of chemokines, it is tempting to speculate that perhaps *in vivo* during CNS development chemokines secreted by astrocytes can engage specific receptors expressed on neurons and may play a role in the directed migration of specific subsets of neurons to distinctive regions of the brain.

Genetic mutations of receptors both natural and induced (by targeted gene disruption) can help to unravel their biological roles. Nature has been generous in this regard by providing us with two naturally

Chemokine Receptors. Figure 1 Biological functions of chemokine receptors as exemplified by the chemokine receptor CXCR4.

occurring examples of gene inactivation for chemokine receptors. Humans homozygous for inherited inactivating mutations of the Duffy (DARC) gene and the CCR5 gene have been identified and appear to be phenotypically normal and healthy. Indeed these gene inactivations appear to be beneficial to their hosts, rendering them resistant to certain infectious diseases. For example, the Duffy negative individuals are resistant to malaria induced by *Plasmodium vivax*, which utilizes DARC to attach to and enter erythrocytes and the CCR5 negative individuals are resistant to HIV-1, which utilizes this chemokine receptor as a coreceptor for invasion (see section role of receptors in HIV infection).

Analysis of receptor-inactivated individuals can also be useful in clarifying their role in disease. For example, it is known that MIP-1a (CCL3) appears to play an important role in multiple sclerosis. This chemokine is a potent agonist for both CCR1 and CCR5 receptors opening the possibility that either of these receptors could be involved in mediating the development of the pathophysiological changes seen in this disease. However, analysis of a large group of individuals, comprising both normal subjects and those suffering from relapsing/remitting multiple sclerosis, showed that there was no significant difference in the allele frequency of the CCR5 mutation between the groups. These studies indicate that CCR5 is not an essential component in the expression of multiple sclerosis and further implicate CCR1 in the disease.

Role in Immune Response

Chemokines are potent chemoattractants that provide directional cues to summon leukocytes. Leukocyte recruitment is a three-step process that involves the formation of solid phase chemokine gradients generated by chemokine binding to extracellular matrix proteins like glycosaminoglycans that decorate the cell surface of endothelial cells. These gradients then attract immune cells which first undergo selectin mediated rolling along the endothelial cells. Chemokine mediated up-regulation of CD11/18 complexes then results in a much firmer adherence of immune cells to the endothelium and this culminates in diapedesis of leukocytes across the endothelial space into the tissues. By regulating the movement of different subsets of leukocytes from the peripheral blood to extravascular sites such as organs, skin or connective tissue, chemokines play a critical role in the maintenance of host defense as well as in the development of the immune response. However, sometimes these molecules can inappropriately target immune cells to attack their own tissues and organs leading to inflammation and cellular destruction. Indeed there is now strong evidence in support of the idea that chemokines play an

important role in the pathogenesis of a number of autoimmune diseases such as ►multiple sclerosis and ►rheumatoid arthritis.

Rheumatoid arthritis is a chronic inflammatory disease characterized in part by a memory T lymphocyte and monocyte infiltrate. The interaction of the same cell types also plays a major role in the demyelinating processes that culminate in multiple sclerosis. Recent studies using neutralizing antibodies have provided strong *in vivo* concept validation for a role of chemokines in animal models of both diseases. For example, in an adjuvant-induced arthritis (AIA) model in the rat, antibodies to CCL5 were able to abrogate the development of the disease in the animals by greatly reducing the infiltration of mononuclear cells into tissue joints. Similarly antibodies to CCL3 prevented the development of both initial and relapsing paralytic disease as well as infiltration of mononuclear cells into the central nervous system of a mouse experimental autoimmune encephalomyelitis (EAE) model of multiple sclerosis. These results strongly suggest that these chemokines play important roles in these T-cell mediated autoimmune diseases.

In contrast to the role of T cells and monocytes in chronic inflammation, the primary hallmark of acute inflammatory diseases such as empyema, acute lung injury, acute respiratory distress syndrome (ARDS) and dermatitis is tissue infiltration by neutrophils. Thus, neutrophil activating CXC chemokines like CXCL8 are most often associated with these diseases. Clear evidence for a role of CXCL8 in acute lung injury and pleurisy has been provided by the finding that antibodies to CXCL8 dramatically increased the survival time of rabbits in models of disease. Not only did the antibodies increase the alveolar-arterial oxygen difference of the animals, increasing the oxygenation of the blood and therefore decreasing breathing difficulties, but they also affected a significant reduction in the infiltration of neutrophils into the lung.

Based on the demonstrated role of chemokines in disease, the generation of small molecule chemokine receptor antagonists has received great interest from pharmaceutical companies, since they are seen as attractive therapeutic approaches. GPCRs like chemokine receptors have in the past been an extremely fertile source of biological targets in the pharmaceutical industry and compound library screening has proven successful in the discovery of antagonists for a number of these receptors, i.e. CCK and neurotensin antagonists. Using similar approaches, several drug companies have now identified potent small molecule antagonists of a number of chemokine receptors, which should find broad utility in a variety of acute and chronic inflammatory diseases.

Clinical Relevance

Chemokine Receptor Inhibitors

Insight into the physiological and pathophysiological roles of chemokine receptors have been provided by studies with potent receptor antagonists for CCR1, CCR2, CCR3, CCR5, CXCR2, CXCR3 and CXCR4, reviewed in Ribeiro and Horuk (8). A number of these antagonists, CCR1, CCR3, CCR5, CXCR3 and CXCR4, are in human clinical trials. For example, the CCR5 antagonists are in phase III clinical trials for the treatment of ►AIDS. In addition, the CCR1 antagonist is in several phase II clinical trials.

The utility of chemokine receptor antagonists as therapeutic agents in disease can be exemplified by the CCR1 antagonist BX 471. BX 471 is a potent functional inhibitor specific for CCR1 based on its ability to inhibit a number of CCR1-mediated effects including CCL3 and CCL5 mediated increases in Ca^{2+} mobilization and extracellular acidification rate, CD11b expression and leukocyte migration. In addition, BX 471 demonstrates a greater than 10,000 fold selectivity for CCR1 compared with 28 different GPCR's. Pharmacokinetic studies demonstrated that BX 471 was orally active with a bioavailability of 60% in dogs. A recent model of renal fibrosis in the mouse showed that inhibition of CCR1 with BX 471 reduced leukocyte infiltration and renal fibrosis. BX 471-treated mice (day 0–10 and day 6–10) revealed a 40–60% reduction in interstitial macrophage and lymphocyte infiltrate compared with controls (v). Treated mice also showed a marked reduction of CCR1 and CCR5 mRNA levels and FACS analysis showed a comparable reduction of CD8+/CCR5+ T cells. Markers of renal fibrosis, such as interstitial fibroblasts, interstitial volume, mRNA and protein expression for collagen I, were all significantly reduced by BX 471- treatment compared with vehicle controls. In summary, blockade of CCR1 substantially reduced cell accumulation and renal fibrosis after UUO. Most interestingly, late onset of treatment was also effective and this is the first published example showing that a CCR1 antagonist is effective when given therapeutically as compared to prophylactically in an animal model of disease.

The CCR1 receptor antagonist BX 471 is also efficacious in a rat heterotopic heart transplant rejection model. Animals treated with BX 471 and a sub-therapeutic dose of cyclosporin, 2.5 mg/kg, which is by itself ineffective in prolonging transplant rejection, showed much more prolonged transplantation rejection than animals treated with either cyclosporin or BX 471 alone. Immunohistology of the rat hearts for infiltrating monocytes confirmed these data. 3 days after transplantation the extent of monocytic graft infiltration was significantly reduced by the combined therapy of BX 471 and cyclosporin. Thus, BX 471 given in combination

with cyclosporin resulted in a clear increase in efficacy in heart transplantation compared to cyclosporin alone. These data were in line with the observed effects of BX 471 in dose-responsively blocking the firm adhesion of monocytes triggered by CCL5 on inflamed endothelium. Together, these data demonstrate a significant role for CCR1 in allograft rejection. The promise of highly specific therapies for a number of devastating diseases is on the horizon, thanks to the identification of chemokine receptor antagonists and we can look forward with anticipation to the day when these drugs are finally marketed as potent therapeutics.

Chemokine Receptors in Pathogen Infection

A number of viruses including those in the *Herpes* and *Pox* families express chemokine-like or chemokine receptor-like molecules that presumably help them to survive immune attack and proliferate. In addition to these strategies, chemoattractant receptors have themselves been targeted as vehicles of cellular invasion by a wide variety of microbes. These range from the Duffy blood group antigen, a promiscuous chemokine receptor on human erythrocytes, which serves as a binding protein for the malarial parasite *Plasmodium vivax*, to the fractalkine receptor, CX3CR1, which is a portal of entry for the respiratory syncytial virus and the HIV-1 virus, which utilizes the chemokine receptors CXCR4 and CCR5 as coreceptors for cellular entry. CCR5 is an entry cofactor for M-tropic isolates of HIV-1 and is important in the early proliferative part of the disease, while CXCR4 is a coreceptor for T-tropic isolates of HIV-1 whose emergence in infected individuals usually correlates with accelerated disease progression.

HIV-1 resistance exhibited by some exposed but uninfected individuals is due, in part, to a 32 bp deletion in the CCR5 gene (CCR5D32), which results in a truncated protein that is not expressed on the cell surface. About 1% of Caucasians are homozygous for the CCR5D32 allele and appear to be healthy with no untoward signs of disease. In fact, recent findings suggest that homozygosity for the CCR5D32 alleles confers other selective advantages to these individuals, rendering them less susceptible to rheumatoid arthritis and asthma and prolonging survival of transplanted solid organs.

Chemokines

Definition

Chemokines (term fused from “chemotactic cytokines”) are protein factors that have initially been defined as attractants for different types of blood leucocytes to sites of infection and inflammation. They are produced locally in the affected tissue and act on leucocytes through selective chemokine receptors. Chemokines help to control leucocyte maturation, traffic and homing of lymphocytes and the development of lymphoid tissues.

Chemotaxis

Definition

Chemotaxis is the movement of a microorganism or a eukaryotic cell in response to a chemical gradient, either towards or away from the substance. For example, the migration of an aggregation-competent *Dictyostelium amoeba* depends on chemotaxis towards cAMP as chemoattractant. In multicellular organisms, chemotaxis is critical in development as well as normal function. In host defense and inflammation, leucocytes show directional migration in response to certain chemotactic signals, like bacterial tripeptides (F-Met-Leu-Phe), complement 5a (C5a) or Chemokines. The phosphoinositides $\text{PtdIns}(3,4,5)\text{P}_3$ (PIP_3) and $\text{PtdIns}(3,4)\text{P}_2$ [$\text{PI}(3,4)\text{P}_2$] are key signaling molecules

for the control of directed movement of a cell in a chemical gradient.

Chemotherapy

Definition

Chemotherapy is the employment of different chemical compounds to kill pathogenic cells. For advanced and metastatic tumors, chemotherapy is the most effective treatment, whereas treatment of the most locally confined malignant tumors is based on surgical and radiotherapeutic approaches. Chemotherapeutics are aimed at interfering of division and growth of cancer cells, particularly based on their fast growth as compared to the controlled growth behavior of normal cells; however, fast growing normal healthy cells might also be affected.

Chimeras (Chimeric Clones)

Definition

The chimera is a mythic beast composed of parts of different animals. In the context of recombinant DNA technology, the term chimera is used to describe a clone consisting of insert DNA fragments not found together in nature. All library construction methods are liable to produce chimeras at some level. For example, chimeric mice contain cells of two different sources (usually, the original pluripotent stem cells from the embryo and the targeted embryonic stem cells of the host blastocyst aggregation chimerae).

Definition

It is not absolutely sure when the expression chip technologies in the context of biomedical science was first used, but the fields of Genomics and Proteomics can hardly be imagined without the use of highly specialized (bio-)chips. (Bio-)chips are small tools typically used for a bioanalytic application. In most cases bio-chips are devices on which a biological molecule, complexes of molecules or even a complete living organism is immobilized on a solid surface and used to analyze the interaction with other biomolecules, complexes of molecules or living organisms. In contrast to other techniques based on immobilization on solid surfaces, the meaning also includes, that the carrier is rather small, in particular when compared to more traditional bioanalytical tools.

In most cases biochips contain more than one species of the immobilized molecules. These are than typically arranged in a geometric array, so that each immobilized molecule can be precisely defined by its position. This typical array design is also the reason that the term (bio-)chip and chip-technologies is used almost synonym to the term microarray. A microarray is a miniaturized array of molecules on a solid surface. If these molecules are biomolecules, the array is also a bio-chip. Chip technologies in bio- and bio-medical sciences including Genomics and Proteomics can be categorized in various ways: the arrangement in which molecules are placed on the chip, microarray (see below); the way they are manufactured, e.g. printed glass slides; the type of molecules they contain as probes, e.g. DNA-, cDNA-, protein-, antibody-chip, cell-chip; the application for which they are used, e.g. gene expression chip, SNP-chip; the way they are used and other technological specifications, e.g. microfluidics chip, microchromatography, BioMEMS (MEMS: micro electro mechanical systems). In recent years also the term lab on a chip became used, describing integrated solutions, that combine analytical applications with integrated fluidic systems that enable a simple work flow and no additional laboratory equipment (except for a dedicated workstation) to perform the designated bioanalytical task.

In the following, the basic design and the manufacturing of chips used in Genomics and Proteomics will be described.

Description

Many bio-chips have in common that probe molecules are immobilized on a solid surface (chip) and used for the detection of interacting molecules in a test solution. To enable the systematic analysis of large numbers of molecules in parallel, probe molecules, each specific for a single analyte, are arranged in a two dimensional array format, so that each position is defined by two coordinates x,y. Given the small micrometer scale

required to deposit hundreds and thousands of probes on a single chip, these types of chips are also called microarrays. The array arrangement ensures that each individual species of immobilized molecules is clearly identified by the coordination system, which is essential for the precise detection and measurement of the detected molecules.

The basis for the manufacturing of microarrays was the development of high precision tools that allow the precise deposition of probe molecules in the array format, as well as improvements for the synthesis of biological macromolecules, especially nucleic acids and peptides. In the latter case, one particular development was from the beginning connected with the fabrication of bio-chips (DNA-chips), light directed synthesis of oligonucleotides (1). This method allows to use photolithographic techniques developed in the computer industry to synthesise nucleic acid polymers (oligonucleotides) directly on a solid chip surface *in situ* (see below). For the versatility of microarrays it was, however, more important, that prefabricated biomolecules, i.e. the synthesis or preparation is performed independent of the microarray surface, could be produced and purified in large quantities. For the production of specific bio-chips, these molecules are then repeatedly deposited on the surfaces of chip substrates using high precision printing tools. This type of technology was in a first application used to spot and immobilise cDNA fragments on microscope glass slides (2).

Solid Support

The basis for all bio-chip and microarray applications is a reliable solid support on which probe molecules can be immobilized. The basic requirements for the solid support are i) compatibility with the detection system, ii) suitable reactive groups on the surface for the immobilization of the probe molecules, iii) compatibility with the immobilization protocol and finally iv) integration into an easy handling system.

- i For most optical detection systems utilising fluorescent dyes, glass surfaces are the preferred substrates. They are translucent, do not interfere significantly with a broad spectrum of light and do not show auto-fluorescence. For specialized applications plastic materials, e.g. polypropylene, may be equally suitable. Silicon wafers, the typical substrate for microelectronics- (computer-) chips are also used but require more specialized detection systems. Some detection systems use specific optical properties at the surface, that require additional surface optimization, e.g. wave guides.
- ii Appropriate reactive groups are not genuinely present on the surfaces described above. These reactive groups are mostly introduced in a two step

process. First reactive groups are generated on the solid support; second the surfaces are coated with thin layer of reactive molecules that contain highly specific reactive groups for immobilization of the probe molecules. This step is also often used to create more flexible, rough surfaces that facilitate accessibility, increases the surface area and provide more reactive groups for coupling of the probe molecules.

- iii Both, the solid support and the surface must be compatible with the immobilization protocol. Most spotting systems work well with any type of surface and solid support. However, immobilization with microfluidic systems is limited to optimal prepared structures, which include alternating hydrophilic and hydrophobic as well as reactive and non reactive areas.
- iv For routine use of chip technologies in research laboratories but especially in diagnostic applications the chip must be integrated in an easy handling system. In many integrated systems, the actual biochips are glass for compatibility with the optical detection system.

Further variations of the solid support contain microstructures, e.g. cavities to deposit cells, hydrophobic barriers, specific reactive positions, porous structures and microsieves.

Surface Chemistry

For efficient immobilization an appropriate surface chemistry is required. Glass surfaces and even more silicon surfaces are only poorly reactive with biomolecules. One technology is the application of a thin transparent gold layer. Gold adsorbs with high efficiency thiol groups (-SH), which can be easily introduced in biomolecules. The association of thiols with gold is very strong and withstands treatment with most aqueous buffer solutions commonly used in all subsequent analytical reactions with the biochip. To introduce alternative reactive groups to the surface linker molecules, that contain two reactive groups, are used. Common reactive groups suitable for immobilization reactions are amino (-NH₂), epoxy (-COC) and aldehyd groups (-COO). An alternative to the gold thiol chemistry is the use of silan-linkers. These linkers contain a silan group on one end and the desired reactive group for coupling of the probe molecule on the other end. The silan group attaches efficiently to the glass surface leading to an efficient coating with the specific reactive groups. The specific probes are then immobilized through groups that are complementary to the reactive groups on the surface. In the pioneering work of Schena and colleagues, cDNA microarrays on microscopic glass slides were prepared using a simple coating with poly-lysine. This single amino-acid

polymer provided a layer of reactive amino groups to which the spotted cDNA could be crosslinked and used as probes for hybridization to detect gene expression (2).

In addition to the creation of simple layers of reactive groups on the surface, various approaches were used to increase the capacity of planar surfaces. These approaches include coating of glass slides with biopolymer layers, e.g. agarose or gelatine, or with chemically defined matrices, like polyacrylamide or nitrocellulose. These surface layers provide a three dimensional matrix which is accessible for reaction by diffusion and – very important – a significantly increased number of reactive groups for the immobilization of probe molecules, which leads to an increased probe concentration in hybridization or other binding reactions.

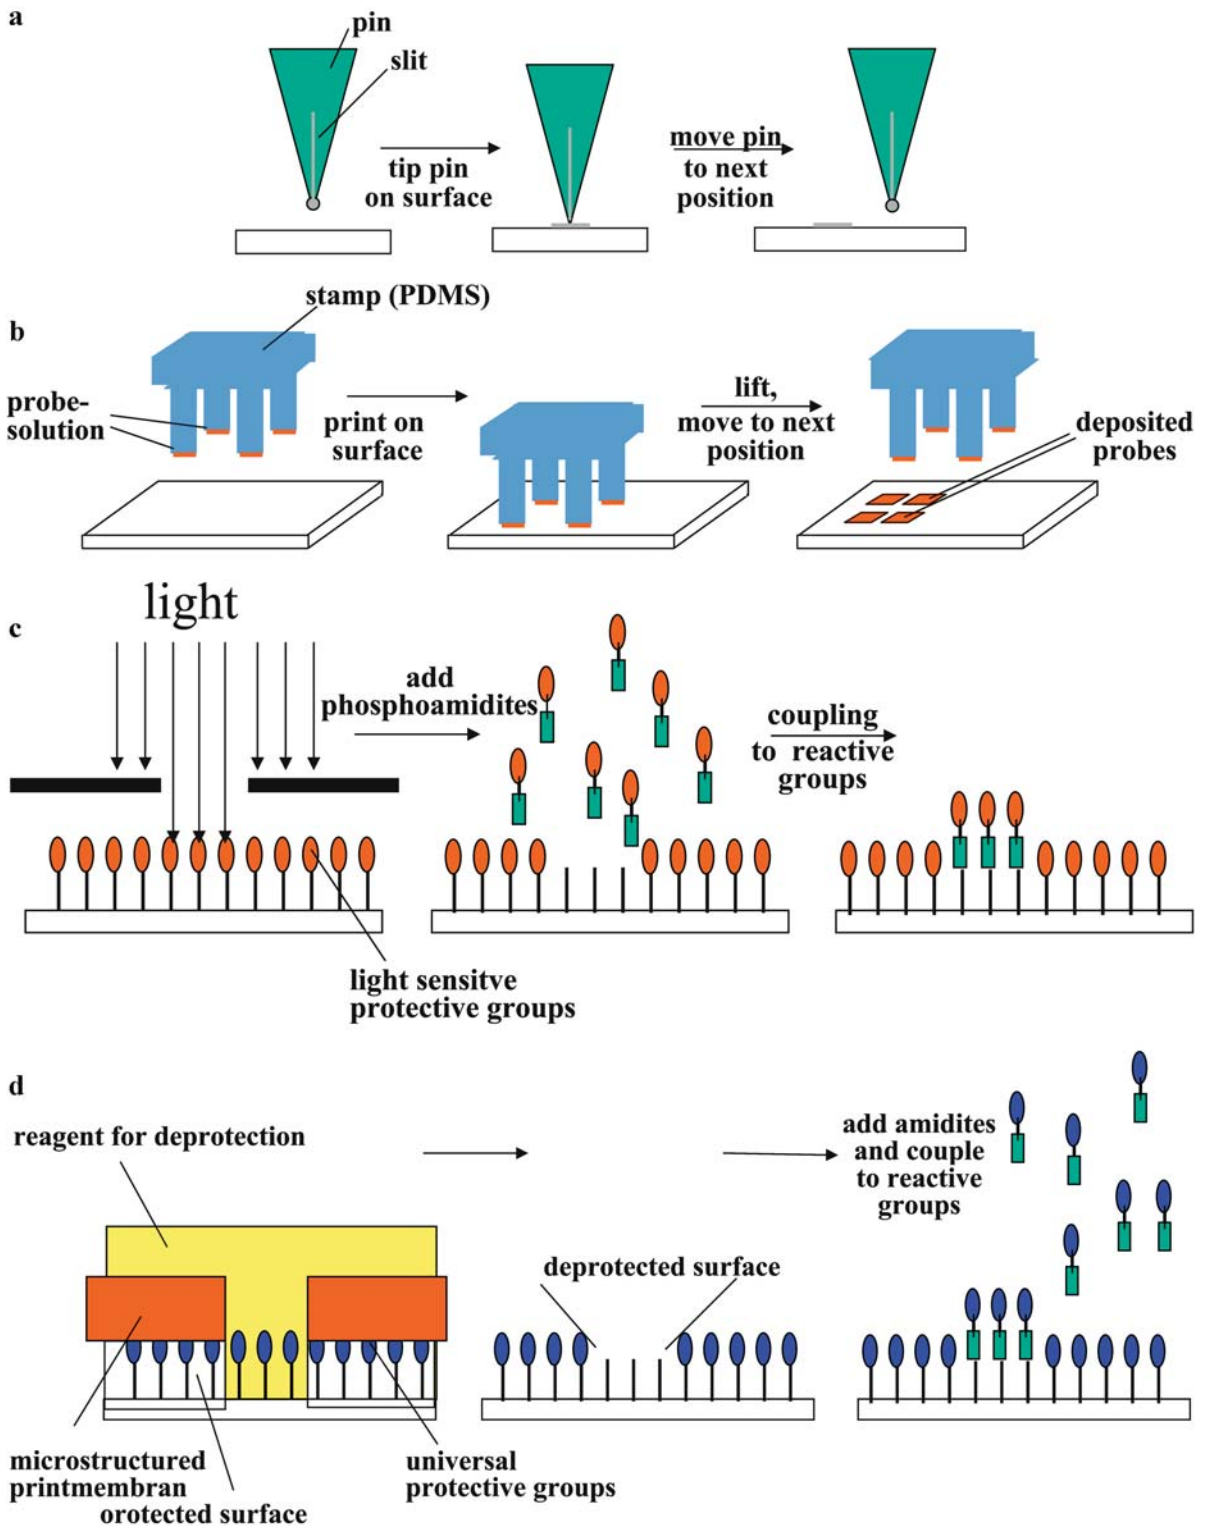

Despite these advantages most applications use the simpler linker based surface chemistry, which at least at present is better compatible with handling and detection methods.

Immobilization

Chips carrying microarrays are prepared following two main procedures. One approach is deposition of prefabricated molecules on the designated positions of the chip. The other is the *in situ* synthesis of the specific molecules on the chip surface. Both approaches are widely used and have their advantages and disadvantages. The first is more widely distributed at present. It uses simpler technology, dedicated robotic systems with sub-micrometer precision, that can be relatively easy set up in any research laboratory. This approach also has the advantage that any type of molecule and even living cells can be arranged on a chip in array format. The latter, *in situ* synthesis, is more suited for large scale manufacturing of identical chips, but requires at present high precision mask aligner technology and clean room facilities.

Deposition of Prefabricated Molecules

The most widely used method at present to deposit prefabricated molecules is contact tip printing using split pins. Split pins function in principal like the feather of a fountain pen. Tipped in a reservoir with liquid, the slit of the pin is filled by capillary forces. The pin is then moved to the desired position on the array substrate, where after contacting the surface it releases a tiny volume of liquid, typically a few nanoliters (nL) (Fig. 1a). The released volume depends on the slit in the pin, the surface of the array and the viscosity of the liquid. Surfaces with extended 3D structures, e.g. (bio-)polymer gels, will soak more liquid from the pin than single molecule reactive layers, leading to higher probe concentrations. Nevertheless, with identical surfaces, the passive dosing will result in

Chip Technologies, Basic Principles. Figure 1 Printing methods (a) Split pin contact tip printing (b) Micro contact printing (c) Photolithographic deprotection (d) Mikrowet Printing (μ WP).

roughly similar amounts of deposited probes in each spot (position). This is a critical point considering precise quantification, which is not obtained by this method.

An other approach to prepare microarrays is the use of precise nanoliter pipetting systems, e.g. piezo-electric microdispensers. These systems deliver the volumes to the chip surface with a much higher precision. At present these type of robotic dispensing is only used when smaller numbers of chips with not to many different features (specific properties of the chip system, which are used alternatively to probe in many microarray applications) but with high precision are needed, because the spotting process is more time consuming compared with the split pin technology.

For high throughput printing of micro arrays a printing technology called top spot printing was also developed. This method uses a printing cartridge with can be filled with hundred different liquids which is then delivered through fine capillaries to the chip surface. The release of drops from the microcapillaries is mediated by applying a short pressure pulse to the liquid reservoir (4). Information about the precision for quantification is not available for this method.

Printing in microscale is also possible using simple microstructured stamps typically made from PDMS. These stamps are made using microstructured templates prepared with photolithography and are then used to transfer thin films of liquid containing reactive molecules to chip surfaces. Like traditional stamps, this type of technology is best if only one type of liquid must be transferred (Fig. 1b). If no repeated deposition is required, high precision micropatterns of reactive groups, can be prepared in large number without any expensive equipment. This method is for example very suitable to deposit peptides, or protein layers to guide the growth of cells to specific positions and in specified form on glass or plastic substrates (5).

Microstructured PDMS but also other technologies allow to create micro fluidic networks that can be place on chip substrates in such a way that tightly sealed channels are generated. These fluidic channels are than filled with reactive molecules for deposition. Using micropatterned surfaces which contain defined reactive positions immobilization can be precisely directed to these positions and specific patterns of immobilized molecules are obtained (6).

In situ Synthesis of Probe Molecules

In situ synthesis of chip-size microarrays is mainly used for nucleic acid microarrays. In principal any type of polymeric probe molecule could be made with these protocols, if the appropriate reactive building blocks are available (1). Light directed chemical synthesis requires polymer synthesis building blocks with protective groups that are removed under the influence

of light (Fig. 1c). These are available for nucleic acids synthesis, but not for protein synthesis. (Nucleic acids require only four different building blocks (amidites), whereas peptide synthesis requires 20 building blocks.) The two other high resolution protocols for *in situ* synthesis, protection with photoresist (7) and micro wet printing (8) (Fig. 1d) can utilize any type of protective group chemistry and thus are suitable for the synthesis of any type of polymeric probes on chip microarrays.

Using light directed chemical synthesis in combination with large glass wafers and mask aligner technology, which – like in the computer industry – yields several hundred chips in parallel, the company Affymetrix Inc., USA (14) produces oligonucleotide arrays, that contain several hundred thousands (the number is still increasing) of oligonucleotide probes, 20–30 nucleotides in length. The photolithographic process allows to create tiny squares for each probe position in the low micrometer scale with nanometer precision. Oligonucleotide arrays fabricated in this way are used for gene expression profiling and genotyping. Readily assembled in a fluidic cartridge, these arrays are easy to handle and deliver highly reproducible results.

(There are also protocols for the *in situ* synthesis of peptide arrays, but although the synthesized peptide arrays are reduced in size, they still can not be considered as chips or microarrays. Nevertheless, peptide macro arrays are a high quality and reliable source for the pre-synthesis of peptides for spotting on other chip platforms (9).)

An alternative approach for the *in situ* synthesis of (micro-) arrays is the use of ink-jet type of printers (10, 11). The limitation here is that unlike the ink used for printing documents, the liquid reagents required for biopolymer synthesis can not be adjusted as easily to the viscosity requirements of these highly specialized dispensers.

Handling and Detection

Handling of chips in the laboratory as well as detection of signals in chips is at present far away from being standardized. The reason for this is, that for many laboratory applications using microscope glass slide based microarrays various low tech solutions can be used to obtain results. For reliable reproduction of the results it is required to constantly agitate (stir, move) the low sample volumes to enhance the poor and slow reactions between the analyte molecules and the immobilized probes. Some commercial microarray systems are preassembled in a microfluidic cartridge in which the on chip reactions are performed. Moreover, microarrays can be integrated into established laboratory reaction tubes or microtitre plates, e.g. ArrayTube® (Clontech Chiptechnologies, Jena, Germany) (12, 15).

The most widely used method for the detection of microarray results is the detection of fluorescence using dedicated high resolution microarray scanners. For this, fluorescent dyes are either directly coupled to the analyte molecules or are added in a final development step, e.g. through binding of fluorescently labelled streptavidin to biotin incorporated in the target molecules.

An alternative to fluorescence is the use of colorimetric detection. This includes various approaches, which lead to the specific deposition of dye (or silver) precipitates at the respective position on the microarray, which can be detected with CCD cameras or by optical scanners in the visible light range (13). Similarly chemiluminescence reactions can be used in the final detection step.

Clinical Applications and Therapeutical Consequences

In the context presented here, chip technologies are the highly parallel analytical tools for the detection of specific biomolecules. In this context they have already a significant impact in clinical research for the identification of molecular changes in disease processes and during therapy that may lead to the development of better diagnostic strategies. (This impact is discussed for specific chip technologies in the chapter ▶Peptide Chips) Considering the wider applications of chip technologies in cell biology or biomedical research, we may see some unexpected advances, that can not be predicted at present.

What can be clearly seen at present, is that chip applications will play a significant role in medical diagnostic. The revolution may be two fold. First we will see that genomics and proteomics knowledge, gained in research (also with chip technologies and bioinformatics) will change the approach to therapy decisions. In particular it will enable the medical profession to take more personal variances into consideration that may influence the decision which therapy will be used. At present we see that genomic variations that influence drug metabolism between individuals are better understood, which influence therapeutic effectiveness and undesired toxic reactions. Dedicated diagnostic chips can be used to identify the metabolic genotype, which than can be included in the selection of drugs and drug concentration.

First chip based diagnostic tools are already available on the market, a chip for the detection of mutations defining the risk for thrombosis (Ogham Diagnostics GmbH, Münster, Germany) (16) or a chip used for the analysis of mutation in cytochrome P450 2D6 and 2C19 (Roche Diagnostics) (17). The use of these diagnostic tools allows the physicians to suggest specific treatments and adjust the dosage of medication that is metabolized by the above mentioned

cytochromes, the activity of which is depending on the existing genotype.

Other potential applications are fast detection of pathogens and the resistance phenotype of the pathogen, and monitoring of the disease progress under a given therapy.

Diagnostic chips in particular as integrated micro (fluidic) devices, hold the promise that they may be used with easy to use small work stations outside a typical diagnostic laboratory. This would enable any person, who can collect the required diagnostic sample material (blood, tissue), to perform the diagnostic test.

Cholesterol Efflux

Definition

Cellular cholesterol is moved to HDL via simple diffusion LCAT-mediated FC gradient force and ABCA1-mediated active transport of free cholesterol.

► High-HDL Syndrome

Cholesterol Modification

Definition

Cholesterol modification refers to the attachment of cholesterol to proteins, especially to secreted signalling proteins that are encoded by the hedgehog gene family. Cholesterol modification involves two autocatalytic steps: a precursor protein is endoproteolytically cleaved and the C-terminal product is modified with cholesterol. Attachment occurs through ester-bond formation between the carboxyl-group at the C-terminus of the

protein and the -OH group of cholesterol. Several hedgehog proteins are also palmitoylated at an N-terminal cysteine residue via an unusual amide-linkage (N-acylation).

Synonyms

Histone acetylation

Definition

Chromatin is the basic organizational form of DNA in the eukaryotic nucleus. The repeat unit of chromatin is the nucleosome in which 146 bp of DNA are wrapped around the histone octamer consisting of two molecules each of the ▶ [histones](#) H2A, H2B, H3 and H4. Lysine residues within the amino-terminal regions of the histones (histone tails) can be posttranslationally acetylated at the ε-N position of the side chain in a process termed chromatin or histone acetylation. The position of acetyltable lysines within the histone tails is highly conserved among different organisms, H3 lysines 9, 14, 18 and 23, and H4 lysines 5, 8, 12 and 16 are targets for acetylation. Acetylation is carried out by histone acetyltransferases (HATs), and it can be reversed by histone deacetylases (HDACs). Two general classes of histone acetylation are recognized: a) acetylation of nucleosomal histones by A-type

nuclear HATs (HAT A) is linked to nuclear processes like transcription, replication and repair (see below) and b) cytoplasmic acetylation of free histones by B-type HATs is related to their deposition during ▶ [chromatin assembly](#). The chromatin acetylation state of a particular chromosomal region correlates with the transcriptional activity of the genes embedded in this region. Active genes generally lie in acetylated chromatin, whereas gene repression is accompanied by chromatin hypoacetylation. Histone acetylation may affect chromatin structure directly by altering DNA-histone interactions within and between nucleosomes, thus resulting in a more open higher-order chromatin structure. An alternative, non-exclusive model is that chromatin acetylation states, in combination with other modifications (▶ [histone methylation](#), phosphorylation, ubiquitination), present an interaction surface for other proteins (co-activators, co-repressors) that bring about gene activation or repression (1).

Characteristics

Transcription-related Chromatin Acetylation

Chromatin acetylation is generally required to overcome the inhibitory effect of chromatin to DNA accessory factors. The best-studied type of chromatin acetylation to date is acetylation coupled to transcription initiation (2). In this process, multisubunit protein complexes containing HATs are recruited by sequence-specific proteins to promoters. Two well-studied examples are yeast SAGA/human PCAF/ Gcn5 and the yeast NuA4/human Tip60 complexes, which both have roles in transcription initiation. The HAT complexes promote the association of TATA-binding protein (TBP) or other general transcription factors to the basal promoter. Promoter chromatin acetylation is also functionally connected to ATP-dependent ▶ [chromatin remodeling](#) (nucleosome sliding). Many promoters require both activities for gene activation, and the order of recruitment is a promoter-specific characteristic. Gene activation by acetylation is self-reinforcing in that both HAT complexes and chromatin remodeling complexes contain ▶ [bromodomain](#) motifs that bind to acetylated nucleosomes. Recognition and binding of effector proteins to acetylated chromatin is proposed to translate the “histone code” into a gene expression state (1).

Chromatin acetylation is also associated with ▶ [transcription elongation](#). The hyperphosphorylated, elongating form of RNA polymerase II is tightly associated with the elongator complex, which contains the HAT Elp3. Chromatin acetylation by Elp3 is proposed to facilitate the passage of the polymerase through chromatin.

In contrast to acetylation, chromatin deacetylation is generally correlated with gene repression. In analogy to HATs, HDACs are recruited to promoters and interfere with transcription initiation. In ▶ [gene silencing](#) and

► **heterochromatin** formation, HDACs deacetylate chromatin, which allows the binding of heterochromatic components that prevent transcription.

Chromatin Acetylation in DNA Repair and Replication

Functional connections exist between chromatin acetylation and DNA repair. The human HAT p300 interacts with proliferating cell nuclear antigen (PCNA), a processivity factor for the DNA polymerases δ and ϵ that functions in DNA replication and repair. Thus, p300 is recruited by PCNA to sites of DNA damage in order to acetylate chromatin in the vicinity of the damaged site. Also, the yeast NuA4 HAT complex plays roles in double-strand break repair and non-homologous end joining. Potential roles for HATs in DNA repair include improved access of repair proteins and DNA polymerases to chromatin, protection of broken DNA ends from loss or degradation and direct recruitment of repair factors, all of which are expected to facilitate damage removal and restoration of chromatin. HATs may likewise be required to facilitate DNA replication. The timing of replication initiation in yeast is advanced by chromatin acetylation, and the human HAT HBO1 interacts with ORC1, a component of the eukaryotic replication initiator, as well as with the replication-licensing factor MCM2.

Global Chromatin Acetylation

In addition to being targeted to promoters, genes or sites of DNA damage (see above), acetylation also occurs throughout the genome in a global and untargeted manner. A balance is maintained between acetylation and deacetylation, thus enabling the chromatin to be a dynamic structure. Global (de)acetylation serves to modulate basal transcription and allows the rapid reversal of changes and the return to a “ground state” after activation. Also, acetylation of specific lysine residues inhibits the binding of heterochromatic proteins to chromatin. Thus, particular HATs fulfill a boundary function in that they prevent the spreading of silencing proteins into euchromatic regions.

Histone Acetyltransferase Families

- The GNAT family includes the transcriptional activator Gcn5, human PCAF and Elp3 (Elongator complex) as well as the HAT B Hat1. In addition to the highly conserved acetyl-CoA binding site, Gcn5 and PCAF contain a bromodomain.
- The members of the MYST family of acetyltransferases also contain the acetyl-CoA binding motif. This family was named for its founding members MOZ, Ybf2/ Sas3, Sas2 and Tip60. Other members include *Drosophila* MOF (required for ► **dosage compensation**), yeast Esa1, which is the catalytic

subunit of NuA4 and human HBO1. MOF and Esa1 carry a ► **chromodomain** that in MOF has RNA-binding activity. MOZ additionally carries a PHD motif. Several members contain an atypical ► **zinc finger** that is required for HAT activity.

- p300 and CREB binding protein (CBP) are two highly related HATs that contain several discrete domains, including three putative zinc fingers, a bromodomain, an acetyl-CoA binding site and at least two independent regions that interact with multiple transcription factors (3).

Histone Deacetylase Families

- The HDAC family consists of the class I HDACs that are similar to yeast Rpd3, and the class II HDACs that resemble yeast Hda1. Four class I and five class II HDACs exist in humans. HDAC1 and HDAC2 are found in several multiprotein complexes: a) the Sin3 complex, a repressor complex that interacts with DNA binding factors, for instance MeCP2 (methyl-cytosine binding protein 2); b) the NuRD chromatin remodeling complex and c) the CoREST complex, which contains the SANT domain protein CoREST.
- The family of Sir2-like deacetylases (sirtuins) is structurally unrelated to the HDAC family. Sirtuins require NAD^+ as a cofactor for the deacetylation reaction. The founding member of the family, yeast Sir2, is required for transcriptional silencing at the silent mating-type loci, the telomeres and in the ribosomal DNA (rDNA) locus in yeast. Four homologs exist in yeast, Hst1-4 (Homolog of Sir Two) and several homologs have been identified in humans, *C. elegans* and *Drosophila*. Yeast and *C. elegans* Sir2 have been linked to aging, which may be mediated by the NAD^+ requirement of Sir2 as a link to metabolic processes and the suppression of rDNA recombination in yeast (4).

Cross-talk Between Chromatin Acetylation and Other Chromatin Modifications

Histones are subject to a diverse set of modifications other than lysine acetylation, including serine phosphorylation, lysine and arginine methylation and lysine ubiquitination. Though classically found on the histone tails, modifications have recently also been identified on the core region of histones. Individual modifications do not occur independently of each other, but rather, exert influences on each other. Thus, combinations of chromatin modifications regulate the binding of downstream proteins and ultimately modulate gene expression (5).

- A particular residue can carry only one modification at a time. For instance, lysine 9 of H3 can be either acetylated or methylated.

- Neighboring modifications influence each other. For example, phosphorylation of Ser10 of H3 by the kinase Snf1 is required for H3 lysine 14 acetylation by Gcn5.
- The modification of one histone tail regulates the modification of another histone tail (trans-tail interactions). Ubiquitination of lysine 123 in the core region of H2B regulates the methylation of lysine 4 on H3.
- Histone modifications can influence DNA methylation. Methyl-cytosine binding proteins interact with HDACs, and H3 histone methyltransferases are required for DNA methylation in *Neurospora* and *Arabidopsis*.

Clinical Relevance

Inappropriate chromatin acetylation can result in the misregulation of genes, which ultimately leads to proliferative and developmental diseases. The central role of acetylation in gene regulation also renders it a target for therapeutic intervention.

Chromatin Acetylation and Cancer

- Alterations in HATs occur in several cancer types. p300 classifies as a tumor suppressor gene, since mutations in p300 are found in epithelial cancers. Mutations in CBP are the cause for [▶Rubinstein-Taybi syndrome](#), a congenital malformation syndrome that is associated with an increased risk of cancer development.
- Several oncogenic translocations involving HAT genes are associated with leukemia. Fusions have been identified between MOZ and CBP, p300 or the transcription factor TIF2, which are postulated to misdirect HAT activity and thus result in inappropriate chromatin acetylation.
- HDACs interact with oncogenes and tumor suppressor genes. HDAC activity becomes redirected by translocations between an HDAC-controlled repressor and the DNA binding domain of a transcription factor. For instance, in translocations of PML or PLZF to retinoic acid receptor- α (RAR α), HDAC-mediated repression blocks myeloid differentiation.
- Several HDAC inhibitors suppress transformed cell growth, differentiation and apoptosis and are being clinically tested as anti-cancer drugs. Their precise mechanism of action remains to be determined, but may include increased expression of the cell-cycle inhibitor p21, which causes cell-cycle arrest in G1 and/ or G2.

Chromatin Acetylation in Other Diseases

Several disorders have been linked to chromatin acetylation and [▶epigenetic](#) control of gene expression. Fragile X syndrome, a hereditary disorder

associated with severe mental retardation, is caused by the expansion of an unstable CGG repeat in the 5' region of the *FMR-1* gene. Subsequent hypermethylation of the DNA in this region cooperates with chromatin hypoacetylation to inactivate *FMR-1*. Also, [▶Rett syndrome](#), a neurological disorder of female humans, is caused by mutations in the X-linked gene encoding MeCP2. MeCP2 mediates gene repression through interactions with the Sin3 HDAC complex. Thus, disruptions in epigenetic gene regulation are the likely molecular mechanism of this disease.

Furthermore, connections have been identified between neurological disorders and chromatin acetylation. Expanded polyglutamine-containing proteins interact with several chromatin regulators. For example, the polyglutamine portion of the Huntington's disease protein, huntingtin, directly binds and inhibits the HATs CBP and p300. Treatment with HDAC inhibitors arrests progressive neuronal degradation and lethality in *Drosophila* models of polyglutamine diseases. Another link is given by the observation that a cleaved portion of the Alzheimer protein APP forms an active HAT complex with Tip60 and thus probably has a function in gene regulation (6).

Chromatin Remodelling

LEONIE RINGROSE

Centre for Molecular Biology (ZMBH), University of Heidelberg, Germany

l.ringrose@zmbh.uni-heidelberg.de

Synonyms

The process of chromatin remodelling is also referred to as nucleosome remodelling, or more precisely, ATP-dependent nucleosome remodelling. The multiprotein complexes that carry out ATP-dependent nucleosome remodelling go by several names: nucleosome (or chromatin) remodelling machines, nucleosome (or chromatin) remodelling factors, nucleosome (or chromatin) remodelling enzymes, or simply remodellers.

Definitions

Chromatin

Chromatin is the eukaryotic cell's solution to the immense problem of genome packaging: how to fit up to 2 meters of DNA into the cell nucleus without losing access to the information it encodes. In chromatin, DNA is wrapped around histone proteins, forming nucleosomes. Each nucleosome contains 8 histone proteins (the histone octamer), that are wrapped by 1.67 turns of DNA, comprising 147 base pairs. The nucleosome is held together by weak interactions between histones and the DNA helix, at 14 sites along the length of the wrapped DNA. The sum of these interactions gives a remarkably stable structure. The

flexible N- terminal tails of the histones protrude from the globular, DNA-wrapped nucleosome core. The nucleosome is the basic repeating unit of chromatin. Nucleosomes are connected by linker DNA, whose length is typically in the range of 50 to 80 bp. In the nucleus, this fibre is folded into higher order structures whose architecture varies with gene activity (1).

Chromatin Remodelling

The term chromatin remodelling is sometimes loosely used to refer to large-scale global changes in the higher order structure of chromatin, or to local changes in the patterns of histone tail modifications, such as phosphorylation, methylation or acetylation. Although these processes are crucial for regulating gene activity and chromatin dynamics, they will not be covered here. This article will be limited to ATP-dependent nucleosome remodelling. This is itself an umbrella term, used to summarise a large number of energy-dependent alterations in the basic nucleosomal structure described above, catalysed by a large family of chromatin remodelling machines. ATP-dependent nucleosome remodelling is vital for ensuring that DNA wrapped in nucleosomes nevertheless remains accessible and open for business: be it gene regulation, replication, or repair (1, 2).

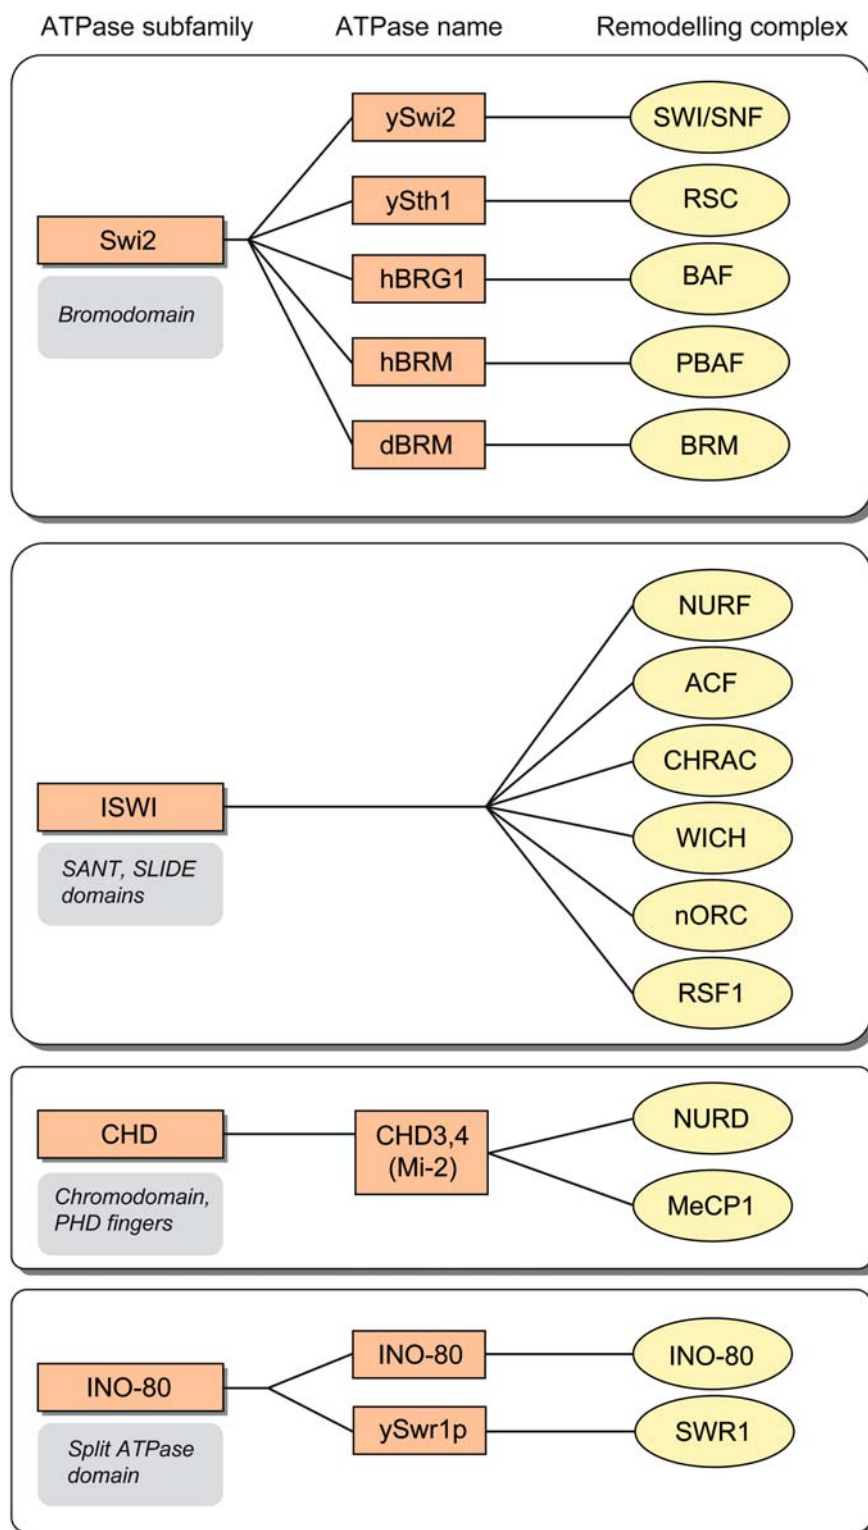

Chromatin Remodelling Machines

Chromatin remodelling machines are multiprotein complexes. All of them contain as their engine an ATPase subunit, which is accompanied by one or more other proteins that modulate its function. Different chromatin remodelling machines contain different ATPases (summarized in figure 1), which are related by the presence of a DEAD box helicase motif, and belong to the Swi2/Snf2 subfamily (2).

Characteristics

A Family Tree of Chromatin Remodelling Machines

Over the past decade, biochemical characterisation of chromatin remodelling machines has generated a bewildering array of acronyms for a menagerie of different complexes and their resident ATPases. There are four well-characterised classes of ATPase, which are united by their DEAD box motif and distinguished by their additional domains (Figure 1). Further differences are seen when isolated ATPases are compared in *in vitro* assays for nucleosome remodelling, in terms of what best stimulates their activity (free DNA or nucleosomes), and their requirement for histone tails (1). In addition, although each isolated ATPase can promote histone octamer sliding *in vitro*, they perform with different efficiencies in other assays for nucleosome mobility. Whether these differences truly reflect different reaction mechanisms for the

Chromatin Remodelling. Figure 1 A family tree of chromatin remodelling machines. Four subfamilies of chromatin remodelling ATPases are shown (orange boxes, left). All ATPases contain a DEAD-box helicase domain. Additional domains that characterize each subfamily are shown (grey boxes, left). Individual family members are listed (orange boxes, centre). Where ATPases have different names in different species, the species is indicated by y = yeast, h = human, d = *Drosophila*. Complexes containing each ATPase are shown (yellow ovals, right). For a comprehensive listing of complex subunits, see references 2, 3 and 5.

different ATPases, or simply kinetic variations on a common reaction theme, is currently a matter of debate (for example, see the opposing views in (1) and (3)). The ATPases do not work alone *in vivo*, but are accompanied by accessory proteins (Figure 1). Indeed, the presence of these proteins generally increases the *in vitro* activity of the ATPases by an order of magnitude or more, and can influence the outcome of the remodelling process. Several recent reviews give comprehensive listings of accessory proteins (1-3); however, new complexes are being discovered and named at an alarming rate. Thus, any list will probably be incomplete within a few years of its making.

Biological Processes: Remodelling Machines for Every Occasion

The main classes of remodelling complex shown in Figure 1 are not only different in terms of their resident ATPases and subunits, but also in terms of their main function in the cell.

The members of the 11 subunit yeast SWI/SNF complex were originally identified genetically as transcriptional activators. Later biochemical characterisation of the complex and its nucleosome remodelling activities lead to the idea that SWI/SNF is important for increasing promoter accessibility. The highly related RSC complex is similarly involved in transcriptional activation, although the two complexes target different genes. An important difference between SWI/SNF and RSC is that only the RSC complex members are essential for viability (2). In mammals, the situation is similar: two highly related complexes containing the BRM and BRG1 ATPases facilitate transcription of distinct sets of target genes. Knockout mice lacking BRM are viable, whilst BRG1 knockout is lethal (2, 4; see also clinical relevance, below). In *Drosophila*, the BRM complex is involved in maintaining active chromatin architecture to counteract the repressive effects of the Polycomb group proteins (2). In summary, the complexes containing Swi2 family ATPases appear to be mainly involved in loosening the repressive effects of nucleosomes during transcriptional activation.

In contrast to Swi2, the ISWI complexes are frequently found to be associated with chromatin assembly during DNA replication: another situation where nucleosomes have to be moved. Many of these complexes were originally identified in chromatin assembly extracts from *Xenopus* or *Drosophila*, as factors that enable newly assembled chromatin to space its nucleosomes in a regular array. The ISWI complexes achieve this by ATP-dependent nucleosome sliding, to “shuffle” nucleosomes into place. Although this sliding activity means that many of these complexes can facilitate transcription from chromatin templates *in vitro*, there

are several lines of evidence that their main *in vivo* role is not in transcriptional regulation, but in chromatin assembly. For example, the ISWI protein in *Drosophila* does not co-localise with RNA Polymerase II on polytene chromosomes (2). In mammals, the ACF complex, comprising ISWI and ACF1, localises to replication foci in pericentric heterochromatin (5). Highly related to ACF is the mammalian WICH complex, comprising of ISWI and WSTF. This complex localises to many sites in replicating chromatin (5; see also clinical relevance below). In summary, the main job of ISWI complexes appears to be in overcoming the repressive effects of nucleosomes at the replication fork.

The Mi2 containing complexes NURD and MeCP1 have yet another role that at first glance appears surprising for remodelling machines: they are involved in transcriptional repression. The NURD complex contains, among other subunits, a histone deacetylase. The *in vitro* deacetylation activity of NURD complexes is strongly stimulated by the ATPase Mi-2. *In vivo*, histone deacetylation is a hallmark of silent repressive chromatin, suggesting a scenario in which the NURD complex may first remodel nucleosomes to render their tails accessible, and then deacetylate, contributing to silencing. In addition, Mi-2 may shuffle nucleosomes into positions that are unfavourable for transcription. The dual action of the NURD complex is refined even further in the related MeCP1 complex, which contains the NURD subunits in addition to the MBD2 protein, which binds preferentially to DNA methylated at CpG positions. CpG methylation is associated with silenced genes. The MeCP1 complex is targeted by MBD2 to nucleosomes containing methylated DNA, where it remodels and deacetylates, thus reinforcing the local silencing marks in chromatin (2).

In yeast, the INO-80 complex is recruited to DNA double strand breaks, where it may be required to clear nucleosomes from the broken end (3). Finally, the recently characterized yeast SWR1 complex, containing the ATPase Swr1p, which is related by its split ATPase domain to INO-80, adds a new twist to the nucleosome remodelling family. This complex catalyses the exchange of histone H2A for its variant H2AZ (in yeast, Htz1), which acts as a buffer to limit the spread of silent heterochromatin, both at telomeres and other locations (3).

Mechanisms: Sliding, Jumping, Ejection and Exchange

Although the nucleosomal particle is a stable structure, it also has an inherent elasticity. Single molecule experiments have shown that by pulling in opposite directions on the two DNA ends, a nucleosome can be almost entirely unwrapped, but will nevertheless snap back to its intact structure once the tension is released. Indeed, even without such extreme experimental

disruption, nucleosomes “breathe” to a certain extent, transiently exposing stretches of their DNA, and the histone octamer will even slip back and forth along its associated DNA at elevated temperatures and salt concentrations (1, 2). The role of remodelling machines can thus be seen as facilitating and regulating this inherent dynamic behaviour.

How exactly do remodellers work? Mechanistic insights have come from *in vitro* studies, usually on single nucleosomes assembled with defined DNA fragments. All remodellers can catalyse sliding, and some can additionally catalyse jumping to another DNA segment (trans-displacement) ejection of histone octamers to entirely denude a DNA segment of nucleosomes, or exchange of histone variants.

The mechanism of nucleosome sliding is the best characterized to date. Early models for sliding envisaged a gradual movement of histone octamer along the DNA one base pair at a time, driven by the ATPase twisting the DNA helix, rather like a screw thread. These models have been laid to rest by studies of both ISWI and Swi2 class ATPases, showing that sliding proceeds in much larger steps: The remodeler attaches both to the histone octamer and to the DNA. It then lifts a section of DNA off the octamer surface, and in its ATP-dependent power stroke, pulls the DNA into a bulge (1, 6). Like a sailor hauling in a rope, the ATPase then attaches to a new site on the DNA, and the bulge is thus pumped around the nucleosome, to emerge on the other side. The net result is sliding of the histone octamer relative to its starting position on the DNA. The histone octamer itself does not appear to be disrupted. Although they both use this basic mechanism, the Swi2 and ISWI classes of remodellers show clear differences in sliding assays *in vitro*. Detailed studies of the molecular interactions of the two classes of remodellers with nucleosomes suggest that these different sliding outcomes may arise from differences in where the remodeler grabs the DNA, where it anchors on the histone octamer, and how fast it pumps DNA into the nucleosome (1, 6).

In vivo, nucleosome sliding by remodellers may provide enough access to DNA for gene activation and replication, as it would transiently expose DNA to competing factors. However, other nucleosome remodelling events such as trans-displacement, and ejection of nucleosomes, are less easy to explain by a sliding action. *In vitro*, the yeast SWI/SNF and RSC complexes can, under certain conditions, move a histone octamer to a different piece of free DNA. It is unclear whether this reaction occurs *in vivo*, since it would depend on the availability of free DNA and the concentration of remodeler (1, 2). More difficult to dismiss is the observation that *in vivo*, many active genes contain stretches of nucleosome-free DNA, showing that nucleosomes have been removed entirely

rather than merely pushed aside. It is not clear exactly what role is played by remodellers in this process. The best studied examples of nucleosome ejection are the yeast PHO5 and PHO8 promoters. Here, the histone chaperone Asf1 plays a role in dismantling nucleosomes upon activation, possibly as part of a remodelling complex (3).

The remodelling events described above all have in common that they disrupt histone – DNA contacts, leaving the histone octamer itself intact. A remarkable exception to this rule has recently been characterized. The yeast SWR1 complex, comprising the Swr1p ATPase and 12 other subunits (Figure 1), disrupts the histone octamer itself, exchanging an H2A- H2B dimer for an H2AZ- H2B dimer, resulting in exchange of the regular histone H2A for its variant H2AZ (called Htz1 in yeast). The SWR1 complex carries out an efficient exchange *in vitro*, whereas other remodellers perform poorly in this assay. Though the exact mechanism of histone exchange by SWR1 remains to be elucidated, the disruption of histone – histone interactions represents a new class of interaction that may be entirely distinct from nucleosome sliding (3).

Clinical Relevance

Several remodelling ATPases or subunits of remodelling complexes are mutated or deleted in human disease. This section covers those proteins whose reduction or disruption causes disease, and for which there is *in vitro* evidence of involvement in ATP-dependent nucleosome remodelling. However, in several cases, a direct causal link between loss of nucleosome remodelling and disease remains to be established.

The BRG1 ATPase (Figure 1) is a central regulator of the cell cycle and a tumour suppressor. The *BRG1* gene is mutated in several tumour cell lines including pancreatic, breast, lung and prostate cancer cell lines. *BRG1* $-/-$ mice die early in development, and *BRG1* $+/-$ mice are predisposed to tumours. There is clear *in vitro* evidence that BRG1 functions in chromatin remodelling, and facilitates transcription from chromatin templates. About 80 targets of BRG1 regulation have been identified by transcriptional microarray analysis (these may include both direct and indirect targets). A plausible scenario is that loss of BRG1 activity leads to loss of remodelling, and thus of transcription at a key set of genes that normally repress tumorigenesis (2, 4). The ATRX protein (α -thalassaemia, mental retardation, X-linked protein) has a long history in disease, and has long been suspected to play a role in ATP-dependent nucleosome remodelling. Recent biochemical evidence shows that the ATRX protein, in complex with the transcription factor Daxx, does indeed catalyze ATP-dependent nucleosome remodelling *in vitro*. The protein itself is huge, (2492 amino acids) and contains

a DEAD box helicase domain, in addition to a zinc finger, a PHD domain, and a plant homeodomain (7). This domain structure renders ATRX difficult to classify into any of the known families of ATPases shown in Figure 1. In humans, 25% of mutations that lead to ATRX syndrome are found in the helicase domain, and 65% are found in the zinc finger and PHD region. It is not yet clear whether loss of remodelling activity is the direct cause of all the dramatic phenotypes associated with ATRX syndrome, which include α -thalassemia, mental retardation, facial anomalies and gonadal and urogenital abnormalities. Complete absence of ATRX in null knockout mice is lethal at day 9.5. Further elucidation of the molecular mechanisms by which reduction or disruption of ATRX activity causes disease will require the identification of interaction partners and target genes (7).

Apart from the ATPases themselves, other subunits of remodelling complexes play a central role in disease, notably INI1 and WSTF. INI1 is an accessory protein shared by both the mammalian BRG1 and BRM complexes (Figure 1), and bears homology to the yeast SNF5 protein, a SWI/SNF subunit. INI1 is a potent tumour suppressor. Malignant rhabdoid tumours of the kidney and brain carry biallelic inactivating mutations of the INI1 gene. Mice in which the INI1 gene has been knocked out in selected cells develop rhabdoid tumours or lymphomas within 11 weeks, and complete knock-out of INI1 is lethal during early embryogenesis. However, it is not clear whether the tumour suppressor function of INI1 depends on its participation in chromatin remodelling complexes: the phenotype of the INI1 knockout is more severe than that of either BRG1 or BRM, suggesting that INI1 may have additional independent functions. Alternatively, it is possible that by removing INI1, both BRG1 and BRM complexes are disabled, giving more severe effects than the loss of a single complex (2, 4).

Williams-Beuren syndrome is a developmental disorder caused by deletion of a 1.6Mb region of chromosome 7, containing 15 genes, one of which encodes the WSTF protein (Williams syndrome transcription factor). Williams syndrome patients show a complex range of phenotypes, including vascular and heart defects, mental retardation and growth deficiency. The WSTF protein, together with the ATPase ISWI, forms the WICH complex (Fig. 1). This complex catalyses ATP-dependent nucleosome remodelling *in vitro*, to give regular spaced nucleosome arrays. *In vivo*, the WICH complex is recruited by PCNA to replication foci, suggesting a role in chromatin assembly. At present, it is not clear to what extent the symptoms of Williams syndrome patients are caused by loss of WICH chromatin remodelling activity. A mouse knockout of the gene encoding WSTF may throw light on this question (5).

Chromatographic Procedures

Definition

Chromatographic procedures refer to separation methods, in which substrate mixtures are dissolved in a liquid or gaseous fluid known as mobile phase. The solution passes through a column filled with a solid matrix, the stationary phase. Individual solutes interact with matrix, which retards their flow-through depending on the properties of each solute.

► [SNP Detection and Mass Spectrometry](#)

Chromodomain

Definition

Chromodomains are highly conserved sequence motifs that have been identified in a variety of animal and plant species. A chromodomain harbours a methylated lysine residue. Chromodomain proteins appear to be either structural components of large macromolecular chromatin complexes, or proteins involved in remodelling the chromatin structure. Some chromodomains have a binding affinity for histone H3 methylated on lysine 9, whereas others have RNA binding capacity.

Synonyms

Chromosome breakage syndromes

Definition

Chromosomal instability ► [syndromes](#) (CIS) are autosomal recessive genetic disorders characterised by a particularly high rate of spontaneous and induced chromosomal breakage in mitotic cells observed in microscope preparations. Chromosomal breaks stem from unrepaired ► [DNA lesions](#) sustained before ► [mitosis](#) and many of the syndromes are caused by mutations in genes required directly or indirectly for the efficient repair of DNA damage. DNA damage

can be due to environmental agents or occur as part of normal physiological processes such as ►DNA replication and ►DNA recombination. However, not all DNA repair deficiencies lead to chromosomal instability.

Chromosomal instability reflects an increased mutation rate in somatic cells and this is responsible for the greatly increased cancer incidence amongst CIS patients. In addition, in some of the syndromes, the orderly ►rearrangement of immunoglobulin genes, which requires DNA cutting and rejoining, is also disturbed, resulting in congenital immunodeficiency.

Characteristics

Table 1 lists the major CIS disorders together with some of their specific features. Although chromosome breakage is common to all, there are differences in the type of aberration observed. Figure 1a shows some of the chromosome aberrations found in cells from CIS patients. In ►Fanconi anaemia (FA) there are frequent chromatid breaks (Fig. 1b) and translocations between chromosomes (Fig. 1c), nearly always non-homologous chromosomes. In contrast, the many translocations observed in Bloom syndrome (BS) are exclusively between homologous chromosomes. In ►ataxia telangiectasia (AT) and Nijmegen breakage syndrome (NBS) lymphocytes there are often inversions and translocations, here involving particular breakpoints on chromosome 7 and chromosome 14 and affecting the genes for the heavy chain of the immunoglobulins and the T-cell receptor. This is an indication that the rearrangement of these genes is disturbed and offers a possible explanation for the immunodeficiency characteristic of AT and NBS but not, for example, of FA. In addition to spontaneous chromosomal breakage, the cells of CIS patients show a specific increase in chromosomal damage after treatment with various ►genotoxins. FA cells are particularly sensitive towards bi-functional alkylating agents that can intercalate into DNA and form covalent crosslinks between the two strands. AT, NBS and ATLD cells are particularly sensitive to ionising irradiation and chemicals such as bleomycin, which produce similar DNA lesions, in particular, DNA double-strand breaks. This differential sensitivity indicates that different pathways of ►DNA repair are involved in the various CIS disorders.

Cellular and Molecular Regulation

Chromosome Breaks and DNA Double-Strand Break Repair

It is generally accepted that visible chromosome damage is the end result of a complex cellular process for dealing with a DNA double-strand break (DSB). During repair of DSBs, DNA ends are rejoined, not, however, necessarily in the correct arrangement. In fact

the repair of DSBs probably always involves exchange of chromosome material and even simple ►chromatid breaks probably represent incomplete translocations (1). Ionising radiation and some chemicals can cause chromosome breakage independently of the phase of the cell-cycle in which the primary DNA damage occurs. Other genotoxins, such as crosslinkers, require that the cell traverses S-phase before a DNA lesion is turned into a chromosome break. This suggests that DNA crosslinks are normally detected and repaired primarily during replication. Indeed many DSBs and anomalous DNA-replication intermediates are expected to occur during replication and will be processed by the enzymes generally considered to be DNA-repair enzymes.

DNA is the only macromolecule of the cell which, when damaged, is repaired rather than replaced. The mechanisms leading to repair of DNA lesions are amongst the oldest cellular processes and have been strongly conserved during evolution. There are several different repair pathways for various types of DNA lesion; in connection with chromosomal instability it is the repair of DSBs that is particularly relevant.

The eukaryotic cell has two principle pathways for repairing DNA DSBs, repair that requires little or no homology between the rejoined sequences and homology-dependent repair (Fig. 2). Homology dependent repair can be further subdivided into 1) ►gene conversion which requires a second DNA molecule containing a copy of the sequence to be repaired and 2) single strand annealing (and related mechanisms) which use homologous sequences within a single DNA molecule to effect repair. The extremely high content of repetitive DNA in the human genome gives this latter process a particular importance.

In non-homologous end joining (NHEJ), the double-strand break is repaired by more or less simple ligation. This requires preparation of the DNA ends and necessarily results in a deletion of genomic DNA. It is, however, independent of the cell-cycle and therefore more universally applicable. Since only 2% of the genome actually codes for proteins, the deletions incurred will be tolerated by most cells.

Single strand annealing (SSA) is similar to NHEJ except that the DNA ends are digested back to regions of homologous sequence, single stranded DNA derived from both sides of the original break can then form a double-strand and DNA polymerase can replace the missing sequence using the complementary strand as a template. The process also leads to deletions.

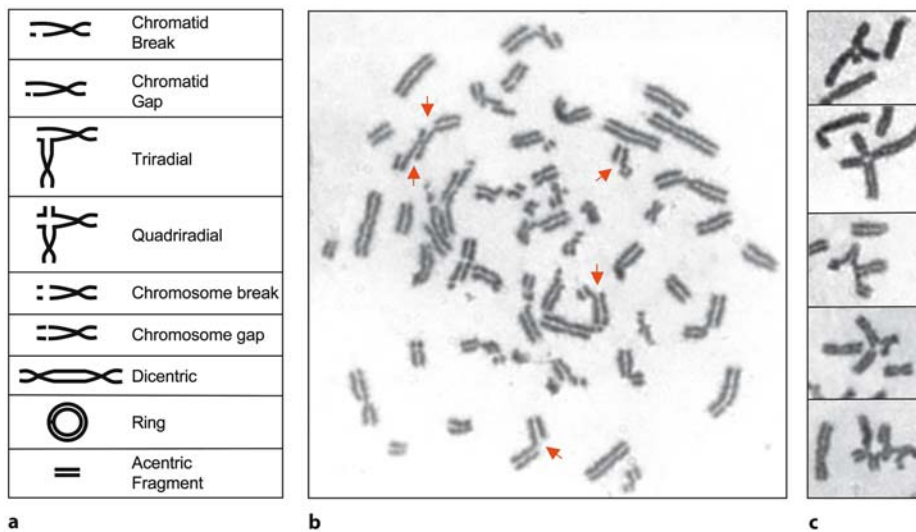

Gene conversion, a form of ►homologous recombination, is the only potentially error free pathway for repair of double-strand breaks. Here, a DNA single strand from the broken molecule invades a homologous DNA helix and searches for a sequence with which it can form complementary base pairs. In bacteria the RecA

Chromosomal Instability Syndromes. Figure 1 Chromosomal instability. (a) Schematic representation of some of the chromosome aberrations seen in lymphocyte chromosomes from CIS patients. (b) The photograph shows the lymphocyte chromosomes of a patient with Fanconi anaemia. This patient has bi-allelic mutations in the *BRCA2* gene. Only some of the chromatid breaks in this massively damaged metaphase are indicated. (c) Examples of the characteristic chromosome reunion figures seen in lymphocyte metaphases from FA patients.

Chromosomal Instability Syndromes. Figure 2 DNA double-strand break repair. The graphic shows a schematic representation of the three main double-strand break repair pathways, non-homologous end joining (NHEJ), single-strand annealing (SSA) and gene conversion (GC). In NHEJ, the DNA ends at the break at position “c” are processed and religated. In SSA, the DNA ends are resected to repetitive sequence “a” which allows complementary base pairing and resynthesis of the missing DNA strands. In GC, a homologous double helix (here in blue) is used as a template for DNA synthesis after invasion by a single strand originating at the double-strand break. Only in the GC pathway is the original “c” sequence restored.

protein is essential for this process. In mammalian cells, RecA is represented by at least 5 proteins of which ►*RAD51* is considered to be the primary functional homologue. The invaded helix generally remains intact and serves merely as a template for DNA synthesis by DNA polymerase. Thus a non-reciprocal exchange of information from the intact DNA to the damaged DNA is the result, a so-called gene conversion. Resolution of the exchange event occasionally results in a reciprocal exchange with a ►crossover event; this is, however, a relatively rare event in human cells.

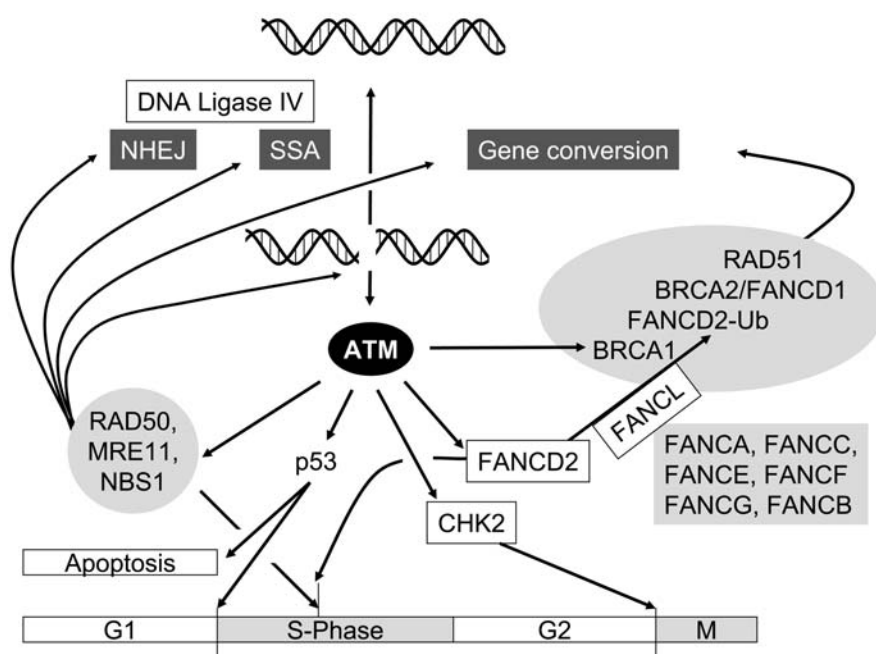

The abundance of repair pathways in the human cell reflects its homeostatic nature and ensures that DNA damage is repaired. On the other hand, it is clear that the pathways have specific inherent error rates, which necessitate the exact matching of the repair pathway with the type of lesion and its time of occurrence within the cell-cycle. It is becoming clear that some of the CIS disorders can best be explained, not by a failure to repair, but rather by the use of inappropriate repair pathways. Indeed, since the different repair pathways are competitors for the same unprocessed double-strand breaks it is understandable that even a modest inefficiency in one pathway will lead to increased use of another.

This seems to be the case at least for those FA cells in which ►*BRCA2* has bi-allelic mutations. For such

cells homology-dependent gene conversion has been shown to be reduced and homology-dependent SSA concomitantly greatly stimulated (2). Cells deficient in another breast cancer predisposition gene, ►*BRCA1*, show a similar pattern of chromosomal breakage and a shift in use of DNA repair mechanisms.

DNA-Repair and the Cell Cycle

The CIS gene, *ATM*, plays a role not only in the repair of DSBs but also in the control of the cell-cycle. Figure 3 shows the interactions of this gene product within the network of the CIS genes. ATM is a protein kinase with an enormous number and variety of target proteins, amongst others, p53, CHK2, BRCA1, NBS1 and the FA protein FANCD2 are all phosphorylated by ATM as a direct result of its induction by DSBs. A cellular characteristic of cells from AT patients and patients with the closely related NBS and ATLD disorders is their so called radioresistant DNA synthesis (RDS); the continued replication of DNA even though DNA lesions are present. This is an indication that the control of the cell-cycle is defective in these cells and indeed, ATM impinges directly on cell-cycle control *via* p53 at the border of G1-phase and S-phase, *via* the RAD50/NBS1/MRE11 protein complex and possibly FANCD2 during S-phase and *via* CHK2 at the border of G2-phase and mitosis. Not surprisingly, RDS

Chromosomal Instability Syndromes. Figure 3 The network of CIS proteins. A highly simplified schematic representation of the interactions of the gene products involved in maintenance of chromosomal stability. FANCA-FANCG, FANCL and BRCA2 (FANCD1) are the products of the 9 known FA genes, a complex of 7 of the FA proteins is required for the monoubiquitination of a further FA protein, FANCD2. The other proteins are described in the text.

is more pronounced in AT cells than in NBS or ATLD cells which are defective in only part of the network. The interaction of ATM with p53 links the detection of DSBs with programmed cell death or ►apoptosis. This is a particularly safe way of dealing with DNA damage and avoiding the risk of its fixation as a mutation. For multicelled organisms, apoptosis can prevent the development of a neoplasia. The phosphorylation of ATM target proteins does occur even in AT cells, albeit with delayed kinetics. In this case a further protein kinase, ATR, takes over the function of ATM. Mutations in ATR have been described in tumours and in a patient with Seckel syndrome, a CIS disorder with some similarities to FA.

Helicases and Ligases

Helicases, particularly the RecQ family of helicases, named after the *E.coli* helicase RecQ, are enzymes required for unwinding the DNA double helix. They are involved in many aspects of DNA metabolism and are essential for the progression of the replication fork during DNA replication. This may be especially important when the replication fork becomes stalled at a DNA lesion such as a DNA strand-break. Of the five RecQ helicases known in man, three are involved in CIS. In addition to chromosome instability and increased cancer risk, patients with Bloom syndrome, Werner syndrome and Rothmund-Thompson syndrome show growth retardation and premature ageing. Differences in the tissues prone to neoplasia are presumably reflections of tissue specificity in the expression of the helicase genes.

DNA ligases, required for the ATP-dependent rejoining of DNA ends are also involved in chromosome stability. DNA ligase I was mutated in a patient whose cells showed hypersensitivity towards a variety of genotoxins including UV, alkylating agents and ionising radiation. This presumably reflects the central role of DNA ligase I in all the DNA repair pathways. However, although this patient had an immunodeficiency, immunoglobulin gene rearrangement was undisturbed. This, and the finding that mutation in such a central gene is at all compatible with life, is yet another indication that loss of one enzyme can be compensated for by the use of other enzymes and pathways.

In contrast to DNA ligase I, mutations in DNA ligase IV do disturb immunoglobulin gene rearrangement and the immunodeficiency of CIS patients with mutations in this gene can be attributed to that disturbance. DNA ligase IV is one of the 5 proteins known to be involved in NHEJ, which is the mechanism involved in immunoglobulin gene rearrangement and is also the major repair pathway for ionising radiation-induced DSBs; ligase IV deficient cells are hypersensitive to ionising radiation.

Genetics

Most CIS disorders are inherited as autosomal recessive traits. The majority of the diseases are genetically homogeneous, however, FA shows extreme ►locus heterogeneity with at least 11 causative genes. The proteins coded by the FA genes interact with BRCA1 and BRCA2 in a multimeric nuclear complex that is involved in the repair of DNA damage, probably via the gene conversion pathway and RAD51 (3). Similarly, the NBS and ATLD gene products associate together with the RAD50 protein and this trimeric complex is activated by the ATM protein. This complex is apparently involved in DNA repair by both NHEJ and homologous recombination and also plays a role in the regulation of the cell-cycle.

Apart from the children of consanguineous parents, the majority of CIS patients are ►compound heterozygotes. Most mutations are found in single individuals or in a very small number of patients. Nijmegen breakage syndrome is an exception since over 90% of the patients are homozygous for a five base pair deletion in the *NBS1* gene (4). Founder mutations in the FA genes *FANCA* in South Africa and *FANCG* in Germany and in Japan have been described. Similarly, approximately 1% of the ►Ashkenazi Jewish population is the carrier of a founder deletion-mutation in *BLM*.

Most mutations in CIS genes lead to truncated proteins and the effect of null mutations in man is generally unknown. In mice, null-mutants for some CIS genes, such as *RAD51*, *MRE11* and *NBS1*, are embryonically lethal whilst others, such as the FA genes have a very mild phenotype. Mutations in the tumour suppressor gene, *BRCA2*, result in a high risk for breast cancer, inherited as an autosomal dominant trait. Breast cancer occurs if the second, wild type allele suffers a somatic mutation. The bi-allelic mutations in *BRCA2* found in FA-D1 patients are hypomorphic (5). Presumably the more damaging mutations are embryonically lethal in man in the homozygous state, as in *BRCA2* null-mutant mice.

Clinical Relevance

Diagnosis of the CIS disorders is routinely conducted by the examination of chromosomal breakage, particularly after a specific genotoxic treatment. However, since many CIS genes have been identified it is also possible to analyse these for mutations in potential CIS patients. This undertaking is complicated, however, by the lack of common mutations, the likelihood of compound heterozygosity and the extreme size of some of the genes, for example *ATM* with 65 exons and 9,171 base pairs of coding sequence and *BRCA2* with 27 exons and 10,257 base pairs.

If DNA from an index patient is available, molecular diagnostics for further family members are often more

efficiently achieved indirectly, by using polymorphic DNA markers to follow the segregation of chromosomes in the family.

Chromosomal Translocation

Definition

Chromosomal translocations are structural irregularities that result from a change in position of a chromosomal segment, but do not alter the total number of genes present in the cell. Translocations are caused by a chromosomal break whose ends rejoin with a non-homologous chromosome, thus generating a novel chromosome carrying segments from each.

► Methylation of Proteins

Chromosome

Definition

A chromosome is a rod-shaped structure containing the genetic material that is found in the cell nucleus. Each chromosome consists of a single, long DNA molecule with a telomere at each end, and a centromere mediating attachment to the mitotic spindle. In general, all human chromosomes have similar structures. The DNA and protein are found in the arms of the chromosomes and the genes are located at specific sites. The two arms of the chromosome can usually be identified as the short and the long arm, separated by a narrow area on each chromosome called the centromere. Every species has a characteristic number of chromosomes that are visualized as separate entities only during mitosis (e.g. humans have 46 chromosomes). Autosomes are chromosomes that occur in equal number in both sexes. Women carry two X while men carry a Y and an X chromosome. X and Y collectively are called sex chromosomes.

Definition

The use of an entire chromosome allows for the analysis of a contiguous piece of DNA large enough to contain many of the variable features of the ► [genome](#). The human chromosome 21 (Hsa21) has attracted considerable attention partly due to its small size (long arm 33.5 Mb, ~1% of the human genome) and partly

due to its association with Down syndrome. Hsa21 is continually used as a model for structural and functional genome studies. Several innovative studies have been done on features of this chromosome, such as establishment of the first ►genetic maps and ►physical maps, systematic exon trapping, sequencing, ►single nucleotide polymorphisms (►SNPs) and ►haplotype mapping and transcriptional activity (4, 6). Similarly, comparative genomics of Hsa21 combining computational, experimental and evolutionary analyses allowed us to provide evidence for a large number of potentially functional but non-genic conserved sequences (1). The development of the genomic infrastructure of Hsa21 and the quality of its ►annotation has greatly facilitated medical related research. To date, 22 Mendelian ►monogenic disorders have been mapped to the chromosome, and for 20 of these, the affected genes and their respective mutations have been identified. These disorders cover a wide range of medical conditions, from autoimmune disorders to cancer, and in some cases they have illustrated novel mutational mechanisms (Table 1).

In this chapter we describe the main features of ►trisomy 21, the monogenic disorders that map to this chromosome, the gene catalogue and other features of the sequence, and some of the tools that can be used to understand how chromosome 21 genes contribute to human pathology.

Characteristics

Trisomy of Chromosome 21—Down Syndrome (OMIM#190685)

Down syndrome (DS) was first described as a clinical entity in 1866 by John Langdon H. Down in a group of patients with a series of common phenotypes including mental retardation, characteristic facies, short stature and muscle hypotonia (2). ►Cytogenetic studies showed that DS was caused by trisomy 21 almost a century later (5). Extensive characterization has revealed a variety of phenotypes in DS individuals such as early-onset Alzheimer disease, congenital malformations in the heart (present in 30–40% of patients) and the gastrointestinal tract, immune system alterations and multiple dysmorphic features. However there is considerable variation in the expression of these phenotypes from patient to patient (3). DS is the most common cause of genetic mental retardation affecting 1 out of 700 live births in all human populations. Moreover there is a pronounced maternal age effect with risk increasing from about 1/1000 at the age of 30 to 9/1000 at the age of 40. In terms of the cytogenetic alterations present in DS individuals, one can distinguish four categories (see schematic representation in Fig. 1):

1. Free trisomy of Hsa21 is the most common cause of DS observed in 92.5% of cases. The extra chromosome originates from a non-disjunction event in maternal ►meiosis I (73% of the free trisomy cases), in maternal meiosis II (18%), in paternal meiosis (4%) or in mitosis (5%).
2. ►Translocation trisomy of Hsa21 with another ►acrocentric chromosome (usually Hsa14 or Hsa21) is observed in 4.8% of DS patients. The t(14;21) translocations originate primarily from *de novo* maternal germ cells rearrangement. The t(21;21) rearrangement is usually an ►isochromosome, generated by a duplication of the long arm of Hsa21 rather than a real robertsonian translocation. The t(21;21) ►duplication can be of maternal or paternal origin.
3. Partial trisomy is a very rare event in which patients present several of the DS phenotypes, but only a partial duplication of the long arm of Hsa21. The study of these rare patients allows definition of gene candidates for each DS phenotype.
4. Trisomy 21 ►mosaicism is observed in 2.8% of patients. Affected individuals have cells with three copies of Hsa21 and cells with two copies of Hsa21. The phenotype of these individuals is highly variable and thus impossible to predict. This can be caused by a mitotic non-disjunction event early in the postzygotic life, or by the early loss of an Hsa21 in trisomic cells.

Monogenic Disorders

There are a number of monogenic disorders that have been linked to Hsa21 (a complete list is available in Table 1). The first of these disorders to be characterized was leukocyte adhesion deficiency (LAD), an autosomal recessive disorder affecting neutrophil function that results in recurrent bacterial infections. The ITGB2 gene was shown to harbor mutations in patients with LAD. Since then additional monogenic disorders have been mapped to chromosome 21, and for the majority of these, the mutated gene has been identified (Table 1). Examples of these include (i) the autoimmune polyendocrinopathy syndrome (APECED), which was the first autoimmune syndrome to be characterized at the molecular level, (ii) progressive myoclonus epilepsy 1 (EPM1), which is caused in most cases by the expansion of a dodecamer repeat upstream of the CSTB gene, a novel mutation mechanism which results in the gene down-regulation and (iii) autosomal recessive congenital neurosensory deafness types 8 and 10 (DFNB 8/10) caused by another novel mutational mechanism, the insertion of a β -satellite repeat in the coding region of the Tmprss3 gene.

Chromosome 21, Disorders. Figure 1 Disorders of Chromosome 21.

Susceptibility Alleles to Complex Common Phenotypes

In addition to the monogenic disorders, there are complex disorders for which there is considerable evidence of [linkage](#) to Hsa21 (Table 1). Complex disorders, usually refer to common diseases with a strong genetic predisposition that segregate in a non-Mendelian fashion. They are thought to be mediated by multiple allelic variations in more than one gene as well as non-genetic factors. For two such disorders, bipolar affective disorder (BPAD), and familial combined hyperlipidemia (FCHL), loci on chromosome 21 are thought to play important roles, however the gene or genes responsible remain elusive.

Cellular and Molecular Regulation Gene Catalogue

Initial annotation of the entire sequence of Hsa21 by a combination of experimental and bioinformatics approaches revealed 127 genes and 98 predicted transcripts (4). However experimental confirmation of the predicted transcripts and more sensitive *in silico* methods for gene detection, together with the completion of the sequencing of several genomes in particular that of the mouse permitted an update of this catalogue, which currently contains around 290 genes. Following characterization of the Hsa21 gene repertoire, the next goal is to uncover the genes' functions and to determine which ones are involved in DS and other disease

Chromosome 21, Disorders. Table 3 Mouse models of DS

Model	Genotype	Neurological phenotype
Segmental trisomy		
Ts16	Trisomy 16	Reduced brain size and some structural changes
Ts65Dn	Trisomic for App-Znf295 (~86 known genes)	Learning and behavioral deficits, degeneration of basal forebrain cholinergic neurons Reduction of the cerebellar volume and granule cell density Reduced cell number and volume in the hippocampal dentate gyrus Reduction in excitatory (asymmetric) synapses in the temporal cortex at advanced ages Age-related degeneration of basal forebrain cholinergic neurons Astrocytic hypertrophy and increased astrocyte numbers
Ts1Cje	Trisomic for Znf295-Sod1 (~53 known genes)	Learning and behavioral deficits (less severe than in Ts65Dn)
Ms1Ts65	Trisomic for App-Sod1 (~33 known genes)	Learning deficits (less severe than in Ts1Cje)
Ts1Rhr	Trisomic for Mx1 to Cbr1	No cranofacial abnormalities
Single Genes		
TgSod1	Transgenic for human SOD1	Learning defects
TgPfkf	cDNA, highly over-expressed	-
TgS100β	2-12 copies	Astrocytosis, neurite degeneration
TgApp	YAC, low copy	Cognitive/behavioral defects
TgEts2	cDNA, highly over-expressed	-
TgHmgn1	2-6 copies	-
TgDyrk1a	YAC, 1-3 copies, and cDNA, highly over-expressed	Learning/memory defects
TgSim2	BAC, 1-2 copies, and cDNA, highly over-expressed	Behavioral defects

phenotypes. Among the known Hsa21 genes there are at least 10 kinases, 5 genes involved in ubiquitination pathways, 20 transcription factors, 5 cell adhesion molecules and 7 ion channels. Second generation annotation by functional genomics approaches will undoubtedly contribute to the understanding of the functions of Hsa21. To this end, the first chromosome-wide “Gene Expression Atlas” was produced using Hsa21 as a model. This resource contains the spatio-temporal expression pattern of all chromosome 21 mouse orthologous genes (7). These data can be used to refine candidate gene lists for both monogenic disorders and Down syndrome sub-phenotypes. The mouse is a well-characterized organism for modeling human disease states. As homologous

recombination in mouse allows the engineering of loss-of-function mutations in specific genes, we can study Hsa21 monogenic disorders and gene function using orthologous genes knockouts as exemplified in Table 2. Furthermore the study of these mouse phenotypes could help to unravel potential novel monogenic disorders that map on Hsa21 (Table 2 also describes phenotypes of mouse mutants for Hsa21 orthologous genes not yet linked to monogenic disorder).

Molecular Mechanisms of Pathogenesis in DS

One of the major current challenges for the chromosome 21 and DS related research is to understand which and how chromosome 21 genes contribute to the specific phenotypes of Down syndrome. The current

working hypothesis is that some but not all genes and non-genic conserved sequences in Hsa21, when present in three copies contribute to DS phenotypes. Some of the contributing genes and non-genic conserved sequences might exert a direct effect, and thus cause specific DS phenotypes, whereas others could have an indirect effect by altering downstream transcription pathways.

In addition, the incomplete penetrance of many DS phenotypes argues for allelic effects, i.e. that a specific DS trait is only present when the individual has inherited a certain combination of alleles in specific loci. In order to dissect each of these mechanisms three main experimental approaches are being taken:

1. Differential gene expression analysis between normal and trisomic cells and tissues. This approach should allow the identification of the genes and pathways that are deregulated in trisomic cells, and therefore might be implicated in pathology.
2. Development of mouse models of human trisomy 21, which can be either single gene trisomic mice, or segmental trisomic mice, described in detail in Table 3. For single gene trisomic mice, a candidate gene is over-expressed and its specific effects can be studied. For segmental trisomies large regions of mouse chromosome [▶syntenic](#) to Hsa21 are duplicated in order to model the human disease.
3. [▶Association studies](#) using single nucleotide polymorphisms (SNPs) in order to identify genetic variation that might contribute to specific DS phenotypes that are present only in a subset of patients.

Clinical Relevance

Understanding the molecular consequences of [▶aneuploidies](#) should lead to the discovery of genes responsible for several phenotypes, including the cognitive impairment of trisomy 21 patients, and provide targets for potential therapeutic interventions (8). Moreover identification of the molecular defect in monogenic disorders allows the discovery of the molecular pathophysiology, which in turn leads to the introduction of novel therapies and new accurate molecular diagnostics. Finally the discovery of susceptibility alleles for common disorders will also contribute to early diagnosis and therapeutic interventions.

Chromosome Bands

Definition

Various chemical and physical treatments, followed by incorporation of dye, may be used to produce a pattern of specific transverse light and dark bands on condensed metaphase chromosomes. These bands correspond to clusters of GC- and AT-rich, and early- and late-replicating DNA, respectively, and thus reflect the underlying longitudinal structural and functional compartmentalisation of chromosomes.

Definition

Chromosomal DNA, if stretched end-to-end, measures about 2 m in any one cell of the human body and therefore it must be highly folded to fit into a nucleus of

only 5 μm diameter. In addition to this, DNA has to condense even more prior to cell division in order to form the highly compacted metaphase **chromosome**. Several levels of packing enable DNA to achieve this packaging and a number of structural proteins are involved. The simplest level of packing involves the winding of DNA around octamers of core histones in a structure called the nucleosome. This shortens DNA about 7-fold relative to naked DNA. The folding of regularly spaced nucleosomes forms a shorter, thicker filament, called the 30 nm chromatin fibre, in which the DNA is about 40-fold more compact than when naked. The most highly condensed and least understood stage takes place prior to chromosome segregation when the DNA in metaphase chromosomes of higher eukaryotic cells is compacted nearly 10,000-fold in length. Each chromosome must not only be compacted, but also resolved into two individual sister chromatids separable in **mitosis**. The way that chromatin organizes into this higher-order structure of mitotic chromosomes is not well understood and the different models that have been proposed remain controversial.

Characteristics

First Level of Compaction: The Nucleosome

Interphase nucleosomal chromatin under low salt conditions appears (by electron microscopy) as “beads on a string” with a diameter of about 10 nm. This packaging results when 166 bp of DNA wind around an octamer of core histones in a left-handed superhelix following a helical path along the surface of the octamer. The histone octamer consists of an $[\text{H3}]_2:[\text{H4}]_2$ tetramer, flanked on either side by an H2A:H2B heterodimer. Each core histone has a compact domain of 70–80 amino acid residues and a flexible N-terminal tail of approximately 30 amino acids outside the nucleosome. These N-terminal tails allow the nucleosomes to pack into a 30 nm fibre, while specific modifications of the tails are crucial for modulation of chromatin structure. Histone H1, or other linker histones, bind to a variable amount of “linker” DNA that extends between adjacent nucleosomes. The N-terminal tails of the histones are also important for extra-nucleosomal interactions. The variants of linker histone differ from the core histones in that the globular central domain is flanked by unstructured basic domains at both the N- and C-termini. Histone H1 resides at the side of nucleosome where DNA enters and exits the nucleosome. The master cell-cycle regulatory kinase, CDK1 (cdc2: cyclin B), phosphorylates serine and threonine residues on the histone H1 tails during mitosis. Hyperphosphorylation of histone H1 was originally thought to be important for mitotic chromosome condensation but recent studies show that it is not required for this process. Mitosis-specific phosphorylation of histone H3 at serine-10 (by Aurora

B kinase) is also not necessary for mitotic chromosome condensation. The N-terminal tails of histones may also be acetylated or methylated, resulting in an epigenetic “histone code” important for gene expression or assembly of heterochromatin.

Above and Beyond the Nucleosome

Chromatin isolated from interphase nuclei has a diameter of 30 nm. This fibre has been variously modelled as either a solenoidal coiling, random or organized folding of the nucleosomal fibre – its actual structure remains undetermined. Fragility of the 30 nm fibre during preparation is probably responsible for the inability to ascertain its architecture unambiguously. However, the 40-fold length compaction within the 30 nm fibre is not nearly enough to account for the compaction of the genome in interphase nuclei or mitotic chromosomes.

Mitotic Chromosome Condensation

The mechanism for packaging the 30 nm fibre into the highly compact, characteristic rod-shaped mitotic chromosomes remains a fundamental question for modern cell biologists. The shortening of DNA by roughly 10,000-fold is essential for the proper physical separation of sister chromatids to opposite poles, e.g. in order to avoid cleavage of the genome by an ingressing cleavage furrow. In addition, chromosomes must be properly aligned *via* their **kinetochores** to ensure that one of each chromatid pair ends up in each new daughter cell. However, early approaches utilizing electron microscopy to examine isolated native mitotic chromosomes only served to confirm that the DNA is indeed very densely packed within chromosomes.

Several approaches have been utilized in an attempt to expose the factors underlying higher order chromosome structure. By depleting core histones from highly purified mitotic chromosomes (either with a high salt concentration or polyanions which compete with histones by charge) under conditions that maintain residual non-histone proteins, some of the first hints about large scale chromatin folding were obtained. Long extended loops of DNA (about 15–100 kb) surrounded a protein core that retained the general size and shape of a native chromosome. These striking images led to a model known as the “radial loop model” in which the folding of the chromatin fibre into loops is mediated by proteins of an insoluble chromosome “scaffold” that is essential for the final size and shape of a chromosome. Others though considered the scaffold to be an artefact, a result of inappropriate protein interactions created during preparation of this fraction. Nonetheless, this model was first proposed more than 25 years ago, and there is a significant amount of data supporting it. A:T-rich DNA sequences (SARs – scaffold attachment regions, or

MARS – matrix attachment regions) have been identified as the *cis*-sequences interacting with the proteinaceous component. The DNA intervening between two SAR sequences bound to the “scaffold,” separated by up to 100 kb of DNA, would form a chromatin loop.

Protein Components – ▶ Topoisomerase II and ▶ Condensin

A biochemical analysis of scaffolds showed there were two major components, Sc1 and Sc2, which later were identified as DNA topoisomerase II and SMC2 (a subunit of the condensin complex), respectively. In addition to this, characterization of chromosomes remodelled from sperm chromatin in *Xenopus* egg extracts, resulted in the identification of several protein components of these *in vitro* assembled structures. The mitotic chromosome fraction contained histones and linker histones, topo II α , chromokinesin, the ▶ **chromatin remodelling** ATPase ISWI, and a complex subsequently named condensin. These studies demonstrated that mitotic chromosomes are rich in ATPases, which are probably important to induce conformational changes in chromosomes and to support microtubule-dependent movement of chromosomes.

Topoisomerase II is an ATP-dependent enzyme that can alter DNA topology by passing one double-strand helix through another *via* a transient double-strand break, an activity necessary for the resolution of catenated sister DNA strands. Topo II is located both at the centromeres and axially along mitotic chromosome arms at the base of loops. All eukaryotic organisms have at least one topo II. Higher eukaryotes though, have two isoforms (topo II α and topo II β) that have similar catalytic activities *in vitro* but different localization *in vivo*. Topo II activity is required for the resolution of the catenated strands of DNA so that each chromatid of a pair becomes an individual unit, facilitating successful separation during anaphase. Indeed, mutations in topo II in both *Saccharomyces cerevisiae* and *Schizosaccharomyces pombe* were lethal in mitosis, with sister chromatids failing to segregate properly. Further analysis in *S. pombe* revealed that topo II was also required for the final stages of chromosome condensation, possibly in collaboration with the condensin complex, but its exact role in this process is not yet clear. In *Drosophila*, depletion of topo II by ▶ **RNAi** resulted in a 2.5-fold decrease in the level of chromatin compaction but overall chromosome condensation occurred without topo II. In the same study, chromosome morphology was abnormal and one or more chromosome arms frequently stretched out from the metaphase plate, suggesting an unexpected role for topo II in chromosome arm congression to the metaphase plate. Even though topo II seems to be important for the establishment of chromosome

condensation in many different organisms, in *Xenopus* egg extracts it seems not to be essential for the maintenance of chromosome condensation, suggesting that topo II might contribute to the early stages of this process. Interestingly, as chromosomes decondense at the end of mitosis, topo II α undergoes specific degradation, only to be resynthesized at the start of S phase if cells are actively cycling.

ScII was identified as SMC2, a structural maintenance of chromosomes protein, and a member of the condensin complex. This complex consists of two ▶ **SMC proteins** (SMC2 and SMC4) and three non-SMC subunits (CAP-D2, CAP-G and CAP-H). SMC2 and SMC4 form a heterodimer and the non-SMC subunits presumably play regulatory roles. The SMCs are present in all species examined and they constitute a family of highly conserved and ubiquitous proteins. All members are large polypeptides with a molecular mass of 115–165 kD and a similar structural organization. The proteins have two extended coiled-coil domains, which are separated by a central globular hinge region. The N- and C-termini flanking the coiled-coil domains are highly conserved among SMC proteins. The N-terminal domain contains a Walker A box (an ATP-binding motif). The C-terminal domain contains a “DA” box resembling a Walker B site (ATP hydrolysis motif) and it has been shown to bind DNA. Eukaryotic SMCs comprise at least six distinct subfamilies (SMC1-SMC6), which form 3 different heterodimers: SMC1/SMC3 (chromatid cohesion), SMC2/SMC4 (chromosome condensation), and SMC5/SMC6 (DNA repair). Recent data suggests that each of the SMC subunits of the ▶ **cohesin** and condensin complex folds intramolecularly and their heterodimerisation is mediated by a hinge-hinge interaction. The intramolecular folding of an SMC molecule allows the association of the N- and C-terminal domains and the formation of an ATP catalytic domain at each end of the heterodimer. The non-SMC subunits bind to one or both of the catalytic domains.

Much of the current understanding of condensin activity comes from the biochemical characterization of the complex from *Xenopus* egg extract. In this system it has been shown that all five subunits are necessary for DNA-stimulated ATPase activity, which reconfigures DNA in an ATP-dependent manner. Condensin introduces positive supercoils into relaxed circular DNA in the presence of topoisomerase I and converts nicked circular DNA into positively knotted forms in the presence of topoisomerase II *in vitro*. Recent observations of the condensin complex by spectroscopic imaging suggest that a single condensin complex organizes two oriented supercoils, thus inducing superhelical tension. A model that emerges from these observations is that each of the two end domains wraps DNA into nearly one superhelical turn

allowing a single condensin complex to create two supercoils. Although the way that DNA interacts with the two-armed structure of condensin is unknown, a recent study showed that the region that binds DNA might be in the coiled-coil arms and not in the catalytic domains. A similar model has been recently proposed for the action of cohesin. Another study suggests that condensin may form a DNA loop by holding two distantly located DNA segments.

Two models have been proposed to explain how condensin may act on chromatin but both models are highly speculative. The first model proposes that local positive supercoiling driven by condensin introduces a compensatory superhelical tension into the neighbouring region of DNA, which in turn acts as a driving force for the compaction of a chromatin fibre. The problem with this model is that there is no evidence for superhelical tension in metaphase chromosomes. The second model is based on the prediction that a single condensin complex introduces two positive supercoils by a trapping mechanism and forms a topological link between the condensin “clamp” and the trapped DNA strands. If a free translocation of the DNA strands were allowed without disrupting the topological link, a positive loop of DNA would be created. A continuing creation of positive loops by the action of condensin might contribute to mitotic chromosome organization.

Even though condensin was originally thought to be responsible for chromosome condensation (hence the name), recent genetic studies in different organisms suggest that this complex is required for the proper organization and segregation of mitotic chromosomes and not condensation *per se*. Yeast mutations in the condensin complex increased the average distance between two loci on a mitotic chromosome arm, in the same way depletion of condensin from *Xenopus* mitotic egg extracts resulted in less compact chromosomes. Condensin however seems to be more than a simple compactor and is essential for resolution between sister chromatids *in vivo*. In *Drosophila* SMC4 mutants, shortening of the longitudinal axis of the chromosomes was unaffected, but chromosomes failed to resolve into two distinct chromatids at prophase, and then showed chromosome bridging in anaphase. Similarly depletion of SMC4 by RNAi in *Caenorhabditis elegans* caused dramatic abnormalities in chromosome morphology at prometaphase, yet a high degree of compaction still occurred by metaphase. Mutation or RNAi of non-SMC condensin subunits also resulted in aberrant chromosome segregation (but apparently normal condensation). In *Drosophila*, depletion of the condensin subunit SMC4 disrupted the localization of topo II in a central axial structure and furthermore to led a reduction of topoisomerase II-dependent DNA decatenation activity *in vitro*.

Condensin appears to be required for proper chromosome organisation, thus facilitating the action of topo II in sister chromatid resolution. Recently in an ScII/SMC2 knockout in chicken cells, it was found that chromosome condensation was delayed but it could finally reach its normal levels. In this study, mitotic chromosomes were missing a number of scaffold proteins and they lacked structural integrity, indicating that condensin was necessary for the establishment of a robust chromosome structure. One of the most important results to date is the observation that when both topo II and condensin are disrupted by RNAi, chromosomes are still able to condense. There are clearly more components essential for mitotic chromosome condensation to be identified.

The supercoiling activity of the condensin complex has been shown in vertebrates to require mitosis specific phosphorylation of the three non-SMC subunits by CDK1, the major mitotic kinase. CAP-D2 is phosphorylated at its C-terminus probably directly by CDK1, while CAP-H is phosphorylated probably by CDK1 or other kinases. The hyperphosphorylation of the non-SMC subunits is proposed to have two dual roles. The first one is to activate the ATPase activity of SMCs and the second to allow the condensin complex to be associated with chromatin in a mitosis-specific manner.

Recently a second condensin (II) complex was identified in vertebrate cells. Both complexes share SMC2/SMC4, but contain different sets of non-SMC subunits. The two complexes may have distinct distributions along chromosome axes, but show a similar distribution at the centromere region. It has been proposed that the two complexes make distinct mechanistic contributions to mitotic chromosome architecture in vertebrate cells. Depletion of condensin I or condensin II produces weaker defects in chromosome morphology, while simultaneous depletion of both complexes causes the severest defect. Furthermore, the centromeric regions were structurally disorganised after the depletion of either condensin I or II subunits, suggesting a role for both complexes in centromere organization. Sequence comparisons suggest that condensin II should exist in other organisms, but experimental data will confirm if that is the case.

Along with the phosphorylation of condensin subunits by the master mitotic kinase CDK1, the phosphorylation of histone H3 at the onset of mitosis has been proposed to play a role in condensin recruitment and chromosome condensation. Histone H3 mutations in *Tetrahymena thermophila* show abnormal chromosome condensation and extensive chromosome loss. In *C. elegans*, *Drosophila* and human cells, Aurora B, a chromosome-bound kinase, is targeted to chromosomes along their length during prophase, becomes concentrated at the centromeric regions during

metaphase and is transferred to the spindle midzone when sister chromatids are separated in anaphase. This kinase is thought to interact with two other molecules, the inner centromere protein (INCENP) and survivin, which together are referred to as chromosomal passengers. Aurora B has been proposed to be the physiological kinase that phosphorylates histone H3 during mitosis. A model that connects the phosphorylation of histone H3 and chromosome condensation is that the modification of the histone may send a signal to initiate chromosome condensation. The phosphorylation could function as a receptor for the recruitment of proteins such as the condensin complex. Experiments in several organisms though, suggest that the phosphorylation of histone H3 is not responsible for the direct recruitment of condensin onto chromosomes and chromosome condensation is not affected when histone H3 phosphorylation is diminished by depletion of Aurora B. Future work will clarify the role of H3 phosphorylation in mitotic chromosome dynamics.

Dependence on Appropriate DNA Replication and Repair

The final condensation of mitotic chromosomes is dependent not only on mitotic events, but also on appropriate timing of DNA replication and the satisfaction of DNA-structure checkpoints. In *Drosophila*, mutations of ORC2/3/5, subunits of the origin recognition complex, result in the formation of irregularly condensed chromosomes in mitosis. Regions of euchromatin that were replicated abnormally late in these mutations showed a severe condensation defect in contrast to other regions of the chromosome. Mutations in RFC4 (subunit 4 of replication factor C) resulted in DNA-structure checkpoint defects, chromosome pulverization (mitotic catastrophe) and also prematurely separated chromosomes in mitosis – as results of interfering with different functions of RFC. Whether the condensation defect observed in these mutants is a direct effect on topo II or condensin, is currently unknown.

A Yin-yang Balance with Cohesion?

Sister chromatid cohesion is established between the two replicated sister chromatids during S phase by an evolutionarily conserved complex called cohesin. The cohesin complex (a heterodimer of SMC1 and SMC3 and two additional non-SMC subunits – Scc1 and Scc3) is essential for holding sister chromatids together until the onset of anaphase, ensuring the accurate 1:1 partitioning of chromatids. In yeast all cohesin dissociates from chromosomes at the beginning of anaphase when the Scc1 subunits are cleaved. In higher eukaryotes, most of the cohesin complex already dissociates from chromosome arms in prophase after

phosphorylation by the polo kinase with only a small amount of cohesin left at centromeric regions. Residual cohesion is lost at the onset of anaphase by the cleavage of the Scc1 non-SMC subunit. The dissociation of cohesin from chromosome arms in prophase could facilitate either the condensation or resolution of chromatids. Alternatively, condensation may help to release cohesion between chromatids. However, loss of Scc1 (and cohesion) by RNAi has no apparent effect on condensation. It is still plausible that a mechanism ensuring the correct balance between cohesin and condensin may exist. A structural and functional link between cohesion and condensation, if it exists, remains to be determined.

We have attempted to highlight some of the most important issues surrounding chromosome organization and condensation throughout the cell-cycle. The organization of a “scaffold” and its association with specific DNA sequences, along with the mechanisms by which chromosomes condense prior to mitosis or decondense after mitosis are poorly understood. Nevertheless, exciting progress is being made through diverse approaches. We also believe there are as yet, uncharacterized factors that play crucial roles in these events, which may even result in the proposal of new models for the dynamics of higher order chromosome architecture.

Clinical Relevance

Chromosome condensation (and segregation) is a necessary part of cell division and the formation of a multi-cellular organism. Not surprisingly therefore, aberrations in this process have extreme implications for human health. The currently accepted rate of aneuploidies in pre-implantation embryos is 20%, while for miscarriages it is 35%! Less than 1% of live births are aneuploid, most commonly with a missing or extra sex chromosome or an additional chromosome 21 (►Down syndrome). Quite obviously, anything but the diploid state is incompatible with normal life.

Aneuploidy is also a factor, albeit less well understood, in the development of cancer (many solid tumours have between 60–90 chromosomes instead of the normal 46 in human). As transformed cells exhibit defective division control, targeting actively dividing cells has long been a chemotherapeutic strategy (with the undesired side effect of damaging normal dividing cells). Intriguingly, however, a number of topoisomerase II inhibitors are used in the clinic to treat particular cancers. This suggests that other proteins important for chromosome organization and dynamics may also be useful therapeutic targets.

Chromosome Instability

Definition

Chromosome instability refers to signs of impaired structural integrity of a chromosome seen at metaphase,

such as breaks, loss of chromosome material, dicentric chromosomes, joining of chromosomes, acentric fragments, ring shaped chromosomes and other deviations from the normal structure.

► [Bloom Syndrome](#)
 ► [Chromosomal Instability Syndromes](#)

Chromosome Passengers

Definition

Chromosome passenger proteins are proteins that are present in the centromeric region of chromosomes in pro-metaphase cells, but translocate to the spindle midzone at the onset of anaphase, and finally collect at the spindle equator just prior to the telophase. It has been suggested that chromosome passenger proteins play a role in the control of cytokines. So far there are 5 known members: INCENP, survivin, Aurora B, TD-60, and borealin.

Circadian Clocks

ACHIM KRAMER

Institute for Medical Immunology, Laboratory of Chronobiology, Charité University Medicine, Berlin, Germany

achim.kramer@charite.de

Definition

► **Circadian** clocks are endogenous ► **oscillators** that drive daily rhythms in physiology, metabolism and behavior. They provide organisms, ranging from unicellular algae to humans, with an internal representation of local time, thus allowing them to anticipate daily recurring chances and challenges in their environment. The components of circadian clocks are highly conserved among all animal species and the fundamental mechanism of circadian timekeeping is cell-autonomous. Within almost every cell, a gene-regulatory network involving clock genes and clock proteins forms a molecular clockwork that regulates many cellular processes including gene expression, neuronal activity, secretion of bioactive molecules, metabolism, mitosis, apoptosis etc. These molecular rhythms ensure temporal coordination of tissue-specific physiology and global behavioral states such as the sleep-wake cycle.

Characteristics

Circadian rhythms are self-sustained, endogenously generated oscillations, i.e. they persist in constant conditions indefinitely without any exogenous time information. The endogenous period of these rhythms is close to but not exactly 24 h. In contrast to other biological oscillations, the circadian period is temperature-compensated, i.e. it is almost invariable over a wide range of temperatures. Circadian rhythms are synchronized (entrained) to the light-dark cycle of the environment by a specialized input pathway (see below) to ensure a stable ► **phase** relation of the endogenous oscillator to the outside world. In mammals, circadian timing is organized in a hierarchy of multiple circadian oscillators. The master clock resides in the suprachiasmatic nucleus (SCN) of the hypothalamus controlling the phase of circadian clocks in other brain areas as well as peripheral organs. In this chapter, the circadian system of mammals is primarily described, for other organisms see (1).

Molecular Interactions

Molecular Basis of Circadian Rhythm Generation in Mammals

A cell-autonomous gene-regulatory network generates circadian rhythms in the mRNA and protein concentrations of clock genes with a delayed negative feedback as the fundamental mechanism (Fig. 1). The basic helix-loop-helix (bHLH) transcription factors CLOCK and BMAL1 activate as a heterodimer the transcription of the *Period* (*Per1*, *Per2*, *Per3*), *Cryptochrome* (*Cry1*, *Cry2*) and *Rev-erb* genes, by binding to ► **E-box** enhancer elements in their promoters. After a delay of several hours, PER and CRY proteins translocate into the nucleus and inhibit CLOCK/BMAL1 transactivation. As a consequence

Circadian Clocks. Figure 1 Schematic view of the gene-regulatory network involving interlocked negative and positive feedback loops that generate molecular circadian rhythms. In a negative feedback loop (red arrows), the transcription factor heterodimer CLOCK/BMAL1 activates the transcription of *Per*, *Cry* and *Rev-erb* genes via binding to E-box elements in their promoters. PER proteins are bound, phosphorylated and thereby destabilized by CK1ε. Complex formation with CRY proteins leads to nuclear accumulation of the PER/CRY/CK1ε, which inhibits the transactivational activity of CLOCK/BMAL1. In a positive feedback loop (green arrows), *Bmal1* transcription is activated (de-repressed) by PER/CRY/CK1ε, because this complex also inhibits REV-ERBa synthesis, which on its part represses *Bmal1* transcription via binding ROR response elements (RORE).

of inhibiting the activators of their own synthesis, PER and CRY levels fall, CLOCK/BMAL1 are no longer inhibited and the cycle restarts.

Not only are the *Per*, *Cry* and *Rev-erb* genes expressed rhythmically, but also *Bmal1* mRNA levels oscillate, with a phase opposite to those of the *Per* and *Cry* mRNAs. This is caused by the orphan nuclear receptor REV-ERBa that rhythmically represses *Bmal1* transcription via binding to ► **ROR response elements** in the *Bmal1* promoter.

The time delay between transcription of *Per* and *Cry* genes and their action as nuclear inhibitors of CLOCK/BMAL1 transactivation is crucial for generating circadian oscillations. Posttranslational processes like phosphorylation, degradation, complex formation and regulated nuclear import and export ensure that the peak of nuclear PER and CRY protein abundance occurs 4–6 h after the peak of their mRNA rhythm. As an example, casein kinase 1ε (CK1ε) binds, phosphorylates and thereby destabilizes PER proteins. Complex

formation with CRY proteins stabilizes PER2 and leads to nuclear accumulation of the PER-CRY-CKI ϵ complex. For a detailed review of current knowledge see (2).

Phenotype of Clock Gene Mutations in Mammals

Most clock gene products are not necessary for viability, but seem to be responsible solely for circadian timekeeping – evidence for clocks being advantageous but not essential to life. Table 1 shows the phenotypes of known mammalian clock gene mutants. PER and CRY proteins are essential for a functional clock, although there is some degree of redundancy in the function of the different PER and CRY family members within the core clock mechanism, which is not yet fully understood. Disruption of either *Per1* and *Per2*

together or both *Cry* genes causes immediate behavioral arrhythmicity when the double-knockout animals are placed in constant conditions. In addition, all molecular rhythms disappear. The same effect is observed, when the *Bmal1* gene is disrupted. Single gene knockouts of *Per* or *Cry* genes do not abolish oscillations immediately, but have an effect on the period of the rhythm.

Circadian Regulation of Transcription

The circadian clock regulates a significant proportion of an organism's entire transcriptome. In cyanobacteria every transcript oscillates with a period of approximately 24 h. In mammals, 6–10% of all transcripts are rhythmically expressed as revealed by global gene chip analysis (3). Most oscillating transcripts are tissue specific, only a few were found to be circadianly expressed in more than one tissue (including the components of the clock core mechanism). Some of the oscillating target genes (e.g. the neuropeptide arginine vasopressin) are directly regulated by CLOCK/BMAL1 *via* E-boxes in their promoters; others are indirectly regulated by rhythmically expressed transcription factors.

Circadian Control of Mitosis and Tumor Development

Cell division in many mammalian tissues including oral mucosa, intestinal epithelium and bone marrow is associated with specific times of day, suggesting an intimate coupling of the circadian clock with the cell cycle. In rapidly proliferating liver cells, the circadian clock controls the expression of cell cycle regulatory genes and thereby modulates the timing of mitosis, e.g. the expression of *Wee-1* is presumably directly regulated by CLOCK/BMAL1 (4). WEE-1 phosphorylates the cell cycle inhibitor CDC2 kinase and thus prevents the liver cells making the transition from the G₂ to the M stage of the cell cycle. Consequently, progression into mitosis is restricted to times of the day when WEE-1 levels are low.

Several epidemiological studies suggest that perturbations of the circadian timing system such as shift work may promote tumorigenesis in humans. In mice, destruction of the SCN accelerates tumor growth and genetic lesions of the *Per2* gene lead to tumor development (5). The mechanisms by which the circadian clock acts as a tumor suppressor are currently unknown.

Regulatory Mechanisms

Clock Cells in the Suprachiasmatic Nucleus

The SCN is a bilateral structure located just above the optic chiasm on the base of the third ventricle in the hypothalamus. It contains about 20,000 neurons, most of which are able to generate circadian rhythms in neuronal activity even when isolated in cell culture.

Circadian Clocks. Table 1 Circadian clocks

Clock gene mutation(s)*	Behavioral phenotype [§]
<i>Bmal1</i>	arrhythmic
<i>Clock</i> [#]	long period, then arrhythmic
<i>Per1</i> (or <i>Per1</i> and <i>Per3</i>)	short period, then arrhythmic

⁺ Autosomal dominant point mutation in human *Per2* resulting in less efficient phosphorylation of PER2 by CKI ϵ .

[&] Affected individuals have a 4-hr advanced sleep phase in entrained conditions.

Ablation of the SCN results in complete loss of all overt physiological and behavioral circadian rhythms. Transplantation of fetal SCN tissue into SCN-ablated hosts rescues some behavioral rhythms including locomotor activity rhythms. The genotype of the graft (Table 1) determines the restored endogenous circadian period. The SCN has direct neural and endocrine links to many neuroendocrine and behavioral control systems, especially in the hypothalamus, brain stem and pituitary. These connections regulate many overt circadian rhythms, such as the sleep-wake cycle, core body temperature rhythms, locomotor activity rhythms and rhythmic ►melatonin and corticosteroid secretion.

►Entrainment of Circadian Clocks by Light

To keep the endogenous oscillators synchronized with the outside world, a critical feature is their ability to respond to environmental stimuli. The endogenous period has evolved to be close to but not exactly 24 h to allow the entrainment process to modify the phase of the internal clocks until internal and external time are in congruence. This not only ensures a unique phase relation between internal clock and external light-dark cycle, it also enables an organism to measure day lengths and to adapt its physiology to seasonal changes. Light is the most potent stimulus to reset the mammalian clock in the SCN. While it has no effect on the clock during ►subjective day when light is present in a natural light-dark cycle, a light pulse administered at early ►subjective night causes a phase delay and a light pulse near the end of subjective night causes a phase advance. This differential sensitivity to light is commonly described in a phase-response curve.

Molecular Mechanism of Entrainment by Light

A specialized small fraction of dispersed retinal ganglion cells in the eye that contain the putative circadian photoreceptor melanopsin is intrinsically photosensitive (6). These ganglion cells transmit light signals along the retinohypothalamic nerve tract to SCN neurons. The principal neurotransmitters used are glutamate and pituitary adenylate cyclase-activating peptide (PACAP). Their release leads to a postsynaptic calcium influx that activates several kinase cascades ending up with the phosphorylation of CREB (cAMP response element binding protein). Phosphorylated CREB binds to specific sites in the promoters of the *Per* genes which leads to the rapid induction of their transcription. Light exposure in the early night induces *Per1* and *Per2* transcription, whereas only that of *Per1* is upregulated in the late night. Changes in nocturnal *Per* mRNA levels phase-shift the core clock oscillator.

Peripheral Oscillators

Cells in other brain areas as well as in peripheral organs, such as heart, liver, kidney, lung and skeletal

muscle contain circadian oscillators that regulate local physiology. Even cell-lines in culture such as rat-1 and NIH3T3 fibroblasts are capable of circadian gene expression after stimulation. Current evidence suggests that the SCN serves as a master synchronizer rather than a ►pacemaker and coordinates the phases of the multiple clocks thereby preventing an internal desynchronization (7), as is the case after traveling across time zones (►jet lag). Since peripheral cells of mammals are not light sensitive, they have to be entrained by non-photic cues. Feeding time is the dominant entrainment agent for peripheral clocks, while leaving the clock in the SCN unaffected. It is not yet known, whether the SCN synchronizes peripheral organs directly by humoral or neural means or indirectly by setting time windows for feeding behavior. Experimentally, many substances have been shown to reset clocks in cell culture, such as glucocorticoids, retinoic acid, endothelin-1, forskolin, fibroblast growth factor, calcium ionophores and butyryl cAMP. Some effects triggered by these components activate the same mechanisms as described for photic entrainment in the SCN including phosphorylation of CREB.

Circadian Control of the Sleep-Wake Cycle in Humans

A current model for the generation of the human sleep-wake cycle is the interaction between the circadian clock and a separate oscillatory process, called the sleep homeostat. The sleep homeostat monitors and reacts to the need for sleep, giving rise to the urge to sleep depending on prior amounts of sleep or wakefulness. The circadian clock in the SCN generates a rhythmic wake or arousal signal that increases during the day, peaks in the evening hours and decreases during the night with a minimum at early morning. In the absence of the SCN, the sleep-wake cycle loses its monophasic organization and is presumably solely driven by the sleep homeostat. By opposing the homeostatic increase or decrease in sleep need during the course of the day or night, respectively, the circadian system consolidates a monophasic sleep-wake cycle and ensures a virtually uninterrupted period of sleep at a defined circadian phase.

Classification of Active Centers

CORNELIUS FRÖMMEL

Faculty of Medicine, Georg August University,
Göttingen, Germany
c.froemmel@med.uni-goettingen.de

Definition

An active center is the small region of a protein which is responsible for the distinct function. There are a large number of synonyms (active site, active center, binding cavity, binding cleft, binding groove, binding pocket; binding site) owing only slightly different meaning.

Description

The biological function of proteins typically depends on the structure of specific binding sites. At the binding site the protein molecule interacts specifically with another molecule, the second molecule is referred to as the ligand of this molecule. In other cases the interaction takes place between a protein molecule and electrons and photons (light), respectively. In all examples the site of physical interaction is called the active site. Due to the ligand binding the structure of the protein can be changed (► [induced fit](#)). In some cases only few atoms move, in others one can observe a strong conformational change.

The binding property of a protein typically depends on the presence of a small number of precisely positioned amino acid residues which are brought together by protein folding. They represent a small fraction of the number of amino acids present in the protein. The region of a protein that interacts with another small molecule usually consists of a pocket (cavity, depression, hole) formed by a specific arrangement of amino acids on the protein surface. These sites are located at the surface or show close contact to the water accessible surface of a protein molecule. If the ligand (substrate, effector) is not present, the binding site is (dynamically) filled by the solvent, normally by water molecules and ions. An exception are membrane proteins which show light harvesting/absorbing properties and light emitting protein (e.g. the green fluorescent protein). In this cases the light can cross protein structures and the active site is completely in the inner of the protein molecule. Active sites consist of tens of non-hydrogen atoms. They represent about 10% of the accessible surface. One ► [protein domain](#) contains mostly one binding site for small ligands.

In literal sense ‘active site’ and its synonyms are used to describe the interaction site between any low molecular weight ligand and a given protein. As ligands can serve metal ions (Na^+ , K^+ , Mg^{++} , Ca^{++} , Zn^{++} , $\text{Fe}^{++(+)}$, etc.), inorganic molecules like phosphate, carbonate and all thinkable organic substances. In case of metal ions the binding sites consists of only few residues (2–6 amino acids).

In a narrower sense the term ‘active sites’ is used for the description of the region of enzymes in which one or more substrate molecules are bound and can be transformed to the product (and vice versa). In nearly

Classification of Active Centers. Figure 1 FK506 binding protein (space filling model) with bound ligand (ball and stick model) (3). The FK506 binding protein is an enzyme (cis-trans-prolyl isomerase) catalysing interconversion of to distinct conformations of the peptide bond preceding a prolyl residue. The atoms located deeply in the binding cavity are coloured in green. They are in close contact with the ligand.

almost of the cases it is formed as a small pocket or hole (a depression on the water accessible surface). Non-covalent binding of ligands is the first step as well as of signal transduction for enzyme catalysis. According to the main steps of enzyme catalysis (binding followed by the chemical reaction) one can differentiate in many but not in all cases between the binding region of the active site and the reactive residues in the active site. Latter catalyse the chemical reaction transforming the substrate in the product in a reversible manner. The close neighbourhood of polar amino acid side chains in active centres can influence strongly their reactivity. The resulting reactivity is one molecular reason for the huge catalytic efficiency of enzymes. E.g. the well known triad in serine proteases (Ser His Asp) is responsible for very fast splitting of peptides. The reactivity is caused by spatial order of the three residues in the active side.

Reversibly bound substrates of enzymes are often co-enzymes which are common used to transfer small molecular pieces from one enzyme to another. In different proteins which bind identical co-enzymes one observe frequently that homologues domains are used.

The binding specificity and strength, respectively depends on the number of non-covalent and attracting interactions. Furthermore, only ligands that can bind tightly to a protein are those that fit precisely onto its surface (molecular complementarity). The specificity can be perfect (only one natural ligand is bound), broader (e.g. a distinct type of chemical compounds like sugars are bound) or very broad (all ligands with a distinct property like hydrophobicity are bound). The dissociation constant K_d shows values between 10 mM and 10^{-12} M and less. Structurally related molecules bind often to the same binding site (►molecular mimicry).

The extended interaction site between different protein molecules (mostly long living protein complexes) are not denoted as active site. In contrast in examples in which proteins are partner of signal transducing molecules (mostly short living complexes) or substrates of enzymes the term 'active site' is used to describe the interaction site.

Ligands can bind to a different place as the active site and influence e.g. the activity of enzymes. Such sites are called allosteric site or regulatory site. Due to their influence on enzyme activity they are important for the regulation of the metabolism.

For several of interactions and chemical reactions the set of ►proteinogenic amino acid residues are not suitable. Therefore active sites include further strongly bound compounds called ►prosthetic groups: e.g. to accept hydrogen flavin nucleotide or to bind electrons iron sulphur cluster or haeme. In another example the retinal molecule in rhodopsin is responsible for absorption photons.

Footprint of active sites on ►primary structure

Normally strictly conserved residues in homologues are predicted to be functionally relevant but this is strongly valid only for amino acid residues relevant in catalytic events. They can be found by sequence similarity searching methods. In the binding site there are more degrees of freedom (1).

Footprint of active sites on ►tertiary structure

In most cases the binding sites can be found by purely geometrical based methods (2) because they are small cavities on the protein surface.

Synonyms to 'active site'

- Active site
- Active center
- Binding cavity
- Binding cleft
- Binding groove
- Binding pocket
- Binding site

Therapeutical Consequences

The knowledge about function, specificity and structure of active site is relevant for in silico search of drugs (drug design). The main goal of drug design is to find low molecular weight substances which compete with natural ligands for specific binding (active) sites or allosteric sites to influence enzyme activity or signal transduction and can be used as therapeutics or diagnostics, respectively.

Clathrin

Definition

Clathrin is the major constituent of the proteinaceous, electron dense ‘coat’ of coated pits and coated vesicles formed from the plasma membrane, and from membranes on the trans- or exit side of the Golgi complex. Clathrin molecules are composed of three heavy and three light chains which stably associate into soluble triskelia. A number of adaptor proteins have been identified that recognize sorting signals, but also bind to clathrin and regulate the multimerization of individual triskelia into polyhedral cages. The polymerization of clathrin and adaptor proteins is thought to drive budding of a coated lipid bilayer. Clathrin-coated buds form at the plasma membrane and at the *trans*-Golgi network. Distinct flat clathrin lattices have been observed on endosomal membranes.

Cl_{Ca}

Definition

Cl_{Ca} refers to a calcium activated chloride channel that is strongly expressed in many ion-transporting epithelia, including the kidney.

- Autosomal Dominant, Polycystic Kidney Disease

CldU

- 5–Chlorodeoxyuridine (CldU) & 5–Bromodeoxyuridine (BrdU)

Cleavable Cross-Linkers

Definition

Chemical cross-linking reagents that contain two or more reactive groups. These are connected by a spacer group containing molecules that can be cleaved by specific chemical reagents.

- Protein Interaction Analysis: Chemical Cross-Linking

Cleavage and Polyadenylation Specificity Factor

Definition

Cleavage and polyadenylation specificity factor (CPSF) refers to a protein complex that is involved in 3′ processing of pre-mRNA. It consists of at least four subunits, binds the AAUAAA signal, and is required for both cleavage of the pre-mRNA and polyadenylation.

- Polyadenylation

Cleavage Factor I (CF I)/Cleavage Factor II (CF II)

Definition

Cleavage factor I (CF I)/Cleavage factor II (CF II) designate protein complexes that are involved in 3′

processing of pre-mRNA. There are likely to be different versions of CF I, consisting of a common small subunit and any one of a number of related large subunits. CF I binds RNA, and CF II contains at least two subunits. Both are only required for cleavage of the pre-mRNA.

►Polyadenylation

Cleavage Stimulation Factor

Definition

Cleavage stimulation factor (CstF) refers to a protein complex that is involved in the 3' processing of pre-mRNA. It consists of three subunits, binds the downstream element of the 3' processing signal, and is only required for cleavage of the pre-mRNA.

►Polyadenylation

Cleft Lip Palate

Synonyms

Orofacial clefts (OFC); Oral-facial clefts

Related Terms

- Cleft lip with or without cleft palate
- Cleft lip
- Cleft palate
- Hare-lip (archaic)
- Primary palate
- Secondary palate

Definition

Orofacial clefts refer to any fusion failure of the structures of the face and oral cavity. Clefts of the lip and palate are by the far the most common such anomalies, although clefts of other parts of the face may occur. Embryologically, orofacial structures develop in roughly two stages with development of the anterior structures followed by development of the posterior

structures. The anterior structures (the lip and the maxillary alveolus) are often referred to as the primary palate, with the posterior structures (the hard palate and the soft palate) referred to as the secondary palate. Orofacial clefts may be unilateral or bilateral, complete or incomplete, and may involve either or both of the primary and secondary palates. Thus, there is a great variety in the types of possible orofacial clefts, ranging from very minor defects such as a notch in the vermillion border or a cleft uvula, to a complete bilateral cleft of the primary and secondary palates. In etiological studies, orofacial clefts are usually grouped into either cleft lip with or without cleft palate (CL/P) or cleft palate alone (CP). In an individual, orofacial clefts may be an isolated anomaly or may occur as part of a ►syndrome.

Characteristics

Orofacial clefts can occur as part of Mendelian syndromes, as part of the phenotype resulting from chromosomal anomalies, or as the result of prenatal exposure to certain ►teratogens. Orofacial clefts demonstrate remarkable differences in frequency by gender and laterality. There is an approximate 2:1 ratio of males:females for CL/P, although slightly more females than males have CP. Within unilateral clefts, the ratio of left-sided to right-sided clefts is also about 2:1. Orofacial cleft birth prevalence shows a wide range, from about 1/500 births to about 1/2000 depending on population; in general, Asian and Amerindian populations have the highest frequencies and African-derived populations the lowest.

Over 300 syndromes exist in which orofacial clefts are part of the phenotype; about half of those are due to ►Mendelian inheritance of alleles at a single genetic locus. Much progress has been made in recent years in delineating Mendelian disorders and in gene discovery of such disorders (refer to ►OMIM on the ►NCBI web site for a catalog of such disorders). However, only a small proportion of individuals with orofacial clefts has

Candidate genes/regions: genes and regions with at least two positive reports of linkage (L) or association (A) in the literature. Genome scan: regions with positive linkage (L) or association (A) results with anonymous markers spaced ≤ 10 cM apart throughout the genome (one or more genome scans); M=positive meta-analysis results over all genome scans (4).

Notable syndrome or MIM designation: listed here are Mendelian syndromes that are mapped to regions with positive candidate gene or genome scan results. Also listed in this column are the MIM designations that have been assigned for three regions (OFC1, 2, 3). MIM# = identification number in OMIM.

Chromosomal rearrangements: regions of chromosomal rearrangements that include clefts in their phenotypic expression

Animal models: genes investigated in animal models with phenotypes that include clefting. K/O = knockout, E=expression studies.

a known etiology (3, 6). Most orofacial clefts are nonsyndromic and are considered **complex** traits. Given the public health importance of orofacial clefts, many etiologic studies have been conducted of nonsyndromic orofacial clefts.

The importance of inheritance in the etiology of cleft lip and cleft palate has been noted by scientists for more than 200 years. The first published description of a family with several affected members was in 1757 (7). Charles Darwin (1) pointed out a publication of “the transmission during a century of hare-lip with a cleft-palate”. Since those early publications, many studies have been undertaken using the tools of statistical and molecular genetics.

The **multifactorial threshold** model was proposed to explain many of the features of nonsyndromic orofacial clefts (such as the altered gender ratio); however, the predictions of that specific model could be rejected when tested in several populations. In the early years of the 20th century, several seminal works were published regarding the inheritance patterns of orofacial clefts, but until recently progress has been slow in determining the exact genes involved. **Segregation analyses** and statistical analyses of familial **recurrence risk** patterns were consistent with hypotheses of either **major locus** involvement, and/or relatively few loci [3–14; see (3, 4)] interacting to cause orofacial clefts. With statistical evidence that orofacial cleft family patterns were consistent with genetic inheritance, several groups began **linkage** and association studies in order to identify the genes contributing to the familiarity of orofacial clefts.

Cellular and Molecular Regulation

Our understanding of the developmental biology of orofacial clefting (both spontaneous and teratogen-induced) in the mouse model is under rapid development, and several pathways have been delineated [see (5) and (8) for reviews]. Our understanding of human orofacial development is less advanced, in part because many details from the mouse model do not seem to translate directly.

Instead, most researchers in human orofacial cleft etiology are attempting to identify susceptibility genes by linkage and association studies. Any identified loci would then provide insights into the human orofacial developmental process. Table 1 summarizes the results found to date [see (3, 4, 5, 8) for additional details] from linkage and association studies of candidate genes, from genome scans, and from chromosomal rearrangements.

Also summarized in the table are several Mendelian syndromes in which some of the affected individuals present as phenocopies of non-syndromic clefting: e.g. van der Woude syndrome, ectrodactyly-ectodermal dysplasia/clefting, basal cell nevus, and others. Each of these syndromes might have mutations in particular domains that could result in or modify non-syndromic CLP. For example, IRF6, the gene identified for van der Woude syndrome also shows strong **allelic association** with CL/P (although not CP, (9)).

A recent CL/P genome scan meta-analysis found genome-wide significant results for 15 regions (4). The chromosomal positions with the most consistent evidence for involvement in orofacial clefting

include 1q, 2p, 2q, 3q, 4p, 4q, 6p, 14q, 17q and 19q (see Table 1). It is important to note that, like many other complex disorders, the results have not been consistent across all studies. Further progress is most likely to be made by using meta-analysis methods to combine statistical results across studies in order to set priorities as to genes and/or regions to investigate by fine mapping, sequencing and other molecular genetic techniques.

Clinical Relevance

Clefts of the lip and palate are the most common craniofacial birth defects and are also among the most common of all birth defects, with birth prevalence ranging from 1/500 to 1/2000 depending on the population. While the severity of orofacial cleft anomalies varies, multidisciplinary treatment is often necessary and may include craniofacial surgery, specialized dental and orthognathic treatment, speech and hearing intervention, and educational, psychological and social assessment and intervention. The multidisciplinary nature of cleft care was realized even in the first recorded surgical repair of a cleft lip (in the annals of the Chin dynasty in China, about A.D. 390; translated by Khoo (2)—detailed post-operative instructions were listed for optimal results).

Orofacial clefts represent a significant public health problem due to the significant lifelong morbidity and complex etiology of these disorders. The extensive psychological, surgical, speech, and dental involvement emphasize the importance of understanding the underlying causes of CL/P, in order to optimize treatment planning, to predict the long-term course of any affected individual's development, to improve recurrence risk estimation, and to provide pre-reproductive counseling.

Clinical Gene Transfer

KLAUS CICHUTEK, MATTHIAS SCHWEIZER, CHRISTIAN BUCHHOLZ, EGBERT FLORY
Paul-Ehrlich-Institute, Division of Medical Biotechnology, Langen, Germany
cickl@pei.de

Definition

► **Medicinal products**, also termed drugs or medicines, are used for the treatment, *in vivo* diagnosis or prevention of diseases in or on human subjects. Gene therapy and somatic cell therapy using genetically modified cells are best summarized under the term clinical gene transfer and involve the treatment of human subjects with gene transfer medicinal products, the latter defined in § 4 of the German Drug Law as follows.

Gene transfer medicinal products (GT-MPs) are medicinal products

- which consist of or contain viral or non-viral vectors or nucleic acid used for genetically modifying human somatic cells *in vivo* (*in vivo* strategy)
- or which consist of *ex vivo* genetically modified autologous, allogeneic or xenogeneic cells (*ex vivo* strategy)
- or which consist of replication competent, recombinant microbes used for other purposes than prevention or therapy of the infectious disease they cause (*in vivo* strategy)
- and which are used for treatment, *in vivo* diagnosis or prevention of diseases in human subjects.

This definition is in agreement with the variety of GT-MPs covered by the current European Note for guidance on the quality, preclinical and clinical aspects of gene transfer medicinal products (CPMP/BWP/3088/99). Viral vectors (replication-incompetent viruses able to transfer a therapeutic gene), non-viral vectors (DNA encompassing the therapeutic gene mixed with ►transfection reagents), “naked” DNA or conditionally replicating microbes (recombinant adenovirus, recombinant Salmonella) are currently used for genetically modifying a cell *in vivo* or *ex vivo*.

The application of antisense nucleic acid itself which does not encompass a gene and which is used without the intention of genetically modifying cells, e.g. ►antisense RNA for the treatment of cytomegalovirus-induced retinitis, is not considered to belong to the field of clinical gene transfer, but rather to molecular medicine in general.

Characteristics

During clinical gene transfer, nucleic acids encompassing one or several (trans)genes are transferred into cells in order to restore normal cellular functions or to add new ones (1). The nucleic acid construct (encompassing promoter, enhancer and other regulatory sequences, one or more cDNAs including a polyadenylation signal and a coding region or a region specifying an RNA product) is termed an ►expression construct, ►expression vector or transfer vector. The ►transgene product is normally a protein with a specific function or an antigen. It may also be a specific RNA transcribed from a transgene, e.g. in ribozymes which mediate inactivation of a target RNA within the modified cell.

The vehicle (also termed viral or non-viral vector or ►vector particle) which allows transfer of the expression vector or nucleic acid (and thereby the transgene(s)) into cells determines the structure of the expression vector and can be of viral or non-viral origin. Viral vector particles, non-viral vectors and free nucleic acids (e.g. naked DNA) which are currently in clinical use are summarized in Table 1 (7). ►Plasmid DNA used as naked DNA or as part of a non-viral vector is

produced from *E. coli* bacteria. Viral vectors are generally produced by mammalian packaging cells in culture. Retroviral and lentiviral transfer vectors can be delivered by using the respective vector particles enveloped with homologous retro- or lentiviral envelope proteins. If heterologous proteins such as the vesicular stomatitis virus G-protein (VSV-G) or heterologous retro- or lentiviral envelope glycoproteins are used as envelope proteins, such vector particles are termed pseudotype vectors. If naked nucleic acids or non-viral vectors (5) are applied, a specific transfer or transfection method rather than a vehicle is used for delivery of the expression construct, which is normally encompassed by a bacterial plasmid. Naked DNA inoculated intramuscularly or intra-dermally is spontaneously taken up by mammalian cells *in vivo*. Delivery can be improved by using instead of needle inoculation, a gene gun (gold particles coated with the plasmid DNA) or a jet gun (plasmid/helium gas under pressure). Future vector applications will involve targeting genes or their expression into specific cell types or tissues (2).

Clinical gene transfer may follow the *in vivo* or the *ex vivo* strategy (6). Examples of *in vivo* strategies include intra-muscular injections of non-complexed, so-called naked DNA, intra-tumoral inoculation of non-viral vectors, infusion of adenoviral vectors *via* the intra-hepatic artery or intra-muscular injection of adeno-associated virus (AAV) vectors. The transgene is thus delivered to human somatic cells *in vivo* and subsequently expressed. Any ►transduction of germ line cells is considered to be a risk which has to be avoided. This risk is assessed by preclinical experiments in animals and suitable biomonitoring during clinical trials.

During *ex vivo* gene transfer, mammalian cells which have been genetically modified in cell culture are delivered to humans. The ►genetic modification may involve viral or non-viral vectors, whatever is considered most suitable. Human autologous cells such as modified CD34-positive cells, encompassing hematopoietic stem cells or progenitor cells, may give rise to a large number of modified daughter cells *in vivo* which may have a long life span. Allogeneic cells may be used as tumor vaccines and are then irradiated before use and readily deleted *in vivo*. They are used in order to induce an immune response against residual tumor cells and their presumed or defined tumor-specific antigens. The use of xenogeneic primary cells in humans is not considered safe because of the theoretical risk of transmitting xenogeneic infectious agents to humans and will therefore not be used in the foreseeable future. A border line application has been the *in vivo* inoculation of genetically modified retroviral packaging cells. These xenogeneic cells produced retroviral

Clinical Gene Transfer. Table 1 Viral vectors currently in clinical use

Origin of vector or carrier nucleic acid	Type	Chromosomal integration	Replication competence	Heterologous envelope proteins

Clinical Gene Transfer. Figure 1 Genetic modification of a cell by free, so-called naked nucleic acid, non-viral vectors or commonly used viral vectors. Informative examples are illustrated. SFV, Semliki Forest Virus.

vectors *in vivo* which were supposed to deliver suicide genes, e.g. the Herpes simplex virus-derived thymidine kinase gene, into human tumor cells in the brain. After subsequent prodrug (ganciclovir) treatment, the delivered genes in the tumor cells and in the packaging cells were able to convert the prodrug into a cell-toxic drug at local sites, thus killing the transgene containing cells *in vivo* and the cells directly in their neighborhood (suicide gene transfer). Examples for recombinant micro-organisms used in clinical gene transfer are replication competent adenoviruses not carrying any transgenes. They are inoculated, e.g., into local head-and-neck tumors and, in conjunction with conventional chemotherapy, local tumor regression has been observed.

Clinical Relevance

Clinical Gene Transfer (Overview)

A variety of clinical trials currently show promising results (see Table 2). It is becoming clear that each disease needs the development of a particular gene transfer method and regimen. Standard use of the first licensed gene transfer medicinal products can be foreseen within the next few years.

More than 7,000 human subjects have probably been treated with gene transfer medicinal products worldwide, most of them in the USA. Within Europe, probably the highest number of clinical gene transfer studies were planned or have been carried out in Germany with a total of about 300 patients that have been treated ([►http://www.pei.de](http://www.pei.de); [►http://www.zks.uni-freiburg.de/dereg.html](http://www.zks.uni-freiburg.de/dereg.html)). A description of regulatory aspects of clinical gene transfer in Germany is available ([►http://www.pei.de/themen/themlink.htm](http://www.pei.de/themen/themlink.htm) → Genterapie). A general perspective of the field's attempts can be obtained from websites ([►http://www.wiley.co.uk/genetherapy](http://www.wiley.co.uk/genetherapy); [►http://www4.od.nih.gov/oba/rac/clinicaltrial.htm](http://www4.od.nih.gov/oba/rac/clinicaltrial.htm)).

Most clinical gene transfer protocols are aimed at the treatment or prevention of cancer, cardio-vascular disease, infectious disease such as AIDS or monogenic disorders. The vectors most often used *ex vivo* are MLV-derived oncoretroviral vectors, whereas adenoviral and poxviral vectors have mostly been used *in vivo*. An increasing number of studies involves the use of non-viral vectors or naked DNA.

Gene Therapy of Monogenic Diseases

The idea of gene therapy was born with the thought that defective genes could be replaced with functional ones in order to treat genetic diseases. A mutation of the gamma-c-chain gene underlies the X-linked form of the severe combined immunodeficiency syndrome (SCID-X1). As a result, immunologically relevant receptors like the interleukin (IL)-2 receptor are not functional and T and B lymphocytes are not developed, due to an early differentiation block. Newborn babies suffering from SCID-X1 therefore have a severely impaired immune system and a limited life expectancy, unless HLA-identical bone marrow transplantation is available. In an attempt at clinical gene therapy, autologous CD34-positive cells retrovirally transduced with the functional gamma-c chain gene were reinfused. As a result, functional T and B cells developed, and for a time period of more than a year, on nine of eleven treated patients, mostly less than one year old, beneficial treatment was achieved. This was the first established success of gene therapy (3). For how long the correction will prevail remains to be seen. If the earliest blood stem cells able to bring about life-long repopulation were genetically modified, the immunological correction would be expected to last life-long. However, a repeated treatment by gene therapy would also be possible.

Clinical Gene Transfer. Table 2 Examples of clinical gene transfer approaches currently showing promising results

Disease	Therapeutic gene	Administration route/vector	Benefit
SCID-X1	<i>Gama-c-chain (IL-2R)</i>	Blood stem cells/ MLV vector	15 babies benefited, 18 treated, 3 leukemias
PAOD	VEGF	i.m./plasmid DNA	Improved vascularization
Head and neck tumors	Cell-dep.repl.adeno-virus, no transgene	Tumor cells	Local tumor regression
Leukemia, graft versus leukemia effect, GvH disease treatment	<i>HSV-tk</i>	T cells/MLV vector	Successful GvH disease treatment
Hemophilia B	Factor IX	i.m./AAV vector	Improved plasma levels

PAOD, Peripheral Artery Occlusive Disease; SCID, Severe Combined Immunodeficiency Disease; i.m., intra-muscular administration

The treatment of hemophilia B is attempted by using mini-cDNAs of the human factor IX gene that allow functional reconstitution of the blood clotting system. On-going trials using intra-muscular injection of adeno-associated virus have shown that detectable increases in the serum level of factor IX can be achieved. However, ongoing clinical trials will have to achieve a further increase in factor IX levels, the time span of clinical benefit and the absence of serious adverse reactions when repeated AAV injections are performed.

Other monogenic disease targets include enzyme or protein deficiencies such as Gaucher disease or immune deficiencies such as adenosine deaminase deficiency (ADA) or chronic granulomatous disease (CGD).

Cancer Gene Therapy

Cancer is a target for various kinds of innovative treatments aiming either at molecular mechanisms underlying the malignant cell transformation, at tumor cell ablation or at enhancing the immune functions able to deplete tumor cells including metastases. Gene therapy using tumor suppressor genes has been attempted, and has progressed to later phases of clinical development. Direct tumor cell ablation by local injection of replicating adenoviral vectors in head and neck cancer has provided local tumor regression, particularly when used in conjunction with chemotherapy. Mutant herpes viruses have also been used in brain tumor injections to lyse the tumor cells *in vivo*. Here, the replicating or conditionally replicating viruses seem to provide the advantage of spreading to some extent *in vivo*, which allows improved tumor cell killing. By such methods, the so-called needle-track transduction observed, for example, during intra-tumoral injection of replication incompetent adenoviral vectors carrying the tumor suppressor gene p53 has been avoided. The latter strategy was aimed at inducing tumor cell killing by apoptosis.

Attempts to enhance the immune recognition of tumors have been made by injecting vectors intra-tumorally which carry foreign MHC genes such as B7.1 or B7.2 or cytokine or interleukin genes such as IL-2 or GM-CSF with little success. In addition, autologous or allogeneic tumor cells modified with immune enhancing or tumor-specific antigen genes were also used as therapeutic tumor vaccines. Here, the only hopeful trial has been a phase I trial where autologous tumor cells were adenovirally transduced with GM-CSF and re-injected. It will take further improvements to lead such attempts to a success.

Clinical Gene Transfer in Cardio-Vascular Disease

Local intra-muscular injection of plasmid DNA encompassing a gene able to potentiate adaptation to hypoxia was shown *in vivo* to lead to improved

vascularization of ischemic tissue. Vascular endothelium growth factor (► **VEGF**) or fibroblast growth factor (FGF) genes have been directly injected at local sites by catheter application or needle-mediated intra-muscular injection of plasmid DNA or adenoviral vectors. This approach is aimed at the treatment of critical limb ischemia or myocardial vascularization problems. Formation of new micro-circulatory vessels has been observed and clinical trials of phase III will have to show objectively curing or improvement of disease.

Restenosis following balloon catheter-mediated cardiac vessel dilatation is probably caused by the proliferation of smooth muscle cells following injury of the vessel endothelium. Adenoviral or plasmid DNA-mediated transfer of the inducible nitric oxide synthase (iNOS) gene are thought to reduce muscle cell proliferation and to induce apoptosis. Adenoviral vectors or non-viral vectors have been used for gene transfer and efficacy will have to be shown.

Prevention and Therapy of Infectious Disease

Chemotherapy of infectious diseases such as AIDS has become a true therapeutic option during the last five to ten years. Combinations of powerful small molecules aiming at inhibiting crucial steps in the replication cycle of HIV-1 have proven to reduce the virus load to sometimes undetectable levels. Due to the necessity for long-term treatment and massive side effects connected with this, gene therapy of HIV infection is an option that still has to be developed. Retroviral transfer of HIV inhibitory genes into peripheral lymphocytes or CD34-positive human cells *ex vivo* has been attempted, so far with very little success. The genes used expressed (i) decoy RNA with multiple Rev or Tat Responsive Elements, so-called poly-TAR or poly-RRE sequences, (ii) scFv able to mediate intra-cellular inactivation of viral gene products, (iii) trans-dominant negative mutants of viral proteins such as RevM10 or (iv) ribozyme RNA able to intra-cellularly cleave viral

Clinical Gene Transfer. Figure 2 *Ex vivo* and *in vivo* application of gene transfer medicinal products (GT-MPs; printed bold).

RNA. Further genes under development will aim at preventing entry or integration of HIV. It will have to be shown whether such therapeutic interventions will provide a therapy option compared to combinations of new chemical or biotechnological drugs.

Prevention of infectious disease is best provided by prophylactic vaccines. Attempts with naked DNA or vectored vaccines to prevent infection of animals with a variety of micro-organisms have been reported. Clinical gene transfer mostly aims at developing vaccines against HIV-1 infection, malaria, hepatitis B and influenza A virus infections. It has been reported that pox virus vectors such as ALVAC or MVA in combination with naked DNA as a priming method and possibly followed by booster injection of subunit vaccines may be most effective in humans. Clinical trials to establish the induction of a suitable immune response and possibly leading to some extent to prevention of infection are on-going.

Clinical Gene Transfer for the Treatment of Other Diseases

Clinical gene transfer may also be applied to other diseases where a gene transfer approach seems promising, although the contribution of genetic factors to the disease has not been clearly defined. ► **Rheumatoid arthritis**, for example, may benefit from a reduction of the inflammatory reactions in the joints which is presumably caused by a cascade of events leading to over-expression of a variety of proinflammatory cytokines. Monoclonal antibodies able to reduce the amount of free tumor necrosis factor alpha (TNF) have been successfully applied to severe cases. Although TNF may not be the initial cytokine priming the inflammatory reactions observed, reduction of its local concentration is obviously able to reduce inflammation and local pain. Clinical gene transfer involves the expression, e.g., of interleukin-1 receptor antagonist by synovial cells in the joints. This is accomplished either by local application of adenoviral vectors or by *ex-vivo* transduction of explanted autologous synovial cells and reimplantation. Clinical gene transfer is applicable to all human diseases where a genetic approach seems potentially helpful. In most cases, it provides for the most natural expression of therapeutic molecules which is the production by human somatic cells *in vivo*.

Current Expectations Concerning Clinical Gene Transfer

Unfortunately, three of the successfully treated SCID-X1 patients (see above) so far developed a leukemia-like lymphoproliferative disorder about three years after treatment. Current state of knowledge led to the interpretation that the leukemia-like diseases were a consequence of chromosomal integration of the retroviral vector. Within the leukemic cells of all three

patients, the vector encompassing the therapeutic gamma c-chain gene was found integrated within the LMO-2 locus and led to over-expression in the leukemic cells, probably *via* a so-called enhancer mechanism. Additional vector-mediated gene activations were found in the third leukemia case. Translocations involving the LMO-2 gene have been found to be associated with some naturally occurring human leukemias. Additional genetic events promoting tumor development may include the influence of the therapeutic gamma c-chain gene on intra-cellular signal transduction and/or differentiation and chromosomal abnormalities that have been observed in the leukemic cells, but have not yet been functionally defined. The latter may have arisen during the massive *in vivo* expansion of the genetically corrected hematopoietic progenitor cells in an almost fully depleted lymphoid cell compartment characteristic for SCID-X1. Depending on whether tumors will be observed as a consequence of retroviral vector use in gene therapy of other diseases, the leukemia development may be classified as being associated with the specific SCID-X1 gene therapy or with other clinical retroviral treatment strategies.

Following infusion of more than 10^{11} adenoviral vector particles per kg into the intra-hepatic artery one of 17 patients treated with the aim of correcting the monogenic disease OTC (ornithine transcarbamylase deficiency) died. Although analysis of the trial led to the detection of shortcomings in good clinical practice, it is believed that the systemic use of a very high number of adenoviral vector particles led to a toxic reaction in the patient Gelsinger which ultimately was the cause of the lethal outcome of the treatment. Clinical trials involving the systemic use of adenoviral particles are therefore carried out only by using a lower number of adenoviral particles measured with the help of adenovirus reference material available. Non-systemic uses of adenoviral particles are not considered unsafe.

Fortunately, a current assessment of the clinical perspectives of gene therapy can be based on an increasing range of clinical experiences. It is no longer believed that gene therapy will replace conventional therapies in a large number of diseases. However, gene therapy will provide valuable therapies in diseases, where current treatment is insufficient or only palliative. It may also provide new therapy options for widespread diseases, but each disease will necessitate the development of a particular molecular and gene transfer strategy. The improvement of gene transfer efficiency alone will not suffice. With the improvement of the clinical gene transfer approaches, the frequency of known serious adverse reactions will increase and theoretical risks will be monitored as real ones, as observed during the development of other novel

therapies. Clinical gene transfer still holds the promise of giving us a new tool to perform evidence-based medicine using current knowledge of the molecular biology underlying a disease.

Clinical Marker Gene

Definition

A gene is a good clinical marker if the distributions of its expression values in two diagnostic entities can be well separated.

► [Computational Diagnostics](#)

Clonal Analysis

Definition

Clonal analysis designates the follow up of the fate or the developmental potential of single cells using either *In Vivo*- or cell culture techniques.

► [Neural Crest Cells and their Derivatives](#)

Clones

Definition

Clones refer to one or more genetically identical copies of a cell or organism, and as such would apply to any

bacterial colony. In the context of molecular biology, it refers to a clone of cells genetically engineered to contain some fragment of DNA, and by extension to the fragment of DNA itself.

► [YAC and PAC Maps](#)

Cloning

Definition

In the context of recombinant DNA technology, cloning (or: molecular cloning, DNA cloning, gene cloning) defines a process by which a DNA fragment of interest is transferred from one organism to a self-replicating genetic element, such as a bacterial plasmid. The DNA of interest can then be propagated in a foreign host cell.

In contrast, reproductive cloning is a technology used to generate an animal that has the same nuclear DNA as another currently or previously existing animal. The term might also be used to describe “therapeutic cloning”, also called “embryo cloning,” which is the production of human embryos for use in research. The goal of this process is not to create cloned human beings, but rather to harvest stem cells that can be used to study human development and treat disease.

► [Protein Microarrays as Tool for Protein Profiling and Identification of Novel Protein-Protein Interactions](#)

Cloning Vector

Definition

Cloning vector refers to a DNA molecule that is designed and constructed to be able to accept fragments of foreign DNA, and propagate them (as a new construct) in a suitable host strain. Sequencing vectors are a specific form of general cloning vectors, normally with a high copy number, and with a specific sequence (the priming site) adjacent to the cloning site.

Cluster Analysis

Definition

Cluster analysis is the clustering, or grouping, of large data sets on the basis of similarity criteria for appropriately scaled variables that represent the data of interest. Similarity criteria among the several clusters facilitate the recognition of patterns and reveal otherwise hidden structures. Cluster analysis uses a set of statistical methods to group variables or observations into strongly inter-related subgroups.

- DNA Microarrays/DNA Arrays

Cluster of Differentiation

Definition

Cluster of differentiation (CD) is a nomenclature for a group of cell-surface molecules, that are recognized by a given set of monoclonal antibodies. This cluster of differentiation then received a number, for example CD1, CD2 etc., which stands only for the order of discovery. In general, each CD is associated with one or more functions, which were discovered through the effects on cell or tissue function of the antibodies that define it. CD cell surface molecules are used to differentiate between leucocyte subsets.

Coat Proteins

Definition

Coat proteins are complex sets of interacting cytoplasmic proteins that can be recruited to intracellular membranes in a selective, compartment-specific fashion. There, they assemble to deform this “donor” membrane into buds and vesicles. Coat proteins select cargo during vesicle budding through selective

Cocaine

Definition

Cocaine is classified as a psychostimulant, as are other drugs of abuse such as amphetamine. Although these stimulants have similar behavioural and physiological effects, there are some major differences in the basic mechanisms of how they work at the level of the nerve cell. Cocaine is quickly removed and almost completely metabolized in the body.

►Addiction, Molecular Biology

Cockayne Syndrome (CS)

Definition

Cockayne syndrome (CS) is an autosomal recessively inherited disorder, which arises from mutations in the CSA and CSB genes. The CS complementation group protein (CSB) is at the interface of transcription and DNA repair and is involved in transcription-coupled and global genome-DNA repair, as well as in general transcription. CS is associated with abnormal UV hypersensitivity, growth retardation, and psycho-neural abnormalities. The disease develops by an age of 6 months. It is not a cancer prone disease.

²Clinic for Abdominal, Endocrine and Thoracic Surgery, Clinical Center Nürnberg, Nürnberg, Germany

jbehrens@molmed.uni-erlangen.de

Definition

Colorectal cancer (CRC) is a malignant tumor disease arising from the epithelium of the colon and rectum.

Characteristics

CRC is the second leading cause of cancer-related deaths in industrialized Western countries. CRCs are treated by surgical resection and by neoadjuvant and adjuvant chemotherapy and radiotherapy. The long-term survival of CRC patients depends on the tumor stage and the presence of distant metastases. Thus, the 5-year-survival rate exceeds 90% in the UICC stage I (limited invasion without regional lymph node

metastasis), but is below 20% in the UICC stage IV (presence of distant metastasis).

CRC develops from normal colorectal epithelium as a result of the accumulation of genetic alterations in defined oncogenes and tumor suppressor genes. In addition, loss of genomic stability leading to chromosomal and/or microsatellite instability (the ►CIN and ►MIN phenotypes, respectively) is an inherent feature of CRC. Much of what is known about the genetics of CRC has been derived from studies on hereditary colorectal cancer syndromes, of which the two best characterized are ►familial adenomatous polyposis (FAP) and ►hereditary nonpolyposis colorectal cancer (HNPCC). FAP is an autosomal dominant inherited disease characterized by the development of hundreds to thousands of polyps in the colon, which eventually transform into cancer. In 1991, the *APC* (►adenomatous polyposis coli) tumor suppressor gene was identified by positional cloning of the FAP locus at chromosome 5q21 (see below). While FAP comprises only around 0.1–1% of all colorectal cancers, HNPCC accounts for about 5% of the cases. Underlying this hereditary form of colorectal cancer is a defect in the DNA mismatch repair system (also known as mutation ►mismatch repair/MMR system). This system consists of a set of proteins that recognizes and repairs base-pair mismatches that occur during DNA replication. Germ-line mutations in *hMSH2* and *hMLH1* account for about 45–70% of the cases in HNPCC. Somatic mutations of the MMR system are also found in approximately 15% of sporadic colon cancers. The most prominent genetic consequence of mismatch repair deficiency is the occurrence of microsatellite instability (MSI), which reflects the deletion or addition of nucleotides in repetitive DNA sequences, leading to frame shifts and protein truncations when present in coding sequences. As an example, mutations of the TGFβ receptor occur frequently in MSI high tumors resulting in escape of tumor cells from growth inhibition by TGFβ. Other hereditary forms of CRC include the ►Peutz-Jeghers syndrome characterized by mutations of the tumor suppressor gene *LKB1* and ►juvenile polyposis in which the *PTEN* and *SMAD 4* tumor suppressors are mutated in an autosomal dominant fashion.

Molecular Interactions

A genetic model of colorectal tumorigenesis by Fearon and Vogelstein proposes that the acquisition of sequential mutations in ►oncogenes and ►tumor suppressor genes leads to progression from single crypt lesions to small benign tumors (adenomatous polyps) to malignant cancer (1). Mutations of the *APC* tumor suppressor gene are thought to initiate the clonal outgrowth of a single cell. *APC* has been considered to be a gatekeeper of colorectal tumorigenesis as it was

found to be mutated in the earliest premalignant lesions of sporadic CRC such as aberrant crypt foci. Additional mutations such as in the oncogene *K-ras* allow these cells to overgrow their sister cells and further mutations in the tumor suppressor gene *p53*, as well as other genes yet to be identified, lead to progression to carcinomas. In the following, we will focus on the signaling mechanisms and genetics of *APC* because mutations in *APC* are highly specific for CRC and initiate the process of CRC tumorigenesis.

Functional Role of APC in ►Wnt Signaling

The first clues to the function of *APC* were provided by the identification of the cytoplasmic protein β-catenin as a binding partner of the APC protein. Subsequently it was shown that APC acts as a major negative regulator of the Wnt signal transduction pathway by inducing degradation of β-catenin. In the absence of Wnt factors, a multiprotein complex (termed the “β-catenin destruction complex”) consisting of APC, the scaffold proteins axin or conductin/axin2 and the glycogen synthase kinase 3β (GSK3β) causes the ubiquitin-mediated proteasomal degradation of β-catenin. ►Axin/conductin interacts with APC and β-catenin and, importantly, recruits GSK3β to the destruction complex. GSK3β phosphorylates β-catenin at specific residues in its amino terminus and thereby earmarks the protein for ►ubiquitination. Wnts are secreted factors that bind to and activate Frizzled receptors leading to the inhibition of GSK3β. As a result β-catenin is stabilized, it enters the nucleus and teams up with ►HMG box transcription factors of the ►LEF/TCF family (below referred to as TCF). The TCF/β-catenin complexes activate target genes by binding to specific promoter elements and so transmit the Wnt signal into the nucleus (2). Mutations in components of the β-catenin destruction complex, most frequently of APC, lead to aberrant stabilization of β-catenin and thus to constitutive, Wnt-independent activation of TCF/β-catenin signaling.

Molecular Consequences of APC Mutations

The APC protein binds to β-catenin via specific repeated sequences called 15 amino acid and 20-amino acid repeats, which occur three and seven times respectively in the central domain of the APC protein. In addition, APC binds to the RGS domain of axin or conductin/axin2 via three so-called ►SAMP repeats. In colorectal tumors mutations of *APC* occur mostly in a mutation cluster region that is located closely 5′ to the sequence encoding the first SAMP repeat. These mutations generate stop codons or frameshifts leading to the deletion of the C-terminal half of the APC protein and thereby removing the interaction sites for axin/conductin (3). In addition, truncated APC also lacks several nuclear export sequences (NES) thought to be

important for the APC-mediated export of β -catenin from the nucleus. In summary, APC mutations disrupt the ability of APC to bind axin/conductin and β -catenin, which leads to increased TFC/ β -catenin interaction and constitutive activation of the Wnt pathway in the absence of exogenous Wnt factors.

APC interacts with a variety of other partners thereby regulating different cellular functions. APC is involved in ►cell migration, chromosomal stability, ►cell-cycle regulation and ►cell adhesion. For instance, APC binds to the APC-stimulated guanine nucleotide exchange factor (ASEF), which can activate the small G-protein rac and plays a role in cell migration. Truncated, but not wild type, APC appears to activate ASEF and hence stimulate cell migration, which could be important for the invasiveness of APC mutated cells. APC is also connected to microtubules and plays a role in the correct establishment of the mitotic spindle. Disturbance of APC function by mutations could lead to ►chromosomal instability (CIN), which is a hallmark of the majority of CRC.

APC Genotypes and Phenotypes in CRC

In FAP, patients harbor germline mutations in one allele of *APC* and lose the second *APC* allele through loss of heterozygosity. *APC* mutations lead to stop codons or truncating frameshifts thereby removing the β -catenin regulatory domains. Depending on the specific mutation sites of the first and second allele, patients develop extra-abdominal manifestations. The most common and well known are congenital hypertrophy of retinal pigment epithelium (CHRPE), which in some cases can be used to identify FAP patients, desmoid tumors, polyps in the upper gastrointestinal tract and thyroid carcinomas. Specific clinical associations are summarized by syndromes, Gardner syndrome (FAP, desmoid tumors, osteomas) and Turcot's syndrome (FAP, brain tumors).

In contrast to the "classical" FAP the "attenuated FAP" (AFAP) is characterized by fewer adenomas that develop at a later age and tend to be more right-sided. Interestingly, the *APC* mutations in AFAP result either in an ultra-short or a very long APC protein.

APC is mutated in about 80% of sporadic carcinomas, leading to a truncated APC protein. Around 60% of the *APC* mutations are found in the mutation cluster region. *APC* can also be inactivated by hypermethylation at CpG sites of the *APC* promoter; these have mostly been detected in sporadic CRC (4).

Catenin Mutations

β -Catenin is mutated in about 10% of all sporadic colon carcinomas by point mutations or in-frame deletions of the serine and threonine residues that are phosphorylated by GSK3 β . Like APC mutations, these mutations result in stabilization of β -catenin and activation of Wnt

signaling. β -Catenin and APC mutations are mutually exclusive, possibly reflecting the fact that both components act in the same pathway. β -Catenin mutations are more frequent in other tumor types such as liver tumors than in CRC.

Axin and Axin2/Conductin Mutations

Germline mutations of *conductin/axin2* associated with oligodontia and colorectal neoplasias in the affected families have been described. Mutations suggesting a tumor suppressor role of axin and the related conductin/axin2 gene have also been identified in various entities such as medulloblastomas, endometrioid ovarian carcinomas, hepatomas and hepatocellular carcinomas.

Mutations in Microsatellite Instable Tumors

Mutations of components of the Wnt signaling pathway also occur in microsatellite instable tumors but at a lower frequency than in the microsatellite stable counterparts. It appears that *β -catenin* is more often mutated than *APC*. In addition, 25% of microsatellite instable tumors show mutations in the *conductin/axin2* gene and *TCF4* mutations occur in about 40%, the consequences of which are not clear yet.

Regulatory Mechanisms

Wnt Target Genes and Cancer Development

Several of the known Wnt target genes have a potential role in CRC development. Among them are regulators of cell-cycle progression, such as *c-myc* and *cyclin D1*, which are directly controlled by TCF/ β -catenin, as well as growth factors and their receptors, such as FGF18 and the c-met tyrosine kinase. c-Met is the receptor for the mesenchyme-derived scatter factor/HGF, which acts as an epithelial growth factor but also promotes cell motility and invasion. Wnt signaling can prevent apoptosis by up-regulating anti-apoptotic proteins such as the caspase inhibitor, survivin. TCF/ β -catenin complexes can also up-regulate VEGF (vascular endothelial growth factor) and may thus induce ►angiogenesis, indicating that aberrant Wnt signaling is not only important for the initial expansion of the transformed cell compartment as implied by the loss of the "gate-keeper" function of APC, but might also lead to the acquisition of properties required for tumor progression. In line with this, several proteases capable of degrading extracellular matrix such as matrilysin/MMP7 and MMP-26 are Wnt targets that could aid the tumor cells in invasion and metastasis. Metastasis formation could also be promoted by up-regulation of Wnt targets such as CD44 and NrCAM. That TCFs control cell differentiation was revealed by the finding that EphB2 and EphB3 receptors were down-regulated by dominant-negative TCF, while their ligand ephrinB1 was up-regulated. Further analysis in

EphB knockout mice showed that this differential regulation served to prevent the intermingling of cells within the intestinal epithelium. Whether this is also relevant for human colon tumor formation remains to be determined.

Feedback Control

The Wnt pathway, like other signal transduction cascades, includes mechanisms for feedback control. The scaffold component of the β -catenin destruction complex, *conductin/axin2* is a direct target gene of Wnt signaling and might play a role in normal embryonic development where it could serve to attenuate the Wnt signal. Conductin is massively over-expressed in early colorectal adenomas and carcinomas as well as in other tumors. Whether this up-regulation has a functional role in tumors remains to be determined.

Negative control of the pathway is also achieved through the induction of dominant-negative forms of TCF-1. *Tcf-1* knockout mice develop spontaneous intestinal adenomas and mammary adenocarcinomas. When *Tcf-1*^{-/-} mice were mated to *min* mice, which carry a mutated *apc* allele and are prone to the development of intestinal adenomas, the number of adenomas was significantly increased in the progeny. Conversely, LEF-1 appears to be involved in a positive feedback loop that may be important in colon tumors. The *LEF-1* gene is activated by TCF/ β -catenin complexes but in this case, activation leads to transcription of full-size LEF-1 that is capable of binding to β -catenin. These LEF-1/ β -catenin complexes could further boost transcription of Wnt target genes.

Mouse Models

Mouse models for intestinal tumorigenesis have been established by introducing germ-line mutations in the *apc* gene or by mutational activation of β -catenin. Unlike the human disease, in all of these models tumors develop mainly in the small intestine. The *min* mouse was generated by chemical mutagenesis that introduced a chain-terminating mutation in murine *apc*. Other mouse models of FAP have been created by gene targeting of *apc*, such as APC Δ 716 and APC 1638N. In another approach a deletion mutant of exon3 encoding the phosphorylation sites of β -catenin was generated using the loxP/Cre system; this also led to intestinal tumorigenesis. Tumorigenesis in *apc* deficient mice could be accelerated in compound mice having additional deletion of the *smad2* or *smad4* tumor suppressor genes. Conversely, tumor formation was reduced when the genes for cyclooxygenase 2 or the multidrug resistance gene *mdr1* were additionally mutated (5).

β -Catenin Localization

In colorectal carcinomas the nuclear staining for β -catenin often shows a heterogeneous pattern with

strong nuclear enrichment at the invasion front and mainly cytoplasmic and membrane staining in the central tumor area. This indicates that high levels of nuclear β -catenin play a role in the transition of the tumor cells to the invasive state. The molecular basis for this differential distribution of β -catenin is not known, but it can be speculated that signals coming from the mesenchyme that surround the invasive tumor cells play a role (6).

Therapeutic Interference with Wnt Signaling

As ►Wnt Signaling is crucial for CRC development, interference with TCF/ β -catenin mediated transcription seems a valid option for rational cancer therapy. Small molecule inhibitors that prevent the TCF/ β -catenin interaction have recently been identified (7).

Definition

Evidence from numerous family studies has shown that the common diseases such as essential hypertension, atherosclerosis and cancer are caused by varying combinations of genetic and environmental factors. Since common diseases are, by definition, those present at 1% or higher in the general population, the resultant morbidity and mortality puts a significant strain on health budgets. Consequently, much effort has been put into elucidating which genes are involved and how they may interact with each other and the environment. In recent years a number of the technologies developed in the interrogation of the more simple monogenic disorders have assisted in the identification of the chromosomal locations and in a few cases genes containing mutations, which contribute to the susceptibility to a particular common disease. These technologies are now being applied in the identification of the genes contributing to the development of the common more complex diseases.

Characteristics

The common diseases are those present at 1% or higher in the general population and are caused by the complex interactions of multiple genes located on several chromosomes. Identification of susceptibility genes along with the unravelling of their interaction with environmental factors presents one of the most exciting challenges in current medical research.

Cellular and Molecular Regulation

Connecting phenotype with genotype is the fundamental aim of all human genetics. Almost 3 billion base pairs of DNA, containing 30,000–40,000 protein-coding regions are housed in the 46 chromosomes of the human genome. The coding regions constitute less than 5% of the genome – the function of the remaining 95% is unclear. The capacity to determine which DNA sequences cause which specific traits was elusive until genome-wide linkage analysis using anonymous DNA polymorphisms was first suggested. The starting point of gene identification is ▶ [linkage analysis](#). Families in which the disease phenotype segregates are analysed using a series of genetic polymorphisms. The earliest and most successful disease in which linkage analysis led to the gene was cystic fibrosis. At that time the DNA markers were ▶ [restriction fragment length polymorphisms](#) (RFLP) and simple sequence repeats such as ▶ [microsatellites](#). Nowadays such endeavours benefit increasingly from ▶ [single nucleotide polymorphisms](#), which have been made available through the sequencing of the human genome. Linkage analysis results in the identification of a chromosomal region which contains the disease causing gene(s), albeit many others as well. The genes are then searched for using ▶ [positional cloning](#) in which the target region of the chromosome is more thoroughly interrogated using a variety of molecular techniques.

To date many of the genes underlying monogenic disorders have been identified using linkage analysis and positional cloning (e.g. cystic fibrosis and Duchenne muscular dystrophy). However, the ▶ [candidate gene approach](#) has had its own successes and identified the ApoE gene as being involved in late onset Alzheimer's disease (1). The genetic paradigm underlying common diseases is often more complicated but the analysis has undoubtedly benefited from the advances in technology, in particular the concept of genomics, implemented in the investigation of the monogenic diseases as described in the rest of this essay.

Common Cancers

The term “cancer” represents a heterogeneous group of growth disorders, caused by a number of interacting genetic and environmental factors, which may occur in any organ of the body. The common cancers include those of the lung, breast and prostate. Cancer occurs when cell division, normally under tight regulation, gets out of control. An extensive network of signalling molecules dictates which cells divide, how often and when. Mutations in one or more of these signals, caused by either a genetic predisposition or an environmental effect such as smoking or a combination of both, can trigger cancer. Recently three different mechanisms have been defined (i) transformation of a

Common Diseases, Genetics. Table 1 Monogenic Forms of Hypertension and Hypotension

Hypertensive	Syndrome	Mode of inheritance ¹	Enzyme/Location
	Apparent mineralocorticoid excess	Recessive	11 β -hydroxysteroid dehydrogenase
	17 α -hydroxylase deficiency	Recessive	17 α -hydroxylase
	11 β -hydroxylase deficiency	Recessive	11 β -hydroxylase
	Liddle's syndrome	Dominant	β or the γ subunit of ENaC
	Hypertension and brachydactyly	Dominant	Chromosome 12p12.2-11.2
	Glucocorticoid remediable aldosteronism.	Dominant	Aldosterone synthase and 11 β -hydroxylase
	Gordon's Syndrome	Dominant	Chromosome 12 and 17. Wnk1 and Wnk4
	Pregnancy related hypertension	Dominant	Mineralocorticoid receptor
Hypotensive			
	Bartter's syndrome type 1	Recessive	Apical Na-K-2Cl cotransporter
	Bartter's syndrome type 2	Recessive	ATP-sensitive K ⁺ channel ROMK
	Bartter's syndrome type 3	Recessive	Cl ⁻ channel <i>CLCNKB</i>
	Recessive PHA1	Recessive	ENaC
	Aldosterone synthase deficiency	Recessive	Aldosterone synthase

	Gitelman's syndrome	Recessive	Thiazide-sensitive Na-Cl cotransporter
	Dominant PHA1	Dominant	Mineralocorticoid receptor

¹ The inheritance in all of these diseases is autosomal

normal gene into an **▶oncogene** (ii) dysfunction of a **▶tumour suppressor gene** and (iii) impairment of a **▶DNA repair** pathway. Lung cancer shows a particularly high association, over 80%, with environmental effects such as cigarette smoking. Small cell lung carcinoma, on the other hand, has been associated with a deletion of part of chromosome 3. Prostate cancer is one of the leading causes of cancer death in men and yet little is known about the genetic predisposition. Numerous studies indicate that a family history may be responsible in up to 10% of all prostate cancers. Identification of a susceptibility locus on chromosome 1 called HPC1 (hereditary prostate cancer 1) presents a promising breakthrough. The next steps will include cloning the gene and characterising it in model systems.

Common Cardiovascular Disorders

Diseases of the cardiovascular system include essential hypertension, coronary artery disease and stroke. Like cancer they are multi-factorial and dissection of the contribution of genetics and environmental factors is

ongoing. Earlier studies of the simpler monogenic forms of hypertension may provide some clues. Molecular genetic studies have identified mutations in several genes that cause **▶Mendelian forms of hypertension** and/or hypotension (2). All of these genes, shown in Table 1, act to alter net renal salt reabsorption in the kidney. Accordingly, efforts to identify genes predisposing to essential hypertension have largely focused on candidates in pathways implicated in blood pressure control. Candidate gene studies have typically compared the prevalence of hypertension among individuals of contrasting genotypes at the candidate locus. Among such studies, common variants in genes of the renin-angiotensin system, the same pathway implicated in Mendelian forms of hypertension, have provided some evidence of effect. For example, a variant in the *angiotensinogen* gene is associated with higher circulating angiotensinogen levels and hypertension in several but not all populations. This variant is in strong **▶linkage disequilibrium** with another variant near the **▶transcription** start site that has been proposed to result in

Common Diseases, Genetics. Table 2 The Contrasting Role Of Genetics And Environment In The Development Of The Three Forms Of Diabetes

	Clinical features	Environmental Component	Genetic component	Causative/Candidate Genes
MODY	Develops in children		+++	Glucokinase
Type 1	Insulin dependent	+	++	Several implicated
Type 2	Non-insulin dependent	++	+	Several implicated

increased transcription of the gene. Interestingly, a mouse model featuring increased expression of the *angiotensinogen* gene demonstrates elevated blood pressure, indicating this as a plausible mechanism. Variants in other genes in the same physiological pathway, such as the ACE (►[angiotensin converting enzyme](#)) gene, have also been investigated with contrasting results in different populations. Poor reproducibility in these studies suggests that these variants impart singly, at most, very modest effects and the true picture will emerge when it is possible to look at the combined effects of several mutations simultaneously.

More recently, several studies have performed a ►[genome-wide analyses](#) of linkage, comparing the inheritance of each chromosome segment to phenotypes such as hypertension or blood pressure. In addition to human studies, investigation of naturally occurring and genetically engineered animal models of disease hold promise for understanding the long-term regulation of blood pressure.

To date, although genetic studies have identified several genes in which rare mutations impart large effects on blood pressure, providing new insight into the causes of hypertension, genetic studies of the general population have until recently been relatively disappointing and suggested that there are no single loci that account for a large fraction of the variation in blood pressure in the general population. However, the recently published British Genetics of Hypertension (BRIGHT) study, the largest blood pressure genome scan performed, in which 2010 severely hypertensive sibling pairs were genotyped, identified one chromosomal region with a significant LOD score at 3.21 on chromosome 6q and three suggestive loci scores on 2q, 5q and 9q.

Further integration of the data obtained from well-designed genetic, molecular, clinical and epidemiological studies could disclose subsets of patients in whom specific combinations of genetic and environmental factors raise blood pressure and lead to more individualised treatment.

Common Endocrine Disorders

Family and twin studies have shown that diabetes has high ►[heritability](#) but for many years an understanding

has been elusive. The first step towards progress was the careful classification of the different types of diabetes (Table 2). Type I and type II diabetes are totally different diseases with different causes and totally different genetics. Maturity onset diabetes of the young (MODY) is a rare variant having the clinical features of type II but the age of onset of Type I. Type II results from a decreased number of pancreatic β cells and/or the development of insulin resistance. Obesity, age and a lack of physical exercise along with unknown genetic factors contribute in the pathogenesis. MODY is highly heritable and in some families has been shown to be caused by a mutation in the gene encoding glucokinase, an enzyme key to glucose metabolism and control of insulin secretion on chromosome 7.

►[Type I diabetes](#) is a complex trait in which mutations in several genes contribute to the disease. About 10 ►[loci](#) in the human genome have been identified which confer susceptibility to type I diabetes. Chromosome 6 harbours at least one of these at a region referred to as IDDM1 (insulin dependent diabetes mellitus). Although it is not yet clear how a mutation at this locus acts to increase susceptibility to diabetes, it is thought that the expression of antigens encoded by genes in this region may be involved. Other possible loci include a gene at IDDM2 on chromosome 11 and the gene for glucokinase, which has been confirmed as causative in MODY.

Common Immunologic Disorders

Complex diseases of the immune system include ►[asthma](#), which now affects over 1 in 10 children. It is a chronic inflammatory disorder of the airways caused by oedema (fluid in the intracellular space) and the influx of inflammatory cells into the walls of the airways. Family and twin studies suggest that asthma has a strong genetic component (60–70%). Genomic screens and positional cloning studies to find the genes responsible are now beginning to come to some agreement with genes located on chromosomes 5, 6, 7, 11, 14 and 12 implicated to contribute. Typical candidate regions include those encoding key molecules such as those seen to be involved in asthma including ►[cytokines](#) and ►[growth factor receptors](#).

Several genetic studies have been performed to find asthma susceptibility genes in large families. The researchers were interested in whether a particular allele of a given polymorphism shows up more frequently in affected individuals *versus* controls and found multiple polymorphisms in the ADAM33 gene, which were associated with an increased risk of asthma. ADAM33 is a membrane bound metalloproteinase whose family members are known to induce cell shedding of proteins such as cytokines and cytokine receptors. However, the link between ADAM33, cell-surface shedding and asthma has still to be established (4). Other studies have revealed the strong association between asthma susceptibility and severity. Laitinen et al. performed a genome scan of a Finish population and found linkage to a region on chromosome 7 for three phenotypes, asthma, high levels of immunoglobulin E and a combination of the two with the strongest being the IgE level. IgE is the best marker for allergies (5).

Clinical Relevance

Molecular biological investigations using well-defined model systems of common diseases, in particular rodents, have already presented us with candidate pathways and target genes for the therapeutic manipulation of common diseases. The publication of the sequence of the human genome and the identification of functional **▶SNPs** will aid in the identification of those genes, which, in combination with environmental effects contribute to the pathogenesis of the disease. The identification of contributory genes will allow screening possibilities and those individuals harbouring combinations putting them at risk may be offered screening opportunities such that the appropriate life-style changes can be implemented to ease the impact of these diseases. In addition, the pattern of SNPs ascribed to an individual will act as a genetic signature of drug efficiency and lead to individualised medicines (pharmacogenetics).

Once a human disease gene has been characterised, molecular genetic tools can be used to design novel therapies. Gene therapy is the genetic modification of the cells of a patient in order to combat disease. This broad definition encompasses many different possible approaches including transfer of cloned human genes, double stranded human gene segments, oligonucleotides and artificial genes such as anti-sense genes. At present most gene therapy aims to alleviate the symptoms of the disease, in a risk-free manner, but in the future will not only be based on improving the clinical situation but also on replacing the combination of mutated genes underlying the disease.

Future Directions

Whilst the first draft of the human genome has brought with it a tremendous step forward in our capacity to

investigate the genetics of common diseases, it will not answer all the questions. In each disease the identification of genes may provide a target for genetic screening and in some cases gene therapy. However, the complexity of the system means that the identification of genes does little to define protein expression and activity underlying the pathogenesis of the disease. There is little doubt that the careful application of model systems and innovative technological developments will signpost the way to the Holy Grail of polygenic diseases.

Model Systems

Model systems, in particular genetically manipulated animals, will be invaluable as a resource in understanding the genetics of common diseases. Inbred strains of mice and rats, selected for a particular disease, have underpinned the identification of key contributory genes. In human genetics, the determination of linkage is essentially a statistical process and requires absolute knowledge of the status of affected individuals. Where misdiagnosis, caused by unrecognised **▶phenocopy**, results in the inclusion of individuals within a disease group, linkage analysis can fail even in a large cohort. Consequently the ability for a more absolute diagnosis in a model system such as the rat or the mouse allows increased power in the statistical approach. Furthermore the relatively short life span of a rodent model means that increased number of individuals can be analysed. In addition the use of transgenic rats and “**▶knock-in** and **▶knock-out**” mice allows the definition of primary events and those that occur as adaptations to the disease.

Technological Advances

The **▶polymerase chain** reaction (PCR) has revolutionised our capacity to examine DNA. PCR provides the capacity to generate large quantities of DNA, from minimal starting material, with a sequence identical to that of the contributing patient. In the past restriction fragment length polymorphisms (RFLP) which identify differences in the sites for restriction enzymes between the DNA of different individuals and more recently automated SNP analysis and sequencing using high speed robotics and automated throughput have been important technologies which will accelerate the discovery of contributing genes. The bioinformatics revolution brings with it the “omics” era consisting of genomics, transcriptomics (analysis of the complement of mRNAs transcribed from a cell’s genome), proteomics and metabonomics (the totality of small metabolite molecules in an organism). Together these offer to fill the gap in our understanding between genes and pathogenesis and in the development of effective strategies for early prognosis and treatment (6). This may be useful in defining the genes and

subsequently the mechanisms and perhaps more importantly point us in the right direction to develop the best therapeutic approaches to treat these common diseases.

Compartment Modeling

Definition

Compartment modelling designates a mathematical technique for the quantitative description of tracer kinetic processes.

► [PET](#)

Complement System

Definition

Complement system refers to a set of plasma or tissue proteins that act together to attack extracellular forms of pathogen. Complement also binds to [immunoglobulins](#) and C-reactive protein (CRP).

► [Inflammatory Response](#)

Complementary Base

Definition

The Watson-Crick model of the double helix of DNA is based on the discovery of Erwin Chargaff, that only purin bases (adenine, guanine) of one polynucleotide strand interacts with pyrimidine bases (cytosine, thymine) of the other strand through hydrogen bonding, thus forming the double helix. Adenine interacts with thymine, guanine interacts with cytosine, and the interacting bases are called complementary.

Complementation

Definition

When it is shown genetically that two (or more) genes control a phenotype, the genes are said to form a

► **complementation** group. Host strain/selection marker combinations rely on the concept of complementation: in the host strain an essential gene, without which cells are not viable, is complemented, i.e. its function is replaced by a gene on the expression plasmids. Therefore, only cells carrying this vector survive on selective media.

► **Recombinant Protein Expression in Yeast**

Complementation Studies

Definition

Complementation studies are aimed at resolving the genetic homo- or heterogeneity of a particular set of disorders, based on fusion of patient fibroblast cells followed by biochemical or cell biological studies.

► **Peroxisomal Disorders**

Complex Diseases/Complex (Multigenic) Traits

Definition

Complex (multigenic) traits/diseases are diseases that are influenced by multiple loci (genes), each of which is known as a quantitative trait locus (QTL). Thus, complex traits are characterized by a genetic component that is not strictly Mendelian (dominant recessive or sex-linked). Additional to genetic variation, environmental factors play an important role. Complex diseases are often characterized by clinically heterogeneous presentation.

Synonyms

Clinical bioinformatics; Classification and clustering of expression profiles

Definition

Computational diagnostics deals with statistical models and algorithms to analyze large-scale genomic datasets for diagnostic and prognostic purposes. The fundamental question of computational diagnostics is “What can be learned about the disease of an individual patient from genomic data?” This differs from classical bioinformatics, where the focus is on functional genomics: “What can be learned about the function of a certain gene?”

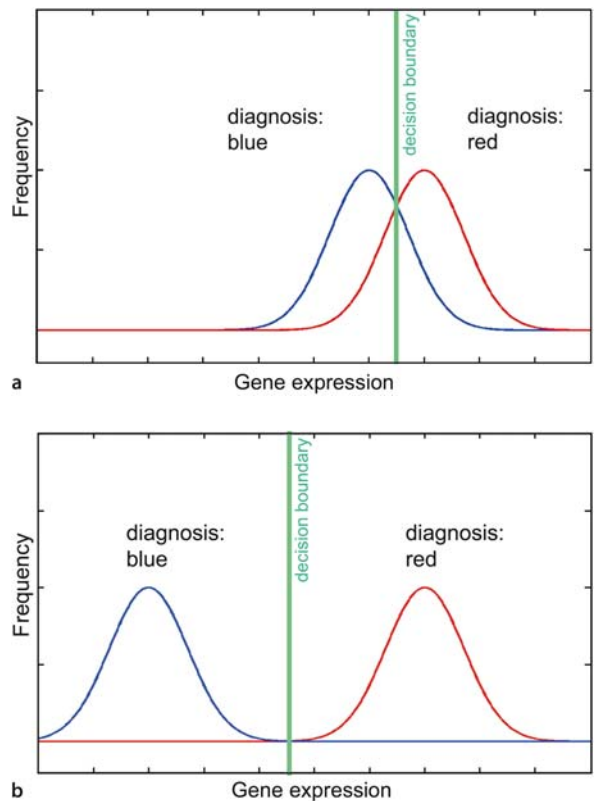

The data used in computational diagnostics is genome scale phenotype data like mRNA expression profiles, protein expression profiles and methylation screens.

► **Association studies** of genotype data like single nucleotide polymorphisms are part of statistical genetics and will not be considered here.

The goal of computational diagnostics is to detect patterns that are predictive for certain disease entities or outcomes. Statistical analysis of microarray data is currently the most applicable approach. The data used in microarray studies is very high dimensional. This requires advanced statistical modeling. The two major problems are (1) screening a huge number of genes for potential clinical markers and (2) learning general features of the given data without ► **overfitting**. The solution lies in statistical methods for feature selection and regularization techniques from ► **machine learning**.

Characteristics

In clinical studies, the analysis of genomic data divides into clinical functional genomics and computational diagnostics. Clinical functional genomics investigates the role of certain genes in molecular disease mechanisms (3). Computational diagnostics explores large-scale genomic data from an individual patient for improved diagnosis and therapy decision-making. We focus here on three central issues in the statistical analysis of microarray data, screening for marker genes, deriving predictive ► **signatures** and detecting new disease entities.

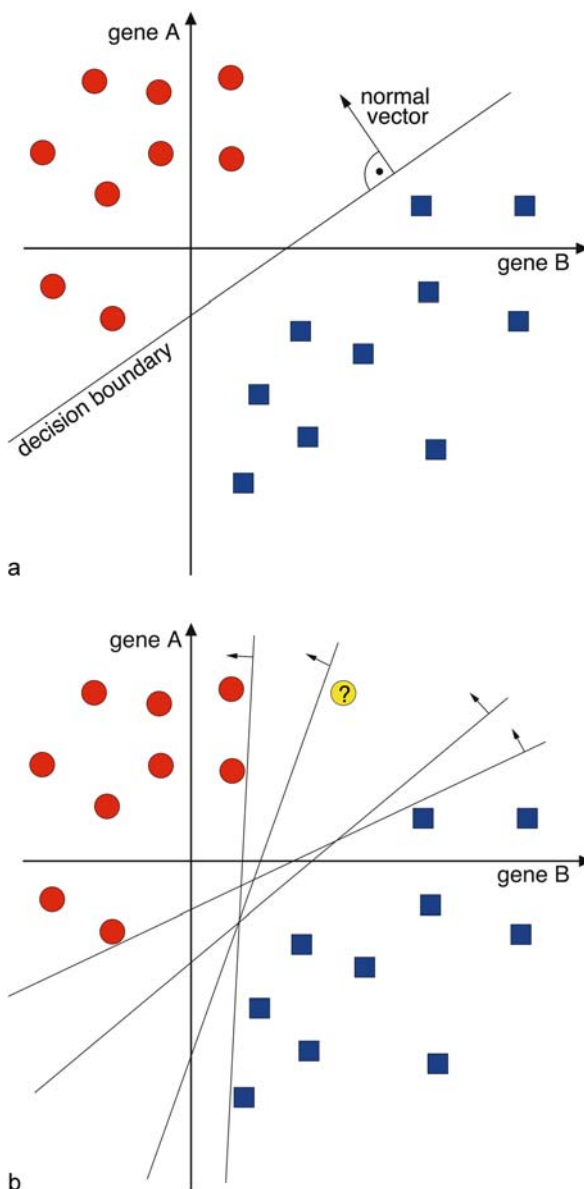

Computational Diagnostics. Figure 1 The distribution of expression levels in two disease groups for a single gene. In (a) one observes a large overlap. The gene is more or less useless as a marker gene, even if the difference between the red and blue distributions can be detected by statistical tests. (b) shows two clearly separated distributions; this gene is an ideal marker gene.

Marker

The commonly used approach to find “interesting” genes is to apply a test for differential gene expression like the t-test and extract genes with low p-value (5). However, genes found significant in a multiple testing scenario need not be valuable clinical markers. The left plot in Fig. 1 gives a schematic view of the distribution of single gene expression levels in two disease groups (blue/red). The difference between the two distributions can be insignificant in statistical tests for small sample sizes and significant for large sample sizes, but due to the large overlap the gene can be useless as a clinical marker.

There is a difference between screening for evidence to disprove that a gene’s expression levels are essentially the same in two disease groups and screening for genes that can serve as clinical markers. The goal of the first one is to improve our understanding of the role of certain genes in a certain disease (functional genomics) and the goal of the second is to find ► **clinical marker**

Computational Diagnostics. Figure 2 (a) two disease entities (red and blue) can be separated by combining gene A with gene B. Points facing in the direction of the normal vector of the hyperplane are classified as red, points on the other side of the hyperplane are classified as blue. (b) Overfitting: many different hyperplanes separate the red points from the blue points. They disagree in their class prediction for the new patient (yellow). This shows that separation of the training set does not guarantee good generalization performance.

genes for improved diagnosis and prognosis (computational diagnostics).

For evaluating the quality of a gene as a diagnostic marker the performance of a decision rule (green line) needs to be evaluated. A gene is a good clinical marker, if the two distributions can be separated by a decision

boundary with only a small number of misclassifications. The right plot of Fig. 1 shows the ideal scenario for a diagnostic marker. Unfortunately, genes with such a classification power are hardly ever found.

Signatures

The solution is often to combine single genes into multi-gene expression patterns, so-called signatures, as is shown in the left part of Fig. 2. Note that both gene A and gene B are poor markers as single genes, but in combination they separate the diagnostic entities perfectly. The signatures are to be defined such that they distinguish the patients with the disease from the patients without the disease. Mathematically, signatures are hyperplanes in high-dimensional spaces separating one class (with disease) from the other class (without disease). A signature is used to predict the class of a new patient by comparing the patient profile to the normal vector of the hyperplane; patients in the direction of the normal vector are predicted as one class, patients on the opposite side of the hyperplane as the other class.

Overfitting

One would expect that finding a separating hyperplane is a difficult task. However, if the number of genes is bigger than the number of patients, there always exists a hyperplane separating the training data without error. But flawless separation of the study data does not necessarily lead to good diagnostic performance in the future. This phenomenon is called overfitting; a hyperplane, which correctly identifies the training set, may be useless to diagnose new patients. In the right part of Fig. 2 we show an example where two groups can be separated by a large number of hyperplanes with conflicting diagnoses for a new patient.

Regularization

The problem of overfitting is addressed by strategies of regularization (2). Regularization means “making the classification problem harder”. This can be done in several ways. The most widely used approach is gene selection; limit the number of genes in the predictive signatures. A second widely used strategy is to choose a classifier that maximizes the margin of separation between the samples of the two classes. Both methods improve diagnostic performance ability.

Evaluation

Excellent performance on the training data does not guarantee good generalization to new patients. It is important to evaluate the performance of a diagnostic signature on independent test data. This can be done by either splitting the data into a test and a training set or by ►crossvalidation. It is important to note that gene selection is part of classifier training. The test data has to be classified using the genes selected only on the

training data, it must not be included into the gene selection procedure. In crossvalidation, gene selection has to be repeated anew in each step (5).

► Clustering

In prediction, we generalize a structure (a class distinction) from training examples to a new specimen. A different task is to find hidden structures in the data (2, 3, 5). The question here is “Does a known disease entity split into several sub-entities, that can be distinguished reliably based on genomic data?” This is called clustering or ► **unsupervised learning**, in contrast to prediction, which is called ► **supervised learning**. The difference between supervised and unsupervised learning is that in the first we need information about the structure of the data (given by the class labels) and in the second we infer this structure from the data. Particular diligence is needed to prove the validity of the results in unsupervised learning.

► Molecular Symptoms

Clustering patients by gene expression profiles can find subtypes of a known disease. These techniques find homogeneous subgroups in the data. Microarrays contain information about thousands of genes; not all of them matter to describe a split between two subclasses. Therefore, one clusters patients according to subsets of genes. This leads to the concept of a molecular symptom: a certain subset of genes that are characteristic for a certain subset of patients. With two-way clustering methods, patients and genes are clustered at the same time (5). In the methods described so far one gene or one patient was a member of only one cluster. More advanced methods use overlapping clusters. One patient can have several distinct molecular symptoms and the same gene can play a role in more than one symptom.

Clinical Relevance

The molecular view of diseases brings clarity to previously muddy diagnostic categories. Detecting new disease entities leads to more stratification options and refined clinical studies. The higher the diagnostic resolution, the more successful the treatment. Given a disease with several subtypes, the overall most successful treatment is not necessarily optimal for each subtype. First diagnosing the subtype and then using the optimal treatment will increase the overall success rate, although no novel therapies have been developed (4).

Identifying prognostic and predictive factors is a labor-intensive process, often requiring the combined expertise of hematologist, oncologist, pathologist and cytogeneticist. Gene expression assays have the potential to supplement cell surface, histological or gross pathological features with a molecular characterization of the abnormal cell. Microarray analysis is now

tested in many fields of medicine. We chose three studies (1, 6, 7), which demonstrate that expression profiling can accurately identify known prognostically important cancer subtypes.

► Leukaemia

► **Acute lymphoblastic leukaemia** is a heterogeneous disease, with individual leukemia subtypes differing in their response to chemotherapy. Yeoh et al. (7) used oligonucleotide microarrays to analyze the pattern of genes expressed in leukemic blasts from 360 pediatric ALL patients. Distinct expression profiles identify each of the prognostically important leukemia subtypes. In addition, another ALL subgroup is identified based on its unique expression profile.

► Breast Cancer

West et al. (6) analyzed expression profiles from 49 breast tumor samples and assessed the validity of their diagnostic model in predicting the status of tumors in crossvalidation determinations. The practical value of this approach relies on two features: (1) they assess relative probabilities of clinical outcomes for future samples and (2) they provide an honest assessment of the uncertainties associated with predictive classifications on the basis of the selection of gene subsets for each validation analysis.

Lymphoma

Alizadeh et al. (1) gave an example for the detection of new disease entities from gene expression profiles. In this study two types of diffuse large B-cell lymphoma (DLBCL) were identified. DLBCL was long known to be clinically heterogeneous; 40% of patients respond well to current therapy, whereas the remainder succumb to the disease. Alizadeh et al. argue that this difference reflects the molecular heterogeneity in tumors. Using hierarchical clustering they split the data into two homogeneous subtypes. The comparison of these gene expression subgroups with survival data of the patients shows significant differences in the overall survival.

Concordance (Rate)

Definition

Concordance (rate) defines the percentage of sharing the same (disease) phenotype in two first degree relatives, especially in monozygotic or dizygotic twins. A significantly higher concordance rate in monozygotic twins (sharing 100% of their genome) compared with dizygotic twins (sharing approximately 50%) indicates a genetic component for disease expression.

Confluent Monolayer/Confluence

Definition

Confluent monolayer refers to cells in tissue culture, e.g. epithelial cells, which form a cohesive sheet comprising of a single cell layer filling the entire surface area of the bottom of the culture dish. Cells have then reached confluence.

► [Desmosomes](#)

Confocal

Definition

Confocal refers to an optical imaging scheme that results in very small measurement volumes. The focal spot of a high resolution objective is projected onto a small field aperture (pinhole) in the image plane, thereby restricting z-resolution and suppressing out-of-focus light.

► [Confocal Laser Scanning Microscope](#)

► [FCS](#)

Confocal Laser Scanning Microscope

Definition

Confocal Laser Scanning Microscope (CLSM) is an imaging instrument that selectively excludes image noise above and below a plane of focus. This is accomplished by filtering out-of-focus information with a pinhole aperture. A field of view is selectively illuminated by a laser beam that is processively moved across the field by rotating mirrors.

► [FRAP](#)

Conformation

Definition

Conformation defines different spatial arrangements of the atoms in a molecule that may arise by rotation around the bonds. The 3D-coordinates of all atoms are completely characterized by the conformation. This also contains information about the stereochemistry (configuration) of all stereotopic atoms. The conformation of a biological molecule is closely connected with its function. The transition from one conformation to another occurs without any breaking of covalent bonds. To account for the dynamic nature of proteins, the term conformation is sometimes used in a wider sense to refer to an ensemble of arrangements that interconvert rapidly at ambient temperatures, and are therefore distinguishable.

Conformation of Double-Stranded DNA

Definition

The B-form DNA is the most common conformation of right-handed, double-stranded DNA, and contains 10 base pairs per turn perpendicular to the DNA axis.

► [Protein/DNA Interaction](#)

locus. Subsequent analysis of the component phenotypes expressed in each of the resultant congenic strains, potentially allows a detailed characterization of the disease component contributed by each susceptibility gene. The focus is thus simplified from studying a polygenic model to examining a series of essentially monogenic models.

► [SLE Pathogenesis Genetic Dissection](#)

Conformational Analysis

Definition

Conformational analysis is the exploration of the accessible conformations of a molecule, frequently with the task of identifying the energetically most favorable conformation.

► [Molecular Dynamics Simulation in Drug Design](#)

Congenic Strain

Definition

A congenic strain bears one or more genetic intervals on selected chromosomes (usually including disease susceptibility loci) that have originated from another strain. Typically, a congenic strain may carry (bear) specific disease susceptibility loci on an otherwise normal genetic background.

► [SLE Pathogenesis Genetic Dissection](#)

Conformational Order

Definition

Conformational order refers to a non-random distribution of protein conformations in an ensemble of protein species, without requiring that the spatial arrangement of atoms be similar in all conformations of the ensemble.

► [Protein Disulfide Bonds](#)

Definition

Congenital describes properties or a defect that are present from birth onward, but is not necessarily genetic.

► [Bone and Cartilage](#)

► [Heritable Skin Disorders](#)

Congenic Dissection

Definition

Congenic dissection is a strategy for identification of disease causing genes. In animal models, congenic dissection separates the multiple genes mediating a polygenic disease into a collection of ► [congenic strains](#), each carrying a different disease susceptibility

Congenital Disorders in Glycosylation

Definition

CDGs (Carbohydrate-deficient Glycoprotein Syndromes) are a newly discovered group of inherited disorders, also called carbohydrate-deficient glycoprotein syndromes (CDGSs). The current identified types of CDG are Type 1a, 1b, 1c, 1d, 1e and IIa. Most of these types have a special physiognomy, neurological problems, liver and/or intestinal problems. CDGs are characterized by a deficiency of glycans or glycan structures in secretory glycoproteins, lysosomal enzymes, and probably also membrane glycoproteins.

► [Glycosylation of Proteins](#)

Congenital Dyserythropoietic Anemia

Definition

Congenital dyserythropoietic anemia defines a heterogeneous group of inborn anemias, in which formation of red blood cells in the bone marrow is abnormal.

► [Hemochromatosis](#)

swelling. Causes include chronic hypertension, cardiomyopathy and myocardial infarction.

► [Proteomics in Cardiovascular Disease](#)

Congenital Heart Disease

Conjugal Pair

Definition

Conjugal pair describes both parents that are affected by the disease of interest.

► [Genetic Predisposition to Multiple Sclerosis](#)

Congenital Myasthenic Syndromes

Definition

Congenital Myasthenic Syndromes (CMS) are a heterogeneous group of diseases caused by genetic defects affecting neuromuscular transmission.

Connective Tissue

Definition

Connective tissue is a general term for mesodermally derived tissue, which is rich in extracellular matrix (collagen, elastic fibers, proteoglycan etc.) and surrounds other more highly ordered tissues and organs.

► [Marfan Syndrome](#)

Congestive Heart Failure

Definition

Congestive heart failure is a condition of ineffective pumping of the heart leading to an accumulation of fluid in the lungs and venous system. Typical symptoms include shortness of breath with exertion, difficult breathing when lying flat, and leg or ankle

Connexin Channelopathies

Definition

Connexin channelopathies are mutations in ► [connexins](#) detected at the genomic and proteomic level that lead

to pathologies caused by gap junction channel dysfunction.

- ▶ CMT
- ▶ Intermediate Filaments

Connexins

Definition

Connexins comprise of a multigene family of membrane proteins with over 20 members identified in human and murine genomes. Connexins oligomerise into hexameric connexons with the subunits arranged around a central pore, forming ▶ [gap junctions](#) between adjacent cells.

- ▶ Gap Junctions
- ▶ Intermediate Filaments

Consanguinity

Definition

Consanguinity refers to a genetic relationship. Consanguineous individuals have at least one common ancestor in the preceding few generations.

- ▶ [High-HDL Syndrome](#)

Consensus Map

Definition

Consensus map denotes the location of all consensus sequences in a series of multiple aligned proteins or polynucleotides.

- ▶ [Protein Databases](#)

Consensus Sequence (Sequon)

Definition

Consensus sequence (sequon) defines the most commonly occurring amino acid or nucleotide at each

position of an aligned series of proteins or polynucleotides. Within a polypeptide, the consensus sequence is commonly found to direct a specific post-translational modification at one of the residues within the sequon.

- ▶ [Glycosylation of Proteins](#)
- ▶ [Protein Databases](#)

Conservation

Definition

Conservation is the substitution of one amino for another that preserves the physicochemical properties of the original residue. For example, when a hydrophobic amino acid residue is replaced by another hydrophobic residue.

Conserved Synteny

Definition

Conserved synteny refers to a linkage of two orthologous genes that is maintained in the different species.

- ▶ [Mutagenesis Approaches in Medeka](#)

Constitutive Expression

Definition

Constitutive expression means the continuous transcription of a gene in an organism.

- ▶ [Recombinant Protein Production in Mammalian Cell Culture](#)

Constitutive Mutation

Definition

Constitutive mutation describes a change in the genetic information resulting in the inability of a gene product to be positively or negatively regulated, thus it cannot be turned on or turned off, respectively.

- ▶ [Bone and Cartilage](#)

Constitutive Splicing

Definition

Constitutive splicing designates a mandatory inclusion of an exon in mRNA.

► [Alternative Splicing](#)

Contact Inhibition

Definition

Contact inhibition refers to growth arrest that is induced in cultured cells that have reached confluence on a cell culture dish. Cultured transformed cells or tumour cells have lost this property.

► [Ras Signalling](#)

Contact Sites

Definition

In the more general cell biological sense, contact sites are those parts of cell membranes where interacting/neighbouring cells contact each other (e.g. contact site between antigen presenting cells and T-cells).

In mitochondria, contact sites are ultrastructurally defined sites where the inner and the outer membrane of mitochondria are observed in direct apposition to each other, with no apparent space in-between. Such contacts may be necessary for a number of central mitochondrial functions such as the channeling of metabolites, coordinated fusion and fission of mitochondria, and protein transport into mitochondria.

Synonyms

Chronic obstructive pulmonary disease (COPD): chronic obstructive lung disease, chronic obstructive airway disease, chronic airflow limitation, Asthma: bronchial asthma.

Definition

Chronic obstructive pulmonary disease (COPD) is characterized by decreased maximal expiratory flow. The Global Initiative on Obstructive Lung Disease (GOLD) has defined COPD as the progressive development of airflow limitation that is not fully reversible. COPD encompasses chronic obstructive bronchitis with obstruction of small airways and emphysema, with enlargement of air spaces due to destruction of lung

parenchyma and loss of lung elasticity. The airflow obstruction may be accompanied by airway hyperreactivity that is partially reversible. Emphysema is defined as a progressive destruction of alveolar wall leading to enlargement of airspaces without obvious fibrosis and with loss of normal architecture. Chronic bronchitis is defined as the presence of a productive cough that cannot be explained by other causes for at least three months in each year over two consecutive years. The major environmental risk factor for COPD is cigarette smoking. Asthma is a chronic inflammatory pulmonary disorder characterized by generalized reversibility of airflow obstruction caused by a multiplicity of stimuli. It is manifested physiologically as a widespread narrowing of the air passages, which may be relieved spontaneously or as a result of therapy and clinically by paroxysms of shortness of breath, cough and wheezing. Both COPD and asthma are ► [complex diseases](#), because they are likely to result from the interactions of multiple genetic and environmental factors. The genetics of COPD and asthma involve the study of the function, ► [polymorphisms](#) and expression of genes involved in ► [phenotypes](#) associated with these diseases.

Characteristics

Evidence of Genetic Background

Severe α_1 -antitrypsin (α_1 AT) deficiency, which follows a simple ► [Mendelian inheritance](#) pattern, has been known to be a genetic risk factor for COPD for four decades. However, convincing evidence of other genetic factors for COPD has been provided by epidemiological studies (1). There is an increased risk of COPD within the families of COPD ► [probands](#) but without clear Mendelian inheritance. Lower forced expiratory volume in one second (FEV_1), chronic bronchitis and COPD are more prevalent among the first-degree relatives of cases after correction for other risk factors such as smoking habits and α_1 AT deficiency. Twin studies have found estimates of ► [heritability](#) for FEV_1 that range from 0.5–0.8. The prevalence of COPD and similarity in lung function decrease with increased genetic distance.

The evidence for a genetic risk for asthma comes from similar epidemiological studies. First, asthma prevalence is especially high in individuals with a positive family history of asthma. Second, twin studies show that the concordance rates for asthma are higher in identical twins than in non-identical twins, irrespective of environmental risk factors. However, the fact that concordance in identical twins is not complete and the significant increase in incidence of asthma during the past two decades indicate that other factors than genetics play a major role in asthma pathogenesis. Currently, it is believed that both genetic and environmental factors contribute to asthma, with a heritability of about 60%.

COPD and Asthma, Genetics. Figure 1 Results of genome screens for asthma and its associated phenotypes. Regions that have been replicated are shown by red circles, regions that have not been replicated are shown by blue circles.

Characteristics of Genetic Studies of COPD and Asthma

Two major approaches have been used to identify susceptibility genes, full **genome screens** and **candidate gene association studies**. A genome screen involves searching the entire **genome** for regions that harbor disease-susceptibility genes by **linkage analysis** using affected families. Two advantages of genome screens are that novel genes can be identified in the pathogenesis of a disease and the approach is not confounded by **population stratification**. However, one disadvantage is the requirement for family data. This requirement makes genetic study of COPD difficult because of the late age of onset of the disease. Only two groups have reported full genome screens in COPD and related phenotypes. However, there have been more than 11 full genome screens for asthma and its related phenotypes (2). There is considerable consensus concerning regions of genetic **linkage** that are relevant to asthma. The linkages that have been replicated are 1p31-36, 2q4-32, 4q13, 5q23-31 (the cytokine gene cluster), 6p21-24 (the major

histocompatibility complex), 7p14, 11q13-31 (near the β chain of the high affinity receptor for IgE), 12q21-24, 13q12-14 and 16q21-23. Three regions of **linkage**, which although not replicated are statistically highly significant ($p < 0.001$), are 3q21-22, 14q24 and 17q12-21. The results of the eleven genomic screens are shown in Fig. 1 with the regions that have and have not been replicated highlighted. Recent studies have shown that evidence of **linkage** to asthma could depend on exposure to an environmental factor, such as environmental tobacco smoke.

Most of our knowledge of COPD genetics is derived from candidate gene association studies. Candidate genes for COPD include genes involved in protease-antiprotease and oxidant-antioxidant balance, inflammation and airway defense. Table 1 lists candidate genes that have been associated with COPD. In addition to severe α_1 AT deficiency, the results of different association studies have identified heterozygosity for α_1 AT, as well as polymorphisms in the tumor necrosis factor alpha (*TNF*), vitamin D binding protein (*GC*), microsomal epoxide hydrolase

COPD and Asthma, Genetics. Table 1 Candidate genes that have been associated with COPD. Bold text indicates those associations that have been replicated

Category	Candidate gene (symbol)	Phenotype
Antiprotease	α_1-antitrypsin (<i>SERPINA1</i>)	COPD, emphysema, rate of decline of lung function, early onset of COPD
	Tissue inhibitors of metalloproteinases-2 (<i>TIMP2</i>)	COPD
	α_1-Antichymotrypsin (<i>SERPINA3</i>)	COPD
	α_2 -Macroglobulin (<i>A2M</i>)	COPD
Protease	Matrix metalloproteinase-1 (<i>MMP1</i>)	Rate of decline of lung function
	Matrix metalloproteinase-9 (<i>MMP9</i>)	Emphysema

Others	ABO blood group antigen secretor status (<i>ABO</i>)	Lung function, COPD

(*EPHX1*) genes and *ABO* blood group antigen secretor status as likely susceptibility factors for COPD. As for asthma, more than 200 association studies have been conducted, and associations that have been replicated with asthma and asthma-related phenotypes are listed in Table 2. Among them, the interleukin-4 (*IL4*)/*IL13* pathway is frequently reported as being associated with asthma or asthma-related phenotypes; these genes include *IL4*, *IL13*, *IL4RA* and signal transducer and activator of transcription 6 (*STAT6*). In addition, arachidonate 5-lipoxygenase (*ALOX5*) and granulocyte-macrophage colony-stimulating factor (*CSF2*) polymorphisms have

been associated with asthma, but these associations have yet to be replicated. Recently, two novel genes, a disintegrin and metalloproteinase domain 33 (*ADAM33*) and PHD finger protein 11 (*PHF11*) genes have been identified as asthma genes by whole genome screens, followed by fine mapping and association studies (3, 4). Van Eerdewegh and colleagues (3) performed genetic [linkage analysis](#) on 460 pairs of siblings from affected families and identified a locus on chromosome 20q, which was not linked to asthma in previous whole genome screens but was linked to asthma and bronchial hyperresponsiveness in this population. They assessed 135 SNPs of 23

COPD and Asthma, Genetics. Table 2 Candidate genes for asthma and related phenotypes that have been replicated

Chromosome location	Candidate gene (symbol)	Phenotype
5q23	Interleukin-4 (IL4)	Atopy, asthma, IgE
5q31	Interleukin-13 (IL13)	Asthma, IgE
5q31	Beta2-adrenoceptor (ADRB2)	Asthma, IgE, BHR, treatment response
5q31.1	Monocyte differentiation antigen CD14 (CD14)	IgE
5q35	Leukotriene C4 synthase (LTC4S)	Asthma
6p21.3	HLA DRB1	Atopy, allergy, asthma, IgE

6p12.3	Platelet-activating factor acetylhydrolase (PLA2G7)	Asthma
11q13	β chain of the high affinity receptor for IgE (MS4A2)	Atopy, asthma, IgE
11q23.1	Clara cell-specific 16-kd protein (SCGB1A1)	Asthma
12q24.2	Nitric oxide synthase 1 (NOS1)	Asthma
12q13	Signal transducer and activator of transcription 6 (STAT6)	Asthma
16p12.1	Interleukin-4 receptor A (IL4RA)	Atopy, asthma, atopic dermatitis

genes in this region and identified the *ADAM33* gene as associated with asthma. Zhang and colleagues localized the underlying quantitative-trait locus in a comprehensive SNP map, based on a previously identified association between total IgE level and a 13q34 [▶microsatellite](#). They replicated the association to IgE and attributed it to several [▶alleles](#) in a single gene, *PHF11*. These alleles are associated with asthma, especially severe asthma (4).

The main problem of the association study approach has been lack of replication. When comparing association studies, three possibilities need to be borne in mind, a false negative study due to lack of power, a false positive original report and true differences between study populations. Three common reasons for inconsistency in association studies cannot be overemphasized. Firstly, there is a risk of false positive and false negative results due to population stratification. Recently, several approaches such as “[▶genomic controls](#)” have been advocated to attempt to correct for population stratification (5). Secondly, multiple comparisons inevitably result in false positive associations; this is particularly true for asthma association studies, since numerous asthma-related phenotypes have been reported. Thirdly, different phenotypes of COPD and

asthma in different studies also contribute to the difficulties of comparison among association studies.

Cellular and Molecular Regulation

DNA sequence variations in the human genome are numerous and there are different ways to categorize them. Variations can be divided to two categories according to frequency, variants and polymorphisms. Variants are variations with a minor allele frequency less than 1%, while polymorphisms are those with a minor allele frequency equal to or more than 1%. When classified according to mechanisms, the most common variations are [▶single nucleotide polymorphisms](#) (SNPs). On average, SNPs occur about every 500–1,000 base pairs. Other types of variations such as differences in repeat number, [▶insertions](#), [▶deletions](#) and duplications also occur but are much less frequent. DNA sequence variations can cause disease by various mechanisms. A common mechanism is loss of function of the protein. A classical example is severe α_1 AT deficiency and emphysema. α_1 AT is the most abundant circulating proteinase inhibitor. α_1 AT is a highly polymorphic gene with over 100 variations. Most of these are the results of SNPs that lead to single or sometimes double amino acid changes. Based on their

migratory distance on isoelectric focusing analysis, they are categorized as normal α_1 AT that migrates in the middle of the gel (M allele) and S and Z variations that migrate more quickly owing to changes in their overall charge. S and Z alleles are caused by amino acid substitutions from Glu to Val at amino acid position 264 and from Glu to Lys at amino acid position 342, respectively. In the Caucasian population, the frequencies of M, S and Z alleles are >95%, 2–3% and 1%, respectively. A small percentage of people inherit a null allele, which leads to complete absence of α_1 AT production. Individuals with MS and MZ **▶genotypes** have ~80% and 60% of normal α_1 AT levels, respectively. Heterozygous PI SZ is rare and individuals with this genotype have α_1 AT levels ~40% of normal. Individuals with two Z alleles or one Z and one null allele are referred to as PI Z. PI Z individuals have approximately 15% of normal plasma α_1 AT levels as 85% of the protein is retained within the rough endoplasmic reticulum of the hepatocyte. The reduced plasma levels are inadequate to protect the lung from the attack of proteinases. Thus the PI Z individuals are susceptible to early onset emphysema. This observation prompted the proteinase-antiproteinase hypothesis of lung injury in emphysema, which is still a dominant view of COPD pathogenesis.

Some sequence variations cause disease through a gain of function, where the protein takes on some new, deleterious or enhanced function. Examples include the coding region SNPs of the IL4 receptor alpha (*IL4RA*) subunit and asthma. The combination of the V75 allele with R576 resulted in expression of an IL4RA with enhanced sensitivity to IL4. There was also a significant association of V75/R576 with atopic asthma.

Many functional alterations are located in the coding sequence of genes, which influence the expression of a phenotype as discussed above. However, DNA sequence variations in regulatory region of genes may also change function. For example, a (GT)_n dinucleotide repeat in the heme oxygenase-1 (*HMOX1*) gene shows length polymorphism and could regulate the level of gene transcription. A large size (GT)_n repeat may reduce *HMOX1* inducibility by reactive oxygen species in cigarette smoke, resulting in the development of emphysema. Another example is the T allele of the C-589T polymorphism in the *IL4* **▶promoter** that was associated with increased luciferase reporter gene activity. The T allele was also associated with increased total IgE, asthma or asthma severity.

DNA sequence variations in other regions of genes also could change function. For example, SNPs within introns and the 3' untranslated region (3'UTR) may affect **▶alternative splicing**, splicing efficiency or messenger RNA turnover. For example, several of the SNPs in the *ADAM33* gene that were associated with

asthma were located in non-coding regions. However, there are no functional data available as to whether the identified sequence variations result in functional changes (3).

Clinical Relevance

Studies of genetic factors that could potentially play a role in determining treatment response led to the emergence of pharmacogenetics and later to pharmacogenomics. Furthermore, a deeper understanding of the genetics that underlies disease pathogenesis will lead to new therapeutic approaches.

Pharmacogenomics uses genome-wide approaches to elucidate the inherited basis of differences between persons in responses to drugs. Genetic polymorphisms could play a direct or indirect roles in drug responses. The best examples are the β_2 adrenoreceptor (*ADRB2*) and *ALOX5* genes.

The human *ADRB2* is an intronless gene on the long arm of chromosome 5 (5q31-33). There are at least seventeen SNPs within the promoter and coding regions. Four single amino acid substitutions have been associated with altered expression, down-regulation, or coupling of the receptor in response to β_2 -agonists. *In vitro* studies have indicated that the *ADRB2* SNPs are associated with physiologically relevant effects. *In vivo*, a study documented that Arg16 homozygotes had almost complete desensitization after continuous exposure to a β_2 -agonist, with vasodilation decreasing more than four fold after 1.5 hours of exposure, whereas Gly16 homozygotes had no significant desensitization. Similarly, another report demonstrated that in patients who receive long-term inhaled β_2 -agonist, those with the homozygous Arg16 genotype had a gradual decline in morning lung function, which was not seen in those with the homozygous Gly16 genotype. These data are consistent with a clinical study that asthmatics homozygous for the Arg16 allele showed a significantly increased number of exacerbations when treated with β_2 -agonist. Individuals with the Arg16 homozygous genotype have therefore been shown to have an altered pharmacologic response to β_2 -agonists. The genotype may be used to predict patients' response to long term therapy with inhaled β_2 -agonist and for those patients predicted to have no beneficial response, other therapeutic modalities may be chosen to avoid any delay in the optimal treatment.

An insertion/deletion polymorphism that affected Sp1 and Egr-1 transcription factor binding sites was found in the 5-lipoxygenase (*ALOX5*) promoter region. The wild type allele consisted of five tandem repeat Sp1 binding sites. Reporter gene experiments demonstrated that alleles consisting of a deletion of one or two binding sites or addition of a sixth binding site resulted in reduced gene expression. It was shown that

individuals with decreased 5-lipoxygenase expression represented a subset of asthma patients that responded poorly to the 5-lipoxygenase inhibitor. Those asthma patients with three, four or six tandem repeats responded poorly to a 5-lipoxygenase inhibitor. This was confirmed by clinical data. Individuals receiving high-dose 5-lipoxygenase inhibitor were genotyped for the promoter polymorphism. The patients who did not have a wild type 5-repeat allele showed no benefit from 5-lipoxygenase inhibitor in terms of percentage change in FEV₁ following treatment. The explanation was that leukotrienes play little role in modulating asthma in those patients who have the mutant promoter and thus they do not benefit from treatment with leukotriene synthesis inhibitors.

It is anticipated that the study of the genetics of COPD and asthma will lead to novel or better understanding of mechanisms of these diseases, thereby, leading to the identification of different types of COPD and asthma. Classification of COPD and asthma according to their underlying pathogenesis may lead to new and better treatments and may help to tailor the most appropriate individual treatments in the future.

COPI Vesicles

Definition

COPI (coat protein I) vesicles are formed by the action of COPI coat proteins, which are involved in a retrograde transport pathway that recycles proteins and lipids between the *cis*-Golgi and the endoplasmic reticulum. The COPI coatomer is a complex of seven subunits (α , β , β' , γ , δ , ϵ and ζ). The γ -subunit is thought to be responsible for cargo recognition, the β -subunit has been shown to interact with ARF1. COPI coat proteins also have complex roles in transport within the Golgi complex and in maintaining the normal structure of the interphase Golgi complex.

- Exocytotic Pathway
- Protein and Membrane Transport in Eukaryotic Cells
- Vesicular Traffic

COPII Complex/COPII Vesicles

Definition

COPII (coat protein II) complex is involved in vesicular transport from the endoplasmic reticulum (ER) to the Golgi apparatus. COPII complex is necessary to form COPII vesicles, which are essential for the exit of newly synthesized proteins from the ER and their delivery to the Golgi complex. COPII vesicles are formed from ribosome-free (“smooth”) regions of the ER, at so-called ER exit sites, defined by COPII coat proteins.

Synonyms

Basal promoter

Definitions

Cell extrinsic signals are transduced to the nucleus through a series of complex biochemical steps, resulting in either amplification or attenuation of eukaryotic gene expression (1). The expression of genes is often controlled at the level of copying of information from

DNA to RNA called ►**transcription**. The process of transcription is regulated by regions of DNA called the ►**promoter** that lies outside the actual “message coding region” of the gene. The nucleus of a eukaryotic cell contains three DNA-dependent ►**RNA polymerase** enzymes, which carry out the actual process of transcription. The enzyme RNA polymerase I (Pol I) transcribes genes coding for ribosomal RNA (rRNA), RNA polymerase II (Pol II) transcribes genes coding for messenger RNA (mRNA) and RNA polymerase III (Pol III) transcribes genes coding for transfer RNA tRNA. Although the polymerase enzymes have the intrinsic ability to carry out transcription, they cannot do so in a specific manner unless they interact with a set of proteins that are commonly present in all nuclei and are called the ►**general transcription factors** (GTFs) or basal factors (2). These factors are necessary and sufficient (in addition to RNA polymerase) to form the transcriptional machinery at the core promoter and direct accurate initiation of transcription *in vitro* (2, 3). Each polymerase interacts with a set of GTFs that is unique to each class of genes, with the notable exception of ►**TATA binding protein** (TBP), which is commonly required for most if not all genes. The resulting “transcriptional or preinitiation complex” for each polymerase specifically recognizes a DNA region near the transcription start site (TSS) called the core promoter in the corresponding genes. The steps in transcription that follow this initial nucleation step include ►**initiation**, ►**promoter clearance**, ►**elongation** and finally ►**termination** (2, 3).

Characteristics

The promoter region of a eukaryotic protein-coding (mRNA) gene is arbitrarily divided into two segments, a proximal region (core promoter) and a distal region (enhancer) relative to the TSS (Fig. 1). The

sequence-specific, multiprotein transcriptional complex formation not only ensures high fidelity of gene expression but also allows for multiple points of regulation. Accordingly, it has been demonstrated that the gene-, lineage- or stage-specific ‘regulatory’ transcription factors interacting at enhancer elements can alter either the rate or the stability of transcriptional complex formation at the core promoter, thereby controlling the expression of the corresponding gene (2, 3). Although originally thought to be inert, it is now clear that the core promoter (and the corresponding transcriptional complex) directly contributes to spatial and/or temporal regulation of transcription. Hence, while a core promoter and enhancer elements can be swapped from different genes *in vitro* and in transient transfection experiments, a heterologous promoter may not faithfully recapitulate proper transcriptional response *in vivo* (4). A core promoter region in the protein-coding genes is comprised approximately of seventy nucleotides abutting the TSS and is defined as the minimal region of naked (non-chromatin) DNA required to direct accurate initiation of transcription *in vitro* when presented with the RNA polymerase and the corresponding GTFs (2, 3, 4). Although an independent core promoter may not exist *in vivo*, it nevertheless directs accurate transcription initiation from DNA templates *in vitro*. Hence, it has been particularly useful to define the minimum sets of GTFs or basal factors necessary to form the transcriptional complex (also called the ►**transcriptional machinery**) and ascertain the sequence of events that result in the preinitiation complex assembly (2).

Core Promoter Elements

There are several key genetic elements within a core promoter. They are the TFIIB recognition element (►**BRE**), the ►**TATA box**, the pyrimidine rich initiator (►**Inr**) element and the downstream promoter

Eukaryotic Core Promoter Elements

Core Promoters. Figure 1 Eukaryotic core promoter elements and their position with respect to the transcription start site (TSS) indicated by the bent arrowhead. These are TFIIB recognition element (BRE), TATA box, initiator element (Inr) and downstream promoter element (DPE). Different classes of promoters may have only a subset of these elements allowing for greater combinatorial responses.

Core Promoters. Figure 2 Mechanism of formation of the transcriptional (Txn) complex in TATA-containing, Inr-less (TATA⁺Inr⁻) or TATA-less, Inr-containing (TATA⁻Inr⁺) core promoters. While binding of TBP initiates the nucleation event in TATA⁺Inr⁻ promoters, binding of IBP is believed to be the nucleation event in TATA⁻Inr⁺ promoters. The IBP could be TAFs or independent proteins like TFII-I or RNA pol II. For the sake of simplicity binding of factors to the BRE and DPE is not shown.

element (►DPE) (Fig. 1) (5). Among these, the TATA box and Inr element are more extensively characterized.

TATA Box

The TATA box (also known as the Goldberg-Hogness box) is usually present approximately 30 bases upstream of the transcription start site of a protein-coding gene and has the consensus sequence of either TATAAA or TATATA. The TATA box is conserved in all eukaryotes as well as in the archaea. In yeast, the position of the TATA box is variable and it can be situated 40–120 bases upstream of the transcription start site. Although initially thought to be highly conserved and required for all eukaryotic protein-coding genes, recent database analysis suggests that in fact more than 60% of eukaryotic genes lack a TATA box (5). However, when present, it directs accurate initiation of transcription (start site selector); mutations in a TATA box result in severely decreased transcription both *in vitro* and *in vivo* (5). The TATA box is recognized by the TATA binding protein, TBP, which is a subunit of a larger protein complex, ►TFIID (Fig. 2). The TATA-mediated basal (activator independent) transcription starts with TATA recognition by the TBP, a step that is sufficient to nucleate the assembly of additional GTFs and RNA polymerase II into a functional transcriptional complex (4). Crystal structure analysis of TBP bound to the TATA box revealed that this binding induces a bend or loop in DNA such that the upstream (enhancer) and downstream (core promoter) regions are brought into closer proximity (2). This step ensures the proper communication between the distinct transcriptional components that is essential for physiologically relevant transcriptional responses. Besides TBP, TFIID also contains TBP associated factors,

called ►TAFs. TAFs serve multiple roles and generally behave as core promoter discriminatory factors (5). There appears to be considerable flexibility in the TATA sequence such that a number of A/T combinations are recognized by TBP and function as TATA boxes. Moreover, a TATA box also functions generally in a heterologous promoter context so that it can be swapped between promoters.

Inr Element

Many of the eukaryotic core promoters instead of a TATA box contain a pyrimidine-rich Inr element encompassing the TSS, the consensus of which is YYA⁺NT/AYY (where A⁺ signifies the transcription start site and Y stands for a pyrimidine base). The Inr element is well conserved among eukaryotic promoters and in archaea (5). It is also found in parasites. There are some viral promoters that tend to be strong promoters and contain both a TATA box and an Inr element (4). The two core promoter elements can act in a synergistic fashion when separated by only 25 to 30 base pairs. However, the Inr element can function independently and in a heterologous promoter context as well, at least *in vitro* (5). The TATA-less but Inr containing core promoters show relatively weak transcriptional activity in *in vitro* reconstituted systems, making it more difficult to ascertain the precise biochemical mechanism for Inr-directed basal transcription (2). Inr-mediated basal transcription appears to require several factors, including TBP associated factors (TAFs) that may not be required for TATA-directed basal transcription (2, 3, 4, 5). Several pathways have been proposed to account for Inr-dependent binding and transcription. One pathway involves direct recognition of the Inr by one or more

TAF components and the adjacent DPE when present, followed by stable TFIID binding and subsequent preinitiation complex assembly (2, 3, 4, 5). A second pathway proposes that recognition of the Inr by independent Inr binding proteins (IBPs, e.g. TFII-I and YY1), followed by secondary interactions with TFIID or associated factors nucleates assembly of the GTFs at the core promoter (3, 4, 5). The third pathway involves recognition of Inr by RNA polymerase II in the absence of both TAFs and IBPs (Fig. 2). These observations could reflect diversity in core promoter Inr elements and corresponding interactions, especially in the light of the loose consensus sequence for such elements (2, 3, 4, 5).

Downstream Promoter Element

The DPE was first found in *Drosophila* promoters and since then has also been shown to be present in core promoters of human genes. It appears to be predominantly present in promoters that lack a TATA-box (5). The DPE, which is present in the intragenic +30 region, functions in conjunction with the Inr element and a mutation in any one element results in greatly diminished basal transcriptional activity due to loss of TFIID binding. Hence DPE does not function as an independent core promoter element (5). The loose consensus of this element is A/GGA/TC/TG/A/C and it appears to be recognized by two of the TAF components of the TFIID complex (5).

TFIIB Recognition Element

This core promoter element, the function of which is not at present fully determined, is present upstream of the TATA box in mammalian and archaeal promoters (5). It is not clear whether it can act independently as a core promoter element in the absence of either a TATA box or an Inr. The BRE, whose consensus is G/CG/CG/ACGCC, is recognized by the GTF, TFIIB through its C-terminal end (5). Because the yeast and plant TFIIB lacks this part, BRE may not be important for gene regulation in these organisms. Interestingly, while BRE augments transcription in archaeal promoters, it inhibits transcription in eukaryotic promoters (5).

PSE and Other Putative Core Promoter Elements

Apart from the well-characterized core promoter elements described above for the protein-coding genes, core promoter elements are also present in genes transcribed by RNA pol III. The best described is the proximal sequence element (PSE) which is located approximately 50 nucleotides upstream of the transcription start site. PSE is recognized by a multiprotein complex and can function synergistically with a TATA box (5). There are also some promoters for protein-coding genes that lack both TATA and Inr elements.

Transcription initiation from these promoters is inaccurate and starts at multiple sites. It is currently unclear how the transcriptional machinery assembles at these promoters. An intragenic sequence motif, called the MED-1 (multiple start site element downstream) that is distinct from the DPE appears to play a significant role in some of these promoters (4, 5).

Clinical Relevance

The presence of multiple core promoter elements, especially in the protein-coding genes, suggests different mechanisms for the formation of the transcriptional complex. This flexibility in transcription initiation process allows for multiple regulatory inputs that are necessary for tight developmental control of higher eukaryotic organisms. Moreover, it also allows for rapid and variable response to extracellular signals that could be detrimental to the organism. Given that the core promoter serves as a “landing pad” for the transcriptional machinery, mutations in the core promoter elements or cognate factors can have profound physiological effects ranging from total loss of gene expression to abnormally high gene expression.

Coreceptor

Definition

Coreceptor is a cell surface molecule which enables and modulates the interaction between ligand and receptor. For example, the T-cell surface molecules CD4 and CD8 are coreceptors that foster the interaction between the T-cell receptor and MHC molecules on antigen-presenting cells. Other coreceptors trigger membrane fusion and entry mediated by the Env protein of some retroviruses.

► Retroviruses

Corepressor

Definition

Corepressor is a small molecule that triggers repression of transcription by binding to a regulator protein.

Synonyms

HpaII tiny fragments (HTFs); HTF islands

Definition

CpG islands are short stretches of DNA with an unusually high GC content and a higher frequency of ► **CpG** dinucleotides (cytosine 5' to a guanine, separated by a phosphodiester bond) compared to the rest of the genome. CpG islands account for about 1–2% of the genome and are usually located in the 5' regulatory regions of genes. They are associated with all ► **house-keeping genes** and up to 40% of ► **tissue-specific genes**.

Characteristics

With the accumulation of raw sequencing data, it became obvious that the four bases, adenine (A), cytosine (C), guanine (G), and thymine (T) are not evenly distributed in the genome. Normal DNA has an average GC content of 40% and an AT content of 60%, and contains only 25% of the number of CpG dinucleotides that would be expected. Early work by

Bird et al. in 1985 (1) identified stretches of genomic sequence characterized by an unusually high number of *HpaII* restriction sites (restriction site: C[^]CGG). These sequences were initially called “*HpaII* tiny fragments (HTFs)” or “► **HTF islands**”. Careful inspection of the sequences in the *HpaII* tiny fragments indicated that the ratio of CpG dinucleotides is higher than in the rest of the genome. These stretches of DNA with a high GC content and a frequency of CpG dinucleotides that is close to the expected value are now called CpG islands. The following three criteria, established by Gardiner-Garden and Frommer in 1987 (2), are commonly used to define CpG islands. First, the sequence must be at least 200 base pairs long. There is no upper limit on the length and some CpG islands are several kilobase pairs long. Second, the GC content is above 50%, while the rest of the genome is about 40%. Third, the CpG ratio (observed/expected) is above 0.6, while the rest of the genome has a CpG ratio of 0.2. Recently Takai and Jones (3) have developed more stringent criteria based on analysis of CpG islands in the completed drafts of chromosomes 21 and 22. These criteria (> 500 base pairs, GC content ≥55%, and CpG ratio of 0.65) allow for higher accuracy of predicting unknown genes while at the same time excluding ► **Alu repetitive elements**. The investigators have constructed a web-based program with which one can analyze any sequence of interest for CpG island characteristics (► <http://www.uscnorris.com/cpgislands/>). In addition, the program allows one to adjust the various criteria mentioned above, to apply more or less stringency as desired.

The human genome contains about 29,000 CpG islands (4) and it is estimated that there are somewhat fewer in the mouse (5). The majority of CpG islands are located in the 5' region (promoter and/or exon 1) of all housekeeping genes and a large number of tissue-specific genes. However, CpG islands are sometimes noted in the 3' ends of genes or intronic regions (Fig. 1). The preferential location of CpG islands in 5' regions of genes can be used for the identification of novel genes. Rare cutting ► **restriction enzymes** with GC rich recognition sequences such as *NotI* (GC[^]GGCCGC), *AscI* (GG[^]CGCGCC), *BssHII* (G[^]CGCGC) and *EagI* (C[^]GGCCG) can be used for the restriction mapping of large genomic clones. Clusters of those restriction enzyme cutting sites would indicate the presence of a CpG island. It is unknown why the mouse has fewer CpG islands than the human when the estimated number of genes in both genomes is expected to be very similar. One possible explanation is that the rate of CpG dinucleotide loss due to ► **deamination** (see below) is higher in the mouse than it is in the human. In general, CpG islands are present in the early replicating, less condensed and GC rich R-bands of chromosomes.

CpG Islands. Figure 1 Examples of various locations of CpG islands within genes. Shown are three genes with differing configurations of CpG islands. *PPP1R3B* has a CpG island located in the 5' region only. *DLX5* has three CpG islands interspersed throughout the length of the gene. A very large CpG island encompasses the entire *DRD4* gene. Exons are depicted by solid rectangles. CpG islands are depicted as open rectangles. CG dinucleotides are depicted as vertical hash marks.

Preservation of CpG Islands

The preservation of CpG islands in vertebrate genomes is inversely related to [DNA methylation](#) and a process called deamination. DNA methylation in vertebrate genomes is found mainly in CpG dinucleotides. CpG dinucleotides that are located within CpG islands are usually unmethylated, while CpG dinucleotides located outside of CpG islands are methylated at the 5' position of the cytosine ([5-methylcytosine](#)). 5-methylcytosine is sometimes referred to as the “5th base”. Methylation of CpG dinucleotides makes these sites vulnerable to spontaneous deamination leading to a transition of the 5-methylcytosine to thymine, a process that is believed to cause the depletion of CpG dinucleotides from the genome. Unmethylated CG dinucleotides in CpG islands are protected from deamination, resulting in CpG island preservation during evolution. However, a small fraction of CpG

islands are methylated in normal tissues as a result of important developmental processes.

Normal Developmentally Regulated CpG Island Methylation

- Most CpG islands on the inactive X-chromosome of females are densely methylated. This normal process of [X-chromosome inactivation](#) is linked to the transcriptional silencing of those genes and is thought to play a role in dosage compensation of the gene product. Examples of such genes include phosphoglycerate kinase 1 (*PGK1*), glucose-6-phosphate dehydrogenase (*G6PD*), and the androgen receptor (*AR*). Exceptions are found in a few CpG islands in genes that escape X-inactivation (e.g. *STS*, *ZFX* or *UBE1*).
- Some CpG islands become methylated in other normal processes including cell differentiation and

aging. The result of this methylation is the selective inactivation of genes in specific tissues or at certain developmental stages (e.g. estrogen receptor).

- Genes that are expressed exclusively from either the paternal or the maternal allele are called imprinted genes (►Imprinting). These genes have CpG island methylation on only one allele (e.g. *H19* and *IGF2*). While methylation usually occurs on the inactive allele, in some instances CpG island methylation has been found on the active allele. Allele-specific methylation in CpG islands was used as a tag for the identification of novel imprinted genes in the mouse using the restriction landmark genomic scanning (►RLGS) technique.

The transfer of a methyl group to a cytosine residue is carried out by DNA ►methyltransferase (Mtase) enzymes. Methylation of normally unmethylated CpG islands is important because of the effect this has on gene expression. Specifically, methylated CpG islands have been correlated with the transcriptional silencing of the associated genes. The detailed molecular process controlling this inactivation is not entirely clear. Protein complexes that contain *Sin3*, histone deacetylases and the methyl CpG-binding protein *MeCP2* bind to methylated promoters and induce the deacetylation of histones, which mediates the formation of transcription-repressing chromatin. In *in vitro* experiments, re-expression could be achieved by adding either 5-aza-2'-deoxycytidine, a demethylating agent, or trichostatin A (TSA), which inhibits histone deacetylases. In certain cases these two agents have a synergistic effect on restoration of gene transcription.

Clinical Relevance

In general, two types of methylation events in CpG islands can be distinguished, the developmentally regulated process of CpG island methylation discussed above and aberrant CpG island methylation in cancer.

Aberrant CpG Island Methylation in Cancer

- ►Hypermethylation of CpG islands in various cancers has been observed and correlates with the transcriptional inactivation of tumor suppressor genes and other cancer related genes (6). It was shown that methylation in a CpG island can serve as one of the two "hits" needed for the inactivation of a tumor suppressor gene. While CpG island methylation in some tumors is restricted to a small number of CpG islands, other tumors show a methylation phenotype with up to 10% methylated CpG islands (7). A subset of CpG islands is methylated in a tumor-type specific manner, while other CpG islands

can be methylated in many different tumor types. Many genes associated with methylated CpG islands can be reactivated in cell lines by *in vitro* demethylation using 5-aza-2'-deoxycytidine. Consequently, this drug is being tested in clinical trials with various types of malignancies and has demonstrated some effectiveness in restoring gene expression.

- ►Hypomethylation of normally methylated CpG dinucleotides has also been demonstrated in tumors. The mechanism(s) by which global hypomethylation paradoxically occurs concurrently with gene-specific hypermethylation is not known. Hypomethylation has been postulated to have an effect on oncogene activation (*HOX11* gene in T-cell acute lymphoblastic leukemia) and on transcriptional activation of mobile genetic elements such as long interspersed nuclear elements (LINEs) and to contribute to chromosomal instability. Any or all of these events would confer a selective growth advantage on a neoplastic cell.

Cre/loxP Strategies

BRIAN SAUER

Stowers Institute for Medical Research, Kansas City, Missouri, KS, USA

bls@stowers-institute.org

Synonyms

Conditional gene knockout; genome engineering; site-specific recombination

Definition

Accurate animal models of human disease are invaluable both in understanding the genetic contribution to disease and in the rigorous evaluation of therapeutic treatments. A remarkably useful molecular tool for making and inducing precisely designed mutational alterations in the genome in a tissue-specific manner is the site-specific DNA recombinase called Cre. The Cre recombinase from *Escherichia coli* ► [bacteriophage P1](#) efficiently catalyzes conservative site-specific DNA recombination at the 34-bp nucleotide *loxP* sequence in the P1 genome. The finding that Cre can also catalyze efficient DNA recombination in higher eukaryotic cells led to the development of site-specific DNA recombination as an important research tool for genetic and chromosome engineering in gene-modified animals (1). A particularly powerful strategy is the design of conditional mutations by targeted excision of a desired gene in the genome in a temporally and spatially controlled manner (2). Similar strategies can be used to design conditional gain-of-function mutations exhibiting temporal and spatial specificity. Cre-based recombination strategies also permit efficient site-directed integration of exogenous DNA into a pre-selected site on the genome, as well as permitting the design of precise chromosome translocations, deletions and duplications that facilitate the genetic manipulation of the eukaryotic genome.

Characteristics

The 38 kD Cre protein is encoded by the *cre* (cyclization recombination) gene of phage P1 and is a member of the Int family of tyrosine site-specific DNA

Cre/loxP Strategies. Figure 1 Site-specific DNA recombination by Cre recombinase. The DNA sequence of the 34 bp *loxP* site is shown, with the two 13 bp inverted repeats indicated by thin arrows above. Two Cre protein molecules bind to each *loxP* site, with the orientation of the site indicated by a horizontal arrow. Recombination proceeds through a Holliday junction intermediate, highlighted by the green magnifying glass.

recombinases (3). The *cre* gene benefits P1, which maintains itself in lysogens as a unit copy extrachromosomal plasmid, primarily by increasing plasmid stability. By catalyzing DNA recombination at a 34 bp site on the P1 genome called *loxP* (locus of X-over of P1) Cre resolves plasmid dimers that arise by DNA replication and/or homologous DNA recombination. Such dimers if unresolved would prevent partitioning of a monomer P1 genome to each daughter cell at cell division and thus lead to increased plasmid loss in a lysogenic bacterial population. Cre also cyclizes the terminally redundant, linear P1 virion genome upon infection of a bacterial host by recombination at *loxP* sites present in the terminal redundancy.

The *loxP* site consists of two 13 bp inverted repeats, each of which serves as a binding site for the Cre protein, flanking an 8 bp core region. The core region is nonpalindromic and so imparts an overall directionality to the site. It is also the region within which DNA recombination occurs (Fig. 1). Upon binding of two Cre molecules per *loxP* site synapsis of two Cre-bound *loxP* sites occurs followed by DNA recombination. Recombination is conservative and proceeds through a transient [Holliday junction](#) intermediate. Excision of a circular DNA molecule results if the two *loxP* sites are directly oriented on a DNA molecule, inversion

occurs if the two *loxP* sites are oppositely oriented. Intermolecular DNA recombination can also be catalyzed by Cre and results in integration of a *loxP*-containing circular molecule into another. If both molecules are linear, intermolecular recombination generates a translocation. Unlike many members of the Int family, Cre requires neither host factors nor a supercoiled DNA substrate for recombination. These minimal biochemical requirements probably contribute to Cre's ability to catalyze efficient DNA recombination in a wide variety of eukaryotic cells, notwithstanding Cre's prokaryotic origin. Because the 34 bp *loxP* site is sufficiently large to be unlikely to occur naturally in the genomes of higher eukaryotic cells, efficient Cre-mediated recombination can be targeted to just those sites in the genome into which *loxP* has been placed. Gene-modified and transgenic mice have become important in developing useful animal models of human disease and in gaining a detailed understanding of mammalian gene function. Cre/loxP and related strategies play a crucial role in the design, construction and genetic manipulation of these mice (3, 4). By targeting DNA recombination events at *loxP* sites placed into the genome, a designated gene can be either ablated or activated simply by controlling expression of Cre recombinase activity. With such conditional

mutations of either endogenous genes or transgenes, a mutant phenotype can be targeted to a particular tissue or to a particular time during development. In addition, recombinase strategies allow the generation of novel chromosomes useful in genetic analysis, removal of unwanted vector DNA sequences from the genome after gene targeting and efficient targeted integration of exogenous DNA's into the genome. Several functional mutant derivatives of Cre and of the *lox* recombination site have also proved useful in these strategies, as well as other site-specific recombinases, such as Flp from the yeast *Saccharomyces cerevisiae*.

Conditional Gene Targeting

There are two components to recombinase-mediated conditional gene targeting in mice: 1) a *loxP*-targeted mouse and 2) a Cre delivery system, commonly a second mouse that expresses Cre in a pre-determined manner. A conditional loss-of-function allele of an endogenous gene in a mouse is generated by first designing a DNA construct carrying a genomic copy of that gene which has been modified by flanking that gene, or a critical region of it, by two directly repeated *loxP* sites. One copy of the gene in the genome is then replaced with the conditional allele by homologous gene targeting in ►embryonic stem (ES) cells. Injection of these modified ES cells into a mouse ►blastocyst leads to the production of a chimeric mouse carrying these modified cells. Breeding this

chimera generates progeny gene-modified mice having the desired conditional ►allele of the target gene. By having placed the *loxP* sites in non-critical regions at the genomic locus the homozygous modified gene is designed to give an unaltered and normal phenotype indistinguishable from wild type. However, introduction of Cre recombinase, for example by mating with a Cre mouse, results in excision of the *loxP*-flanked target gene in those cells, and only those cells, expressing Cre and thus produces a mouse in which the target gene, or any other unwanted bit of DNA, has been removed from the genome. Because various Cre transgenic mice can be designed with different promoters the *cre* transgene can be expressed in a tissue-specific or developmentally specific manner in each of these different Cre mouse lines. By choosing the appropriate Cre mouse with which to mate the conditionally mutant mouse, gene ablation can be targeted in whatever developmental and/or directed tissue-specific manner required because gene ablation mirrors the spatial and temporal expression specificity of the Cre mice used (Fig. 2). Conditional gene disruption thus permits the determination of the function of a gene in a particular tissue or type of cell without disturbing its function in other cells in the body. Moreover, because many genes are either essential for viability or fertility, this binary strategy allows the generation and propagation of a (conditional) ►knockout mouse for any gene in the genome.

Cre/loxP Strategies. Figure 2 Conditional gene knockout. The conditional knockout (KO) mouse carries a target gene flanked by directly repeated *loxP* sites (red arrowheads). When crossed with a *cre* mouse (here diagrammed to express only in the heart) progeny mice are produced in which Cre-mediated recombination has ablated the target gene specifically in the heart. In surrounding tissues the gene is not deleted.

Cre/loxP Strategies. Figure 3 Conditional gene activation. A synthetic DNA sequence called STOP is interposed between a promoter and the structural gene to be controlled. STOP is a DNA sequence designed to block gene expression and is flanked by two directly repeated *loxP* sites (red arrowheads). In mice having this construct STOP can be deleted in a tissue-specific fashion, activating downstream gene expression, by mating with the appropriate *cre* mouse.

Classical genetic approaches to elucidate gene function have relied not only on ►[loss-of-function](#) mutations but also on ►[gain-of-function](#) mutations. Using recombinase strategies, conditional gain-of-function gene mutations can be designed to pinpoint turn-on of a gene to a particular tissue at a pre-specified time. A common strategy is to interpose a *loxP*² STOP cassette between the promoter and the reporter or other gene to be regulated (Fig. 3). In such a transgene construct two *loxP* sites flank “STOP,” a DNA sequence designed to prevent downstream gene expression. This *loxP* transgenic mouse (►[Transgenic and Knock-out Animals](#)) is crossed with a Cre mouse having a desired pattern of expression to excise the STOP cassette specifically and only in those cells expressing Cre, thus turning on expression of the downstream gene. Conditional oncogene expression has been used to develop tissue-specific tumor models, and conditional expression of a toxic gene such as diphtheria toxin A-chain has been used to specifically ablate particular dopamine receptor neurons in the brain to better understand their role. Such recombinase-dependent gene activation strategies can be particularly valuable for cell lineage analysis and fate mapping because only brief transitory expression of Cre is sufficient to activate a reporter gene that will be expressed not only in the cell in which recombination has occurred but also in all of its descendants.

There are several ways to specify the spatial and temporal pattern of conditional gene ablation or activation. Tissue-specific promoters can specify the cells in which Cre is expressed and development-specific promoters can give some specification of timing. Greater temporal control of Cre expression has been achieved by placing the *cre* gene under the control of inducible promoters such as the MX promoter or synthetic “Tet” promoters. These two inducible promoters can be regulated in mice by dosing with interferon or tetracycline analogues, respectively. A second way to exert precise temporal control over Cre-mediated recombination has been to use a modified *cre* gene that encodes a variant protein having fused to Cre a ligand binding domain (LBD) derived from a steroid receptor. In eukaryotic cells this Cre-LBD fusion protein is inactive in the absence of ligand. Recombination is thus made dependent upon dosing the mouse with a synthetic steroid designed to activate Cre-LBD but not disturb normal signaling from endogenous steroid receptors. Thus, tissue-specific expression of the Cre-LBD protein followed by dosing of the animal at a desired time with the appropriate ligand (such as the estrogen analogue RU486) provides a remarkable strategy to specify in both time and space the ablation of a gene from the genome in a living organism. Lastly, the *cre* gene can be incorporated into a viral vector that is then used to infect a conditional knockout mouse,

with the tropism and/or infection route of the viral vector specifying the particular tissues in which Cre-mediated recombination is to occur.

DNA Integration and Genome Engineering

A major confounding problem in the generation of transgenic animals is the variability and unreliability of transgene expression between animals carrying the same transgenic construct but at different integration sites. This commonly necessitates the generation of several transgenic animals to obtain one that expresses the transgene in a suitable fashion. Variability occurs because injection of DNA into fertilized ►[zygotes](#) for transgenic animal production results in random integration of the transgene into the genome. Due to ►[position effects](#) on gene expression, transgenes at dissimilar chromosomal positions in different transgenic lines show variation in the level and tissue specificity of expression. In principle, this problem can be minimized by precise targeting, or knocking-in, a transgene to a particular chromosomal locus by ►[homologous recombination](#) in ES cells. Unfortunately the frequency of homologous targeting is too low for this to be a rapid strategy for this purpose. Cre-mediated integrative (intermolecular) targeting of a transgene to a chromosomal *lox* cassette can be a hundred times more efficient, however. When cells carrying a *lox* integration target in the genome are co-transfected with a *lox* transgene plasmid and a Cre transient expression construct, intermolecular recombination by Cre results in integration of a single copy of the transgene into the genome precisely at the genomic *lox* target. Although placement of the *lox* target, for example by homologous recombination, may still be a slow step, subsequent Cre-mediated targeting is precise and rapid, thus allowing one to quickly build a series of mutant alleles for a gene at a defined locus. Such transgene genomic placement by Cre is a powerful tool for genetic analysis. It has already become a useful method for constructing cell lines and is becoming increasingly useful for various types of genetic manipulation in mice.

The high efficiency in eukaryotic cells of Cre-mediated recombination between *lox* sites that are quite far from each other or even on different chromosomes has led to the ability to design novel chromosomes. Large chromosomal deletions, duplications and inversions can be generated in a precise fashion by first placing *lox* sites at defined chromosomal sites (5), for example by homologous targeting in ES cells. This is followed by Cre-mediated recombination to produce the desired novel chromosome rearrangement and mice are then generated from cells harboring the desired rearrangement. Such novel chromosomes are invaluable genetic tools. Large chromosomal deletions facilitate gene mapping, both deletions and duplications are useful for phenotypic determination of ploidy effects such as occur

in a variety of human genetic disorders, for example ►[Down Syndrome](#), and inversion chromosomes can serve as genetic ►[balancer chromosomes](#). ►[Chromosomal translocations](#) have often been found in various specific human cancers and these too can be modeled in the mouse by genome engineering using Cre (6).

Clinical Relevance

Recombinase strategies using Cre and other DNA recombinases, either singly or in combination, are of great utility in the genetic design of precise mouse models of human disease. In addition, Cre recombinase has been exploited in the design and genetic manipulation of various viral vectors, a number of which can be used for gene therapy in patients. For example, in adenovirus-based vectors Cre-mediated removal of a “stuffer fragment” vastly increases the vector’s capacity to carry therapeutic genes. The major current application for Cre/*loxP* strategies, though, is as a superb research tool for the genetic manipulation of DNA and chromosomes in living organisms, especially gene-modified mice, and to thus provide deeper insight into the roles of specific genes in specific cells and into the roles of specific cells in the body.

C-Reactive Protein

Definition

CRP is an acute-phase protein featuring a homopentameric structure and calcium-binding specificity for

lyso-phosphatidylcholine. The wide distribution of phosphatidylcholine in polysaccharides of pathogens and in cellular membranes, allows CRP to recognize a range of pathogenic targets as well as membranes of apoptotic and necrotic host cells. CRP is an inflammatory marker.

►[Inflammatory Response](#)

Creatine Kinase

Definition

Creatine Kinase (CK) is a dimeric enzyme that is present in skeletal ►[muscle](#), cardiac muscle and the brain, and catalyses the ATP-dependent phosphorylation of creatine. CK levels in the blood stream can be elevated due to damage to the muscle caused by exercise injury or heart infarction and the muscular dystrophies.

►[Duchenne Muscular Dystrophy](#)

CREB

Definition

Cyclic AMP response element binding protein (CREB) is a 43 kD basic leucine zipper transcription factor that binds the ►[CRE](#) (cyclic AMP response element) consensus motif TGACGTCA. CREB was originally isolated as the protein that bound CRE in the somatostatin gene. CREB was first shown to be activated by elevated levels of cAMP, which results in its phosphorylation on serine-133 by PKA. CREB phosphorylation can be achieved by signalling cascades (e.g. the MAP kinase signalling cascade), eventually triggering transcription of the somatostatin gene as well as other genes that contain the CRE sequence in their promoter.

►[Wnt/Beta-Catenin Signaling Pathway](#)

Creb Binding Protein

Definition

Creb binding protein (CBP) is a transcriptional co-factor that modulates cyclic AMP signaling and

functions as a co-activator for the e.g. β -catenin/TCF complex.

► [Wnt/Beta-Catenin Signaling Pathway](#)

Cre-ERT

Definition

Cre-ERT is a modified form of Cre in which the ligand-binding domain of a mutated human estrogen receptor (ERT) that recognises tamoxifen has been added to Cre. *LoxP* recombination in cells in mice carrying the Cre-ERT transgene will not occur until exposed to tamoxifen (either by injection or in the food/drinking water).

Synonyms

Crohn disease is a heterogeneous syndrome that belongs to the group of inflammatory bowel disease 1 (OMIM 266600; IBD 1). Crohn disease can be differentiated from ulcerative colitis (OMIM 191390)

by clinical, endoscopic, radiological and histopathological parameters.

Definition

Typical presentation of Crohn disease includes inflammation in the terminal ileum. However, this typical presentation with ileitis is seen only in 70% of cases. 25% of patients present with disease confined only to the colon (Crohn colitis) and in 5% exclusive involvement of the upper gastrointestinal tract is seen. The diagnosis is mostly based on a suggestive clinical course, a typical distribution of affected areas throughout the gastrointestinal tract ("skip lesions") and a typical type of endoscopic lesions (Fig. 1). Histological characteristics (i.e. granuloma formation) are only seen in a minority of the patients.

Characteristics

Crohn disease was first described as a clinical entity in 1920. It is a chronic relapsing complex disease, that can present with diarrhoea, right lower quadrant pain, weight loss, malaise, fever and a host of extraintestinal manifestations in joints (arthralgia, arthritis), skin (pyoderma gangrenosum), vessels (erythema nodosum), liver (autoimmune hepatitis, rarely primary sclerosing cholangitis), eyes (uveitis, episcleritis), pancreas (hyperamylasemia and pancreatitis), lung (pneumonitis) and heart (rarely myocarditis). Complications include the development of intestinal strictures, fistula, osteoporosis and an increased risk for colonic cancer. Since the second World War a growing ►incidence of cases was observed in Western civilisations but is now also observed in Asian countries

Crohn Disease. Figure 1 Endoscopic presentation of Crohn disease (b) in comparison to normal colon (a).

including Japan, Korea and China. “Hot spots” of incidence and ►prevalence have been described in Western Canada and Iceland. Lifetime prevalence in Northern countries has been estimated at up to 0.5%. Typical age of onset peaks in the 2nd and 3rd decades of life, but the disease can also manifest in young children or in the elderly. Genetic anticipation has been proposed in Crohn disease. However, large epidemiologic studies suggest that the increase in incidence since World War II due to an accumulation of confounders has been confused with genetic anticipation.

Epidemiological studies have identified a significant genetic contribution to the aetiology of inflammatory bowel disease. Familial clustering is seen, with estimates of sibling relative risk (λ_s) ranging from 15 to 35 for Crohn disease and 5 to 17 for ulcerative colitis. Simple Mendelian models of inheritance are not supported by segregation analyses of inflammatory bowel disease. Concordance of Crohn disease in identical twins is seen in up to 56% in comparison with 4% in dizygotic twins. Therefore, disease concordance data in monozygotic and dizygotic twins suggest that both genetic and environmental factors are involved. Disease characteristics (subphenotypes) cluster in families and show concordance in identical twins, too. These observations support a complex immunogenetic model for inflammatory bowel disease, whereby genetically susceptible individuals harbour an aberrant response to yet unidentified environmental influences that most likely are included in the life-style of industrialized societies.

Cellular and Molecular Regulation

Attempts to localise susceptibility genes for inflammatory bowel disease through genome-wide linkage studies have identified putative loci on many human chromosomes with eight of them having been listed in

OMIM thus far (chromosomes 16p, 16q, 12, 6p, 14q11/12, 5q31, 19p13, 1q36 – Table 1); the original finding of the linkage on chromosome 16 has been replicated in several independent populations and by the IBD International Genetics Consortium. Recently three groups showed that sequence variations within the ►CARD15 (NOD2) gene (OMIM 605956) on chromosome 16q12, were strongly associated with susceptibility to Crohn disease but not to ulcerative colitis. P268S, R702W and 3020insC (Fig. 2) were found as the main disease associated variations with an ODDs ratio for the development of CD ranging between 2.4 (heterozygotes) and 40 (compound heterozygotes and homozygotes). The three main variations (P268S, R702W, 3020insC) result in amino acid exchanges or in a truncation, respectively, of leucine rich repeats at the C-terminal part of the CARD15 protein. A series of additional “private” mutations has been found in patients with Crohn disease in this part of the gene. Taken together it appears that variants in the CARD15 gene alone could explain the risk for development of Crohn disease in up to 15% of cases (compound heterozygotes and homozygotes) and may contribute to another 15% in concert with other disease genes (heterozygotes).

CARD15 is a member of a family of genes (Apaf-1, Ced-4, CARD-4/NOD1) implicated in activation of NF κ B, pro-inflammatory ►cytokine induction and ►apoptosis. They represent regulatory proteins with a central nucleotide-binding oligomerization domain (NOD) and N-terminal caspase recruitment domains (CARD) that are involved in programmed cell death and immune responses. A high degree of homology is apparent to a group of disease resistance (R) genes in plants that encode cytosolic and membrane-bound proteins mediating recognition of pathogens. Membrane-bound R proteins are homologous to

Crohn Disease. Figure 2 Structure of the CARD15 gene and its protein product (reprinted from Cuthbert et al., 2002).

►**toll-like receptors** (TLRs) because they contain leucine-rich repeats (LRR) and recognize pathogenic components at the cell surface.

CARD15 is expressed in monocytes, B-cells and activated epithelial cells. It encodes the protein NOD2 that demonstrates a strictly intracellular distribution. Expression of *CARD15* mRNA and protein is regulated synergistically by ►**TNF** and interferon- γ . Preliminary functional evidence for *CARD15* as a susceptibility gene for Crohn disease was suggested by its ability to activate NF κ B following exposure to bacterial lipopolysaccharides (probably more specifically muramyl dipeptide). Most importantly, activation of NF κ B was impaired in cells transfected with *CARD15* constructs carrying the disease-associated variations. It is therefore currently assumed that *CARD15* variations may impair intestinal barrier function and lead to a defect in epithelial defence against the commensal flora. In support of the hypothesis, an increased presence of intracellular *E. coli* has been described earlier in colonic epithelial cells of patients with Crohn disease. A more detailed molecular definition of the role of *CARD15* in mucosal barrier function remains to be established.

The disease susceptibility locus on chromosome 5q31 could be resolved to a disease-associated haplotype called "IBD5". An interaction between *CARD15* and IBD5 in the risk for Crohn disease has been suggested. An independent association between ulcerative colitis and IBD5 was described recently in a large series of

patients. However, identification of putatively causative variants in a disease gene is still pending in this (IBD5) and other chromosomal regions.

Hierarchical mapping using the TDT in European CD patients identified a disease-associated haplotype block in the suggestive linkage region on chromosome 10q 51. This block contained exactly one gene, *DLG5*, which led to the conclusion that it represented a susceptibility gene for inflammatory bowel disease. This association has recently been replicated in Japanese CD patients albeit with different susceptibility alleles from those in European populations. Further replication in populations of European descent will be necessary. In contrast to the strong genetic effect of NOD2, where the associated variant confers a relative risk greater than 40 for homozygotes and compound heterozygotes, the risk of *DLG5* appears to be much smaller, with observed odds ratios of approximately 1.5. *DLG5* that codes for a protein involved in cell-cell contacts, is a disease gene that could be easily integrated into a hypothetical mechanism of a defect in barrier integrity as a main cause for Crohn disease. The haplotype structure of 5q31 has rendered the identification of the respective disease gene more problematic than on 10q and 16q. A strong linkage signal on 5q31 led to the identification of a large haplotype block that could not be resolved further by means of genetic epidemiological methods. Instead, Peltekova and colleagues used (7) a combination of functional and genetic evidence to implicate variants

around the *SLC22A4* and *SLC22A5* genes in the etiology of Crohn disease. Although the identification of the disease-associated variants in these genes has evoked clear functional consequences, the exact mechanism by which alteration of the encoded transporter proteins OCTN1/2 contribute to disease is still unknown.

Clinical Relevance

Disease-associated variants in the *CARD15* gene are associated with development of a particular subphenotype of Crohn disease. In particular, homozygosity or compound heterozygosity of 3020insC is associated with the “typical” presentation of the disease with ileal inflammation. It also appears that Crohn disease manifests at a younger age in patients presenting with a combination of *CARD15* variants and the IBD5 haplotype.

The example of *CARD15* also shows the heterogeneity of population from different ethnicities but also within the European white population. It underlines the importance of population representative assessment (i.e. through biobanks). The haplotypes and causative variants that are strongly associated with Crohn disease in white populations of European descent are completely absent in Asian populations and almost absent in African Americans. Even within Europe a great variation is seen as to the population frequencies and to the relative risk for carriers. Any future concept for a medical use must therefore take the specific population background into account.

Crohn disease is a chronic relapsing disorder. On average 40% of patients in remission relapse during 12 month of follow up. In some cases primary chronic active disease is developed despite adequate therapy. Short-term therapy with glucocorticoids is a hallmark of anti-inflammatory management of acute disease. However, it leads in 30% of cases to glucocorticoid-refractory or -dependent chronic active disease with additional complications through the long-term use of glucocorticoids. To date only azathioprine, methotrexate and infliximab (i.e. a monoclonal antibody directed against ▶*TNF-alpha*) are effective for remission maintenance.

Outcome of a therapy with infliximab has raised particularly interest in pharmacogenetic explorations. The targeted intervention (infusion of a monoclonal antibody which is directed against TNF) induces remission in approximately 40% of patients with active Crohn disease, while improvement is seen in another 20% and no response in the remainder. The availability of several large trials that were conducted for approval of the drug in the EU and in the USA facilitated a pharmacogenetic investigation with a design characterized by a high statistical power. Unfortunately neither variants in the TNF/TNF-receptor system nor variants

of the *CARD15* gene were associated with therapeutic outcome to anti-TNF therapy with infliximab.

Cryo Electron Crystallography

Definition

Cryo electron crystallography uses electrons for diffraction. Since electrons are diffracted much stronger than X-rays, very tiny crystals can be studied. Accordingly, cryo electron crystallography has been applied to extremely thin, so-called two-dimensional crystals, composed of membrane-bound proteins. However, the experimental requirements for this method are more demanding than for usual protein crystallography, and only limited resolution of the structures can be obtained.

►Structure-Based Drug Design

Cryo-Electron Microscopy: Single-Particle Reconstruction

ROLAND BECKMANN

Institute for Biochemistry, Charité University Medicine Berlin, Germany
roland.beckmann@charite.de

Definition

Cryo-electron microscopy (cryo-►EM) in combination with ►single-particle reconstruction refers to the combined application of two methods used for

structure determination of macromolecular assemblies: (i) ►**cryo-EM** describes the usage of transmission electron microscopy for the visualization of a specimen in a thin layer of ►**vitreous ice** at very low temperature and (ii) single-particle reconstruction describes two- (2D) and, preferably, three-dimensional (3D) reconstruction of the specimen structure by application of image processing techniques to the obtained two-dimensional EM images of the so-called ►**single particles**. Importantly, the term ‘single particles’ in this context refers to macromolecular assemblies as isolated and unordered particles with identical structure (1).

Description

Characteristics

In recent years it has become clear that many of the key functions of the cell depend on large macromolecular assemblies also termed molecular machines. They are often very large and flexible, which makes structure determination by the classical techniques of X-ray diffraction or NMR very difficult and sometimes impossible. In these cases cryo-EM in combination with single particle reconstruction turned out to be an excellent tool. An important advantage of cryo-EM is that the specimen can be visualized in a fully hydrated state without the need for crystal formation. Thus, under conditions that are very close to physiological conditions, a wide range of specimens can be studied in different functional and dynamic states or with a variety of ligands bound (1).

The images initially obtained by cryo-EM represent ►**projections** of the specimen. That means that the 3D structural information of the entire particle is combined along the optical axis of the microscope resulting in a 2D image. A large number of these 2D images of the specimen in different orientations can be combined in order to reconstruct the 3D structure by a process called ►**back-projection**. In contrast to X-ray and NMR techniques, however, the resolution achieved by the different cryo-EM techniques is limited. It ranges, dependent on the kind of specimen and reconstruction method, from more than 30 Å to atomic resolution. Well-ordered specimens such as two-dimensional (2D) or helical crystals allow for atomic or near atomic resolution. Unordered specimens such as single particles are more difficult to resolve at high resolution. Particles with very high symmetry, such as icosahedral viruses, are an exception and can be reconstructed more easily to a resolution under 10 Å. Particles with low or no symmetry, which represent the majority of cellular assemblies, yield reconstructions in a resolution range of 10–30 Å. A clear limit of the method is the size of the particles. The molecular weight should be at least a few hundred kD, preferably higher. The larger and more rigid the particle, the easier it is to determine its structure by single particle reconstruction.

The reason for the differences in resolution described lies in the fact that cryo-EM images are extremely noisy, so that all reconstruction methods require averaging of many images. Superposition of the same structural elements for averaging, however, is much easier with an ordered specimen, as in crystals or symmetrical particles, than with randomly oriented unordered particles. In the latter case, one has to determine the relative orientation of every single particle before averaging and 3D-reconstruction is possible. The accuracy of this process leads to limits of the method regarding the achievable resolution and the size of the studied particle.

The low signal to noise ratio of cryo-EM images is a result of the image formation. This is dependent on the interaction of the electron beam with the specimen, which, unfortunately, causes damage to the specimen at the same time. This reduces the applicable electron doses to 5–40 electrons/Å². The classical method of negative staining uses the salts of heavy metals to air-dry and form a cast around the specimen. This cast is relatively resistant to high electron doses and provides high contrast information about the contour of the particle. However, no information about the density distribution inside the particle can be obtained and the particles are often distorted by the staining procedure. In cryo-EM, the specimen is embedded in vitreous ice and the interaction of the beam with the structure itself provides the weak contrast that can be enhanced by averaging and used for 3D reconstruction (Fig. 1).

Determination of a 3D Structure

The first and very decisive step on the way to structure determination by single particle reconstruction (Fig. 2) is the isolation of a homogenous population of particles. Notably, very small amounts (a few µg) and imperfect homogeneity of the isolated material still allow successful structure determination. However, especially at higher resolution, heterogeneity of conformational states or low ligand occupancy can be limiting. When recognized, heterogeneous particle populations can sometimes be sorted computationally. In the best case, however, the procedure starts with a sample that is as homogeneous and well characterized as possible.

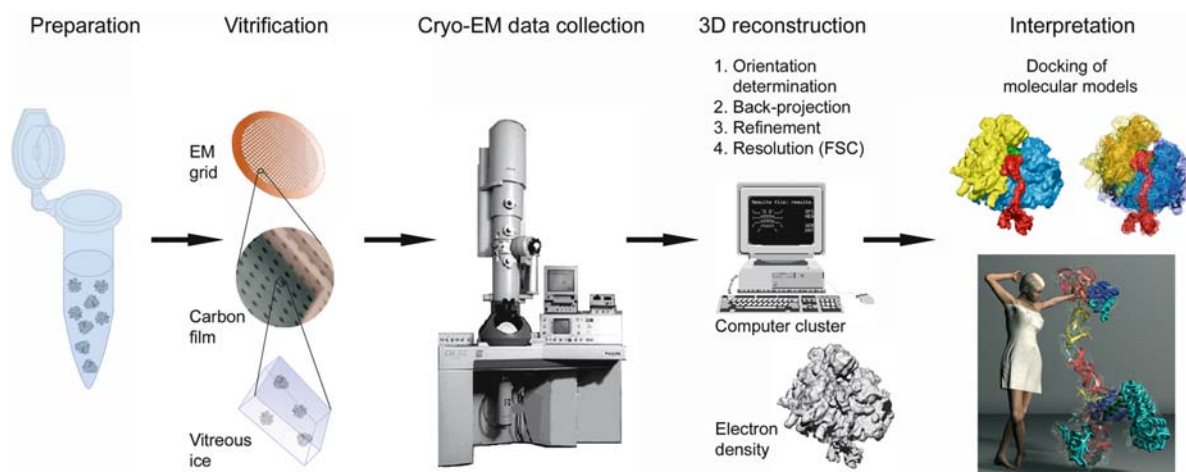

In the next step the sample has to be vitrified. This is done by application of the sample to a holey carbon film supported by an EM grid, blotting away excess sample and flash freezing the grid in liquid ethane that is cooled by liquid nitrogen. The very small mass of the grid allows for a sufficiently fast cooling rate to prevent ice crystal formation. As a result the particles are preserved in a very thin (30–100 nm) layer of vitreous ice.

Cryo-Electron Microscopy: Single-Particle Reconstruction. Figure 1 (a) Electron micrograph of negatively stained 80S ribosomes from yeast (1% uranyl acetate). Asterisks indicate dimeric translating ribosomes. (b) Electron micrograph of 80S ribosomes embedded in vitreous ice (left) and averaged images of 80S particles in three distinct orientations (right). Note the differences in contrast.

The third step is the data collection on a cryo-electron microscope usually yielding dozens to hundreds of micrographs with thousands to hundreds of thousands of particle images. The grid is inserted and kept in the vacuum of the microscope using a holder (or microscope stage) that maintains temperatures below -150°C . This can be achieved by cooling with liquid nitrogen (in standard cryo-microscopes) or even liquid helium. Micrographs are taken in the so-called ‘low-dose mode’ which exposes the area of interest only once to the electron beam. In this way the electron dose can be controlled in order to avoid radiation damage. Note that to increase the contrast of the images, they must be taken with the sample in a position just a little bit below the true focus of the objective lens. This leads to a distortion (or blurring) of the images described by the so-called point spread function (or in reciprocal space by the contrast transfer function, CTF), which needs to be corrected for later on, when reconstructing the 3D structure.

The fourth step is the first image-processing step. After the micrographs have been digitized and single particles selected, the relative orientation of every particle has to be determined in a process called alignment. The orientation can be described by five parameters, two shifts in the plane and three so-called

Cryo-Electron Microscopy: Single-Particle Reconstruction. Figure 2 Scheme of structure determination using cryo-electron microscopy (cryo-EM) in combination with single particle reconstruction. Preparation of the sample is followed by shock freezing (vitrification) on EM grids (usually copper) covered with a holey carbon film. The particles are captured in a thin film of vitreous ice and visualized in a transmission EM at very low temperatures (between -180°C and -260°C , maintained by liquid nitrogen or liquid helium). The images are digitized and then processed using large computer systems. After the determination of particle orientations (using several distinct methods, see text) they can be back-projected in order to generate a 3D density map. After refinement of the map the resolution is determined on the basis of the Fourier shell correlation (FSC). In many cases atomic models can be docked into the electron density map, which allows interpretation on a molecular level. Here, the mammalian signal recognition particle bound to the 80S ribosome is shown in red and transparent with docked atomic models (5).

Eulerian angles. It makes an important difference whether the structure is known (to a first approximation) or has to be determined *de novo*. If the particle belongs to a family with similar structures, one can use a known structure as a reference for the so-called ‘projection matching’ method. In this case, projections of the reference structure are generated computationally and compared with the experimentally obtained projections using cross correlation functions. The parameters of the best fitting reference projection are then assigned to every individual experimental projection. For *de novo* structure determination three different methods are commonly used to determine parameters. (i) Tomography creates a series of images of the same sample area tilted at different angles. The known tilt angles describe the geometrical relation between the different views for individual particles providing the needed parameters. (ii) The ‘random conical tilt’ method uses pairs of micrographs of a tilted and a non-tilted sample area in order to establish the geometrical relation between particles that are oriented in the same way in the plane of the grid. (iii) The ‘common line’ or ‘angular reconstitution’ approach needs only untilted images and takes advantage of the fact that in reciprocal space every two projections (2D) of the same 3D object share a common line. These shared lines can be identified and used to reconstitute an angular system in which all experimental projections are positioned. However, the handedness of an object is

not revealed by this method. Often, multivariate statistical methods such as principal component analysis or correspondence analysis are used in order to sort the particles and to group similar particle projections. The grouped images can then be averaged to enhance the signal to noise ratio as a prerequisite for finding common lines or to select a group of particles with a certain orientation for the random conical tilt approach.

In the fifth step, the obtained orientation parameters can be used for back-projection in order to reconstruct a first 3D structure. This first structure subsequently serves as a new reference in the so-called refinement of the reconstruction. In most cases, the refinement follows the projection matching method in an iterative way. Usually, during this step (or already on the original images) the detrimental effects of the CTF are corrected; this is obligatory when attempting to reach higher resolutions (below 15 Å).

In the sixth step, the resolution of the reconstruction is assessed by randomly dividing the dataset into two halves and determining the correlation of the resulting two reconstructions in reciprocal space as a function of spatial frequency (► [Fourier shell correlation](#), (FSC)). The resolution limits are obtained by finding the spatial frequency corresponding to a certain correlation cutoff; commonly a cutoff of 0.5 is used, which corresponds to a signal to noise ratio of 1. The interpretation of the structure is then guided by this limit.

Cryo-Electron Microscopy: Single-Particle Reconstruction. Figure 3 Examples of symmetrical (icosahedral) and asymmetrical cryo-EM single particle reconstructions. (a) Surface representation of an electron density map of the hepatitis B virus (HBV) capsid at 7.4 Å resolution generated by cryo-EM (2). Note the rod-like features representing the α -helical secondary fold of the capsid protein, which assembles in an icosahedral structure with 60-fold symmetry. (b) A surface representation of the asymmetrical 80S ribosome from wheat germ (Halic et al., unpublished) is shown at a resolution of 8 Å. (c) A molecular model of the translating 80S ribosome from yeast in complex with the protein-conducting channel (Sec61 complex, in red) is shown (3). Although the EM-map has only 15 Å resolution, a molecular interpretation is facilitated by docking of homology models into the separated densities for ribosomal protein and RNA (4). The gray features contacting the Sec61 complex indicate the likely position of the lipid bilayer.

In a seventh step, it is possible in many cases to dock atomic structures or molecular models of components (obtained by X-ray, NMR or homology modeling) into the EM-density of molecular assemblies, thereby positioning them in their functional context. The molecular models can either be docked as rigid bodies or, in the case of recognizable and significant conformational changes, the orientation of individual domains can be adjusted in a procedure called flexible ►**docking**. This often leads to a situation where a low-resolution structure can be reliably interpreted on a molecular level, exceeding the resolution limit of the EM density several-fold. In these instances, the identification of domains or specific regions of a macromolecule that are involved in interactions or dynamic behavior can be facilitated.

Clinical Applications

The technique described has been successfully applied to a wide variety of samples. Some of them have direct clinical relevance, such as the structures of viral pathogens. Most samples, however, represent macromolecular assemblies and machines of the cell in different functional states, for instance RNA polymerases, nuclear pore complexes, spliceosomes, ribosomes, chaperones, proteasomes, ion channels, ATPases etc.

A prominent example of the structure of a pathogen is the hepatitis B virus (HBV). The structure of the HBV capsid (2) was one of the first viral structures resolved by cryo-EM at a sufficiently high resolution to allow assignment of α -helical secondary structure (Fig. 3). In this case, the 60-fold icosahedral symmetry of the capsid structure could be exploited for the reconstruction and revealed the unusual fold of the HBV capsid protein.

The most prominent example for a non-symmetrical particle investigated by cryo-EM and single particle reconstruction is the ribosome (Fig. 3). For this technique it represents a perfect sample because it is large (several MD), dense (due its high RNA content), almost spherical (leading to random orientations) and displays a definite dynamic behavior. Many cryo-EM structures of 70S and also of 80S ribosomes in complex with tRNAs, translation factors and other ligands contributed significantly to the understanding of such fundamental processes as translation, protein targeting and protein translocation (3, 4, 5). Notably, a resolution of below 10 Å can be achieved for this asymmetrical particle. Moreover, the ribosome is an excellent example of combining cryo-EM with other structural methods in order to create molecular models by docking atomic models of subunits into EM density. The first molecular model (Fig. 3) for a eukaryotic ribosome (from *S. cerevisiae*) was generated in this way (3, 4).

Cyclin

Definition

Cyclins are a family of proteins that bind to and activate cyclin-dependent kinases, thus regulating the progression of cells in the cell cycle. Cyclins were originally discovered as proteins that are periodically expressed during the cell cycle.

► Cell Cycle – Overview

Cyclin D1

Definition

Cyclin D1 belongs to a family of proteins involved in progression to cell division.

► Cell Cycle – Overview

► Cell Division

► Hyper- and Hypoparathyroidism

Cyclin-Dependent Kinase

Definition

Cyclin-dependent kinases (Cdks) are closely related catalytic subunits of serine/threonine kinases, which require association with the positive regulatory cyclin for activation to control progression through the cell cycle. In yeast, a single Cdk (CDC28 in budding yeast and CDC2 in fission yeast) acts throughout the cell cycle with change in cyclins appropriate for each step. The situation is more complicated in mammalian cells.

Cyclin D/Cdk4 or 6 and cyclin E/Cdk2 are the G1 Cdks that phosphorylate Rb proteins to release E2F transcription factors. Cyclin E/Cdk2 and cyclin A/Cdk2 are the S phase promoting Cdks, and cyclin B/Cdk1 is the mitotic Cdk. In addition, cyclin A/Cdk1 appears active during S, G2 and M phases, although the biological consequences have yet to be clarified.

Cycling Genes

Definition

Cycling genes are genes which show oscillating rostrocaudal expression in the presomitic mesoderm during early embryonic development.

► Somitogenesis

Cyclooxygenases

Definition

Cyclooxygenases are enzymes that metabolize arachidonic acid to generate prostaglandin H₂ (PGH₂). PGH₂ is the precursor of many other prostaglandin metabolites such as PGE₂, thromboxan and PGI₂. Amongst many other activities, prostaglandins regulate inflammatory responses. Cyclooxygenases are the targets of aspirin-like drugs.

► Cytokines

Cyclopamine

Definition

Cyclopamine is a teratogenic steroidal alkaloid isolated from lily *Veratrum californicum*. The progeny of ewes feeding on this plant in the 1950's displayed a severe defect characterised by cyclopia, absent midline facial structures and a failure of forebrain division (holoprosencephaly). The ► [Hedgehog Signalling Pathway](#) is specifically inhibited by cyclopamine.

Cyclophilins

► Immunophilins and Cyclophilins

Cyclosporin A

Definition

Cyclosporin A is a cyclic undecapeptide that belongs to a family of secondary metabolites from the fungus imperfectus *Beauveria Nivea*. It has immunosuppressive, anti-inflammatory and anti-chemotactic properties. It shows strong affinity for ►Peptidyl Prolyl Isomerases of the cyclophilin family.

► Immunophilus and Cyclophilus
► Peptidyl Prolyl Cis/Trans Isomerases

Cysteine Proteases

Definition

Cysteine proteases constitute an important class of enzymes involved in the formation and hydrolysis of the peptide amide bond; these proteases require a cysteine in the active site for activity. Cysteine proteases have vital roles in mammalian cellular turnover and apoptosis, they are also very important in the life cycle of many parasites. A few examples of cysteine proteases are given: caspases, cathepsin F, and SUMO.

► Limb Girdle Muscular Dystrophies
► Sumoylation

Cystic Fibrosis (CF)

Definition

Cystic fibrosis, a common autosomal recessively inherited disease of the lung, intestines and pancreas, is caused by mutations in the gene encoding the cystic fibrosis transmembrane conductance regulator (►CFTR) protein, which functions as a chloride ion channel in the cells of secretory epithelia. The $\Delta F508$ CFTR mutation, which is carried by ~90% of Caucasian CF patients, results in the production of a misfolded but functionally active CFTR protein that is retained in the endoplasmic reticulum and targeted for degradation.

► Epistasis in Cystic Fibrosis

Cystic Fibrosis Transmembrane Conductance Regulator

Definition

Cystic fibrosis transmembrane conductance regulator (CFTR) is a protein that mediates and regulates a plasma membrane chloride conductance pathway required for transepithelial fluid secretion in many organs including the lung, intestines and pancreas. Loss of function of this protein results in ►cystic fibrosis.

► Autosomal Dominant (Inherited Disorder)
► Polycystic Kidney Disease, Autosomal Dominant

Cystine Knot

Definition

Cystine knot defines a structural conformation of a protein due to an unusual arrangement of six cysteines and the formation of three disulfide bonds.

► Neutrophilic Factors

Cytochrome P450

Definition

Cytochrome P450 (CYP) is a hemecontaining superfamily of enzymes that function as terminal oxygenases in cytochrome P450-dependent monooxygenase systems, and the reduced complex with carbon monoxide absorbs maximally at 450 nm.

CYP450 enzymes catalyze xenobiotics including drugs. They are also involved in the biosynthesis of steroid hormones, bile acids, fatty acids, and eicosanoids.

► Pharmacogenomics

Cytochrome C

Definition

Cytochrome c is an essential component of the mitochondrial respiratory chain. It is a soluble protein,

localized in the intermembrane space and loosely attached to the surface of the inner mitochondrial membrane. Cytochrome c carries electrons, which are transferred to molecular oxygen by the cytochrome oxidase. In the process of apoptosis, cytochrome c is released into the cytoplasm and induces, together with other molecules, caspase activation.

Cytokines

MICHAEL KRACHT, HELMUT HOLTMANN
Medizinische Hochschule Hannover, Hannover,
Germany
kracht.michael@mh-hannover.de
holtmann.helmut@mh-hannover.de

Definition

Cytokines are a large and heterogeneous group of small polypeptides, most of them with a molecular mass between 8–30 kD. They are mostly soluble extracellular mediators (some exist in membrane-associated form) and function through high affinity cell surface receptors. Released by cells of hematopoietic origin (reflected in the terms “lymphokines” and “monokines”) as well as by a wide variety of non-hematopoietic cells, cytokines are critical for the normal functioning of the immune defense, which they coordinate by communicating between participating cells.

As cytokines are not a structurally defined entity, the following terms are used as synonyms or for subgroups: lymphokines, monokines, interleukins, chemokines, interferons, growth factors.

Characteristics

Historically, many cytokines were discovered by means of their immunoregulatory properties, hence the term interleukins. However, cytokines regulate not only functions of the specific immune system, but also many aspects of infection and inflammation. At the cellular level they control proliferation, differentiation, migration, functional activity and apoptosis. As a whole, they are synthesized by a broad variety of different cell types. This also holds true for many cytokines individually (e.g. interleukin (IL)-6, IL-8, interferon (IFN)- β , for further information on individual cytokines see ► <http://www.copewithcytokines.de> (1)), whereas synthesis of others is restricted to one or a few cell types (e.g. IL-2, IL-4, IFN- γ). While some cytokines are continuously formed and play a role in normal homeostasis, for most of them biosynthesis is rapidly and highly inducible by changes in the cell's microenvironment. Cytokines often have a short half-life and production is restricted to potentially pathological conditions. Uncontrolled synthesis results in chronic inflammatory or other diseases. All cytokines act locally in an autocrine or paracrine manner, but some may also act systemically. Examples of the latter are the induction of fever by IL-1 and tumor necrosis factor (TNF) and the induction of acute phase proteins

Cytokines. Figure 1 Schematic representation of mechanisms that regulate cytokine-dependent gene expression. Proinflammatory cytokines (IL-1, IL-17, IL-18, TNF), but also ligands of toll-like receptors (TLRs) induce the aggregation of their plasma membrane receptor chains. The cytosolic portions of these receptors trigger oligomerization of adaptor proteins such as TRAF molecules, which in turn activate protein kinase cascades. Subsequently, a sequence of reversible phosphorylation steps results in activation of the MAP kinases JNK, p38 and ERK and in activation of the transcription factor NF-κB. MAP kinases induce and activate AP-1 proteins. Activity of AP-1 proteins and of NF-κB is modulated by phosphorylation. Modifications of histone H3 and H4 allow remodeling of the chromatin structure in promoter regions to facilitate binding of AP-1 and of NF-κB transcription factors to DNA. NF-κB and AP-1 in conjunction with components of the basal transcriptional machinery (TBP, TAF_{II}s) and many additional proteins form a large multimeric protein complex whose composition is specific for each individual gene (7). This complex ultimately allows rapid and efficient recruitment of RNA polymerase II. The newly formed RNA is capped, spliced, polyadenylated and exported to the cytoplasm. Half-life and in some cases translation is limited by AU-rich elements in the 3' untranslated regions of many cytokine and other rapidly inducible genes. This restriction is

in the liver by IL-6. Cytokines can therefore also be regarded as hormones. Cytokines are pleiotropic, i.e. they control multiple biological responses (2, 8). There is considerable functional overlap between certain cytokines (e.g. TNF and IL-1). In general, activation of a cell by a cytokine results in reprogramming of the cell's gene expression profile.

Cytokines in Medicine

Knowledge on cytokines has been exploited to improve the therapy of many diseases, basically in two ways:

Application of Cytokines as Drugs

Recombinant cytokines can be used to boost immune reactions during infection and cancer or to substitute cytokine deficiencies. In general, treatment with cytokines has turned out to be problematic due to their pleiotropic nature of function. Thus tumor necrosis factor, apart from its antitumoral effect, has severe systemic side effects as manifestations of its activity, which largely precludes its use as an anticancer drug. Similar toxicity has been observed for several other inflammatory cytokines.

Interferons induce the expression of antiviral, anti-proliferative and immunomodulatory genes. They are applied in the treatment of viral diseases, including chronic hepatitis B and C, certain malignancies and (IFN- β) multiple sclerosis.

Human recombinant colony-stimulating factors (GM-CSF, G-CSF) promote the differentiation of pluripotent bone marrow stem cells to leukocytes. They are effective in the treatment of congenital and acquired neutropenias during chemotherapy of cancer or bone marrow transplantation. Interleukin 2, a growth factor and activator of T-lymphocytes, is applied in the therapy of metastasizing renal carcinoma and melanoma. Erythropoietin is physiologically produced in the kidney and regulates proliferation of committed progenitors of red blood cells. It is used to supplement erythropoietin in

severe anemias due to end stage renal disease or treatment of cancer with cytostatic agents.

Interference with Cytokine Action

Inhibition of cytokine synthesis has turned out to be a major component of the activity of anti-inflammatory drugs, glucocorticoids being a prominent example. Because the molecular mechanisms of the actions of many cytokines have been worked out in detail, rational strategies for interfering with their biological activities have been or are being developed. The action of cytokines can be suppressed pharmacologically by different means.

1. Inhibition of their synthesis by drugs. The immunosuppressants cyclosporine and tacrolimus inhibit T-lymphocyte activation and IL-2 gene expression. Sirolimus inhibits IL-2-dependent progression of activated T-lymphocytes through the cell-cycle. All three drugs suppress clonal expansion of antigen-activated T-lymphocytes and are used to prevent rejection after organ transplantation.
2. Prevention of their interaction with cell surface receptors by soluble receptors, anti-cytokine or -cytokine receptor antibodies or natural antagonists. Etanercept, a chimeric molecule consisting of two extracellular domains of the TNF receptor I linked by Fc portions of human IgG1, binds with high affinity to extracellular TNF and reduces TNF activity. It is used to treat Crohn's disease and rheumatoid arthritis (4, 5). Side effects include immunosuppression and increased risk of infections.
3. Blockade of specific events in the intracellular signaling pathways (protein kinase inhibitors). Imatinib (Glivec[®]) is used to treat chronic myeloid leukemia in Philadelphia-chromosome positive patients. In these patients translocation of parts of chromosomes 9 and 22 results in the expression of a fusion protein with increased tyrosine kinase activity, called Bcr-Abl. Imatinib is a small

found to be alleviated—further boosting expression—by some of the signaling pathways activated by inflammatory inducers, including the p38, JNK and ERK as well as PI-3 kinase pathways. Likely targets are proteins that bind to the AU-rich elements and control mRNA metabolism (9). These proteins presumably act by interfering with the closed loop structure of cytoplasmic mRNA, formed by proteins that bind to its cap and poly(A) tail, limit access of degrading enzymes and facilitate translation.

All together these mechanisms allow rapid and tightly controlled synthesis of many pro-inflammatory proteins (e.g. many other cytokines and chemokines). Central steps in these pathways are inhibited by glucocorticoids (G), protein kinase inhibitors (SP600125, SB203580, SB20129), NO-donors (SNAP; S-nitro-N-acetyl-DL-penicillamine), salicylates and the anti-inflammatory cytokine IL-10, explaining the well-known anti-inflammatory properties of these agents.

Abbreviations: Ac, acetylation; AP-1, activating protein-1; ARE, AU-rich element; eIF, eukaryotic initiation factor; ERK, extracellular-regulated kinase; I κ B, inhibitor of NF κ B; JNK, JUN-N-terminal kinase, LPS, lipopolysaccharide; MAPK, mitogen-activated protein kinase; MKKK, MAPK kinase kinase; MKK, MAPK kinase; MK-2, MAPK-activated protein kinase 2; P, phosphorylation; Pol II, polymerase II; PABP1, poly(A)-binding protein 1; TAF_{II}, TBP-associated factor; TBP, TATA Box-binding protein, TLR, toll-like receptor; TRAF, TNF-receptor associated factor.

molecular weight inhibitor selective for the tyrosine kinase activity of Bcr-Abl. It thereby inhibits the Bcr-Abl induced cell-cycle progression and the uncontrolled proliferation of tumor cells.

Clinically used cytokines or cytokine antagonists are proteins. Repeated application, especially of those of non-human origin, bears the risk of recognition by the immune system and antibody production against them with subsequent loss in effectiveness of the drug. Therefore the proteins are often genetically engineered, i.e. humanized to be as homologous as possible to human proteins.

Structural/functional groups of cytokines (examples):

interferons	(IFN- α , β , γ)
hematopoietic cytokines/ colony-stimulating factors	(IL-3, IL-5, IL-7, GM-CSF, G-CSF, M-CSF)
IL-1 family	(IL-1 α , IL-1 β , IL-18, IL- 1RA)
TNF family	(TNF- α , TNF- β , CD40 li- gand, CD95 ligand, TRAIL)
chemokines	(IL-8, MIP-1- α , RANTES)
immunoregulatory cyto- kines	(IL-2, IL-4, IL-10, IL-12)

Molecular Interactions

The interaction partners of cytokines are receptors on the plasma membrane to which they bind with high affinity and specificity. These receptors fall into different classes, those with enzymatic tyrosine kinase activity (e.g. the receptors of certain hematopoietic growth factors (M-CSF, SCF)), G-protein-coupled receptors (chemokine receptors) and several groups that bind to other intracellular adaptor proteins (IL-1-, TNF-, interferon- and hematopoietic cytokine-receptor families). Ligand-dependent receptor clustering activates several intracellular signaling pathways. These pathways consist of consecutive interactions between protein components that in part involve enzymatic activities. The activity of many proteins in a given cytokine-activated pathway is regulated by reversible phosphorylation. The ►MAPK (mitogen-activated protein kinase) cascades (Fig. 1) and the ►JAK/STAT and ►PI-3 kinase pathways are intensively studied examples. Certain receptors (of the TNF-R family) can activate ►caspases; a family of proteases that execute ►programmed cell death. Other protein synthesis-independent effects of cytokines include cytoskeletal changes and modulation of cell surface receptors and adhesion molecules. Most cytokine-activated intracellular pathways ultimately turn on expression of genes whose products change the biological function of the

same or a neighboring cell. These include cytokines (hence the term “cytokine network”), cell surface receptors and adhesion molecules and enzymes involved in degradative processes (e.g. collagenases) and in formation of small molecular weight mediators (e.g. ►cyclooxygenase I and II, inducible NO-synthase).

Receptors for a number of cytokines have been demonstrated to exist in soluble forms, derived from their cell surface counterparts either by alternative splicing or by proteolytic cleavage of the extracellular domain. The soluble receptors are able to bind their ligands, which can have fundamentally different consequences; in the case of TNF, they can sequester the ligand and prevent it from acting on the cell surface receptors, a principle used in pharmacotherapy (see above). Soluble IL-6 receptors on the other hand can bind the ligand and then associate with a signal-transducing β -chain shared with other receptors (gp130). This can occur even on cells lacking the specific α -chain and result in responsiveness of these cells to IL-6 (4).

Regulatory Mechanisms

Most cytokines are rapidly induced in response to several groups of external cues that include:

bacterial, viral, fungal and parasite structures that are recognized by members of the Toll-like receptor family (3).

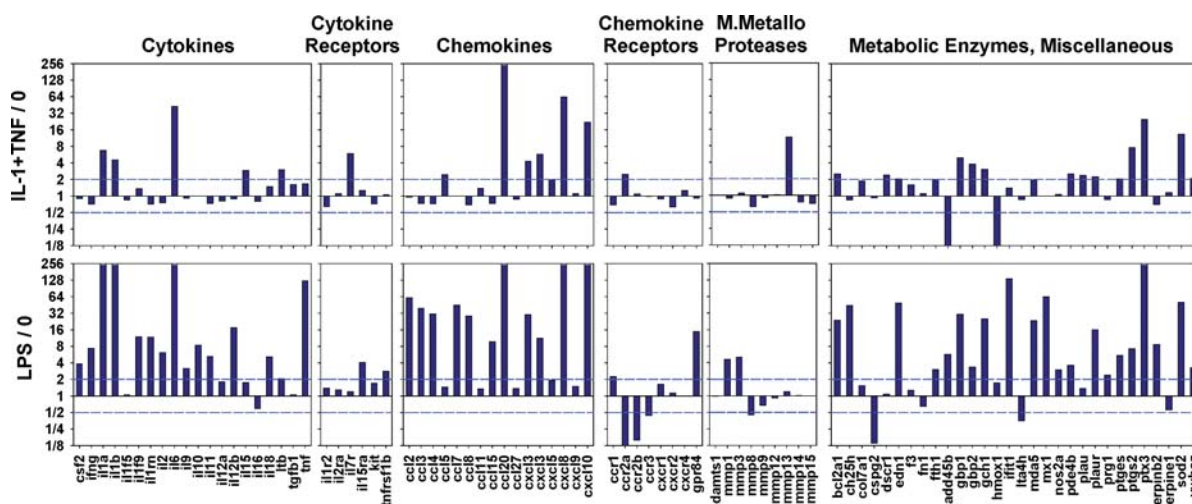

nonspecific physicochemical stress/cell damage

molecules formed/activated in response to the above stimuli:

- released cytokines (e.g. TNF, IL-1)
- activated complement components
- structures of the specific immune system (antibodies, T cell receptors).

The intracellular pathways activated by these stimuli are manifold, among them those depicted in Fig. 1. They have to enable stringent spatial, temporal and qualitative control of the response, necessitated by the potentially hazardous consequences of unscheduled cytokine activities. Absence of cytokine formation under normal conditions is the consequence of low promoter activity and rapid turnover of the mRNAs. Several thousand fold increases in cytokine formation are achieved within minutes by simultaneous activation of transcription, stabilization of the mRNA and increase in translational efficiency (7). Several mechanisms restrict the response and let the system return to its basal state, e.g. down regulation of receptors, induction of phosphatases that inactivate components of the signaling pathways, etc. Systemically the release of glucocorticoids is a major feedback mechanism that dampens the response at multiple levels, as depicted in Fig. 1.

The sets of cytokines induced by the different conditions and mechanisms imposing selectivity of induction are

Cytokines. Figure 2 Distinct and common patterns of genes induced by cytokines or pathogenic stimuli. Human epithelial cells were treated with IL-1 (10ng/ml) plus TNF (20ng/ml) for 4 hours or left untreated. Then, total RNA was isolated and transcribed into cDNA followed by fluorophore-labeled cRNA synthesis. The cRNA mixtures from both samples were hybridized to DNA microarrays containing oligonucleotide probes for 136 human genes with known relevance to inflammation. Fluorescence intensity bound indicates the amount of the corresponding mRNA expressed. Results are depicted as ratio of expression comparing treated with untreated cells. The lower panel shows an analogous experiment comparing gene expression of untreated peripheral blood mononuclear cells with cells that were treated for 3 hours with lipopolysaccharide (LPS, 100ng/ml), a cell wall component of Gram-negative bacteria. The blue lines indicate twofold regulation. Note that LPS induces many cytokine and chemokine genes, among others IL-1 and TNF. Cytokines (e.g. IL-1 and TNF) and LPS also induce metabolic enzymes such as MnSOD (sod2) or prostaglandin synthases (ptgs2, ptges) and NO-synthases (nos2a), which produce prostaglandins and NO, crucial mediators of acute inflammation. Persistent induction of destructive enzymes (e.g. matrix metalloproteases) contributes to the tissue damage observed in chronic inflammation (data provided by Michael Kracht and Oliver Dittrich-Breiholz).

under investigation. This involves DNA microarray-based approaches (6). An example is shown in Fig. 2.

Cytokines

Definition

Cytokinesis is the process in which the cytoplasmic content, organelles and cytoplasm are separated. It is usually part of cell division.

- Cell Division

Cytolysis

Definition

Cytolysis is the pathological breakdown of cells by the destruction of their outer membrane.

► [Heritable Skin Disorders](#)

Cytolytic T Lymphocytes

► [CTL](#)

Cytoplasm

Definition

The compartment in the cell that is delineated by the plasma membrane in eukaryotic cells, exterior to the nucleus. The cytoplasm contains the mitochondrial network and several other important components of the cell, also called cytosol.

► [Cell Polarity](#)

► [Mitochondrial Myopathies](#)

Cytoskeletal Linkers

Definition

Cytoskeletal linkers are proteins that have the capacity to associate with more than one cytoskeletal system, enabling them to integrate two or all three cytoskeletal elements (actin filaments, microtubules and intermediate filaments).

Cytoskeleton

Definition

Cytoskeleton is a dense network of various filamentous proteins in eukaryotic cells, which are essential for cell shape, cell division or cell migration. Actin filaments, microtubules, and intermediate filaments form the major components of the cytoskeleton. They interact with many other proteins in the cell. Recently, a number of inter-► [cytoskeletal linkers](#) have been described.

Cytoskeleton: Microtubules and Intermediate Filaments

DIETER K. MEYER

Institute for Experimental and Clinical Pharmacology and Toxicology, Albert Ludwig University Freiburg, Freiburg, Germany
dieter.meyer@pharmakol.uni-freiburg.de

Definition

► [Microtubules](#), microfilaments (F-actin) and ► [intermediate filaments](#) form the cytoskeleton. These polymers made from homo- or hetero-meric subunits are highly dynamic structures, which adapt the cellular architecture in response to intra- and extra-cellular signals. They are essential for cell morphology and attachment as well as motility. They play an important role in proliferation and organize intracellular compartments and transport. In addition, cytoskeletal elements anchor receptors and ion channels in the cell membrane and take part in the subsequent signal transduction pathways. In this chapter, only microtubules and intermediate filaments will be discussed.

Cytoskeleton: Microtubules and Intermediate Filaments. Figure 1 Microtubules and intermediate filaments are composed of monomers. (a) Microtubules. α - and β -subunits form dimers, which are added at the plus end of a microtubule and released from its minus end during the process of treadmilling. During the process of dynamic instability, dimers are added and released from the plus end. (b) Intermediate Filaments. Two monomers of an intermediate filament (I) form a coiled-coil dimer (II). Different colours are used for better resolution and to remind one of the fact that different monomers can associate to a dimer. Two dimers then associate in a half-staggered manner to anti-parallel tetramers (III). Head to tail addition of further tetramers causes elongation (IV). (c) Interactions of microtubules and intermediate filaments in axons. In axonal extensions of neurons, microtubules and neurofilaments (type IV intermediate filaments) interact. The C-terminal of neurofilaments (blue ellipsoids) can link to microtubules, as can plakin (brown bar), which binds to neurofilaments (modified from Lariviere and Julien (2003)).

Characteristics

Microtubules (MTs)

The globular polypeptides α - and β -tubulin have molecular weights of about 50 kD. Whereas both tubulins bind GTP, only the GTP bound by β -tubulin is exchangeable. Higher eukaryotes have up to 7 isoforms of α - and β -tubulin, respectively, which are encoded by

different genes. Via non-covalent bonds, α - and β -tubulins associate to heterodimers, which polymerize head to tail to form protofilaments. Thirteen protofilaments make up a hollow tube with a diameter of 25 nm, a microtubule (MT) (Fig. 1a). These polarized structures have β -tubulins at the plus ends and α -tubulins at the minus ends. Within the MTs, non-covalent bonds between α - and β -subunits cause lateral stabilization. When the β -tubulins at the plus end of the protofilament are in the GTP binding state, addition of further heterodimers is possible, if the concentration of free heterodimers is higher than a certain critical concentration (Fig. 1). GTP bound β -tubulins at the plus end protect the MT from degradation. They form a GTP cap. When the β -tubulins at the plus end of the protofilament are in the GDP binding state however, depolymerization is more likely. The transition from growing to pause and shortening observed at the plus end is called “**dynamic instability**”. In contrast, “**treadmilling**” is a net addition of tubulin heterodimers at the plus end and the balanced net loss from the minus end, so that the total length of the MT remains constant. In most cells there are at least 2 pools of MTs, i.e. dynamic MTs, which show dynamic instability with a half-life of 10 min and stabilized MTs, which can persist for several hours. De-tyrosination of the C-terminal of the α -subunit exposes a Glu residue and stabilizes MTs. Dimers cannot be added or removed (5).

MTs are stabilized at their minus ends by the **centrosome** (also called the MT organizing center, MTOC). Centrosomes are protein complexes containing among other proteins 2 centrioles (ring-like structures) and γ -tubulin. Centrosomes serve as nucleation points for microtubular polymerization and constrain the lattice structure of an MT to 13 protofilaments. Centrosome-independent nucleation is possible and may be induced by DNA or proteins such as cadherin.

Intermediate Filaments

The proteins of the intermediate filament superfamily form polymeric filaments with a diameter of 10 nm, which serve as scaffolds and stabilize cells. Proteins of the lamin family are found only in cell nuclei, whereas the filaments of the other families occur cytosolically. The various subunits have in common a central rod domain with 4 highly conserved alpha-helical domains (1a, 1b, 2a, 2b), which are separated by linkers (Fig. 1b). The alpha-helical domains consist of heptad repeats with apolar residues in positions 1 and 4 at the outside of the helix, which are essential for dimerization. Gene specific amino-terminal head domains and a carboxy-terminal tail domain flank the rod domain. Hydrophobic interactions cause the rod domains of 2 subunits to wrap around each other, thus generating a coiled-coil (Fig. 1b). Vimentin or desmin

filaments form homodimers, while keratin filaments or neurofilaments form heterodimers. Two dimers then associate in a half-staggered manner to antiparallel tetramers (Fig. 1b). Longitudinal growth is due to head to tail addition of further tetramers. Eight tetramers packed together side-by-side in a helical array form a filament with a diameter of 10 nm.

Six Types of Intermediate Filaments Are Known

Type I and II intermediate filaments comprise the acidic and basic keratins. Type I keratins (subunits K9 to K20, IRSa1-Irsa3, Ha1-Ha9) are acidic, whereas type II keratins (subunits K1-K8, Hb1-Hb6) are neutral to basic. Both types form heterodimers. Keratins are present in endothelia, epithelia and epidermis as well as in hair follicles and nails. Keratins have also been found in hepatocytes. Expression of the various subunits is tissue-specific and, in the ►epidermis, layer-specific (6).

Type III filaments are also called vimentin-like filaments and form homodimers. Vimentin is present in fibroblasts and embryonic tissues, desmin in muscle cells, glial fibrillary acidic protein in non-myelinated Schwann cells and astroglial cells and peripherin in developing neurons. Nestin is found in early neuroectodermal cells.

Type IV filaments comprise the neurofilaments and α -internexin. Neurofilaments consist of the subunits NF-H (115 kD), NF-M (90 kD) and NF-L (61 kD). They form obligatory heterodimers, which consist of NF-L together with NF-M or NF-H. Neurofilaments are present in developing and mature neurons. α -internexin (also called NF66; 64–66 kD) is considered to be a neurofilament protein. It can form homopolymers, although co-assembly with NF subunits is possible. It is present in neurons during early development.

Type V: nuclear lamins. Intermediate filaments of the lamin family (lamins A/C and B) line the inner nuclear membrane.

Type VI intermediate filaments are filensin and phakinin. Little is known about the function of these recent additions to the group of intermediate filament proteins.

Molecular Interactions

Microtubules (MTs)

►Microtubule associated proteins (MAPs) bind to MTs *in vivo* and play a role in their nucleation, growth, stabilization (by cross-linking) and motion. Of the numerous MAPs (MAP1, MAP2 and tau in neurons; MAP4 in non-neuronal cells), the tau family proteins have received special attention, since they have been implicated in neurodegeneration (see below). MAPs are negatively regulated in their activity by phosphorylation.

►Motor proteins move along MTs in an ATP-dependent manner. Members of the superfamily of

kinesin motors move only to the plus and dynein motors only to the minus end. The respective motor domains are linked to their cargoes *via* adaptor proteins. The binding of the motors to MTs is regulated by kinases and phosphatases. When motors are immobilized at their cargo binding area, they can move MTs.

MTs extend from the centrosome throughout the cytoplasm to the plasma membrane, where they are stabilized by caps. Sliding along the MTs, kinesin and dynein motors transport their cargoes between the center and the periphery of the cell. MTs present in the axons of neurons are extended not only by addition of heterodimers to the plus ends but also by use of short MTs that have been initiated in the centrosome. Their axonal transport is mediated by dynein motors, which are passively moved along actin filaments. Once formed in the axon, MTs serve as tracks for fast axonal transport, i.e., the movement of membranous organelles and membrane proteins to the nerve ending.

Some specialized eukaryotic cells have cilia, which show a whip-like motion. Sperm cells move with one flagellum, which is much longer than a cilium but has a nearly identical internal structure called an axoneme. It is composed of nine doublet MTs which form a ring around a pair of single MTs. Numerous proteins bind to the MTs. Ciliary dynein motors generate the force by which MTs slide along each other to cause the bending of the axoneme necessary for motion.

Intermediate Filaments

Since the regulatory mechanisms of the intermediate filaments are little known, their molecular interactions and defects resulting from mutations will be briefly summarized.

Intermediate Filaments of Type I and II (Keratins)

In some cell types, e.g. in epidermis, hair follicle or nail bed, keratins of type I and II make up a large percentage of the total protein content. Keratin filaments are essential for cellular resistance to mechanical strain. Mutations in keratins can thus result in the rupture of epidermal layers or of epithelial coherence. Numerous disorders related to keratin mutations have been reported (6). They include various epidermolytic diseases, corneal dystrophy, cryptogenic liver disease and disturbances of hair follicles and nails.

Intermediate Filaments of Type III (Vimentin-like Filaments)

Vimentin filaments are bundled by plectin, i.e. a member of the phakin protein family. Mutations resulting in diseases have not been reported.

Glial fibrillary acidic protein plays an important role in the function of astroglial cells. There is increasing evidence that heterozygous missense mutations in the

gene are connected to Alexander's disease, which is characterized by leukodystrophy, mental retardation and developmental delay (4).

Missense mutations and deletions of the desmin gene (located on chromosome 2q35) can lead to myopathies including cardiomyopathy (desmin-related myopathy) with autosomal-dominant or autosomal-recessive inheritance (7).

Peripherin can form polymers with neurofilament subunits. In the exploration of neurodegeneration, the role of peripherin currently elicits great interest (2).

Intermediate Filaments of Type IV (Neurofilaments)

Links of neurofilaments to cytoskeletal structures, such as MTs, are possible *via* the nonhelical C-terminal domains of the polymerized subunits, as exemplified by the tails of NF-M and NF-H in neuronal axons (Fig. 1C). Although neurofilaments are not necessary for axon elongation in neurons, deletions of the subunits NF-M, NF-H and NF-L cause loss of motor axons. In addition, deletions of NF-M or NF-L reduce the axonal diameter by >50%. Since the caliber of the axon determines its conductance, neurofilaments seem to play an important role in neuronal function (2). It is noteworthy that decreased levels of NF-L have been found in some patients with Alzheimer disease or **▶amyotrophic lateral sclerosis** (ALS). In addition, mutations in the NF-H gene and in the NF-L gene have been found in subpopulations of patients with ALS and **▶Charcot-Marie-Tooth disease**, respectively. Of the proteins interacting with neurofilaments those of the plakin family (such as plectins, BPAG1, ACF7, desmoplakin, envoplakin or periplakin) have been studied most. Plakins link neurofilaments to other cytoskeletal structures (Fig. 1). Deletion of BPAG1 causes neurodegeneration characterized by disorganization of MTs and neurofilaments (2).

Intermediate Filaments of Type V (Lamins B and A/C)

The lamins form a meshwork, which lines the inner surface of the nuclear membrane. Since heterochromatin can attach to the lamin lining, mutations in lamins A/C may alter the organization of heterochromatin and thus of gene expression. Mutations in lamin A/C may also cause mechanical strain within a cell nucleus, which results in changes in gene expression. These hypotheses are currently being studied to explain why mutations in lamins A/C, which are present in all nuclei of an organism, can cause tissue-specific defects, such as myopathy in striated muscle, partial lipodystrophy syndromes and peripheral neuropathy as well as premature aging syndromes (8).

Extensive information on intermediate filaments, i.e. their structures, gene sequences, mutations and connected diseases, is available at <http://www.interfil.org>.

Regulatory Mechanisms

Microtubules (MTs)

The membrane tubules and lamellae of the endoplasmic reticulum (ER) are extended in the cell with the use of MTs and actin filaments. Kinesin motors are required for stretching out the ER, whereas depolymerization of MTs causes the retraction of the ER to the cell centre in an actin-dependent manner. Dynein motors move proteins synthesized in the ER along MTs to the Golgi complex (GC), where they are modified and packaged. The resulting vesicles move along the MTs to the cell periphery transported by kinesin motors. MTs also determine the shape and the position of the GC. Their depolymerization causes the fragmentation and dispersal of the GC. Dynein motors are required to rebuild the GC.

When cells enter **▶mitosis**, the interphase array of MTs is dismantled. The centrosome duplicates, and the daughters move to opposite poles of the nucleus. After disassembly of the nuclear envelope, MTs emanating from both centrosomes show pronounced dynamic instability. They grow and shorten and thus probe the cytoplasm until they find attachment sites at the condensed chromosomes, the **▶kinetochores**. Dynein motors are involved in the attachment and in the subsequent segregation of the two sets of chromosomes. In some cells, spindles are formed in the absence of centrosomes. Here, DNA itself initiates microtubular nucleation at the kinetochores with the help of the GTPase Ran and/or the MT-destabilizing factor stathmin. Kinesin and dynein motors then bundle and focus the MTs at their minus ends (1).

MTs are present in neuronal axons and dendrites. In axons, they are linked to neurofilaments (Fig. 1C). They extend and stabilize axons and facilitate their internal transport. Tau protein binds to and stabilizes MTs, unless it is hyper-phosphorylated. There is accumulating evidence that tau is involved in several neurodegenerative diseases (so-called **▶tauopathies**), such as Alzheimer disease, frontotemporal dementia, progressive supranuclear palsy and corticobasal degeneration. These diseases have in common neurofibrillary tangles, i.e. filamentous cytosolic inclusions containing tau, which can lead to cell death. The cytotoxic effect of the inclusions is currently being investigated. They may either sequester tau or other proteins, which then cannot perform their normal functions, or may have direct toxic effects

Therapeutic Use of Agents with Action on Microtubules

The alkaloids **▶vinblastine** and vincristine extracted from the plant *Catharantus roseus* (also called *Vinca rosea*) and the semisynthetic derivatives vindesine, vinorelbine and vinflunine can block mitosis and are used clinically for cancer treatment. When used at

micromolar concentrations, the alkaloids bind with 1:1 stoichiometry to β -tubulin in a region between residues 175 and 213. The bound disassembled tubulin heterodimers can no longer polymerize to MTs and form paracrystalline tubulin-*Vinca* alkaloid arrays. Pre-existent MTs are subsequently depolymerized. Chromosomes are no longer separated but dispersed or clumped in the cytoplasm. The cells undergo apoptosis. When used at nanomolar concentrations, *Vinca* alkaloids may block mitosis at the metaphase-anaphase transition by inhibiting the dynamic instability and treadmilling of MTs, without affecting microtubular mass. The cytostatic agent estramustin has similar effects. It blocks heterodimer polymerization at micromolar concentrations and inhibits dynamic instability at nanomolar concentrations.

In contrast, ►**paclitaxel** (from the bark of the Western yew tree) and its more potent analogue docetaxel bind to MTs, when used at nanomolar concentrations. By attaching to β -tubulin between amino acids 239 and 254, the agents block the release of heterodimers from MTs and prevent the dynamic instability necessary for the capturing of chromosomes without affecting microtubular mass. Both taxols are used for cancer treatment. Labeled paclitaxel is also used for the immunocytochemical localization of MTs.

The alkaloid ►**colchicine** (from *Colchicum autumnale*) blocks tubulin polymerization by binding to heterodimeric β -tubulin between amino acids 239 and 254. Since it inhibits the MT-dependent migration of granulocytes into areas of inflammation and their MT-dependent release of pro-inflammatory agents, it is used to treat attacks of gout. Its antimitotic effect in the gastrointestinal system induces diarrhea. Nocodazole competes for the same binding site as colchicine and has similar effects on heterodimeric β -tubulin.

Definition

The recent increase in the amount of biological data raises the questions of storage and accessing, modelling and computing, description and understanding of these

data ... and makes data mining indispensable. Fortunately, in the same period, new and cheaper computers with a larger storage capacity and faster processing have been produced, enabling storage and computing of this information (= cheap data). New machine learning methods based on logic programming have been developed. Associated with the traditional statistical tools, they have made the modelling and analysis of these data possible and easier. Storage in databases allows the linkage of this information and assignation of functions. Here we have reached an apparently illogical point; we have first produced and collected more and more data, and now we try to find a use for them, a question which they could answer, whereas the classical scientific approach is first to have a question and then to collect data to try to answer it. In fact, the amount of data may be voluminous, but it is of low value, as no direct use can be made of it. It is the information hidden in this large volume of raw data that is useful. The idea is that it is possible to strike gold in unexpected places by extracting information not obviously discernable (or so obvious that no-one noticed it before!). Data mining is the process of automatically extracting such hidden knowledge. It can be like searching for a needle in a haystack ... and it often is!

The following review describes data mining in general and then focuses on data mining in biology with the example of ►Expressed Sequence Tag (EST) mining.

Characteristics

General Method or “How to Mine Data”

Data processing can be divided into several steps (Fig. 1). Scientists do not really agree on a common definition; some argue that it is the extraction of data, others that it is the whole process of data processing or a part only of this process. Let us consider in this review three general stages in data mining.

Exploration

This stage usually starts with data preparation, which involves data cleaning, data transformation, data selection and feature selection if data are characterized by a large number of features.

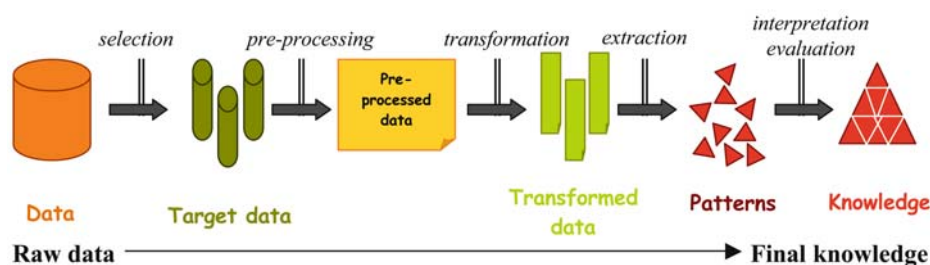

The data-cleaning step has to be done carefully. The old saying “garbage-in, garbage out” is particularly applicable to data mining projects where large sets of automatically collected data serve as input. The method of gathering data is often not well controlled and data might contain out of range values (e.g. sequence size: – 100) or impossible combinations (e.g. newborn – age: 30 years), producing highly misleading results.

If the dataset is too large, it has to be reduced to a more manageable size by selecting specific data or reducing the feature number. Data can be selected according to some criteria (e.g. sequences >500 bp) or reduced using aggregation (e.g. group together sequences >500 bp) or ►clustering. The selection of features consists of discarding those that are not useful for the actual model-building phase.

Optimal Representation of the data structure and Validation

This stage involves considering various models and choosing the best one based on its predictive performances, i.e. in explaining the variability in question and producing stable results across samples. This may sound like a simple operation but it sometimes involves a very elaborate process. There are a variety of techniques developed to achieve this goal; many of them are based on the “competitive evaluation model”. This consists of applying different models, based on different methods, to the same set of data and comparing their performances to choose the best. Classical methods are based on ►nearest neighbour, clustering, ►decision tree, ►neural networks and ►genetic algorithms. The choice of one or the other method depends on the data gathered, on the problem to be solved and on the available computing tools.

Data verification is a primordial step often neglected to save time. Exploration of data is only the first stage of the analysis and the results cannot be considered as reliable as long as they are not confirmed. The validation of the results can be achieved by applying the model to another data set - or independent subsets - and checking for the predictions or experimentally confirming the results.

Data-Mining in Biology, “How to Find a Needle in a Haystack?”. Figure 1 The pipeline of data processing.

Application of the model to New Data in order to generate predictions

The final stage involves using the model selected as best in the previous stage and applying it to new data in order to generate predictions or estimate the predicted outcome.

EST Mining

Applications of data mining in biology are countless, sequence mining (6), pattern identification (5, 9), pathway discovery (7, 12), gene expression analysis (micro arrays, ESTs, ►SAGE...) to the whole genome or to specific tissues (4, 8, 10, 13) and much more.

►ESTs are tags representing expressed genes, thus they are often used in genome annotation or in pseudogene discovery. Because the frequency of ESTs representing a gene gives information on its abundance, ESTs are widely used in gene expression analysis as well. Moreover, the large amount of EST data allows analysis of a large number of genes from a given organism(s) and in a given condition(s). Countless resource centres based in almost every country provide EST data and/or tools to help in EST mining. The main ones are the NCBI (National Centre for Biotechnology Information) and the EBI (European Bioinformatics Center). Besides storing all kinds of data, they provide tools for their analysis such as sequence comparison, expression analysis and genome comparison (Table 1).

The analysis of EST generally involves the following steps.

Exploration

• Data Selection

dbEST lists all the ESTs and libraries publicly available. In April 2004, dbEST contained 20,624,959 entries (release 040204) in more than 700 organisms. But not all of them are useful in a given analysis. Thus the first step in any EST analysis is to select the useful ESTs and libraries. Some ESTs are too short to be of any use and must be removed. Others contain repeats, vectors or low quality sequences that have to be masked (using RepeatMasker – A.Smit and P.Green, unpublished data). Some libraries containing too few ESTs are not considered reliable enough for analysis of the gene expression level and have to be discarded. Libraries generated from the same organ can be pooled because the protocols used to generate them are more or less the same. Such virtual libraries are often used instead of the individual libraries. For each new study, this step of data selection has to be redone because the criteria for EST or library usefulness may vary.

• EST Clustering

Because a gene can be represented by several ESTs, the next step is often an EST clustering. It consists of grouping ESTs corresponding to a single gene. Depending on the stringency of the clustering, a gene can be represented by one cluster or by as many clusters as it has transcripts. Some clusterings already exist. UniGene for example, contains GenBank sequences partitioned into a non-redundant set of gene-oriented clusters. Each UniGene cluster contains sequences representing a unique gene and related information, such as the tissue types in which the gene is expressed and the genomic location. But some prefer to do their own clustering, choosing parameters more suitable to their study. For example, ESTs can be pairwise compared using the well known program ►BLAST (1) and overlapping ESTs are grouped in the same clusters. This solution is time consuming but generally gives better results because the clustering fits the study requirements exactly.

• EST Contiguing

In some cases, a last step of EST contiguing is done. EST from a cluster are concatenated in one or several sequences, depending on the stringency of the clustering and the concatenation, representing a gene and its transcripts. “Ready-to-use” contigs were generated by some groups. In GeneNest, for example, each gene is represented by a single

cluster of ESTs and/or mRNAs. A cluster might be sub-divided into several contigs because of alternative splicing, genomic sequences or artefacts like chimeric sequences. Such gene indices are available for a few organisms, including human. Again, some prefer to do their own concatenation. Using CAP3 from the STADEN package, for example, ESTs from the same cluster are aligned and a consensus sequence representing the alignment is generated. A putative identity can be assigned to each gene by querying it against the GenBank database.

Representation and Validation

Several pieces of information can be obtained for the genes represented by these clusters and/or contigs.

- **Genomic Location**

The consensus sequence of a gene generated through this method could be the basis for mapping to the genome. Because the consensus sequences represent expressed genes, it helps to discard genes (expressed) to pseudogenes (non expressed). ENSEMBL provides genomic maps of genes for various species. If available, the EST information is shown on the maps.

- **Expression Profiles and Differential Expression**

The expression profile of a gene can be derived from the frequency of the cognate ESTs in the various libraries. This method is called Northern electronic as opposed to the classical Northern (inappropriate for large scale analysis) or to micro-arrays and is cheaper and easier to develop. However, more and more micro-array analyses are now available on the Internet. The Gene Expression Omnibus from the NCBI is a repository for gene expression and molecular abundance data and contains micro-array data. Similarly, the EBI provides access to a public repository for micro-array based gene expression data through ArrayExpress. The probability of differential expression of a gene can be derived from its expression profile. Several tests were developed, according to the initial data set and the question (2). Most biologists do not really like using statistics; fortunately several "ready-to-use" tests exist. Expression Profiler developed at the EBI, is a set of tools for clustering, analysis and visualization of gene expression and other genomic data. It even allows integration of a specific test or method.

- **Co-regulation? Co-expression?**

By comparing expression profiles of several genes, co-expressed genes can be identified. Such genes can be involved in the same metabolic pathway and/or be co-regulated. Gene correlation is a powerful tool to determine the function of unknown genes or the regulation pattern.

If a gene of unknown function is co-expressed with genes of known function, it may have the same function or be involved in the same pathway. By comparison of the promoter regions of co-expressed genes, common motifs can be identified. Such motifs are potentially involved in the regulation of genes.

The last step of data mining previously described, "Application to new data", is not represented here. However, the same protocol can be applied to any other tissue and/or condition, given that there are enough EST data.

Conclusion

Everybody can do data mining; provided that the data set is large enough. The questions we must ask are "Are the results reliable?", "Did the user take all the precautions required?". Always remember that data mining has limitations (noisy, dynamic and missing data). It is not always possible to eliminate, or at least to minimize these problems, but being aware of these limitations enables us to better interpret the results.

Clinical Relevance

EST mining is not a final analysis *en-soi*. The expression profiles generated for hundreds of genes suggest more questions. Are genes co-expressed? Are they co-regulated? Are they specific to a tissue? These questions are more relevant to the medical field. By combining the results of EST mining with *in situ* hybridisation techniques, Gitton et al. (3) have associated a list of genes with a potential biological role and suggested candidates for Down syndrome. But the biological role of these candidates has to be confirmed before any clinical use. If EST mining, and data mining in general, raise some questions, they do not ultimately answer any of them, they only give predictions that have to be experimentally validated.

Death Domain Fold Protein Superfamily

Definition

The death domain (DD), death effector domain (DED), and caspase recruitment domain (CARD) comprise of families of proteins that share a conserved fold characterized by a bundle of six helices. The proteins of these families are therefore grouped together in the death domain-fold super family. Based on computational analysis, the recently discovered PYRIN domain has also been predicted to accomplish a death domain-fold like structure. The death domain-fold represents a functional unit mediating protein-protein interactions found in many proteins with a role in signaling events that regulate apoptosis and inflammation. Typically, the subfamilies of the death domain-fold proteins undergo homophilic interactions. Thus, a DD interacts with a DD, a DED with a DED and a CARD with a CARD.

Synonyms

Amyloidosis; protein conformational diseases; protein misfolding disorders; proteopathies

Definition

Defective ►protein folding disorders (DPFDs) are a group of diverse neurological and systemic diseases in which the hallmark pathological event is the misfolding, aggregation and accumulation of a protein in different organs, inducing cellular ►apoptosis, tissue damage and organ dysfunction (Fig. 1). This group includes ►Alzheimer's disease, transmissible spongiform encephalopathies, serpin-deficiency disorders, sickle cell anemia, ►Huntington's disease, diabetes type II, amyotrophic lateral sclerosis, ►Parkinson's disease, dialysis-related amyloidosis, spinocerebellar ataxias, secondary or reactive amyloidosis and more than 15 other less well-known diseases (Table 1).

Defective Protein Folding Disorders. Figure 1 A working hypothesis for the molecular mechanism of defective protein folding disorders. Misfolding, aggregation and accumulation in tissues leading to cell death and organ failure might be the common cause of several etiologically diverse human diseases.

Characteristics

DPFDs include diseases with very different clinical manifestations and symptoms. However, these disorders share some common features, namely most of them have both sporadic and inherited origins, all of them appear later in life (usually after the fourth or fifth decade) and their pathology is characterized by cellular loss and protein deposits in the dysfunctional organ. Several studies from different disciplines and of distinct diseases strongly support the hypothesis that the central event in DPFDs is a change in the secondary and/or tertiary structure of a normal protein, which is not always linked to alterations in the primary structure (Fig. 1). There is no evident sequence or structural homology among the proteins implicated in DPFDs. However, the striking feature of these proteins is their ability to fold into a stable alternative conformation, which in most cases is rich in β -pleated sheet structure and has a high tendency to aggregate and accumulate as intra- or extra-cellular fibrillar deposits known as **►amyloid**. The correlation and co-localization of protein aggregates with degenerating tissue and disease symptoms is a strong indication of the involvement of protein misfolding and aggregation in the pathogenesis of DPFDs. Moreover, protein deposits have become a typical signature of these diseases and their presence is used for definitive diagnosis. However, it is still a matter of controversy as to whether the deposits of aggregated protein are the cause of the disease or an inseparable epiphenomenon.

Mechanism of Protein Misfolding and Aggregation

Structural studies have shown a large conformational re-arrangement of the polypeptide chain during the process of misfolding and aggregation. The starting point in DPFDs is the natural protein folded in the native and active conformation, which is usually a mixture of α -helical and random structure and the end point is the same protein aggregated and adopting a β -pleated sheet conformation (Fig. 1). However, it is unknown whether the misfolding triggers protein aggregation or protein oligomerization induces the conformational changes. On the basis of the available evidence, it is likely that slight conformational changes result in the formation of a misfolded intermediate, which is unstable in an aqueous environment because of exposure of hydrophobic segments to the solvent. This unstable intermediate is stabilized by intermolecular interactions with other molecules, forming small β -sheet oligomers, which by further growth produce amyloid fibrils. In this model the conversion of the folded protein into the pathological form is triggered by structural changes, but complete misfolding depends upon protein oligomerization.

Several environmental factors have been proposed to promote protein misfolding and aggregation, including metal ions, pathological **►chaperone proteins**, pH, **►oxidative stress**, macromolecular crowding and an increase in the concentration of the misfolded protein. Many of these alterations are associated with aging, consistent with the late onset of most DPFDs. Kinetic

Defective Protein Folding Disorders. Table 1 A list of some Defective Protein Folding Disorders and the protein implicated

Diseases	Protein involved
Alzheimer's disease	Amyloid- β protein, Tau
Parkinson's disease	α -synuclein
Huntington's disease	Huntingtin
Spinocerebral ataxias	Ataxins
Transmissible spongiform encephalopathies (Creutzfeldt-Jakob disease, Gerstmann-Straussler, etc)	Prion protein
Amyotrophic lateral sclerosis	Superoxide dismutase
Type II diabetes	Islet amyloid polypeptide
Primary amyloidosis (implicated in multiple myeloma, β -cell dyscrasias)	Immunoglobulin light chain
Secondary or reactive amyloidosis (implicated in familial Mediterranean fever, rheumatoid arthritis, etc)	Amyloid-A
Hemodialysis-related amyloidosis	β 2-microglobulin
Senile systemic amyloidosis, familial amyloid polyneuropathy	Transthyretin
Hereditary cerebral hemorrhage with amyloidosis Icelandic-type	Cystatin C
Familial amyloidosis, Finnish-type	Gelsolin
Sickle cell anemia, inclusion-body hemolysis	Hemoglobin
Familial amyloid polyneuropathy	Apolipoprotein A-I
Amyloidosis in senescence	Apolipoprotein A-II
Hereditary non-neuropathic systemic amyloidosis, familial visceral amyloidosis	Lysozyme
Serpin deficiency disorders (cirrhosis, thromboembolic disease, angioedema)	Serpins (α 1-antitrypsin, α 1-antichymotrypsin, etc)

studies have shown that protein aggregation follows a seeding/nucleation mechanism, which resembles a crystallization process. The critical event is the formation of protein oligomers that act as a nucleus to direct further growth of aggregates. Nucleation-dependent polymerization is characterized by a slow lag phase in which a series of unfavorable interactions forms an oligomeric nucleus, which then rapidly grows to form larger polymers. The lag phase can be minimized or removed by addition of pre-formed nuclei or seeds.

Mechanism of Tissue Damage by Misfolded Proteins

The conformational change may promote the disease by either the toxic activity of the misfolded protein or

by the lack of the biological function of the natively folded protein, which is depleted during misfolding and aggregation. Some of the proteins associated with DPFs have known biological functions. However, knock out animals lacking these proteins have in general failed to show a phenotype similar to the disease. The most widely accepted theory of tissue degeneration in DPFs proposes that misfolding and aggregation result in the acquisition of a toxic function by the misfolded protein. This concept is based on direct induction of cellular apoptosis *in vitro* by aggregates of several misfolded proteins (or fragments of the proteins). Additional support for this hypothesis comes from experiments with ►transgenic animals, where incorporation of the human mutated gene for the

misfolded protein has been shown to be enough to trigger protein accumulation and tissue degeneration. There is also evidence that β -sheet oligomerization of non-disease-related proteins result in highly cytotoxic structures, indicating that misfolding and aggregation of any protein may lead to inherent toxicity. This concept provides a unifying mechanism of cell death and tissue degeneration in protein misfolding disorders. Several mechanisms have been proposed for the neurotoxic activity of misfolded aggregates, and it is likely that different pathways operate, depending on whether the proteins accumulate intra- or extracellularly. Extracellular aggregates might activate a signal transduction pathway leading to apoptosis by interacting with specific cellular receptors. Intracellular aggregates might damage cells by recruiting factors essential for cell viability into the fibrillar aggregates. Another proposed mechanism is membrane disruption and depolarization mediated by incorporation of the misfolded aggregates into the membrane inducing the formation of ion channels, resulting in alteration of ion homeostasis and deregulation of cellular signal transduction leading to cell death. Finally, protein aggregates could induce oxidative stress by producing free radical species, resulting in protein and lipid oxidation, elevation of intracellular calcium and mitochondrial dysfunction.

Genetics

Most DPDFs have both inherited and sporadic origins. The percentage of hereditary cases varies depending on the particular disease. Interestingly, mutations in the genes encoding the protein component of fibrillar aggregates are genetically associated with inherited forms of the disease. The familial forms usually have an earlier onset and higher severity than sporadic cases. In the familial cases, a mutation may destabilize the normal protein folding, favoring the misfolding and aggregation of the protein. Mutations in the respective fibrillar proteins have been associated with familial forms of many diseases, including Alzheimer's, Parkinson's, Huntington disease and related polyglutamine disorders, amyloid polyneuropathy, cardiac amyloidosis, visceral amyloidosis, cerebral hemorrhage with amyloidosis of the Dutch and Icelandic types, cerebral amyloidosis of the British and Danish types, thromboembolic disease, angioedema, emphysema, sickle cell anemia, amyotrophic lateral sclerosis, etc.

► **Transmissible spongiform encephalopathies** (TSEs) are unique among DPDFs in that, in addition to having genetic and sporadic origins, they can also be transmitted by infection. TSEs, also known as prion disorders, include Creutzfeldt-Jakob disease, fatal familial insomnia, Gerstmann-Straussler syndrome in humans and bovine spongiform encephalopathy,

chronic wasting disease and scrapie in animals. The TSE infectious agent, known as a prion, is composed mainly (or exclusively) of misfolded prion protein, which is called PrP^{Sc} to differentiate it from the normally folded protein, termed PrP^{C} . The fact that the full pathological and clinical characteristics of prion diseases can be propagated from individual to individual by serial passage of pure PrP^{Sc} is a good indication that the misfolding of the prion protein is the most likely cause of the disease. Transmission depends on the conversion of host PrP^{C} into the misfolded protein, which is induced by infectious PrP^{Sc} . None of the other protein conformational disorders has been convincingly shown to be transmissible. However, in animal models of Alzheimer's disease and systemic conformational disorders associated with deposition of amyloid-A in spleen and apolipoprotein A-II in several organs, the disease pathology can be accelerated by injection of tissue homogenate enriched in the misfolded protein. Although not associated with a disease, other examples of propagation of phenotypic changes by transmission of protein misfolding have been found in yeast and other fungi. In these organisms different proteins can adopt alternative conformations with different activities, and the misfolded protein aggregates can convert the monomeric folded protein *in vitro* and *in vivo*.

Molecular Diagnostics and Therapy

At present there is no accurate molecular diagnosis for DPDFs. The diagnosis is done mostly by observation of the clinical symptoms and by exclusion of other similar pathologies. The accuracy of clinical diagnosis is variable depending on the specific disease of the group. Since many of these diseases have an inherited origin, genetic testing for mutations associated to proteins involved in misfolding is very useful for diagnosis. However, in most DPDFs only a fraction (sometimes less than 1%) of the cases are inherited. Therefore, genetic testing cannot be used as the only diagnostic tool in these diseases. In many cases the definitive diagnosis is established by post-mortem examination and detection of misfolded aggregates accumulated in the tissue. In the diseases where the protein is deposited in organs in which biopsy is possible, this helps to establish a definitive diagnosis. No imaging technology or biochemical markers have been validated for diagnosis of diseases associated with protein misfolding and aggregation. However, recent efforts have resulted in the identification of small chemical compounds, amyloid binding proteins and peptides that can bind specifically to the aggregates. Labeling of these molecules with a reagent that allows imaging may lead to the design of non-invasive diagnostic tools.

Despite dramatic progress in understanding the contribution of defective protein folding to the pathogenesis of DFPDs, none of these diseases has, as yet, a treatment aimed at inhibiting and correcting protein misfolding. Many of the illnesses of the group have no efficient treatment, some have a therapy directed to alleviation of the clinical symptoms, but there is certainly an important need for treatments focused on altering the cause of the disease. At least four approaches have been proposed to attack protein misfolding and aggregation, stabilization of the native protein conformation, inhibition and reversal of defective protein folding, competitive inhibition of protein oligomerization and increased clearance of the misfolded protein. Recent exciting research has shown *in vitro* and in animal models the validity of these strategies and some compounds are already in clinical trials to evaluate their efficacy in humans. The results of these tests might provide not only novel and more efficient therapies, but might also definitively prove the involvement of protein misfolding and aggregation in the pathogenesis of a variety of diseases.

Degradation Signals

Definition

In early experiments, the Varshawsky group searched for special destruction signals for the ubiquitin system. One of the most prominent signals was deg-1, which represents the N-terminal part of the yeast Mat α 2-repressor. The fusion protein between deg-1 and other proteins is rapidly degraded by the ubiquitin-proteasome system. Two other destruction signals are the Destruction-box (D-box) and the KEN-box. Both are located in the N-terminus of cyclins and CDC20, which are substrates for the APC.

kgreen@northwestern.edu

Definition

The desmosome is a ►cytoskeleton-linked attachment junction connecting cells to each other in epithelia and some muscle cell tissues. Desmosomes form structural connections between keratin networks from one cell to another. Keratins bind to desmoplakin proteins in the cytoplasmic plaques of these junctions and special cadherins, the desmogleins and desmocollins, span the membrane and interact across the intercellular space with desmosomal cadherins of the neighbouring cell, forming electron-dense threads and the midline overlap of the junction. Other components provide stability and regulation of the junctions.

Characteristics

Desmosomes, also known as maculae adherens, are specialized cellular structures required for strong ►cell-cell adhesion. One of several types of ►intercellular junctions, desmosomes mediate strong adhesion by anchoring the ►intermediate filament (IF) cytoskeleton to molecular plaques, or “spot welds” between adjacent cells. Desmosomes are found in several tissues including the epidermis and within the myocardium. Due to the fact that these tissues are subject to frequent mechanical stress, strong intercellular adhesion is necessary to

maintain their integrity (1). Desmosomes have also been described in non-stress bearing tissues such as the arachnoid meningeal layer and dendritic cells in lymphoid follicles (2, 3).

The desmosomal plaque is composed of three major protein families, ►cadherins, ►Armadillo proteins, and plakins (2). The desmosome is similar to the ►adherens junction in that it forms cadherin mediated cell-cell attachments by anchoring cytoskeletal filaments into a juxtamembrane plaque. Whereas adherens junctions contain classical E-cadherin and are associated with the ►actin cytoskeleton, desmosomes have a more heterogeneous collection of desmosomal cadherins and are coupled to the IF cytoskeleton through different adaptor proteins (Fig. 1). While the plaque components differ between the adherens junction and the desmosome, several desmosomal plaque proteins have been observed to associate with adherens junction components. During processes such as wound healing in which migrating cells are brought into contact, adherens junctions form earlier in the process than desmosomes and the formation of adherens junctions is thought to be required for the ensuing formation of desmosomes (2, 4).

Recently, additional roles for desmosomal adhesion have been elucidated. Desmosome components are important in inhibiting the motility and invasive activity of tumor cells, regulating tissue development and morphogenesis and wound healing and have been implicated in non-adhesive functions including modulation of intracellular signaling pathways, transcriptional gene activation, cellular response to growth factor stimulation and ►apoptosis.

Ultrastructural Appearance

In the electron microscope, the desmosome appears as an electron-dense structure at cell-cell appositions.

Desmosomes. Figure 1 Desmosome and Adherens Junction Schematic Diagram. This simplified diagram demonstrates cadherin heterodimer-mediated adhesion between adjacent cells. The desmosomal cadherins desmoglein and desmocollin span the plasma membrane and interact with other desmosomal cadherins through conserved residues in the amino-terminal domains in the extracellular space. Armadillo proteins plakoglobin and plakophilin interact with the cytoplasmic domains of the cadherins and mediate the attachment of intermediate filament-binding plakin protein desmoplakin to the cadherin complex.

This structure has been divided ultrastructurally into three domains, the extracellular domain, the outer dense plaque and the inner dense plaque. Flanked by the adjacent plasma membranes is a 30 nm-wide extracellular domain with a dense midline resembling a zipper. This extracellular domain is composed of the ectodomains of the desmosomal cadherins desmoglein and desmocollin. Immediately adjacent to the plasma membrane in the cytoplasm one finds the outer dense plaque (ODP). The outer dense plaque is a 15–20 nm-wide electron-dense band that includes the intracellular domain of the cadherins, the Armadillo proteins plakoglobin and plakophilin, and the amino-terminal domain of desmoplakin. Intracellular to the ODP is a region called the inner dense plaque, which is less electron-dense than the ODP and contains the desmoplakins. IFs can be observed to insert directly into the IDP (Fig. 2) (1, 5).

By immunofluorescence light microscopy, desmosomes appear at the cell-cell borders in epithelial colonies in cell culture. Whereas adherens junctions stained by fluorophore-conjugated antibodies have a more continuous, linear appearance around the cell-cell borders, desmosomes appear in a discontinuous “railroad track” pattern. Viewed *en-face*, desmosomes display a punctate, “spot-weld”-like appearance. When the IF cytoskeleton is counterstained, the filaments appear to project almost to the plasma membrane where they co-localize with the desmosomal components. While desmosomes are present at the lateral borders of cells in a monolayer or in simple epithelial tissues, desmosomes in a

▶**stratified epithelium** are found on all cell-cell interfaces except at the basement membrane.

Physiological Significance

The importance of desmosomes in maintaining tissue integrity is demonstrated by the phenotypes of the ▶**bullous** skin diseases. ▶**Autoimmune** diseases ▶**pemphigus** vulgaris and pemphigus foliaceus are two such skin diseases in which desmosome components are the specific targets of autoantibodies. Additionally, bacterial toxins can target desmosome components in the skin and achieve similar skin pathologies. Certain genetic mutations in desmosome components result in congenital diseases involving multiple organ systems including the skin and its appendages and the cardiovascular system. Mouse models of these genetic diseases display severe skin defects or even lethality during embryogenesis. Finally, loss of desmosomal intercellular adhesion occurs in some types of tumor cells, conferring to these transformed cells a more metastatic tumor profile.

Molecular Interactions

Desmosomal Cadherins

Desmosomal cadherins are calcium dependent ▶**type I transmembrane glycoproteins** that mediate direct intercellular attachment most likely through heterotypic cadherin-cadherin interactions. There are two subfamilies of desmosomal cadherins, the desmogleins (Dsgs), and the desmocollins (Dscs).

Desmosomes. Figure 2 Electron Micrograph Image of Bovine Tongue Epithelium. Desmosomes appear as electron-dense “spot weld” structures between adjacent epithelial cells (arrows). Regions of the plasma membrane that contain desmosomes are closely apposed whereas extracellular spaces are observed in regions without desmosomes. Intermediate filaments project from the cytoplasm into the plaque, where they act to anchor the junction and strengthen intercellular adherence. ES, extracellular space; IF, intermediate filaments.

There are four Dsg isoforms in humans, Dsg 1–4, encoded by separate genes on chromosome 18. Dsgs contain four conserved extracellular ectodomains important in calcium binding and cadherin hetero- and homophilic interactions. Flanking the membrane-spanning region are two more variable anchor domains, the extracellular and intracellular anchors. The cytoplasmic region of the Dsgs contains an intracellular cadherin-type segment (ICS), which is highly conserved among the cadherins, and a proline rich linker (IPL) region. At the carboxy-terminal, the Dsgs have a long intracellular tail encoding a repeating unit domain (RUD), and a Dsg terminal domain (DTD). The three Dsc isoforms are similar in structure to the Dsgs except for a truncated intracellular region consisting only of the intracellular cadherin segment followed by eleven amino acids specific to one of the Dsc isoforms (2, 3, 6). In stratified epithelia such as the skin, [▶keratinocytes](#) originate at the basal layer and move superficially as they become terminally differentiated. The different Dsg and Dsc isoforms are expressed at distinct stages of epithelial differentiation. The Dsg 1/Dsc 1 pair is concentrated in the superficial layers of the epidermis whereas the Dsg 3/Dsc 3 pair is expressed abundantly in the less differentiated basal and suprabasal layers. Dsg 2 and Dsc 2 are expressed basally with Dsc 2 tapering off more superficially than Dsg 2 (2). Variations in this differential expression pattern are associated with different types of complex epithelia. For example, the ratio of Dsg 3 to Dsg 1 is high in the basal layers of skin epidermis, but it drops off sharply in the superficial layers where Dsc 1 is concentrated. On the other hand, the Dsg 3/Dsg 1 ratio is high throughout all layers of oral mucous membrane, where Dsg 3 is expressed more uniformly compared with epidermis (7). Furthermore, desmosomal cadherin differential expression is considered to be a possible mechanism for the regulation of epithelial development and differentiation.

Cadherin Related Diseases

Desmosomal cadherins are the targets of both autoimmune and bacterial pathogenesis. Autoimmune blistering diseases pemphigus vulgaris (PV) and pemphigus foliaceus (PF) are caused by autoantibody production against Dsg proteins in the epidermis. Inactivation of desmosomal cadherin interactions then leads to [▶acantholysis](#), which is the formation of intercellular spaces within the epidermis between keratinocytes. This loss of adhesion leads to weakened skin integrity and the development of large blisters develop upon mechanical insult.

In mucosal PV, production of autoimmune antibodies against Dsg 3 leads to disruption of desmosomal junctions between cells in the deep basal layers of the

epidermis resulting in erosions in the oral mucosa. In this form of PV, the skin is less affected by anti-Dsg 3 antibodies than the mucosa because Dsg 1 expression compensates for the loss of Dsg 3. However, in the mucocutaneous form of PV, autoantibodies against Dsg 3 and Dsg 1 result in oral and epidermal blistering. In PF, autoantibodies target Dsg 1, leading to less severe blistering due to the more superficial expression of Dsg 1 relative to Dsg 3. PF-like blisters can be observed in *Staphylococcus aureus* infections such as [▶staphylococcal scalded skin syndrome](#) (SSSS) and [▶bullous impetigo](#). Rather than an autoantibody attack on Dsgs, the secreted bacterial exfoliative toxin targets and cleaves Dsg 1 resulting in loss of adhesion in the epidermis (7).

Mutations in the *DSG* genes manifest in an array of dermatologic and cardiac diseases. Loss of Dsg 1 expression results in a skin disorder called striate palmoplantar keratoderma (SPPK), in which the patient's palms and soles exhibit [▶hyperkeratosis](#) or epidermal thickening in a striped or striated pattern and superficial epidermal blisters. Mutations in Dsg 4 result in defective hair follicle differentiation. Similar epidermal fragility phenotypes were observed in *DSG/DSC* knockout mouse models (3).

Armadillo Proteins

The presence of desmosomal cadherins alone is not sufficient to form desmosomal cell-cell adhesion. Adaptor proteins, which mediate the attachment of the IF cytoskeleton to the intracellular plaque are required for the formation of mature desmosomes. One group of such adaptor proteins comprises Armadillo family members that directly interact with the cadherins. Both desmosomes and adherens junctions contain Armadillo protein family members that link IF- or actin-binding proteins to the cadherin cytoplasmic tail. Armadillo, a *Drosophila* protein, activates gene transcription when it accumulates in the cytoplasm in response to [▶Wnt/Wg](#) signaling and is important for determining segment polarity during *Drosophila* morphogenesis. Armadillo related proteins contain three major domains, an amino-terminal head domain followed by a central domain consisting of arm repeats and a carboxy-terminal tail. The central arm domain is highly conserved between the different family members and comprises twelve imperfect 42-amino acid repeats. This region is important in mediating protein-protein interactions and is responsible for binding to cadherins and other proteins. In the desmosome, plakoglobin (γ -catenin) and the plakophilins are the major Armadillo proteins whereas [▶ \$\beta\$ -catenin](#) and p120-catenin are the major Armadillo proteins present in the adherens junction.

Plakoglobin

In the desmosome, the Armadillo family member plakoglobin acts as a linker between the cadherin cytoplasmic tail and the IF-binding protein desmoplakin. While it is required for keratinocyte cell-cell adhesion and desmosome formation, plakoglobin, like β -catenin can be found in the nucleus and is implicated in the modulation of \blacktriangleright TCF/Lef transcriptional activation and in regulating desmosome size. Plakoglobin binds directly to desmosomal or classical cadherins, IF- or actin-binding proteins and plakophilins (see below). In contrast to β -catenin, whose junctional localization is limited to the adherens junction, plakoglobin can associate with both desmosomes and adherens junctions. These junctional interactions are mutually exclusive, meaning that plakoglobin bound to desmosomal components cannot also bind to adherens junction components, and *vice versa* (2). The ability of plakoglobin to associate with both types of adhesion junctions suggests a possible role in mediating cross talk between junctions.

The importance of plakoglobin in maintaining the desmosomal plaque is underscored by the diseases in which plakoglobin is not present. Plakoglobin truncation mutations in humans result in Naxos disease, which is a congenital syndrome consisting of woolly hair, SPPK and arrhythmogenic right ventricular cardiomyopathy. Some plakoglobin-null mice die in the embryonic stage due to heart failure, and some die later due to epidermal defects (3).

Outside of its desmosomal role, plakoglobin has been implicated in a number of signaling pathways in certain cell types. In addition to interacting with LEF/Tcf signaling molecules, plakoglobin may regulate intracellular signaling by binding to and acting as a substrate for tyrosine kinases like epidermal growth factor receptor (EGFR) and Src and some phosphatases (2). Plakoglobin may also play a role in neoplastic transformation and tumor progression. This idea is supported by its ability to induce proliferation when over-expressed in tumor cells, and to stimulate the anti-apoptotic pathway by induction of Bcl-2 (8). However, plakoglobin can also act as a tumor suppressor by suppressing hyperproliferation in other cell types. Moreover, loss of plakoglobin expression has been exhibited in some types of ovarian, lung and breast cancers.

Plakophilin

The desmosomal adaptor protein plakophilin is another Armadillo family member that plays structural and possible regulatory roles in the desmosome and in mediating transcriptional activation within the nucleus. Plakophilin is closely related to the Armadillo protein p120catenin, which is present in the adherens junction and in the nucleus and plays similar structural and

possibly signaling roles. Plakophilins have been suggested to mediate lateral junctional interactions, possibly by stabilizing junctions and increasing adhesive strength. There are three plakophilin isoforms, plakophilins 1–3, which are expressed in a differential tissue distribution. Junctional plakophilin 1 is expressed suprabasally in stratified epidermis. Plakophilin 2 is the most widely expressed plakophilin, found in all layers of epithelia, myocardium and in lymph nodes. Plakophilin 3 is found in most simple and stratified epithelia. Only one human plakophilin-related disease has been described to date. Congenitally inherited loss of plakophilin 1 expression leads to ectodermal dysplasia or skin fragility syndrome in which patients exhibit cutaneous fragility, and epidermal thickening of the palms of the hands and soles of the feet (2, 3).

The role of plakophilin is not as well characterized as that of other Armadillo proteins; however, there is biochemical evidence demonstrating that the plakophilins bind to the desmosomal cadherins, keratin (an IF expressed in keratinocytes and other epithelial cells), plakoglobin, and the adherens junction protein β -catenin. The plakophilins also bind directly to desmoplakin and serve in its recruitment to cell-cell borders. It is thought that plakophilin and p120catenin are also important in regulating the actin cytoskeleton because over-expression of p120catenin and some plakophilins has been shown to induce the formation of filopodial-like cytoplasmic protrusions in several different cell types. Other signaling functions of the plakophilins are demonstrated by their ability regulate cytoplasmic β -catenin signaling and by the localization of plakophilin 2 to the nucleus where it binds to the RNA polymerase III complex (2, 3, 6). However, plakophilin's specific role in these signaling pathways has yet to be elucidated.

Desmoplakin

Desmoplakin is the major mediator of IF attachment to desmosomal cadherins and is essential for desmosome formation. Desmoplakin is a member of the plakin family, which also includes, but is not limited to, plectin, envoplakin and periplakin. Desmoplakin mRNA is alternatively spliced to yield two isoforms, desmoplakin I and desmoplakin II. Desmoplakin is a large dumbbell-shaped molecule with globular amino- and carboxy-terminal domains and a coiled coil central rod domain. In desmosomes, desmoplakin interacts with cadherins and Armadillo proteins through its amino-terminal domain and with the IF cytoskeleton through its carboxy-terminal domain (3).

Haploinsufficiency or loss of desmoplakin results in SPPK. Patients with SPPK exhibit striations on the palms and soles, woolly hair and can also develop arrhythmogenic right ventricular cardiomyopathy

(ARVC). Desmoplakin is critical for the maintenance of desmosome strength through its attachments to the IF cytoskeleton (2, 3). Desmoplakin-null mouse models die very early in embryogenesis, however chimeric desmoplakin knockouts in which only extra-embryonic tissues express desmoplakin die later in embryogenesis due to abnormalities in the vascular, epidermal-, cardiac- and neuroepithelial-tissue precursors. Conditional desmoplakin-null mice in which desmoplakin is knocked out in the epidermis display abnormal desmosomes and severe skin fragility (3).

Regulatory Mechanisms

Regulation of desmosome assembly and disassembly is the focus of current studies. It is known that desmosomal cadherin interactions are calcium sensitive. Early, immature desmosomal junctions disengage in the presence of low calcium and reform when calcium levels are restored to higher levels. However, when desmosomes mature they become less susceptible to disengagement due to alterations in calcium concentrations. It is thought that desmosomes are formed by the movement of desmosomal precursors containing some of the desmosomal components to the plasma membrane (2, 4).

Regulation of cadherin turnover and desmosome stability might also occur through phosphorylation of desmosomal components. Growth factor receptor signaling pathways lead to the phosphorylation of Dsgs and plakoglobin, resulting in disruption of the interactions between desmosomal components and the eventual dissolution of the junction. Evidence from some tumor systems reveals the over-expression or over-activation of Epidermal Growth Factor Receptor (EGFR) and a more motile, non-adherent tumor cell phenotype. Activation of such intracellular signaling pathways results in negative regulation of cell-cell adhesion (2, 6).

Once considered to be static complexes acting solely as anchors for cell adhesion, desmosomes and their components are becoming understood to display complex and dynamic behaviors as they relate to cell adhesion, signaling, growth, shape, motility and development.

Diabetes Insipidus, a Water Homeostasis Disease

MARIEL BIRNBAUMER

Receptor Regulation Section, Laboratory of Signal Transduction, National Institute of Environmental Health Sciences, Research Triangle Park, N.C., USA
birnbau2@niehs.nih.gov

Definition

Diabetes insipidus (DI) is a water ►homeostasis disorder characterized by the partial or total inability of the patient kidneys to produce concentrated urine. The most dramatic symptom of this condition is the passage of large volumes of dilute urine. The urine of these patients contains low concentrations of salts and metabolic products and as a consequence it is less colored. The English rendition of the term diabetes insipidus is “tasteless ►polyuria” as opposed to diabetes mellitus (honey flavored polyuria). The names emphasize the distinction between the polyuria associated with poor water reabsorption and the one caused by urinary excretion of large quantities of glucose. The impairment in water recovery characteristic of DI increases the sodium concentration in blood (hypernatremia), triggering a physiological increase in thirst. If water intake is restricted, hypernatremia can damage the central nervous system leading to mental retardation and death. Individuals suffering any form of DI are very susceptible to severe dehydration.

Characteristics

Water Homeostasis

Production of urine by the mammalian kidney is a consequence of filtration, re-absorption and secretion. The filtered plasma (►glomerular filtrate) is processed by the kidney; amino acids, salts, and glucose are reabsorbed whereas urea, inorganic acids and other products of dietary metabolism are secreted and excreted. Re-absorption is aimed at recovering nutrients and water necessary to maintain the composition of body fluids. The selective process reabsorbs close to 99% of the nutrients and glucose but only 95% of the water. Filtered metabolic waste products and secreted substances remain in the filtrate and become the solutes found in urine. It is estimated that a healthy adult produces approximately 180 l of glomerular filtrate in 24 h. Approximately 170 l/day of filtrate are reabsorbed together with salts, glucose and nutrients, whereas most of the remaining volume (approximately 8 l/day) is re-absorbed by a specific water recovery mechanism. In normal individuals water recovery is hormonally regulated by arginine vasopressin (AVP, also known as antidiuretic hormone or ►ADH), and results in around 2 l of urine/day, a process that is defective in DI patients.

AVP is secreted from the posterior pituitary when special brain receptors detect increases in the plasma concentration of salts. The process is very sensitive, since increases of 1% are sufficient to promote AVP release and stimulate water re-absorption in the kidney collecting ducts. Once the reabsorbed water brings the plasma salt concentration back to normal values (around 300 mOsmol), hormone secretion is inhibited.

AVP controls re-absorption by regulating water permeability in the last portion of the kidney tubules that process the glomerular filtrate.

The V2 vasopressin receptor (►V2R) mediates AVP regulation of collecting duct water permeability. Specialized V2R-containing cells of the renal collecting duct termed ►principal cells are responsible for regulated water recovery. Activation of the V2R by AVP stimulates the production of 3'5'-cyclic adenosine monophosphate (cAMP) by the enzyme ►adenylyl cyclase. The elevated intracellular levels of cAMP activate the enzyme protein kinase A that in turn promotes the movement of the aquaporin2 water channel from the intracellular vesicles where it resides to the apical membrane of the cells that form the tubule. Tubular permeability to water augments due to the increased abundance of aquaporin2 in the membrane and re-absorption is facilitated by the high concentration of salt and urea in the tissue surrounding the collecting tubules. Thus, AVP adjusts the volume of urine excreted to match water intake, producing concentrated urine when the intake is restricted and allowing the excretion of dilute urine when fluid intake is abundant.

Cellular and Molecular Regulation

The Genetics of Diabetes Insipidus

A combination of traditional genetic linkage studies and new molecular biology methods applied to individuals suffering DI identified three genes that if altered can produce this disease. These genes encode the hormone arginine vasopressin (AVP), the V2 vasopressin receptor and the water channel aquaporin2. A mutation in any of these genes can cause DI. The characteristics of the different genotypes are summarized in Table 1; all are rare diseases.

Familial neurogenic or neurohypophyseal DI is caused by lack of the hormone AVP. Its manifestation is autosomal dominant, the gene does not reside in a sex chromosome and a single mutant allele produces the phenotype. Nephrogenic DI is caused by a lack of active V2 receptors or functional aquaporin2 channels. Alterations of the V2 receptor cause approximately 95% of the cases of nephrogenic DI (NDI), while aquaporin2 changes account for the remaining 5%. Both proteins are expressed only in the principal cells of the collecting ducts and are required for AVP regulation of water re-absorption. These diseases have distinct inheritance patterns determined by the chromosomal location of the genes, autosomal for aquaporin2 or sex-linked for the V2 receptor.

Some medications and toxic agents can alter water re-absorption in the kidney mimicking diabetes insipidus; whether their target is specific or not, remains speculative. This summary focuses on the genetic causes of the disease.

Diabetes Insipidus, a Water Homeostasis Disease. Figure 1 The diagram summarizes the anatomical location of the organs involved in maintaining water balance, the pituitary gland located at the base of the brain that releases AVP and the nephron, the functional unit of the kidney. The segments of the nephron where filtration and re-absorption take place are color-coded. The segment of the nephron where water permeability depends on the blood level of AVP (collecting tubule) is identified by the yellow color.

Diabetes Insipidus, a Water Homeostasis Disease. Table 1 Genetics of Diabetes Insipidus: a water homeostasis disease

Gene	Phenotype	Defect	Inheritance	Chromosomal Locus
AVP precursor	Neurogenic DI	No hormone	Autosomal dominant	20p13
AVP V2 receptor	Nephrogenic DI	No cell signaling	X-linked recessive	Xq28-ter
Aquaporin2 channel	Nephrogenic DI	No water channel	Autosomal recessive	12q13

Lack of AVP - Familial Neurohypophyseal DI

The hormone AVP is a peptide of nine amino acids synthesized in the neuronal cells of the supraoptic and magnocellular nuclei of the hypothalamus as a precursor protein; this precursor protein is processed and cleaved to produce neurophysin and AVP (see Fig. 2). Mutations in the gene encoding the precursor protein change its amino acid composition and interfere with the proteolytic processing, thereby blocking hormone production. The accumulation of unprocessed precursor leads to degeneration of the neuronal cells. The presence of one mutant allele that disrupts AVP production is sufficient to damage or kill the neurons and prevent expression of the normal allele. As a

consequence one mutant allele often has a dominant phenotype. The devastating consequence of the accumulation of defective protein in the neuron is analogous to the retinal degeneration leading to blindness caused by one mutant rhodopsin allele in a heterozygous patient suffering retinitis pigmentosa. More than 40 mutations of the AVP-encoding gene have been described with prevalence of the dominant presentation.

Defective V2R - X-linked Recessive NDI

The V2 receptor gene was identified as the one responsible for this disease almost one hundred years after the symptoms and inheritance pattern were

Diabetes Insipidus, a Water Homeostasis Disease.

Figure 2 The diagram represents an AVP producing neuron from the hypothalamus. The newly synthesized precursor protein is cleaved by special enzymes, represented here by the scissors, producing the nine amino acid hormone AVP and the larger accompanying protein neurophysin. Both are transported along the axon to reach the posterior pituitary where they are secreted in response to increased sodium concentration in the blood.

described. More than 180 mutations of the V2R gene have been identified. Most mutations disrupt protein synthesis by promoting alterations in receptor structure that interfere with the normal placing of the protein in the plasma membrane of the principal cell. As a consequence, the majority of the mutant receptors accumulate inside the cell, and the small percentage that reaches the cell surface is usually functionally defective. Mutations that cause the appearance of premature stop codons produce truncated proteins that are trapped inside the cell and never reach the surface. A few mutations with less dramatic effects on protein synthesis lower the ability of the receptor to promote intracellular signaling, thereby reducing the increase of intracellular levels of cAMP. These faulty receptors mobilize water channels to the apical surface of the cell only when AVP blood levels are very high. Hence, these mutations cause a partial phenotype of the disease; the kidneys produce concentrated urine only when circulating AVP reach the peak levels induced by dehydration. When blood salt concentration returns to normal values causing a drop in AVP levels, the symptoms reappear.

The gene for the V2 receptor resides in the human X-chromosome and, as is the case with most X-linked recessive disorders, the heterozygous female carriers are asymptomatic whilst the sons that inherit the mutant allele have the disease. The existence of heterozygous females with NDI symptoms puzzled researchers for

Diabetes Insipidus, a Water Homeostasis Disease.

Figure 3 Diagram of a *principal cell* of the collecting duct where water re-absorption takes place. The vasopressin V2 receptor (V2R) is present in the basolateral surface where AVP arrives by diffusing through the intracellular fluid. All surfaces of the cell are water permeable except for the apical surface, which only allows water passage when the aquaporin2 (AQ2) water channels have translocated from the intracellular vesicles to the cell surface. Mutations that interfere with the normal traffic of the V2R or AQ2 from the endoplasmic reticulum (ER) where they are synthesized to the cell surface or to the aggregophore vesicles, respectively, produce the blockade identified as A. Mutations that interfere with the ability of the V2R to stimulate cAMP production by adenylyl cyclase are identified as B. Finally, mutations of the AQ2 gene interfering with water channel activity or its insertion into the apical surface are identified as C. The green arrows identify the direction of water movement when re-absorption takes place.

some time. Recently, evidence of altered lyonization of the X chromosome has been reported in those symptomatic female carriers. The term lyonization describes the inactivation of one of the alleles of every gene present in the X chromosome. The inactivation or silencing of the genes is a consequence of a chemical change (DNA methylation) that takes place in cells bearing two X-chromosomes. Gene silencing works in a random manner inactivating one or the other allele. The consequence for the locus heterozygous for a mutation is that 50% of the cells will express a normal gene and 50% will express the mutant one. An alteration of the randomness of lyonization has been found to be a genetic trait in some families. This results in a skewed inactivation process that favors one allele over another. If silencing of the normal allele is favored, the abnormal protein will predominate and the heterozygous female will suffer NDI.

Defective Aquaporin2 - Autosomal NDI

Mutations identified in the aquaporin2 gene affect the activity and location of the water channel in the principal cells. Depending on the phase of protein synthesis and processing that is altered, the phenotype of this form of DI can be autosomal dominant or autosomal recessive.

In most cases, the disease is recessive. Mutation of a single allele does not interfere with the synthesis of the water channel from the normal allele and sufficient molecules are made to allow effective AVP regulation of water permeability without interference by the abnormal protein. The mutant channel protein is often unable to mature properly and remains trapped inside the ►[endoplasmic reticulum](#) where it is synthesized. Other mutant AQP2 channels may not be translocated properly from the intracellular vesicles to the cell surface without interfering with the movement of AQP2 normal proteins. Patients bearing such mutations will manifest the disease only if they have mutations in both alleles.

Recently, a dominant form of autosomal NDI has been characterized. In this form the presence of a single mutant gene results in a dominant phenotype. Water channels are homo-tetramers of identical subunits as seen by high-resolution electron microscopy and confirmed in biochemical experiments. The newly identified mutant subunit moves from the ER to the trans Golgi network where it mixes with the normal subunit produced by the normal allele giving rise to inactive heterogeneous channels. Simultaneous expression of normal and mutant aquaporin2 proteins in the same cells (*Xenopus* oocytes), confirmed that the ►[trans-Golgi network](#) is the formation site of the tetrameric channels and that mutant subunits can produce inactive heterogeneous water channels leading to a dominant phenotype.

Diabetes Mellitus

Definition

Diabetes mellitus is a group of metabolic disorders with one common manifestation: hyperglycemia. If untreated, hyperglycemia causes damage to the eyes, kidneys, nerves, heart and blood vessels. There are two major forms of diabetes mellitus: Type 1 diabetes mellitus (formerly called Type I, IDDM or juvenile diabetes) is characterized by destruction of the pancreatic beta cells caused by an autoimmune process, usually leading to absolute insulin deficiency. Type 2 diabetes mellitus (formerly called NIDDM, Type II or adult-onset) is characterized by insulin resistance in peripheral tissue, and an insulin secretory defect of the pancreatic beta cells. The latter is the most common form of diabetes mellitus, and is highly associated with a family history of diabetes, older age, obesity and lack of exercise.

Synonyms

Type 1 diabetes mellitus: type 1 diabetes; juvenile diabetes; insulin dependent diabetes

Type 2 diabetes mellitus: type 2 diabetes; maturity onset diabetes (MODY); noninsulin dependent diabetes

Definition

►[Diabetes mellitus](#) is one of the most common chronic diseases in the world. Diabetes mellitus is characterized

by the inability to metabolize glucose efficiently, resulting in abnormally high levels of glucose (►**hyperglycemia**) in the blood. Continued hyperglycemia over time can lead to serious medical complications of diabetes, including heart disease (►**cardiovascular disease**), kidney disease (►**nephropathy**), damage to vision (►**retinopathy**), and nerve damage (►**neuropathy**) that contribute to early mortality and disability. There are two common forms of diabetes mellitus: ►**type 1 diabetes**, characterized by early age of onset and the inability to produce ►**insulin**, the key hormone for glucose metabolism, due to ►**autoimmune** destruction of insulin producing β -cells of the pancreas and ►**type 2 diabetes**, characterized by late age of onset and inability to utilize insulin properly.

It is widely accepted that susceptibility to type 1 diabetes, type 2 diabetes, and diabetes complications results from genes that individuals inherit acting in combination with their lifestyle and environment.

Characteristics

Evidence for Genetic Contributions to Diabetes

Multiple studies suggest that genes contribute to diabetes. In twin studies of either type 1 or type 2 diabetes, ►**monozygotic twins** have a higher concordance for diabetes than ►**dizygotic twins**. Concordance rates for monozygotic type 1 diabetes twins are 30–40% compared to 6% for dizygotic twins. Concordance rates for monozygotic type 2 diabetes twins are approximately 75% compared to 35% for dizygotic twins. ►**Familial aggregation** studies compare the frequency of diabetes within families to the frequency of diabetes in the general population. If a child with type 1 diabetes has a sibling, that sibling is 10–15 times more likely to develop type 1 diabetes than an unrelated child. For type 2 diabetes this sibling risk is 2–3.5 higher for a sibling of a type 2 diabetes affected individual. The incidences of type 1 and type 2 diabetes vary greatly between different ethnic and racial groups, which has been interpreted as being due to both genetic and lifestyle/environment differences between peoples.

Approaches for Locating and Identifying Genes for Diabetes and Diabetic Complications

Many researchers have sought to identify and characterize the genes contributing to diabetes and associated complications. There are two commonly followed molecular strategies, ►**candidate gene** analysis and whole ►**genome scans**, and two analytical approaches, ►**association studies** and ►**linkage** studies. Association studies compare the frequency of specific alleles of a genetic marker between different populations, conventionally case:control populations. Linkage studies evaluate the inheritance of a genetic locus in

families. Association and linkage studies have different strengths and limitations. Association studies can detect small (e.g., approximately 5% or less of the risk) genetic contributions. The limitation of this type of study is that results are frequently difficult to replicate independently. Technically association studies are “short-sighted”, they are able to look at only very limited lengths of DNA in the genome (approximately 50,000 bp). Linkage analysis in family sets is more robust, but less sensitive. Linkage analysis has the power to detect only significant (e.g., 25% of the risk or more) genetic contributions. Linkage analysis in family sets is “far-sighted” with an ability to detect genetic factors at a distance of 5 million base pairs or more, but has little ability to locate genes precisely. The genome scan is based on linkage analysis. In the genome scan a systematic survey of the entire human genome is carried out by collecting inheritance data on 400 or more genetic guideposts spaced at uniform intervals across all of the human chromosomes in a collection of appropriate families. These are major undertakings, but have the ability to located previously unknown genes contributing to diabetes or its complications.

Type 1 Diabetes

The human leukocyte antigen (*HLA*) gene complex was recognized as the major genetic contributor to type 1 diabetes over 30 years ago. The *HLA* complex of genes encompasses approximately 3.5 million base pairs of DNA on chromosome 6 and contains approximately 150 genes, many of which are directly involved in regulating the immune system. Imperfect regulation of the immune system is believed to lead to the autoimmune destruction of insulin producing β -cells in the pancreas. Detailed investigation of the *HLA* gene complex has lead to finer and finer mapping of the genes that contribute most directly to type 1 diabetes. A current focus is on the *HLA-DQ* ►**locus** made up of 2 genes, *HLA-DQA1* and *HLA-DQB1*. These genes present foreign antigens to helper T-cells and help mediate the immune response. The *HLA-DQ* genes are highly ►**polymorphic**, meaning there are multiple different forms of the DNA sequence, each of which is called an ►**allele**, for the same locus in the population. The alleles designated *DQA1*0301* and *DQB1*0302* are 3–4-fold more common in type 1 diabetes patients than in non-diabetic subjects. Other alleles show less dramatic differences between diabetic and non-diabetic individuals. The “risk” alleles are associated with a higher likelihood of developing diabetes, but are also common in the general population and only a small percentage of individuals with the risk alleles will develop diabetes. Combinations of *DQA1* and *DQB1* alleles, called ►**haplotypes**, may contribute greater risk than individual alleles. In addition, the risk can be modified by other *HLA* genes and other genes

in the genome. Due to these complexities, prediction of type 1 diabetes by DNA analysis is still not possible.

It has been estimated that *HLA* contributes approximately 42% of the genetic risk that a person will develop type 1 diabetes, with the rest of the risk being due to other genes and additional risk being contributed by environmental factors. At least 17 additional regions of the human chromosomes have been implicated in the development of type 1 diabetes, but the impact of these other putative genes is modest compared to *HLA*. Of these genes, the gene coding for insulin has the strongest impact, contributing an estimated 10% of the genetic risk of type 1 diabetes susceptibility.

Environmental factors undoubtedly play a key role, in concert with genetic factors, in type 1 diabetes susceptibility. These environmental factors are poorly understood but race, geography, viruses and nutrition have been suggested as possible factors. Clinical trials (1) are currently underway to assess whether early intervention can prevent or delay the onset of type 1 diabetes in individuals at high genetic risk for developing type 1 diabetes.

Type 2 Diabetes

Type 2 diabetes risk is also thought to be due to a combination of genetic, lifestyle and environmental factors. In contrast to type 1 diabetes, the major lifestyle and environment risk factors, obesity, poor nutrition, sedentary lifestyle and tobacco use, contributing to type 2 diabetes have been identified and extensively documented for decades. The genetic contributors to type 2 diabetes are, in contrast, poorly understood. A current hypothesis is that two metabolic defects, resistance to the action of insulin in peripheral tissues (such as skeletal muscle) and defects in the β -cell production of insulin are necessary for the development of type 2 diabetes. These defects are believed to have a genetic basis that is modified by lifestyle and environment factors such as obesity. In spite of 20 years or more of research, no major genes for type 2 diabetes susceptibility have been identified, which suggests that genetic risk for type 2 diabetes is due to the combination of many genes, each contributing a relatively small amount of risk.

Over 100 different genes have been genetically tested for contributing to type 2 diabetes. These candidate genes have been implicated in type 2 diabetes due to their known or hypothesized function in metabolism. A characteristic of these candidate gene studies is that multiple studies of the same gene often result in conflicting results as to whether the gene is a true contributor to type 2 diabetes. Evidence is now clear, however, that the most obvious candidate genes, insulin, insulin receptor and the common glucose transporter genes do not contribute significantly to type 2 diabetes in the general population. Only rarely have

genetic mutations been found in such genes and individuals affected by such mutations often have dramatic clinical presentations markedly different from type 1 or type 2 diabetes.

Some of the strongest evidence that a gene contributes to type 2 diabetes susceptibility is for the [▶peroxisome proliferator-activated receptor](#) (PPAR γ [▶ gene](#)), which is a member of the nuclear hormone receptor subfamily of transcription factors. PPAR γ regulates transcription of many genes and is believed to be involved in adipocyte differentiation. A common genetic polymorphism that changes the coding sequence of PPAR γ from proline to alanine at amino acid 12 of the coding sequence (Pro12Ala) has been evaluated in a large number of studies. Altshuler et al. (2) combined the results of 16 studies encompassing over 3000 subjects and carried out a [▶meta analysis](#) of the genetic data. They found that the common proline coding allele contributes a 1.25-fold increased risk for developing type 2 diabetes that was statistically significant and which could contribute to as much as 25% of the risk to develop type 2 diabetes in the general population.

A second gene for type 2 diabetes is the [▶calpain 10](#) gene identified in Hispanic American families (3). The *calpain 10* gene codes for a member of the calpain (a calcium activated protease)-like cysteine protease family. This gene was identified through its position on the long arm of human chromosome 5, which was inherited with type 2 diabetes in Hispanic American families in a genome scan. This gene was previously unknown and the mechanism by which a calcium activated protease could contribute to type 2 diabetes is unclear. Molecular genetic analysis suggested that combinations of alleles in different polymorphisms within the gene, called haplotypes, are the likely source of diabetes susceptibility. Individuals with the "risk" haplotypes are at 3–7 times greater risk of developing type 2 diabetes than other Hispanic Americans. Most surprisingly, the DNA sequences that make up the risk alleles are in non-coding intronic sequences within the gene, i.e. they do not directly affect the protein sequence. These non-coding sequences play a role in processing the RNA transcribed from the *calpain 10* gene and ultimately could affect levels of *calpain 10* protein levels. These results have puzzled researchers, but similar observations have now been made with other genes identified in common diseases such as Crohn's disease, asthma and schizophrenia. The identification and analysis of *calpain 10* could thus represent a window into previously unknown mechanisms for regulation of cellular metabolism.

Over 20 genome scans have been carried out in collections of type 2 diabetes families in an effort to locate type 2 diabetes genes. These studies have genetically analyzed many different populations and ethnic groups including Caucasian Americans,

Caucasian Europeans (French, Finnish, English), Hispanic Americans, Native Americans and Han Chinese. Three locations on the human chromosomes, the long arms of chromosomes 1, 10, and 20, have been consistently implicated as probable locations for genes that contribute to type 2 diabetes. The gene (or genes) within these regions have not, as yet, been identified

Maturity Onset Diabetes of the Young (MODY)

Maturity onset diabetes of the young (►MODY) (4) is a distinct subtype of type 2 diabetes, which constitutes 1–3% of type 2 diabetes. In contrast to type 2 diabetes in the general population, characterized by complex patterns of inheritance and late age of onset, MODY is recognized as a clearly defined pattern of ►autosomal dominant inheritance and early age of onset (childhood to early adulthood). Clinically MODY-affected individuals are ►hypoinsulinemic; they produce reduced amounts of insulin. Great progress has been made in understanding the molecular basis of MODY with the identification of mutations in at least 8 genes. Seven of these genes code for transcription factors that are involved in a wide variety of regulatory pathways for gene expression. For example the MODY1 form of diabetes is caused by defects in the ►HNF4A gene, which codes for ►hepatocyte nuclear factor 4 α protein. This protein interacts with regulatory elements in the promoters and enhancers of more than 40 target genes involved in glucose, cholesterol, and fatty acid metabolism. Mutations in the *insulin promoter factor 1* gene, *IPF1*, are responsible for the MODY4 form of diabetes. The *IPF1* coded transcription factor binds to specific sequences in the promoter of the insulin and other genes. Mutations in *IPF1* lead to reduced expression of insulin and abnormalities in pancreas development. Distinct from the transcription factor related diseases, MODY2 is caused by mutations in the glucokinase gene leading to dysfunctional glucokinase, which performs the rate-limiting step in glycolysis. Despite the many insights that MODY genes have provided into the molecular basis of glucose metabolism, none of these genes have been implicated as contributors to type 2 diabetes in the general population.

Genetics of Diabetes Complications

Like the disease entities of type 1 and type 2 diabetes, there is considerable evidence that the complications associated with diabetes have a genetic component. It has been widely observed that complications appear at different times and progress at different rates in diabetes-affected patients, even when they have similar glucose control and have had diabetes for similar durations. These observations have led to efforts to quantify the magnitude of the genetic components of

complications and identify the genes that contribute to susceptibility to developing complications.

A primary hypothesis is that genes that contribute to diabetic complications are different from the genes that contribute directly to diabetes. Susceptibility to cardiovascular (CVD) or renal disease, for example, is thought to be amplified by the environment of diabetes.

Evidence for Genetic Contributions to Diabetic Complications

Renal disease can be evaluated clinically by relatively inexpensive methods such as measuring urinary protein and serum creatinine. This has facilitated accumulation of extensive evidence that renal disease in diabetes has a genetic component. These conclusions are based on the results of familial aggregation studies and the observation of significantly different incidence rates in disparate racial and ethnic groups. For example, relatives of an African American with type 2 diabetes and nephropathy are at an 8-fold greater risk of developing diabetic nephropathy than an individual without nephropathic family members. These qualitative assessments have been complemented by mathematical modeling studies of renal disease called ►segregation analysis that quantitatively estimate the genetic contribution to diabetic renal disease. In such a study (5) it was calculated that 27% of a measure of renal health (albumin/creatinine ratio) in Caucasian type 2 diabetes families is contributed by genetic factors.

The genetic component of CVD in diabetes is less well documented since few studies have focused on purely diabetes affected populations and evaluation of CVD is more technically challenging than renal disease. Using a mathematical modeling approach called variance components analysis that calculates an estimate of the genetic and environmental contributions to a trait, subclinical cardiovascular disease has been estimated to be due 30–40% to environmental factors and 40–50% to genetic factors (6).

There is also evidence that genetics plays a role in retinopathy. In the Diabetes Control and Complications Trial family members of type 1 diabetes patients with severe retinopathy were at a 3-fold higher risk of developing retinopathy than families of retinopathy negative patients. In a study of racial/ethnic differences, African Americans are 2.5-fold as likely to develop retinopathy as a Caucasian American control group. It is likely that other diabetes complications, such as neuropathy also have genetic contributors, though definitive studies have not been completed.

The Search for Diabetes Complications Genes

Searches for diabetes complications genes have been fewer in number and are less advanced than searches for diabetes genes, though hundreds of reports of

analyses of candidate genes have been published. Of note are studies of the angiotensin converting enzyme > (►*ACE*) gene, which have been so extensive that meta analyses, are possible. In meta analyses of up to 50,000 subjects, the *ACE* gene is associated with both nephropathy and cardiovascular disease, but not retinopathy. Given that these effects are most clearly seen in a very large sample suggests the actual contribution of *ACE* to these traits is significant, but of small magnitude. Multiple other genes from the renin-angiotensin system, cytokines and growth factors, inflammatory and vascular factors, glycosylation genes, nitric oxide synthases, and genes of metabolic regulation have varying degrees of evidence for association with specific complications.

Genome scans targeted at locating complication genes are few in number. A study of Pima Indian families for both nephropathy and retinopathy revealed evidence for nephropathy genes on the long arm of chromosome 7. Additional segments of chromosomes 3, 9, and 20 showed some evidence of linkage to nephropathy and chromosomes 3 and 9 showed evidence of linkage to retinopathy. Other genome scans have been recently completed or are under way. A genome scan of Turkish kindreds with multiple diabetic nephropathy-affected individuals found strong evidence for linkage to chromosome 18. Evaluation of this location in the Pima Indian dataset showed evidence of confirmation.

Cellular and Molecular Regulation

Type 1 diabetes, type 2 diabetes, and diabetic complications have complex patterns of inheritance presumably due to the effects of multiple genes interacting with environmental and lifestyle factors. In only a few cases, e.g. *PPAR γ* in type 2 diabetes and the transcription factors identified in MODY, is the actual mechanism of action of these gene products understood. Even in these cases where the protein action is understood at a molecular level, extrapolation to prediction of physiological impact on the whole organism is difficult. The mechanisms by which the *HLA* genes in type 1 diabetes contribute to autoimmune destruction of the β -cells remain poorly understood. Knowledge of genes that contribute to the complications of diabetes remains limited, but these genes are likely to be different from the diabetes susceptibility genes themselves.

Clinical Relevance

It is currently possible to identify individuals that are at increased risk for developing type 1 diabetes due to the presence of higher risk *HLA* haplotypes. The presence of these haplotypes is in no way predictive however. If desired, confirmation of MODY can now frequently be determined through DNA analysis, and this same

technology could be used to predict this autosomal dominant form of diabetes. The primary genetic components of type 2 diabetes in the general population remain to be identified. Though at an early stage, efforts to identify genes that contribute to complications may have a significant impact on diabetes care. Identification of individuals at higher risk for developing specific complications early in the course of their diabetes may provide a window of opportunity to prevent or delay complications.

Definition

Differential Scanning Calorimetry is an extremely versatile technique to characterize quantitatively protein stability and conformational equilibria. It probes temperature inducible reactions by monitoring the apparent heat capacity of a sample solution relative to that of a reference solution as a function of temperature. The biologically interesting temperature range from 0°C to 130°C can be studied. The differential arrangement of two, practically identical measuring

units, which are filled with the sample and reference solution, respectively, allows for the compensation of the large background heat capacity of water. This constitutes an enormous improvement of the signal to noise ratio of the measurement. ► **DSC** is most powerful in the analysis of mechanisms of reversible reactions, however, for simple models irreversible processes can also be treated.

Description

Isothermal Titration Calorimetry measures at constant temperature the enthalpy change resulting from a reaction. In contrast Differential Scanning Calorimetry monitors the changes in apparent heat capacity of a sample in the course of a constant-rate temperature scan.

Application in Life Sciences

DSC is ideally suited to the thermodynamic characterization of all temperature inducible processes such as folding-unfolding transitions of proteins, helix to coil transitions of nucleic-acids, phase changes in membranes and changes in the degree of oligomerization. This implies that characterisation of stability of proteins, nucleic acids and membranes as well as of their complexes is a major domain of DSC.

Instrumental Aspects and Principles of Operation

To maintain equilibrium conditions during the temperature scan heating rates must be slower than the relaxation rates of the reaction observed. This can lead to very slow scan rates (1/1000 of a degree per min) for example in case of some lipid phase transitions. However, generally protein or nucleic acid solutions can be scanned at rates between 0.1 and 2 K/min. As in ► **ITC** modern DSC instruments use twin cells that operate in differential mode. Thus Fig. 1 of the article on ITC is also representative for a DSC instrument with the exception of the stirrer. The reference cell – filled with the identical equilibrium dialysis buffer solution as the sample cell (excluding the sample) – compensates for the 99.9% heat capacity signal of the buffer in a 1mg/ml solution. This arrangement improves the signal to noise ratio significantly and results in a differential heat capacity signal as a function of temperature, $\Delta c_{p,app}(T)$, that originates solely from the replacement of buffer solution by sample.

$$\Delta c_{p,app}(T) = c_{p,buffer} \cdot m_{buffer} - c_{p,sample}(T) \cdot m_{sample} \quad (1)$$

m_{buffer} is the mass of buffer solution replaced by the mass of the sample, m_{sample} . As sample and reference cell have the same volume, V_{cell} , one can express the masses by the partial specific volumes, $\bar{v} \left[\frac{cm^3}{g} \right]$.

Differential Scanning Calorimetry . Figure 1 Heat capacity profile and fit (blue) of Myoglobin ($c = 10$ g/l, 50 mM NaAc pH = 4.3), low temperature peak: $r = 0.2$ K/min, high temperature peak: $r = 0.5$ K/min.

$$m_{\text{buffer}} = \frac{V_{\text{cell}}}{\bar{V}_{\text{buffer}}}, m_{\text{sample}} = \frac{V_{\text{cell}}}{\bar{V}_{\text{sample}}}$$

Introducing these expression into eq.(1) and solving for the heat capacity of the sample one obtains the working equation of DSC

$$c_{p,\text{sample}}(T) = c_{p,\text{buffer}}(T) \frac{\bar{V}_{\text{sample}}(T)}{\bar{V}_{\text{buffer}}(T)} - \frac{\Delta c_{p,\text{app}}(T)}{m_{\text{sample}}} \quad (2)$$

Unless strong intermolecular interactions occur, the partial specific volumes do not significantly differ from the specific volumes at the low concentrations employed usually. However, for precise c_p data the partial specific volume should be used. $c_{p,\text{buffer}}$ is usually assumed to be equal to $c_{p,\text{water}}$. This is only acceptable for very low buffer concentrations. To obtain accurate absolute heat capacities for the biopolymer systems, $c_{p,\text{buffer}}$ must be determined by a reference run with one cell filled with buffer and the other one filled with water.

$$T_{1/2} = 333.4 \text{ K}, \Delta H^0(T_{1/2}) = 212 \text{ kJ/mol}, \Delta C_p^0(T_{1/2}) = 6.8 \text{ J/molK}$$

Figure 1 shows a typical DSC study on myoglobin at pH = 4.3. At this pH myoglobin is unfolded at low temperature, refolds as indicated by the low temperature peak to form the native structure between 2 and 16°C, and finally unfolds again at high temperature. The enthalpy changes accompanying the low temperature renaturation and the high temperature denaturation

can be obtained without a model assumption by integration of the excess heat capacity, which is defined as the difference between the observed heat capacity $c_p(T)$ and the baseline $c_{p,\text{baseline}}$.

$$c_{p,\text{excess}}(T) = c_p(T) - c_{p,\text{baseline}}(T) \quad (3)$$

$$\Delta H^0(T_{1/2}) \equiv \int_{T_1}^{T_2} c_{p,\text{excess}} dT; \quad (4)$$

$$\Delta S^0(T_{1/2}) = \frac{\Delta H^0(T_{1/2}) - \Delta G^0(T_{1/2})}{T_{1/2}}$$

T_1 and T_2 refer to the temperatures of the start and end, respectively, of the corresponding low or high temperature heat capacity peak. Although the transition extends over the temperature range $T_2 - T_1$, both the transition enthalpy and entropy are assigned by definition to the temperature of half conversion, $T_{1/2}$. For an N to D transition $\Delta G^0(T_{1/2})$ vanishes at $T_{1/2}$ and

$$\Delta S^0(T_{1/2}) \text{ equals } \frac{\Delta H^0(T_{1/2})}{T_{1/2}}.$$

The exact values of the so-called transition temperatures, $T_{1/2}$, which are defined as those temperatures at which 50% conversion of the sample has occurred, are given in the figure legend. The heat capacity curve of myoglobin is unique compared to that of the large majority of other proteins in that the so-called cold

denaturation is observed in addition to heat denaturation in the accessible temperature range of about 0°C–130°C. The reason is the large positive heat capacity change ΔC_p associated with unfolding and the relatively small ΔH^0 value. This combination renders possible a fast change in the fractions of both native, $\alpha_N(T)$, and unfolded proteins, $\alpha_D(T)$, as a function of temperature. This becomes evident from the equations for a simple two state transition

$$\begin{aligned} N &\rightleftharpoons D; \\ K &= \frac{[D]}{[N]}; \\ \alpha_N(T) &= \frac{[N]}{[N] + [D]} = \frac{1}{1 + K}; \\ \alpha_D(T) &= \frac{[D]}{[N] + [D]} = \frac{K}{1 + K}; \end{aligned} \quad (5)$$

The equilibrium constant is related to the standard Gibbs energy change, ΔG^0 , via the relation

$$\begin{aligned} K(T) &= e^{-\frac{\Delta G^0(T)}{RT}} \\ \Delta G^0(T) &= \Delta H^0(T) - T\Delta S^0(T) \\ &= \Delta H^0(T_{1/2}) + \Delta C_p(T - T_{1/2}) \\ &\quad - T \left\{ \frac{\Delta H^0(T_{1/2})}{T_{1/2}} + \Delta C_p \ln \frac{T}{T_{1/2}} \right\} \end{aligned} \quad (6)$$

Equation (6) implies a linear temperature dependence of the enthalpy as described by $\Delta H^0(T) = \Delta H^0(T_{1/2}) + C_p(T - T_{1/2})$ and the corresponding relation for the entropy change: $\Delta S^0(T) = \Delta S^0(T_{1/2}) + \Delta C_p \ln \frac{T}{T_{1/2}}$.

For the N (D) transition ΔG^0 equals 0 at $T_{1/2}$. A comparison with eq. (24) in the chapter on ITC shows the identity of the two equations. Here the reference temperature is $T_{1/2}$, the temperature of half conversion, while there it is any convenient experimental reference temperature T_R . Inspection of eq.(6) reveals that for a vanishing ΔC_p there will be no cold unfolding, since ΔG^0 does not turn negative with decreasing temperature. However, in general unfolding of proteins is associated with a significantly positive value of ΔC_p and this can lead in combination with a moderate enthalpy change at $T_{1/2}$ to a change in sign of ΔG^0 above 0°C, as seen in Fig. 1 for myoglobin.

Fitting of Heat Capacity Curves to Different Transition Models Using Partition Functions

Insight into the mechanism of the reaction underlying the heat capacity curve can be obtained by fitting of the heat capacity data to analytical equations describing various transition models. An elegant approach is based

again on the relative partition function Z . One of the prominent models used in abundance for protein unfolding is the so-called **two-state** model. Within the framework of this model it is assumed that only two populations of protein molecules exist, native (N) and unfolded (D) molecules and that the relative fractions α_N and α_D are shifted by temperature.

The relative partition function Z for this model is defined as

$$Z = \frac{[N] + [D]}{[N]} = 1 + K \quad (7)$$

The enthalpy relative to the native state N can be calculated from eq.(8)

$$H(T) - H_N(T) = RT^2 \frac{\partial \ln Z}{\partial T} = \frac{K}{1 + K} \Delta H^0(T) = \alpha_D(T) \cdot \Delta H^0(T) \quad (8)$$

The heat capacity $c_p(T)$ is the variation of the enthalpy with temperature and is described by the following equation

$$\begin{aligned} C_p(T) &= C_{p,N}(T) + \frac{\partial(H - H_N)}{\partial T} \\ &= C_{p,N}(T) + \Delta C_p(T) \frac{K}{1 + K} \\ &\quad + \frac{[\Delta H^0(T)]^2}{RT^2} \cdot \frac{K}{1 + K} \cdot \frac{1}{1 + K} \\ &= C_{p,N}(T) + \Delta C_p(T) \cdot \alpha_D \\ &\quad + \frac{[\Delta H^0(T)]^2}{RT^2} \cdot \alpha_N \alpha_D \end{aligned} \quad (9)$$

$C_{p,N}(T)$ is the heat capacity function of the native state. For small globular proteins it can be represented by a linear function, having values of approximately $1 - 2.5 \text{ JK}^{-1}\text{g}^{-1}$ near 25°C and a slope of $(6 - 8) \cdot 10^{-3} \text{ JK}^{-2}\text{g}^{-1}$. Deviations from these average values have been interpreted as indicating loose structural packing with concomitant large conformational fluctuations. $\Delta C_p(T) = C_{p,D}(T) - C_{p,N}(T)$ is the difference between the extrapolated heat capacity functions of the denatured and native states at temperature T .

$C_{p,N}(T) + \Delta C_p(T) \cdot \alpha_D(T)$ is the equation for the baseline and the third term in eq.(9) represents the excess heat capacity function resulting from the transition.

There is another transition mechanism which applies to a large number of protein- and DNA reactions. It is the dissociation of a dimer with concomitant loss of native structure. The corresponding equilibrium constants are

$$N_2 \rightleftharpoons 2D \quad K = \frac{[D]^2}{[N_2]} \quad (10)$$

$$AB \rightleftharpoons A + B \quad K = \frac{[A][B]}{[AB]} \quad (11)$$

Equation (10) refers for example to unfolding of a homodimeric protein, while eq.(11) describes melting of double-stranded DNA. The relative partition function Z for the $N_2 = 2D$ equilibrium is

$$Z = \frac{[N] + [D]}{[N]} = \frac{2[N_2] + [D]}{2[N_2]} = 1 + \frac{2}{\sqrt{1 + \frac{8c}{K}} - 1} \quad (12)$$

Z has been formulated in terms of subunit monomer concentrations with $c = 2[N_2] + [D] = \text{const.}$ being the total monomer concentration.

Proper derivation of the relative partition function with respect to temperature provides the enthalpy relative to the native state.

$$H - H_N = RT^2 \frac{\partial \ln Z}{\partial T} = \Delta H^0 \frac{\alpha_D}{1 + \alpha_D} \quad (13)$$

$\alpha_D(T) = \frac{K}{1+K}$ is the degree of unfolding, $K(T) = e^{-\frac{\Delta G^0(T)}{RT}}$ is the equilibrium constant and ΔH^0 is the transition enthalpy.

The heat capacity function is the variation with temperature of the enthalpy.

$$\begin{aligned} C_p - C_{p,N} &= \frac{\partial(H - H_N)}{\partial T} \\ &= \frac{\partial}{\partial T} \left\{ RT^2 \frac{\partial \ln Z}{\partial T} \right\} \\ &= C_{p,N} + \Delta_N^D c_p \frac{\alpha_D}{1 + \alpha_D} \\ &\quad + \frac{(\Delta H^0)^2}{RT^2} \cdot \frac{2\alpha_N \alpha_D}{(1 + \alpha_D)^3} \end{aligned} \quad (14)$$

It is important to note that the weighting factors for both ΔH^0 in eq.(13) and (ΔH^0) in eq.(14) are different from those reported previously in the literature.

An analogous treatment of the reaction $AB \rightleftharpoons A + B$ yields the following expressions:

$$Z = \frac{[AB] + [A] + [B]}{[AB]} \quad (15)$$

The total monomer concentration is constant due to mass conservation

$$c = 2[AB] + [A] + [B] = 2[AB] + 2[A] \quad (16)$$

$$Z = 1 + \frac{2[A]}{[AB]} = 1 + \frac{2[A]}{\frac{[A]^2}{K}} = 1 + \frac{2K}{[A]} \quad (17)$$

The enthalpy relative to the native AB complex is given by the following equation

$$H - H_N = \Delta H^0 \cdot \frac{Q - 1}{Q + 1} \quad (18)$$

The expression for Q is:

$$Q = 1 + \frac{2}{\left(\sqrt{1 + \frac{2c}{K}} - 1\right)} \quad (18a)$$

The heat capacity function is again obtained by the derivation of the enthalpy function with respect to temperature:

$$C_p - C_{p,N} = \Delta C_p^0 \frac{Q - 1}{Q + 1} + \frac{(\Delta H^0)^2}{RT^2} \cdot \frac{2Q(Q - 1)}{(Q + 1)^3} \quad (18b)$$

The differences in the formulae for the two dimer-to-monomer equilibria are the result of the non-identity of subunits in the $[AB] = [A] + [B]$ case.

Cooperativity Parameters

A variety of further unfolding mechanisms is elaborated in reference [1]. The enthalpy values obtained by the fitting routines from the heat capacity curves are so-called van't Hoff enthalpies, $\Delta H^0 = \Delta H_{vH}$, as they are derived ultimately from the variation with temperature of the equilibrium constant.

The ratio between the model free calorimetric enthalpy, ΔH_{cal} , obtained by integration of the transition peak and the ΔH_{vH}^0 value derived from the fit, is a rigid criterion for the size of the cooperative unit defined by the ratio $(\Delta H_{cal} / \Delta H_{vH})$. A ratio of $\frac{\Delta H_{cal}}{\Delta H_{vH}^0} = 1$ indicates unambiguously the occurrence of a cooperative two-state transition involving the complete protein or DNA macromolecule. Ratios larger than one signify that probably intermediate states are populated in the course of the transition. Intermediate transitions are likely to require less than the maximal enthalpy for the transformation between the native state and the intermediate conformation.

A ratio of $\frac{\Delta H_{cal}}{\Delta H_{vH}^0}$ is obtained, if intermolecular co-operation exists as, for example, in phase transitions of lipid vesicles. Such a ratio smaller than 1 can, however, also point to an irreversible process coupled to unfolding, as for example the aggregation of unfolded proteins during a heating scan.

Stoichiometry Tests

DSC provides an excellent test of the stoichiometry of a reaction. For the $N_n \rightleftharpoons nD$ transition the equilibrium constant at the transition temperature $T_{1/2}$ can be expressed as

$$K(T_{1/2}) = n\left(\frac{c}{2}\right)^{n-1} \quad (19)$$

with $c = n[N] + [D]$ being the constant, analytical monomer concentration.

By performing several DSC studies at different concentrations c the variation of the transition temperature $T_{1/2}$ with $\ln c$ can be analyzed. To estimate the stoichiometry n of the reaction the following equation is used:

$$\frac{1}{T_{1/2}} = \frac{R \ln \left[n \left(\frac{c}{2} \right)^{n-1} \right]}{\Delta H^0(T_{1/2})} - \frac{\Delta S^0(T_{1/2})}{\Delta H^0(T_{1/2})} \quad (20)$$

$\Delta H^0(T_{1/2})$ and $\Delta S^0(T_{1/2})$ are the respective standard transition enthalpies and entropies at $T_{1/2}$.

Treatment of Irreversible Reactions

Several protein unfolding reactions are associated with irreversible behaviour of the unfolded species. If the reaction can be described by a so-called Lumry-Eyring- or, equivalently, Michaelis-Menten type mechanism, both equilibrium and kinetic parameters can be deduced from the heat capacity curve. The following equations apply to this mechanism:

If the rate constant k is small compared to the rate constants governing the equilibrium, the equilibrium constant K is to a good approximation represented by the ratio of the fractions of denatured (α_D) and native protein (α_N)

$$K = \frac{(\alpha_D)}{(\alpha_N)} \quad (22)$$

Considering mass conservation by the condition $1 = \alpha_D + \alpha_N + \alpha_P$ and introducing the rate of product formation by

$$\frac{\partial \alpha_P}{\partial t} = k \cdot \alpha_D = k \cdot \alpha_D^{\text{eq}} (1 - \alpha_P) \quad (23)$$

The fraction of irreversible product, α_P , at temperature T can be obtained by integration

$$\alpha_P = 1 - \exp \left(- \int_{T_0}^T \frac{k \alpha_D^{\text{eq}}}{r} dT \right) \quad (24)$$

The time t can be transformed to temperature T by using the definition of heating rate $r = \frac{dT}{dt}$.

The enthalpy relative to the native state results from the following equation

$$\begin{aligned} H - H_N &= \Delta H_N^0 (\alpha_D + \alpha_F) + \Delta H_P^0 \alpha_P \\ &= \Delta H^0 [\alpha_D^{\text{eq}} (1 - \alpha_P) + \alpha_P] + \Delta H_P^0 \alpha_P \end{aligned} \quad (25)$$

ΔH^0 is the enthalpy change associated with the $N \rightleftharpoons D$ equilibrium, ΔH_P^0 that accompanying the irreversible reaction forming P . α_D^{eq} is the equilibrium fraction of unfolded protein defined by $\alpha_D^{\text{eq}} = \frac{K}{1+K}$.

The final fitting equation is obtained from the temperature derivative of the enthalpy

$$\begin{aligned} C_p &= \frac{\partial}{\partial T} (H - H_N) \\ &= C_{p,N} + \Delta_N^D C_p (\alpha_D + \alpha_F) + \Delta_D^P C_p \alpha_P \\ &\quad + \frac{(\Delta_N^D H^0)^2}{RT^2} - \alpha_D^{\text{eq}} \alpha_D^{\text{eq}} \exp \left(- \int_{T_0}^T \frac{k \alpha_D^{\text{eq}}}{r} dT \right) \\ &\quad + \{ (1 - \alpha_D^{\text{eq}}) \Delta_N^D H^0 + \Delta_D^P H^0 \} \frac{k \alpha_D^{\text{eq}}}{r} \\ &\quad \times \exp \left(- \int_{T_0}^T \frac{k \alpha_D^{\text{eq}}}{r} dT \right) \end{aligned} \quad (26)$$

As ancillary condition one usually assumes Arrhenius behaviour for the rate constant $k(T)$

$$k(T) = k(T_{1/2}) \exp \left[- \frac{E_a}{R} \left(\frac{1}{T} - \frac{1}{T_{1/2}} \right) \right] \quad (27)$$

E_a is the activation energy of the irreversible $D \rightarrow P$ process. R is the gas constant and $T_{1/2}$ is the temperature of 50% transition.

Estimation of the Average Degree of Ligandation

DSC is favourably used for quantifying the stabilization of proteins by ligand binding. Particularly the average degree of ligand binding, \bar{X} , can be conveniently estimated from the variation of the transition temperature $T_{1/2}$ with the logarithm of the ligand concentration, x , using the equation

$$\frac{\partial \left(\frac{1}{T_{1/2}} \right)}{\partial \ln x} = -R \frac{\bar{X}}{\Delta H^0(T_{1/2})} \quad (28)$$

The slope of a plot of the reciprocal transition temperature versus $\ln x$ gives the average number of ligands bound per mole of protein provided the overall transition enthalpy in the presence of ligands, $\Delta H^0 \times (T_{1/2})$, at $T_{1/2}$ is known. This first estimate of \bar{X} forms a convenient basis for quantitative numerical fitting strategies described in [1].

Summary

This concise description of DSC neglected the wealth of information available for the molecular interpretation of the thermodynamic parameters. Instead it has emphasized the quantitative aspects of the method. DSC is the only technique that provides a direct access to all thermodynamic parameters relevant to protein- or in general biopolymer stability. These are the standard Gibbs energy change, ΔG^0 , the transition enthalpy, ΔH^0 , the heat capacity change, ΔC_p , that determines the dependence on temperature of ΔH^0 . As these parameters are usually obtained by DSC at the upper biologically significant temperature range compared to values from ITC, the two techniques are favourably complementary.

There is a growing awareness that, specifically for rational drug design, for the quantification of mutational effects on the stability of proteins, for the characterization of conformational changes and for ligand interactions, structural information alone is insufficient for a deeper understanding of the forces responsible for biomolecular interactions. However, the combination of thermodynamic and structural knowledge has opened new strategies with increased predictive power for a successful route in drug design (4, 5).

In this context both ITC and DSC play a dominant role which will even become more prominent on the basis of new high-throughput instruments currently under construction.

DNA Amplification

ERHARD WINTERSBERGER

Institute of Medical Biochemistry, Division of Molecular Biology, Medical University of Vienna, Vienna, Austria

erhard.wintersberger@univie.ac.at

Definition

DNA amplification is a process whereby a limited part of the genome is increased in copy number. It can comprise DNA sequences of the length of ►oligonucleotides up to large parts of the genome. Usually the definition of DNA amplification does not include polyploidization, where the total genome (i.e. the number of chromosomes) increases by an integral number. In some organisms, amplification of specific genes takes place in particular cells and is necessary for normal development. In other cases DNA amplification gives cells a growth advantage by partially releasing them from normal regulation or allowing them to survive under otherwise unfavorable conditions (2).

Finally, DNA amplification also means a technique by which, with the help of specific oligonucleotides and the polymerase chain reaction, the presence of a

particular DNA sequence can be determined qualitatively and quantitatively. This procedure is widely used for diagnostic purposes. Examples for specific applications of this technique are described in numerous reviews and original papers. The subject will not be dealt with any further here.

Characteristics

Among the developmentally regulated DNA amplifications, the almost complete overreplication of the genome during the formation of ►polytene chromosomes in some organisms other than mammals (e.g. in the salivary glands of *Diptera*) is the extreme case. Less extensive amplification events serve the purpose of providing particular cells with supernumerary copies of selected genes to cope with a temporary and exceptionally high demand for transcripts of these genes. One well-studied example is the amplification of the genes for ribosomal RNA in the macronucleus of *Tetrahymena* and during amphibian oogenesis, which leads to a more than thousand-fold increase in rDNA. Genes for ribosomal RNA are present in many copies in the genome in nearly all organisms. This is necessary to cope with the need for heavy transcription of the gene for a sufficient supply of ribosomal RNA in all cells. During oogenesis an even larger stock of ribosomal RNA has to be produced because transcription does not take place in fertilized eggs for several cell-cycles. Hence, in order to avoid oogenesis taking too long, genes for ribosomal RNA are heavily overreplicated. The overreplicated DNA is present extrachromosomally. The programmed amplification of the chorion genes in follicular cells of the ovary of *Drosophila* is also well known. In this case the extra copies of the gene remain side by side in the genome, like the DNA puffs of *Sciara*.

In contrast to developmentally regulated amplification processes, many aberrant cases are known that occur rarely in cells and that are noticed if they involve genes carrying selectable markers such as those conferring drug resistance. Such amplification events are frequently seen in cells of tumor patients receiving chemotherapy, where amplification gives cells a growth advantage and selects against the effects of the drug. Also relevant in this context are amplifications which are again frequently observed in tumor cells and which involve genes whose products play a role in growth control such as cyclins or transcription factors like c-myc. Normal human cells grown in culture are incapable of amplification (3). This contrasts with the majority of immortal cell lines and tumor cells. There are two types of cytological manifestation of amplified DNA in such cells namely homogeneously staining regions (►HSRs) and double minute chromosomes (►DMs). The preferred

DNA Amplification. Figure 1 DNA amplification by overreplication (regulated or unscheduled) from the same origin of replication. This gives rise to structures resembling onionskins.

DNA Amplification. Figure 2 Rolling circle mechanism of DNA amplification. Replication starts from circular double stranded DNA. This mechanism is used in the replication of the DNA of some bacteriophages and in the amplification of DNA sequences coding for ribosomal RNA in amphibia.

cytological characteristic of amplified DNA is in part cell type specific and in part depends on whether cells are grown in culture or isolated from solid tumors. Cultured mouse cells, for instance, display mostly DMs, rat and hamster cells mostly HSRs while human cells have either HSRs or DMs. Very rarely are the two forms seen side by side within one cell. It is interesting that human tumor cell lines in culture display mainly HSRs, while the presence of amplified DNA in tumor cells *in vivo* is manifested by the occurrence of DMs. In some cases one form can be converted into the other, i.e. when cell lines are established from tumors exhibiting amplified DNA in the form of DMs, these disappear and are converted into HSRs and *vice versa*. In a well established experimental system, the Chinese hamster ovary cells selected for ▶methotrexate resistance and carrying the amplified gene coding for dihydrofolate reductase in the form of HSRs, it was found that even the earliest detectable HSRs already contain several extra copies of the gene plus sequences surrounding it (4). This is of relevance when mechanisms of DNA amplification are considered.

Amplification events involving short tandemly repeated sequences can include trinucleotide repeats,

minisatellites and microsatellites. Amplification of trinucleotide motifs is the cause of a variety of human diseases (repeat expansion diseases) and may result in long chains of the same amino acid (often glutamine, more rarely other amino acids like alanine).

Mechanisms of DNA Amplification

The mechanisms of DNA amplification vary between different amplification events. The simplest way to amplify specific parts of the genome is a violation of the rule that the total genome is replicated once and only once during one cell-cycle. This mechanism could be regulated or accidental. Regulated rereplication appears to be the mechanism by which polytene chromosomes are formed in flies. Here large parts of the genome are replicated many times during one S phase in particular cells. Some sequences however are saved from this process and remain unamplified (or amplified to a significantly lower degree than the rest of the genome). Hence this process does not lead to polyploidization. Regulated rereplication from a specific origin of DNA replication was also proven in case of the amplification of chorion genes during oogenesis in *Drosophila*. In this case this process leads to the

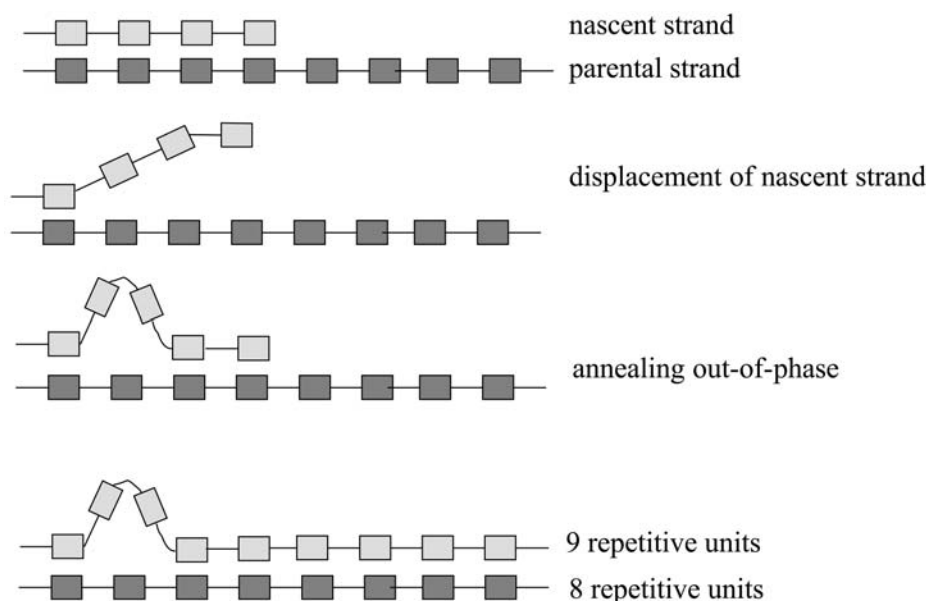

DNA Amplification. Figure 3 Initiation of B-F-B (breakage-fusion-bridge) cycles occurs by chromosome breakage, loss of telomeres (as in I) or by unequal sister chromatid exchange, an example of which is shown in II. In both cases dicentric chromosomes arise which are again broken in the next mitosis. The two lines of different thickness represent sister chromatids, the filled circle is the centromere and the horizontal bar the gene that will be amplified.

appearance of structures resembling onionskins, hence this mechanism was named ►onionskin mechanism (Fig. 1). Interestingly, in another case of developmentally regulated amplification, that of the genes coding for ribosomal RNA during oogenesis in frogs, a different mechanism is used. Here rereplication is carried out by the so-called ►rolling circle mechanism (Fig. 2). Since the rolling circle mechanism to be started requires that the genes are present in circular form, it is likely that this amplification process starts with a homologous recombination process in which one or a few of the repeating units of rRNA genes present in the genome are excised. Such excision of parts of repetitive genomic sequences are well known. Unregulated DNA amplification events which may accidentally take place in some cells and which are manifest by the emergence of DMs or HSRs occur by a different mechanism. The two forms can interchange, but the question is which form, DMs or HSRs, emanates first. During the selection of methotrexate-resistant hamster cells with amplified genes for dihydrofolate reductase HSRs were observed early. This

was interpreted to indicate that breakage-fusion-bridge (B-F-B) cycles rather than overreplication are responsible for their formation. B-F-B cycles could be initiated by double strand breaks (Fig. 3). Erosion of telomeres leads to chromosome ends which resemble double strand breaks, which may in addition arise elsewhere in the chromosome when replication forks are stalled for prolonged periods of time or the replication apparatus did not remain at the stalled fork until the cause for the replication block is eliminated. Such double strand breaks may be repaired by fusion of two broken chromosomes. Alternatively B-F-B cycles could be started by unequal sister chromatid exchange (Fig. 3). Either case leads to ►dicentric chromosomes that are likely to be broken during the next mitosis. This leads to more broken chromosomes that are healed by fusion, again giving rise to dicentrics continuing the B-F-B cycle. Normal cells are unlikely to initiate such a reaction chain because intact check point controls would drive cells with double-strand breaks which are not properly repaired, or those with too short or lost telomeres into apoptosis. This is probably the reason why methotrexate-resistant cells arise at a frequency below the detection limit in normal human cells (3). In other words, cells have to have previously acquired mutations in control systems to allow DNA amplification, a situation that is characteristic of tumor cells. Among the different DNA amplifications thus arising, those that provide a growth advantage for the cell will be selected. The very same reactions are very likely responsible for the emergence of drug resistance in patients receiving chemotherapy.

While the mechanism leading to HSRs was proven for the formation of methotrexate resistant hamster cells, it is clear that other possibilities for the initiation of DNA amplification exist. DMs could arise by unscheduled DNA synthesis starting from normal replication origins (just as it is the case in developmentally regulated overreplication). Alternatively they may form by recombination events in which portions of a chromosome are removed in circular form (5). Such circular structures will persist in the cells if they carry a functional origin of replication. Because DMs lack centromeres, their segregation to daughter cells occurs at random with the result that one of the daughter cells may receive more DMs (and therefore has a higher grade of amplification) than the other one. DMs may fuse to larger circles and reintegrate into the genome to give rise to HSRs. It is very likely that all these possibilities occur and that different cells differ in the way DNA amplification is initiated.

Amplification of short tandemly repeated DNA sequences present in satellite DNA or in trinucleotide repeats most probably occurs by slippage of the replication apparatus during DNA replication (Fig. 4).

DNA Amplification. Figure 4 Replication slippage. During the replication of repetitive sequences (indicated by the blocks) hybridisation of nascent single stranded DNA can occur with nearby copies of the repetitive units. Continuation of the replication process then leads to an extension of the units in the replicated DNA.

Amplification of trinucleotide repeats can happen within 5' untranslated regions of genes or within genes themselves. In the first case such amplifications can interfere with the regulation of gene expression (as it may be the case in the fragile X syndrome). They may also give rise to polyglutamine repeats within the protein coded by the gene (as in the case of Huntington chorea). Such polyglutamine regions were recently found to interact with specific components of the transcription apparatus, which again may result in a deterioration of gene expression.

Clinical Relevance

Amplification of oncogenes, growth promoting transcription factors or G1 cyclins like cyclin D is often observed in tumor cells (1). The important question is whether these amplifications have a role in the initiation of tumor formation or whether they are secondary and late incidents. The evidence from *in vitro* studies in cell culture indicates that intact control systems in normal cells do not allow the survival of cells with chromosomal abnormalities as they turn up in the course of unscheduled DNA amplification. This would favor the idea that DNA amplification is an event which takes place later in the evolution of tumor cells when changes in check point controls have already occurred and cells are defective in mechanisms which control the intactness of the genome and the

karyotype. Mutational inactivation of p53 in particular appears to assist DNA amplification. Such a situation seems also to be responsible for the frequently observed emergence of tumor cells that resist chemotherapy. In this case the DNA amplification events, such as those involving dihydrofolate reductase (resistance to methotrexate) or multi drug resistance (MDR, resistance to inhibitors of mitosis) result in a decline in the effectiveness of chemotherapy. Amplifications of trinucleotide repeats can lead to severe, frequently slowly developing neurodegenerative diseases such as Huntington chorea, muscular dystrophy or the fragile X syndrome.

► DNA Microarrays/DNA Arrays

DNA Binding Domains

Definition

The recognition and binding of specific DNA sequences is achieved by protein domains structured as basic domains next to helix-loop-helix or leucine zipper structures, or as zinc finger, helix-turn-helix, or less well defined motifs.

► Transcription Factors and Regulation of Gene Expression

DNA Catenanes

Definition

DNA catenanes are topoisomers of circular DNA molecules consisting of two or more circular DNA molecules, which are held together noncovalently by one DNA circle encircling the DNA strand of another like links of a chain. Catenanes are products of replication of circular DNA when Type II topoisomerases are absent. In order to segregate into daughter cells, DNA catenanes must be resolved by the reaction catalyzed by Type II topoisomerase.

Definition

Each human diploid cell contains in the pre-replicating state 6×10^9 base pairs in the DNA, which corresponds to a total amount of 12×10^{22} nucleotides in the human body (given that the body consists of 10^{13} cells). This huge amount of DNA, packed into 46 chromosomes (diploid), is under constant attack by endogenous and exogenous reactive molecules that causes damage in DNA bases or its sugar phosphate backbone. Furthermore, some DNA damaging agents (DDA) may cause the formation of covalent bonds between DNA and proteins (DNA protein cross-links) thus affecting DNA-histone and DNA-transcription factor interactions. This has impact on DNA packing (in the case of histones), cell division, replication and transcription of DNA.

Characteristics

Most of the DNA lesions that are formed spontaneously or by the attack of endogenous and exogenous reactive molecules are repaired, i.e. removed in an error-free manner (for review see ref. 1). Some of the lesions, although they block transcription and replication, are tolerated because of the existence of tolerance mechanisms, which include low-fidelity DNA polymerases and recombination processes. The occurrence of lesion tolerance mediated by low-fidelity DNA polymerases leads to an increase in mutation frequency. Lesion tolerance, by recombination bypass, is supposed to be error-free (2), although it may also result in incorrect recombination, which will lead to chromosomal aberrations. The final outcome of ► DNA damage induced in the genome depends on the structure of the DNA lesion, the cellular repair and replication

capacity, and the signaling that a given lesion evokes. Therefore, specific lesions can be considered as pre-cytotoxic (O^6 -methylguanine, pyrimidine dimers, most bulky DNA lesions), pre-mutagenic (O^6 -methylguanine, 8-oxo-guanine, O^4 -methylthymine, (6-4) photoproducts), and pre-clastogenic (apurinic sites, double-strand breaks, CPDs). Here, the various classes of DNA damaging agents will be reviewed briefly. This review will include their action on DNA and the lesions they induce. The mechanisms of repair of these lesions will be reviewed separately in this monograph.

Classification of DNA Damaging Agents (DDA)

In Table 1, several classes of DDA are summarized. The most prominent source for “spontaneous” DNA base modifications are reactive oxygen species (ROS) that are formed inside the cell during normal metabolism (respiratory function), or outside of the cells, e.g. during inflammatory processes. Another source of endogenous damage results from (cellular) methylating species. Thus, the intracellular methyl group donor S-adenosylmethionine has been shown to

be able to methylate DNA (3). Another important cause of “spontaneous” DNA damage is the inherent instability of DNA that results in $\sim 10^4$ base depurinations/cell/day, base deaminations and DNA strand breaks. The most important exogenous DDA are radiation and chemical mutagens (Table 1).

Ionizing Radiation

Humans are exposed to ionizing radiation (IR) every day due to cosmic radiation, terrestrial γ -radiation e.g. by K-40, Uran-238 (external irradiation) and due to ingestion and inhalation (internal irradiation). The natural radiation load is (2.4 mSv/year from cosmic and terrestrial sources and in the range of 4–6 mSv/year for man-made sources. Several sub-populations, such as nuclear plant workers, flight personal and smokers, are exposed to additional IR doses of 6 mSv/year. Tobacco smoke contains natural radioisotopes (Pb210 and Po210) causing an effective dose of 1.2 μ Sv/cigarette and an accumulative load of 8.8 mSv/year (lung dose: 106 mSv/year). This is important to note in view of the discussion of human exposure due to emission from nuclear plants, which is low in

D

DNA Damaging Agents. Table 1 DNA damaging agents

Type of agent	Example	Type of reaction with DNA
Radiation		
Ionizing radiation	X-ray, K-40, Pb210, Po210	a) DNA single and double strand breaks b) Oxidative DNA damage, e.g. Formamidopyrimidine Guanine 8-Hydroxyguanine 5-Hydroxyhydantoin Thymine glycol Cyclobutane pyrimidine dimer (CPD) 6-4-photoproduct Oxidative DNA damage
Ultraviolet light	UV-A, UV-B, UV-C light	
Chemical mutagens		
Aromatic hydrocarbons (PAH)	Benzo(a)pyren 7,12-Dimethylbenzanthrazen	N2 of guanine N2 of guanine
Halogenated hydrocarbons	Vinylchloride	N1 of adenine
Aromatic amines	N-acetyl-aminofluorene (AAF)	C8 and N2 of guanine
Alkylating agents	Dimethylnitrosamine (DMNA) Alkyl nitrosamides Mustards Mono- and bifunctional)	N1, N3, N7 of adenine; N3, N7, O6 of guanine and phosphate ester Inter- and intrastrand cross-links
Natural compounds	Aflatoxine Saflrol	Adduct at O6 and N7 of guanine Adduct at N1 and N3 of adenine Adduct at O6 of guanine

comparison. IR causes the formation of DNA single-strand breaks (SSB), double-strand breaks (DSB), oxidation of bases, DNA protein cross-links and local denaturation of DNA due to base damage. Since SSB are repaired quickly, they are usually not harmful for the cell. More dangerous are DSBs (induction ratio 25:1 for SSB and DSB) which, unless repaired, causes the generation of chromosomal breaks, sister-chromatid exchanges, gene inactivation and cell death (4). Other critical lesions are purine and pyrimidine modifications (Fig. 1a). A replication-blocking lesion induced by IR is thymine glycol that might account for replication-dependent cytotoxic effects. The most critical mutagenic lesion after IR exposure is 8-oxo-guanine (the isomeric form is 8-hydroxyguanine). 8-Oxo-G mispairs with adenine giving rise to GC → TA transversion ► [mutations](#). 8-Oxo-G is also formed spontaneously at detectable levels (estimations range from 100–500 lesions/cell/day). It is repaired by the enzyme 8-oxoguanine-DNA glycosylase, which facilitates the repair of the lesion via the base excision repair (BER) pathway. Whether gene mutations and malignant transformation induced by IR is due to non-repaired base damage or DSBs, which form chromosomal aberrations, is still a matter of debate.

Ultraviolet Light (UV)

UV-light is classified as UV-C (220–280 nm), UV-B (280–320 nm) and UV-A (320–400 nm) according to differences in wavelength. The atmosphere absorbs UV-C, whereas UV-B and UV-A reaches the earth and

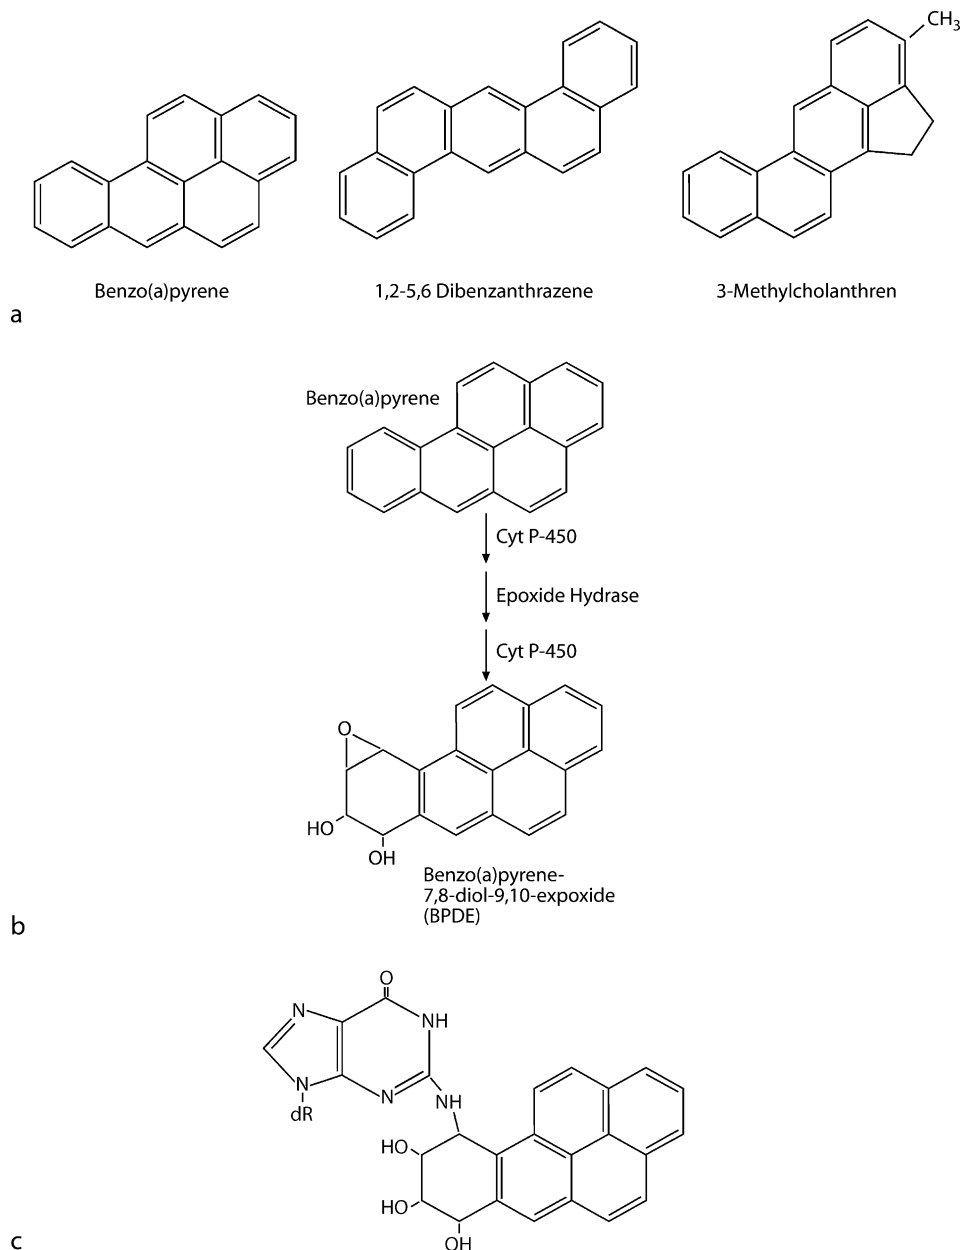

accounts for 10 and 90% of the natural UV exposure, respectively. UV-A light is considered to be responsible for sun-based effects on skin. It causes, upon chronic exposure, aging of skin and skin ► [cancer](#) (among them malignant melanomas). UV-A and UV-B irradiation induces cyclobutane pyrimidine dimers (CPDs) and (6-4) photoproducts (6-4PPs) (Fig. 1B). CPDs are induced at a three times higher frequency than 6-4PPs. UV-light also induces oxidative stress, which is true notably for long-wave UV-light and, therefore, causes the formation of 8-oxo-G and DNA-protein cross-links. There is evidence that CPDs and 6-4PPs account for most of the harmful effects of UV-light, including cell death, mutation and cancer formation. The lesions cause severe blockage in DNA replication and, thereby, provoke cell death via apoptosis (5). They also cause, in cells that survived exposure, the formation of chromosomal aberrations and gene mutations. The latter is due to error-prone (SOS) polymerases that allow cells to tolerate pre-toxic DNA lesions at the cost of mutation accumulation. The importance of ► [DNA repair](#) for defense against UV-light is strikingly illustrated by various DNA repair deficient disorders that lead to hypersensitivity to sunlight and also various metabolic defects (1). These hereditary disorders comprise xeroderma pigmentosum, Cockayne's syndrome, trichothiodystrophy, and xeroderma pigmentosum variant.

Chemical DDA

Some chemical DDA (DNA damaging agents) are listed in Table 1. Most of the agents are powerful

DNA Damaging Agents. Figure 1 Base damage in DNA induced by (a) ionizing radiation and (b) ultraviolet light.

DNA Damaging Agents. Figure 2 Polycyclic aromatic hydrocarbons. (a) Structure of various polycyclic aromatic hydrocarbons, (b) its metabolism and (c) site of attack in DNA of benzo(a)pyrene forming N²-guanine adduct.

mutagens and carcinogens. Many chemical DDA are stable. They do not react with DNA unless they are activated by metabolic conversion (e.g. many polycyclic hydrocarbons and nitrosamines). Metabolic activation occurs notably by cytochrome P450, converting the substances into reactive, ultimate carcinogens and mutagens. Various other chemical DDA are inherently active or undergo spontaneous hydrolysis

(e.g. nitrosamides) thereby forming reactive metabolites without the need for enzymatic metabolization.

Aromatic Hydrocarbons (PAH)

PAHs such as benzo(a)pyrene, dibenzanthracene, dimethylbenzanthracene, and methylcholanthrene are formed during incomplete combustion of coal, oil, gas, or tobacco. In order to become carcinogenic, they

need metabolic conversion, which is accomplished by cytochrome P450 mono-oxygenases. The structure of various PAHs is illustrated in Fig. 2a. As an paradigmatic example, the metabolic conversion and reaction with DNA of benzo(a)pyrene, a major carcinogen in cigarette smoke, is outlined in Fig. 2b. Upon metabolism by Cyp1A1, a diol epoxide is formed that reacts with DNA at the exocyclic amino group of deoxyguanosine, forming an N²-BP-adduct (Fig. 2C). This adduct provokes severe steric alteration of DNA that impairs DNA-dependent metabolic functions, including DNA replication and transcription. These adducts can be removed from DNA by nucleotide excision repair (NER), which is the main cellular defense mechanism against these types of lesions. A more distal defense mechanism is mediated by detoxifying (phase II) enzymes, which includes epoxide hydrolases and glutathione transferases.

Halogenated Hydrocarbons (HHC)

HHC such as chloroform, halothan, CCl₄, trichlorethan or trichlorethylen are narcotic and highly cytotoxic for liver and/or kidney, because of the formation of radicals that lead to lipid peroxidation. Some of the HHC's, such as vinylchloride, dibromoethane or epichlorhydrine, are carcinogenic. Vinylchloride, which is extensively used for PVC production, is enzymatically converted into an epoxide, which in turn leads to a non-enzymatic formation of chloroacetaldehyde. Both metabolites attack DNA at N1 position of adenosine. Rearrangements of the molecule gives finally rise to an ethano-adenosine-adduct (Fig. 3).

Aromatic Amines (AA)

AA such as benzidine, naphtylamine, toluidine, aminoanthracene or acetylaminofluorene (AAF) (Fig. 4a) are widely distributed industrial compounds used e.g. for the synthesis of colored dyes, pestizides and manufacturing of plastics. They can also be formed upon high heating of food. Upon metabolic activation (i.e. N-hydroxylation) by cytochrome P450 1A2 a reactive metabolite is generated which is responsible

for both cytotoxic effects (i.e. formation of methemoglobin) and DNA adduct formation which occurs mostly on position C8 and N2 of guanine (Fig. 4b). One main detoxification reaction consists of N-acetylation catalyzed by polymorphic N-acetyltransferases. In human, the main target organ for AA-induced cancer is the bladder.

Alkylating Agents: N-Nitrosamines and N-Nitrosamides

Perhaps the most powerful DNA reactive agents and, at the same time, mutagens, clastogens and carcinogens are alkylating agents. Most relevant, both as environmental carcinogens and endogenously formed alkylating agents, are the N-nitrosamines (Table 1 and Fig. 5a). N-nitrosamines, e.g. dimethylnitrosamine (DMNA), are stable compounds that need metabolic activation in order to turn into the ultimate reactive agents, which are highly reactive electrophilic species (Fig. 5b). In contrast, N-nitrosamides, e.g. N-methyl-N-nitrosourea, are quite unstable, undergoing spontaneous hydrolysis in aqueous solution that yields again electrophils (e.g. carbenium ions). These electrophilic species react with DNA at 12 different sites (Table 2). The extent of the reaction with these DNA alkylation sites is dependent on the electrophilicity of the agents (i.e. their S_N1 or S_N2 character). The major alkylation site for all S_N1 and S_N2 agents is N7 of guanine, followed by the phosphate in the DNA backbone and the N3 of adenine. Irrespective of this, the most biologically important attack occurs at a minor alkylation site, the O⁶ of guanine. O⁶-alkylguanine encompasses 0.3–8% of total DNA alkylation. The mutagenic and carcinogenic potency of simple alkylating agents correlates with their O-alkylating potency. Thus, methyl methanesulfonate (MMS) is a very weak carcinogen and induces point mutations at low frequency, whereas N-methyl-N-nitrosourea and, even better, N-ethyl-N-nitrosourea are highly carcinogenic and induce point mutations at high frequency. The underlying reason for this has been clarified: O⁶-methylguanine and O⁶-ethylguanine mispair with

DNA Damaging Agents. Figure 3 Metabolic activation and mode of action of vinylchloride forming an etheno adenosine adduct.

DNA Damaging Agents. Figure 4 Aromatic amines. (a) Structure and (b) metabolism of AAF inducing guanine adducts.

thymine, which gives rise to GC \rightarrow AT transition mutations. O⁶-alkylguanine is repaired by the repair protein MGMT (1).

Simple alkylating agents exert a marked organotropy in tumor formation. Thus, ENU is extremely powerful in inducing brain tumors in rats; DMNA induces liver tumors and MNU thymic lymphomas. Brain tumor formation was shown to be related to the lack of MGMT expression at various stages of development of the rat brain, whereas liver tumor formation upon chronic exposure of rats with DMNA is likely due to cytochrome P450 metabolism of this agent in the liver.

Simple alkylating agents, notably the N-nitrosamines, are found widely in the environment (6). They are also formed endogenously, e.g. in the stomach from nitrite and secondary amines and also, presumably, by microbial metabolism in the stomach and intestine. It should also be noted that tobacco smoke contains high amounts of dimethylnitrosamine and at least 5 tobacco smoke-specific carcinogens, which are degradation products of nicotine (see below). Nitrosamines can also be formed during the preparation of food, e.g. roasted meat and alcoholic beverages such as Whisky.

Various alkylating drugs exhibit crosslinking activity, because they are either bifunctional agents or monofunctional mutagens forming adducts that undergo secondary rearrangement in the DNA. Paradigmatic examples of bifunctional alkylating agents are N-Lost and S-Lost compounds (Fig. 5a). N-Lost (LOST = Lommel and Steinkopf, according to the German chemists who discovered compounds to be used as chemical weapons in world war I) alkylates guanines, without metabolic activation, at N7 of guanine, forming an interstrand N7-G-N7-G crosslink. These crosslinks are considered to be highly cytotoxic. This principle has been utilized in tumor therapy: a derivative of N-Lost is cyclophosphamide, which is most often applied in cancer treatment. Monofunctional crosslinking agents are chloroethylating nitrosoureas (BCNU, ACNU, CCNU) that are used in the therapy of glioblastomas, malignant melanomas and various hematopoietic tumors.

DDA in Tobacco Smoke

Tobacco smoke contains more than 3200 different compounds. These compounds include 47 well-known

DNA Damaging Agents. Figure 5 Alkylating agents. (a) Structure of different mono- and bifunctional alkylating agents and (b) conversion into electrophilic species.

DNA Damaging Agents. Table 2 Sites of attack of alkylating agents

DNA adduct	Dimethylnitrosamine N-methyl-N-nitrosourea1, 2-dimethylhydrazine	Methyl methanesulfonate	Diethylnitrosamine N-ethyl-N-nitrosourea
N1-Alkyladenine	0.7	1.2	0.3
N3-Alkyladenine	8.0	11.0	4.0
N7-Alkyladenine	1.5	1.9	0.4
N3-Alkylguanine	0.8	0.7	0.6

Alkylphosphate	12.0	1.0	53.0

carcinogens. The major DDAs in tobacco smoke are benzo(a)pyrene, benzanthrazene, dimethylnitrosamine, the tobacco-smoke-specific nitrosamine N-nitroso-nornicotine, cadmium, nickel, anilin, acrolein and formaldehyde. Tobacco smoke also contains ROS that cause oxidative DNA damage. Overall, tobacco smoke is a main source of exogenous man-made DNA damage. Because of the diversity of the DDA it contains, it is difficult to assess the component that is most dangerous and that is also responsible for tobacco smoke-induced tumor formation, such as lung cancer.

DDA in the Natural Environment

Microorganisms, fungi, and plants produce various highly reactive DNA damaging agents. They are considered as a serious hazard for man, even contributing to some types of cancer. Most important are aflatoxins such as aflatoxin B₁ (AFT-B₁). It is a mycotoxin produced by different aspergillus species. Food contaminated with aspergillus (rice, soy, peanuts) contains high amounts of aflatoxins. AFT-B₁ is a powerful hepatocarcinogen. Chronic exposure causes liver cirrhosis. AFT-B₁ is metabolically activated in the liver by Cyp P450, forming a reactive epoxide that reacts with DNA preferably at the N7 position of guanine.

Another DNA damaging agent that causes liver cancer in animals is saffrol. The compound was found in pepper, anise, celery, and the tree *Sassafras albidum*. There are various other compounds produced in plants that have been described to be mutagenic and carcinogenic. These compounds include cycasin, arecolin, coumarin, limonene, aristolochic acid and reserpine. For some of them the DNA reaction products still need to be defined.

Some DDAs produced by microorganisms are in use as well-established anticancer drugs. Examples are mitomycin D and bleomycin. Mitomycin C causes DNA interstrand crosslinks that are cytotoxic. Bleomycin is an example of a chemical that induces radiomimetic effects, notably DNA strand breaks.

Heavy Metals

Various heavy metal ions, such as Ni, Cd, and As, are mutagenic and carcinogenic. They cause DNA strand breaks, which could be due to direct attack of DNA or intracellular radical formation. There are data available indicating that heavy metals inhibit specific DNA repair enzymes of the BER and NER pathway and, therefore, cause accumulation of DNA damage.

Topoisomerase Inhibitors

Various agents that play an important role in tumor therapy cause DNA damage indirectly, for example by

inhibition of topoisomerase I or II. Topo I and II are DNA helicases that cleave DNA, thereby facilitating their unwinding. Topo I causes single-strand breaks, topo II double-strand breaks. The breaks they induce in DNA are transient and become religated by a second catalytic function of the topoisomerases themselves. Camptothecin and etoposide inhibit this religation function of topo I and II, respectively, thereby causing an accumulation of DNA strand breaks due to the inability of the enzyme to reseal the formed breaks. Topoisomerase inhibitors are examples of agents that cause DNA damage by inhibiting cellular enzymatic functions involved in DNA metabolism.

DNA Double-Strand Break Repair

► Double-Strand Break Repair

DNA Gyrase

Definition

DNA gyrase is a bacterial Type IIA topoisomerase that introduces negative supercoiling into circular DNA. The reaction mechanism involves the wrapping of DNA around the gyrase molecule in a positive superhelical turn, which is then converted into a negative one by strand passage. The negative supercoiling of bacterial DNA produced by gyrase serves to monitor DNA integrity, as any single or double strand DNA break would result in relaxation of supercoiling.

Definition

The unwinding of double-stranded DNA is an important cellular function essential to a variety of nucleic acid transactions such as ► [DNA replication](#), ► [DNA repair](#), ► [DNA recombination](#) and mRNA ► [transcription](#). Unwinding can be catalyzed by a group of ubiquitous enzymes referred to as DNA helicases (reviewed in 1, 2, 3, 4, 5, 6, 7). DNA helicases are molecular motors that disrupt the hydrogen bonds holding together the two strands of the DNA duplex to produce single-stranded DNA. The reaction is driven forward by the hydrolysis of nucleoside 5'-triphosphate (most often ATP), owing to an intrinsic ► [NTPase](#) activity. Unwinding provides access to the single-stranded DNA that other proteins require to carry out their functions (1, 2, 3, 4, 5, 6, 7). Another class of structurally similar enzymes, the RNA helicases, bind and unwind RNA as substrate. A small number of enzymes can unwind both RNA and DNA (6).

Characteristics

The DNA helicases have been studied at the biochemical, molecular, cellular and biophysical levels. Classification as a DNA helicase requires the biochemical demonstration of unwinding activity (2). However,

large numbers of similar molecules have been identified by bioinformatic criteria as putative helicases or, at the very least, putative molecular motors whose activities and functions require further characterization. For example, by informatic analyses it is estimated that 2% of *Saccharomyces cerevisiae* genes are helicase-related proteins (4).

Biochemical Characteristics

The biochemical activities shared by DNA helicases include DNA binding, specificity for the NTP or dNTP bound and hydrolyzed, DNA-dependent or DNA-stimulated NTP (or dNTP) hydrolysis and NTP (or dNTP) hydrolysis-dependent unwinding of double-stranded DNA. Mg²⁺ is invariably a cofactor required in these reactions. Helicases are characterized based on their biochemical properties such as substrate specificity, affinity for single-stranded as compared to double-stranded DNA, the directionality of the enzyme's movement along single-stranded DNA, i.e., movement in a 5' to 3' direction *versus* in a 3' to 5' direction, processivity, efficiency, ► [oligomerization](#) and other proteins with which they interact (1, 2, 3, 4, 5, 6, 7).

The substrate specificity of a DNA helicase is defined by the kinds of nucleic acids they unwind (Fig. 1). Substrates are usually formed experimentally by annealing a labeled oligonucleotide with a complementary oligonucleotide(s) or purified viral or plasmid DNAs. Experimental substrates are constructed to resemble substrates that might be encountered in the cell, such as a frayed broken DNA end, a ► [telomere](#), a replication fork, a recombination intermediate, etc. Most DNA helicases bind efficiently to and translocate along a single strand of DNA. Some can unwind a DNA-RNA hybrid, but most often they do so by translocating along the DNA strand and displacing the complementary RNA strand as they would the complementary DNA strand (6).

The processivity of a given helicase is defined as the probability that the enzyme will move forward one step from a distinct position along the nucleic acid substrate divided by the probability that the enzyme will dissociate from that position. The efficiency is defined by the number of nucleotides unwound per single ATP molecule hydrolyzed by the helicase (also known as the step size). Both processivity and efficiency can be affected by other proteins with which a helicase might interact (7). For example, the hexameric helicase DnaB of *Escherichia coli*, which unwinds DNA ahead of the replication fork, interacts with ► [DNA polymerase III](#); this interaction enhances its processivity and efficiency >10 fold. DNA helicases are typically present as part of a specific macromolecular complex (es), where activity is coupled to other nucleic acid transactions (2) (Table 1).

DNA Helicases. Figure 1 Schematic drawing of selected cellular DNA helicase substrates. DNA helicases often require some single-stranded DNA to begin unwinding. For example, single-stranded DNA can be exposed at the end of DNA duplex by an exonuclease. Cyclopurine dimers generated by UV irradiation are recognized by XPC protein or RNA polymerase. These enzymes expose single-stranded DNA and recruit the TFIIH helicase to the lesion-containing site. Similarly, TFIIH is recruited to the promoter regions of genes by other transcription factors that bind DNA and presumably expose single-stranded DNA by distorting the DNA helix. Replicative DNA helicases that unwind DNA helix ahead of the replication fork are recruited to the origin of replication by specific replication proteins. Structure-specific DNA helicases recognize and resolve recombination intermediates such as Holliday junctions. These proteins stabilize a form of the Holliday junction in which the four strands entering the junction are unbasepaired.

Bioinformatic Characteristics

Sequence homology analyses of many DNA and RNA helicases from a wide spectrum of prokaryotic and eukaryotic organisms and viruses have identified the presence of seven highly conserved motifs (I, Ia, II, III, IV, V, and VI), which led to the classification of many known and putative helicases into two superfamilies—superfamily 1 (SF1) and superfamily 2 (SF2). From the amount of sequence homology between the motifs, the predicted secondary structures of SF1 and SF2 members are similar (3, 4). Because motifs I and II are homologous to Walker boxes A and B, they are believed to take part in NTP and Mg^{2+} binding. These two motifs are shared among many ATPases as well. The remaining motifs participate in binding the substrate and in coordinating the enzyme's movements during catalysis (6).

Superfamily 3 (SF3) consists of a smaller group of proteins whose members are found in only RNA and DNA viruses, and they have only three conserved motifs (A, B, and C). Only one member of this family—SV40 T antigen—has been shown to possess helicase activity. Family 4 members, also small in number, are present in bacteria and **bacteriophages**, share five conserved motifs (1, 1a, 2, 3, and 4) and are presumed to act in DNA replication, because the enzymes tested interact with **DNA primases** (e.g., *E. coli* DnaB is in family 4) (3, 4).

Other helicases that do not belong to any of these families include the hexameric Rho transcription factor and the **MCM** (minichromosome maintenance) protein complex (3, 4). The MCM complex belongs to the AAA family of ATPases (ATPases associated with various cellular activities, such as DNA replication, protein folding and degradation, etc.). This family of ATPases carries out chaperone-like functions to assist in the assembly and disassembly or the efficient operation of various protein complexes. Members of this family share a conserved region of about 220 amino acids that contains an ATP-binding site. It is thought that AAA domains act as ATP-dependent protein clamps. Along with the conserved N-terminal Walker motifs A and B, they contain another highly conserved region in the central part of the ATPase domain. The utilization of the AAA domain in DNA unwinding activity is not currently understood.

The presence of the seven SF1 or SF2 helicase motifs in a protein does not guarantee the presence of helicase activity *in vitro*. An example is eukaryotic SWI2/SNF2 that has a DNA-dependent ATPase activity but no helicase activity. SWI2/SNF2 is part of a large protein complex that is thought to re-model chromatin as part of its function in transcriptional regulation, DNA repair and recombination (6). The SWI2/SNF2 protein appears to act as a molecular motor that changes the disposition of histones on the DNA.

^a Abbreviations for the associated proteins are as follows: SSB, single-stranded DNA binding protein; CDC45, an essential protein required for the initiation of DNA replication; ORC, origin recognition complex, consisting of six subunits ORC (1-6), that recognize the origin of replication and load MCM's onto the origin; UvrA, a base excision repair protein, functioning in the recognition of DNA damage; TFIIH, a transcription factor, consisting of six core peptide chains XPB, XPD, p44, p62, p52, and p34 and three interacting proteins Mat1, cdk7, and cyclin H; σ factor, a transcription factor, that binds to the RNA polymerase core enzyme and enhances promoter specificity; RecA, an essential prokaryotic DNA recombination gene, that facilitates strand invasion during homologous recombination; TOPIII, DNA topoisomerase III; RAD51, an essential recombination protein physically and functionally homologous to RecA protein; RPA, replication protein A, that binds single-stranded DNA and is comprised of three subunits p70, p34, and p17; MLH1, a DNA mismatch repair protein, of which mutation leads to colon cancer predisposition; FANC proteins are encoded by the gene mutated in the rare genetic disease Fanconi anemia; Ku70/Ku80, a DNA double-strand break repair protein, that binds DNA-dependent protein kinase (DNA-PK) and to the broken DNA end; TRF2, telomeric repeat binding factor 2, that protects telomeres against end-to-end fusion of chromosomes.

^b Though RNA polymerase is not biochemically classified as DNA helicase, it is capable of unwinding DNA during transcription.

^c RecBCD consists of three peptide chains RecB, RecC and RecD and it has exonuclease activities.

DNA Helicases. Figure 2 Proposed mechanism of action for PcrA helicase. ATP binding and hydrolysis mediates conformational changes that allow for DNA translocation and duplex destabilization. PcrA is comprised of four domains 1A (green), 1B (yellow), 2A (red), and 2B (blue). The binding of domains 1A and 2A to ssDNA induces swiveling of domain 2B, which in turn prepares the potential to bind duplex DNA. Together domains 1A and 2A form the RecA-like domains, which when bound to ATP, act as a crosslinking bridge leading to a cleft closure that bring these two domains closer. This conformational change within the recA like domains spreads a larger conformational change across the surface of domains 1B and 2B, which results in direct interaction with the duplex. Domain 2B 'grabs' the duplex at 12-13 bases away from the ss-dsDNA junction (distal contact) and pulls it toward the protein. Meanwhile, domain 1B forms a contact with the duplex closer to the junction (proximal contact) leading to destabilization in the duplex for half a helical turn as well as strand separation at the junction. Upon ATP hydrolysis, the bridge formed between domains 1A and 2A is broken, which is translated in a reversal of the conformational changes in domains 1B and 2B. While domain 1B releases the duplex, 2B pushes the DNA away from the protein while maintaining contact. This process allows the duplex to translocate across the surface of the protein. Reprinted with permission from (5).

^a There is variable expressivity of many of these clinical features.

^b There are seven major complementation groups in XP that have been identified (A, B, C, D, E, F, and G). All of these components are essential for the nucleotide excision repair pathway. XP variant (XPV) syndrome shows typical XP features, but an absence of a defect in NER. XPV cells have a defect in post-replication repair.

^c Only in complementation groups XPA, XPB, XPD, and XPG.

^d Average lifespan of these persons is low, but a lack of cancer predisposition is suggested by the clinical data.

Structural Studies

Recent crystal structures have provided new insights into the mechanism of catalysis by DNA helicases (Fig. 2). The helicases studied in this way consist of 4 domains (1A, 1B, 2A, and 2B) with a central lateral groove along which single-stranded DNA binds. Domains 1A and 2A are structurally similar to the ►*RecA* protein. ATP binds in the groove between 1A and 2A. Translocation along single-stranded DNA follows an inchworm model. The various states of ATP/ADP binding are associated with dynamic changes in the enzyme's conformation and changes in the interactions between conserved amino acid residues in the central lateral groove and the single-stranded DNA. Hydrolysis of ATP accompanies a power stroke, in which the leading edge of the enzyme (domains 2A and 2B) pumps forward on the DNA while the lagging edge (domains 1A and 1B) holds onto the DNA (5).

Clinical Relevance

Helicases and Human Disease

Mutational defects in several DNA helicase genes can cause distinctive genetic disorders. Six human genetic disorders have been reported thus far, including xeroderma pigmentosum (XP), Cockayne syndrome (CS), trichothiodystrophy (TTD), Bloom syndrome (BS), Werner syndrome (WS) and Rothmund-Thomson syndrome (RTS) (Table 2). These syndromes represent a subset of disorders in which DNA repair deficiency, ►*genomic instability* and cancer predisposition are common features.

Persons with XP exhibit a defect in nucleotide excision repair (NER). NER is an important DNA repair mechanism that removes cyclopurine dimers and other lesions generated by UV irradiation and bulky DNA

adducts, such as those generated by cis-platinum treatment. A defective NER pathway results in increased mutagenesis particularly in the skin from failure to repair sunlight-generated lesions, which explains the development of skin cancers in XP. Two DNA helicases function in the NER pathway, XPB and XPD, which have opposite directionalities on single-stranded DNA. The XPB and XPD helicases are part of the transcription factor complex, TFIIH, which contains up to 9 proteins. In NER, the XPB and XPD subunits of TFIIH provide helicase activities that open up the DNA duplex so that the lesion-containing DNA can be cleaved from the duplex by specific endonucleases. In transcription, TFIIH opens up the DNA duplex so that RNA polymerase can bind to the transcribed DNA strand. Thus, the role of TFIIH in each process is similar. Some ►*mutations* of *XPB* and *XPD* result in XP, whereas other mutations in these genes result in either of the clinically distinct syndromes CS and TTD. The defects of CS and TTD cells are also distinct from those of XP cells, and they are believed to be caused by a deficiency of TFIIH in transcription but not NER. A small number of persons with *XPB* or *XPD* mutations have XP and CS or TTD, and presumably these mutations affect both NER and transcription. CS is a progeroid syndrome, and mouse models of these syndromes have shown that these genes are important in mechanisms of aging (6).

The DNA helicases that are defective in persons with BS, WS, and RTS belong to a family of DNA helicases referred to as the RecQ helicases, which is conserved from bacteria to humans. The corresponding genes that are mutated in these syndromes are *BLM*, *WRN*, and *RECQL4* (also referred to as *RTS*), respectively. The syndromes are clinically distinct (Table 2): BS is characterized by proportional dwarfism and a sun-sensitive facial rash, WS by progeroid features such

as alopecia, atherosclerosis and osteoporosis and RTS by small size, poikiloderma and alopecia. A common feature of cells that contain mutations in one of the RecQ genes is a disturbance in recombination. For example, BS cells exhibit excessive recombination between homologous chromosomes and between sister chromatids, as well as chromosome breakage and WS cells exhibit increased chromosome translocations. The genomic instability that is prominent in these syndromes is associated with susceptibility to a wide spectrum of cancers. The RecQ enzymes are unusual DNA helicases in that they are most efficient in binding and unwinding substrates that resemble recombination intermediates, including Holliday junctions, D-loops, and [▶G-quartet DNA](#). Although the function of the RecQ helicases is elusive, a number of functions have been proposed, including resolution of Holliday junctions, suppression of illegitimate recombination events that might occur between imperfectly homologous DNA sequences and participation in one or more of the processes involved in restarting a stalled replication fork, which can occur when the replication machinery (i.e. the polymerase) encounters DNA damage (6). Mutations in RecQ helicases have uncovered the important connections between DNA recombination, genomic stability, cancer predisposition and mechanisms of aging

DNA Lesion

Definition

DNA lesion refers to a section of a DNA molecule containing a primary damaged site i.e. a base alteration,

a base deletion, a sugar alteration or a strand break. Replication before repair, or inefficient repair, can result in the fixation of a primary lesion as a permanent mutation.

[▶Chromosomal Instability Syndromes](#)

DNA Ligases

ALESSANDRA MONTECUCCO, ROSSELLA ROSSI
Istituto di Genetica Molecolare, CNR, Pavia, Italy
montecucco@igm.cnr.it

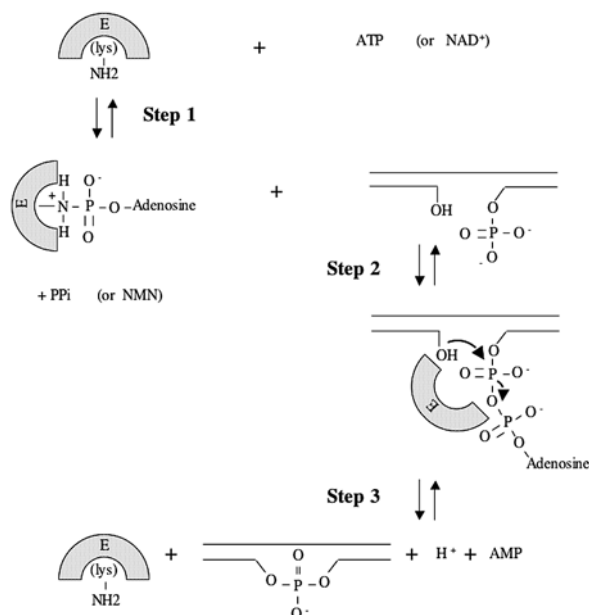

Definition

DNA ligases are a large family of evolutionarily related enzymes that catalyze the joining of single-strand or double-strand breaks between adjacent 3'-hydroxyl and 5'-phosphate termini in the phosphodiester backbone of double-strand DNA. For this reason they play a vital role in DNA metabolism. DNA strand breaks can occur as a result either of the direct action of [▶DNA damaging agents](#) or as reaction intermediates during [▶DNA replication](#), repair and recombination; therefore the sealing of these breaks by DNA ligase is critical for maintaining genome integrity.

Characteristics

Reaction Mechanism

The joining reaction is coupled to the hydrolysis of a high-energy bond in the cofactor molecule. On the basis of the required cofactor DNA ligases are separated into two major groups, [▶ATP-dependent](#) and NAD^+ ([▶NADPH+H+NAD⁺](#))-dependent enzymes. DNA ligases from most organisms break down ATP to [▶AMP](#) and pyrophosphate (PPi). Eubacterial enzymes, instead, utilize NAD^+ with the production of AMP and nicotinamide mononucleotide (NMN). One ATP (or NAD^+) molecule is consumed per nick-sealing event. The DNA joining reaction involves three successive steps. The first is a nucleophilic attack on the α -phosphate of ATP (or the adenyl-phosphate of NAD^+) by the lysine residue in the active site of the enzyme resulting in a covalent enzyme-AMP intermediate (Fig. 1). Certain cofactor analogs, such as dATP, can be used, but the anomalous enzyme-nucleotide intermediates appear to function poorly in the successive steps. During the second step, the AMP group is transferred to the phosphorylated 5'-end of a single-strand break to produce an inverted (5')-(5') pyrophosphate bridge structure. In the final step the enzyme catalyzes the sealing of the nick with the displacement of AMP.

DNA Ligases. Figure 1 DNA joining reaction catalyzed by DNA ligase. Step 1: DNA ligase (E) interacts with ATP or NAD⁺ depending on the class of the enzyme, to form an enzyme-AMP intermediate in which the AMP group is covalently linked to the lysine (lys) of the active site. Step 2: the AMP is transferred from the enzyme to the 5'-phosphate terminus of a nick in duplex DNA to form a DNA-adenylate intermediate. Step 3: the interaction of non-adenylated DNA ligase with the DNA-adenylate complex results in phosphodiester bond formation and the release of AMP.

In the so-called ‘reverse reaction’ the AMP group can be used as a cofactor for the ligase-directed removal of superhelical turns from a covalently closed **▶supercoiled DNA**. This occurs through a nicking/closing mechanism mimicking the DNA topoisomerase activity. The lysine of the active site is required also for the AMP-dependent **▶DNA relaxation**.

Some DNA ligases are also able to catalyze blunt-end ligation. Blunt-end joining proceeds less efficiently than ligation of nicks or of cohesive ends and is stimulated by polyethylene glycol.

Structure

The three-dimensional structures of both an ATP-dependent and a NAD⁺-dependent DNA ligase have been determined by X-ray crystallography (1). Immediately apparent from the structures is the conservation of a common ‘core’ domain between the two enzymes. Alignment of DNA ligase sequences from different sources has identified a series of co-linear conserved motifs (motif I, III, IIIa, IV, V, VI) that define a family of related nucleotidyl transferases including eukaryotic GTP-dependent mRNA-capping enzymes.

With the exception of motif VI, these lie in the core domain. Motif I corresponds to the active site and contains the consensus sequence ‘lys-x-asp-gly’ shared with RNA ligases. The lysine in motif I is engaged in the covalent binding to AMP. The similarity of structural features between DNA ligases and mRNA capping enzymes suggests a similar mechanism of catalysis and the evolution of these two classes of enzymes from a common ancestral nucleotidyl transferase. The polynucleotide specificity of the enzyme (RNA or DNA) is dictated by additional protein ‘modules’ around the catalytic conserved core.

NAD⁺-Dependent DNA Ligases

Eubacterial DNA ligases appear to be almost unique in utilizing NAD⁺ as high-energy cofactor. The prototype of this class is the *Escherichia coli* (*E. coli*) enzyme encoded by the essential *ligA* gene. NAD⁺-dependent DNA ligases are also found in *Bacillus subtilis* and *Staphylococcus aureus* and probably are essential genes in all eubacteria. The enzymes from different bacteria have now been cloned and sequenced. They show a high degree of sequence similarity and a similar size (about 75 kD). The fact that NAD⁺-dependent DNA ligases are specific to eubacteria and are essential for cell survival makes these proteins potential targets for novel antibacterial strategies.

ATP-Dependent DNA Ligases

Most eukaryotic DNA ligases together with archeal and bacteriophage enzymes use ATP as a cofactor. In eukaryotic cells there are three classes of ATP-dependent DNA ligases that are related in sequence and structure. These enzymes are built around a common catalytic core that is similar to the smaller ATP-dependent DNA ligase of the T7-bacteriophage. Numerous pieces of evidence indicate that the three classes of DNA ligases are targeted to different pathways in DNA replication, repair and recombination and show a limited, if any, ability to substitute for each other. The main functional differences between these DNA ligases seem to be mediated by large regions located outside the catalytic core that can establish specific protein-protein interactions and govern the sub-cellular distribution.

The three mammalian enzymes are called DNA ligase I, III and IV (Table 1).

DNA ligase I is required for chromosomal DNA replication as well as for several DNA-repair pathways. Orthologs have been identified in organisms as diverse as yeast and mammals. The human *lig1* gene has been mapped on chromosome 19q13.2-13.3 close to other DNA repair genes. This proximity is conserved in mouse. During chromosome replication DNA ligase I is responsible for the joining of the **▶Okazaki fragments**. The enzyme acts as part of a replication complex called

DNA Ligases. Table 1

the replisome formed by several different replication proteins. DNA ligase I is divided into two clearly distinct regions, a highly conserved C-terminal region, containing the active site and a less conserved hydrophilic N-terminal portion (residues 1–216), that functions as a regulatory domain. The N-terminal domain controls the sub-cellular distribution of the enzyme and mediates the interaction with other replicative proteins. Human DNA ligase I is phosphorylated *in vivo* on four serine residues (at positions 51, 66, 76, 91) and is a substrate for both casein kinase II (CKII) and cyclin-dependent kinases (CDK). Consistently with its role in DNA replication, the DNA ligase I gene is more expressed in proliferating than in resting cells. DNA ligase I activity during the cell cycle is controlled by both phosphorylation and sub-nuclear compartmentalization. The enzyme associates with [▶replication foci](#) during S-phase while displaying a diffuse nucleoplasmic distribution in non-S phase nuclei. Its function requires interaction with the proliferating cell nuclear antigen (PCNA) mediated by a p21-type PCNA-binding motif in the first 20 amino acids of the protein (2). The PCNA binding site is required for recruitment to the replication foci and for the efficient joining of the Okazaki fragments during DNA replication.

Similarly to other enzymes involved in the maturation of the Okazaki fragments, DNA ligase I functions in

long-patch base excision repair ([▶BER](#)). In addition DNA ligase I interacts with DNA polymerase β that catalyzes DNA synthesis in short-patch BER. Finally, *in vitro* reconstitution assays have implicated DNA ligase I in nucleotide excision repair (NER).

A case of DNA ligase I-deficiency in humans has been described which is responsible for the 46BR syndrome, characterized by growth retardation, abnormal development, sun sensitivity and immunodeficiency (3). Different point mutations have been found in each of the *lig1* alleles resulting in extremely reduced enzyme activity. Skin fibroblasts from this patient show hypersensitivity to DNA damaging agents, replication defects and genetic instability. Transgenic mice carrying the same mutation display an increased incidence of spontaneous epithelial tumors (4). *Lig1* knock out mice have been recently obtained. DNA ligase I null mutants die during embryogenesis and fibroblasts from these embryos show accumulation of DNA replication intermediates and increased genome instability.

DNA ligase III is unique to vertebrates, and functions both in the nucleus and in mitochondria. It is involved mainly in nuclear and mitochondrial DNA repair. Alternative splicing of *lig3* transcripts produces two isoforms called DNA ligases III α and β with different carboxyl-terminal sequences (5). DNA ligase III α is ubiquitously distributed and has a role in the

short-patch BER. DNA ligase III β is expressed only in the testes where it is believed to play a role in homologous recombination during meiosis. DNA ligase III α but not the β form, has a C-terminal **►BRCT domain** through which it interacts with the repair protein XRCC1 (X-ray cross complementing factor 1). The heterodimeric complex formed by XRCC1 and DNA ligase III α functions *in vivo* in short-patch BER. At the N-terminus of both DNA ligase III α and β there is a consensus sequence for a **►zinc finger** DNA binding domain that could trigger the binding of the enzyme and of associated proteins to sites of DNA damage. Both isoforms can be targeted to mitochondria thanks to a mitochondrial targeting sequence (MTS) located upstream of the first amino acid of the mature protein. This raises the possibility that both enzymes play a part in the repair of mitochondrial DNA. Upon import into the mitochondria, the MTS is cleaved by a mitochondrial peptidase. DNA ligase IV is conserved in all eukaryotes. Orthologs have been identified in yeast, higher plants and vertebrates. It functions in non-homologous end joining (NHEJ), which is the main repair pathway for double strand breaks caused by ionizing radiation or certain classes of chemical mutagens. This pathway is also required for V(D)J recombination, the process by which immunoglobulin and T-cell receptor genes are rearranged to generate antibody diversity. *In vivo* DNA ligase IV is strongly associated with XRCC4, a nuclear phosphoprotein. XRCC4 stabilizes DNA ligase IV and stimulates its activity by targeting the protein to sites of DNA double strand breaks. DNA ligase IV is characterized by a C-terminal region comprising two BRCT domains separated by a short linker that contains the binding site for XRCC4. DNA ligase IV is a nuclear protein and is associated with chromosomes during mitosis. Recent evidence indicates that DNA ligase IV co-localizes with a human condensin subunit, a member of the structural maintenance of chromosome (SMC) super-family proteins. Inactivation of the *lig4* gene in mouse leads to late embryonic lethality associated with a block of lymphopoiesis, V(D)J recombination failure and extensive apoptotic cell death in the embryonic central nervous system (6). DNA ligase IV-deficient embryonic fibroblasts also show marked sensitivity to ionizing radiation, growth defects and premature senescence. All of these phenotypic characteristics, except embryonic lethality, resemble those associated with deficiencies in other proteins involved in NHEJ. To date five patients have been described with a defect in DNA ligase IV. One patient was homozygous for a missense mutation that reduced the adenylation and ligation activities of the enzyme. The patient did not display any overt immunodeficiency but he developed leukemia at the age of 14 and showed pronounced radio-sensitivity.

The other four patients had mutations that disrupted the catalytic domain or impaired the interaction with XRCC4. All of them showed common features including immunodeficiency, developmental and growth delay and chromosomal instability. Their clinical phenotype closely resembled the DNA damage response disorder, Nijmegen breakage syndrome (NBS). Unlike NBS, *lig4* cells showed a normal cell-cycle checkpoint response but impaired DNA double strand break rejoining. These findings have unveiled the existence of an inherited disorder, designated *lig4* syndrome that arises from a specific DNA repair defect and is associated with primary human immunodeficiency, genomic instability and developmental delay (7).

Clinical Relevance

Similarly to other replicative enzymes, DNA ligase I is a marker of cell proliferation and its sub-nuclear distribution is regulated during the cell cycle. It is therefore possible to use anti-DNA ligase I antibodies to recognize S-phase cells by immunohistochemistry and to determine the labeling index of a cell population.

DNA Ligase Inhibitors with Anticancer Activity

Given its role in DNA replication, DNA ligase I is a target for a number of anticancer drugs. Antitumor anthracyclines and distamycins are strong inhibitors of human DNA ligase I. Anthracyclines block the joining reaction without affecting enzyme adenylation. This inhibition is mediated by the interaction of anthracyclines with the DNA substrate. A potent and specific inhibitor of human DNA ligase I is tallimustine, a distamycin derivative with antitumor activity. Unlike the anthracyclines, this drug inhibits the adenylation of human DNA ligase I, preventing the successive steps of the joining reaction. Etoposide is an anticancer drug belonging to the topoisomerase poisons. Although unable to inhibit the DNA joining reaction *in vitro*, this drug has a dramatic effect on the phosphorylation and sub-nuclear distribution of DNA ligase I.

DNA Ligase Inhibitors with Antibiotic Activity

Multiple drug resistance among bacterial pathogens has made many of the currently available antibiotics ineffective. As a consequence the search for novel antibacterial classes with innovative mechanisms of action is crucial. NAD⁺-dependent DNA ligases are promising target candidates because they are indispensable for many fundamental aspects of DNA metabolism. The different cofactor requirements raise the chance of finding specific inhibitors directed exclusively against the eubacterial enzymes. Derivatives of the anti-malaria drug chloroquine inhibit the *E. coli* DNA ligase. Human DNA ligase I is also affected but at a 10-fold higher concentration. More recently

pyridochromanones that possess substantial antibacterial activity have been identified as a novel class of potent DNA ligase inhibitors. The compounds specifically inhibited the purified NAD⁺-dependent enzymes from both *E. coli* and *Streptococcus pneumoniae* in the nanomolar concentration range.

Mouse Models

Both DNA ligase I null mouse cells and a mouse model for the 46BR syndrome have been recently produced. These mutants represent useful models to investigate the relationship between DNA replication failure, genome instability and cancer susceptibility. New insights into the role of DNA ligase IV have come from the targeted disruption of the gene encoding DNA ligase IV in mice. Unlike other partners in NHEJ, DNA ligase IV has an essential function in early mammalian development.

DNA Marker

Definition

DNA marker defines any unique DNA sequence in the genome that can be used in DNA hybridization, PCR or

restriction mapping experiments as a landmark for genetic analysis of phenotypes such as a disease.

► [SNP Detection and Mass Spectrometry](#)

DNA Methylation

Definition

DNA methylation is a covalent modification of the DNA. In mammals, the most frequent modification is the addition of a methyl group to cytosine usually found in CG doublets. This type of modification does not change the nucleotide sequence. Methylation can change the ability of some proteins to bind to a sequence that contains methylated CGs, and by this means it can influence the chromatin structure and activity, and consequently, gene expression. Therefore, DNA methylation is an epigenetic mark. The modification is catalyzed by methyltransferases, a family of enzymes with several identified members.

DNA Microarrays/DNA Arrays

Definition

DNA arrays/DNA microarrays (also referred to as ► [DNA chips](#)) denote an analytical tool to probe RNA expression levels in a cell. DNA probes or oligonucleotides are immobilized at high density onto a microcarrier. The underlying principle of DNA microarray technology is nucleobase-pairing. A single array may represent parts of a genome or the entire set of genes of a given organism/cell. The most common gene expression microarrays fall into two categories: Affymetrix Genechips (a proprietary commercial array using 25 base oligonucleotides probe sets), and spotted DNA microarrays in which long cDNA probes or oligos are deposited and bound to a substrate, usually a coated glass microscope slide.

Definition

The balance between stability and variability in the human genome influences the development of inherited diseases such as cancer and modulates adaptability to new environments and the immunoresponse. DNA polymerases are at the heart of human DNA metabolism and act as DNA synthesis machines. Thus, they play a central role in the mechanisms of genome stability as well as its instability (for additional discussion see ▶ [Replication Fork](#)). In the human cell, four extended protein families A, B, X and Y have evolved to cope with the different tasks of sustaining the genome as well as inducing specific mutations in certain regions or 'rescuing' the genome after specific stress situation e.g. DNA damage (Table 1). This orchestra of human DNA polymerases requires tight regulation of the various DNA synthetic tasks, which has been only partially understood (Table 2).

DNA polymerases catalyse DNA synthesis in a template-dependent fashion. They require a divalent cation, preferentially Mg^{2+} , to incorporate the deoxyribonucleoside monophosphate (dNMP) in a 5'-3' direction. DNA polymerases are not able to start DNA synthesis *de novo* since they depend completely on the presence of a free 3'-OH group. The reaction is driven energetically by the fact that the incoming dNTP reacts chemically with the 3'-OH of the primer to produce the corresponding dNMP and pyrophosphate, which is hydrolysed to inorganic phosphate. During this reaction, the dNMP is covalently linked to the primer, which is extended by one nucleotide, and a free 3'-OH is 'created' again. The reaction occurs with high fidelity as regards correspondence of the incorporated nucleotide with the template. The error rates in formation of A-T and G-C pairs are in the range of 10^{-3} to 10^{-5} depending on the DNA polymerase. The accuracy of the DNA synthesis reaction is further enhanced by 3'-5' proofreading ▶ [exonucleases](#), which are often an intrinsic activity of DNA polymerase polypeptides, although the two activities are usually located on different domains (Table 2).

Characteristics

DNA Polymerase α -Primase

Since DNA polymerases cannot start a DNA reaction *de novo*, a special activity – the primase – has been evolved which associates with one specific DNA polymerase and synthesises a short oligonucleotide – the primer – to start the DNA synthesis reaction. The heterotetrameric DNA polymerase α -primase complex (Pol α -prim) initiates eukaryotic DNA replication at the

DNA Polymerases. Table 1 Distribution of DNA polymerases in Archaea, Bacteria, Eukaryotes and Viruses

DNA polymerase family

^f REV1 is a DNA-dependent deoxycytidyl transferase, since it only incorporates dCMP, but no other nucleotides into DNA

origin of DNA replication to start leading strand replication, synthesises RNA primer on the lagging strand and elongates them to produce the 5'-end of Okazaki fragments (for review see 1, 2; see Replication Fork). These activities are also necessary in DNA repair processes, especially homologous DNA recombination and DNA checkpoint signalling. Of the constituent four subunits the largest, p180, has DNA polymerase activity whereas the smallest subunit, p48, is a primase (1, 2). The remaining subunits, called p58 and B subunit or p67/p70, have no known enzymatic activities but evidence exists that they fulfil regulatory roles (2).

The largest subunit p180 contains at least seven sequence motifs conserved between eukaryotic Pol α homologues (2). The central part of p180 shows the highest sequence conservation and is sufficient to support the catalysis of DNA synthesis since it contains phosphoryl transfer and Mg^{2+} , DNA and dNTP binding activities (2). The C-terminus is required for the assembly of the heterotetrameric complex (3). Although Pol α -prim lacks exonuclease activity, it interacts with the tumour suppressor protein p53, which has an intrinsic exonuclease activity and which can co-operate with Pol α -prim to exchange a mispaired 3'-primer end on a template (4). In addition, the protein binds various cellular and viral proteins such as replication protein A (RPA), poly(ADP-ribose) polymerase, Simian Virus 40 (SV40) T antigen and HPV protein E2. Pol α -prim is also involved in the maintenance of telomere length probably *via* its interaction with the telomere-associated protein Cdc13 (2).

The second largest subunit has an apparent molecular mass of about 66–70 kD depending on its posttranslational modifications (1,2). This polypeptide, also known as the B subunit, shows the highest sequence variation of the four Pol-prim subunits. Interestingly, each of the eukaryotic multisubunit replicase complexes – Pol α -prim, Pol δ and Pol ϵ – contains a distantly related B subunit (5). Recently it was reported that the B subunit of mouse Pol α -prim is required for the nuclear import of p180 (2). In addition, the human B subunit interacts with the initiator protein Cdc45 and various viral initiator proteins such as SV40 T antigen, HPV11 and HPV18 E1 (2). These associations with replication initiation factors suggest that the B subunit of Pol α -prim might be involved in formation and regulation of the initiation complex at DNA replication origins. Its cell- cycle-dependent phosphorylation by cyclin-dependent kinases (Cdks) supports the view that the B subunit carries out regulatory functions in DNA replication. Recent results suggest that other subunits of Pol α -prim are targets of protein kinases. p180 is a substrate of Cdks, Dbf4-Cdc7 and casein kinase II in a cell cycle-dependent manner (2).

Its ability to synthesise RNA primer is the central function of Pol α -prim. p48 carries the catalytic centre for the RNA polymerase (primase) (2, 6). The p48 subunit is highly conserved in eukaryotic primases and even has homologies to archaeal primases (2). Three conserved aspartates (D109, D111 and D306) are involved in metal ion binding. In addition, a conserved arginine at position 304 probably contacts the synthesised primer as occurs in yeast RNA polymerase II (7). In the N-terminus, the p48 polypeptide contains a motif with 4 conserved cysteines, which probably bind Zn. The p58 subunit stabilises the DNA primase activity of the p48 subunit and fully functional DNA primase activity requires both subunits' activities, e.g. p58 is required for the nuclear import of p48, for the binding of p48 to p180 and for control of the primase product lengths (6). Each primase subunit contains sequences with homology to Pol β , which is reflected in the three-dimensional structures of Pol β and an archaeal primase p40 (2).

DNA Polymerase β

The 3-D structure and catalytic mechanism of Pol β have been thoroughly studied (1, 8). It is a single polypeptide of 39 kD, composed of two domains, an 8 kD N-terminal domain and a 31 kD C-terminal domain, connected by a protease sensitive hinge region. The N-terminal domain has a template binding and 5'-►**deoxyribophosphate lyase** (5'-dRP lyase, see glossary) activity that removes an abasic 5'-deoxyribose phosphate from the 5'-primed side of a single-strand break, while the C-terminal domain carries the polymerase activity.

Consistent with its ability to deal with ►**abasic sites** of DNA, known intermediates of base excision repair (BER), Pol β has a role in DNA repair (8). The enzyme is well suited for a small gap-filling function in BER. Besides overwhelming evidence on the importance of this enzyme in BER, there is some indication that Pol β may have additional roles associated with DNA nucleotide excision repair (NER) and meiotic recombination. The repair role of Pol β is further supported by the fact that mutated forms of Pol β occur in numerous cancers. Targeted deletion of the mouse Pol β gene indicates that the enzyme is not essential for mammalian cell viability. However, homozygous mice die immediately after birth showing respiratory failure and defective neurogenesis.

DNA Polymerase γ

Pol γ is the principal DNA replicase and also the sole repair DNA polymerase in human mitochondria (1). Since aberrations in the mitochondrial DNA have been associated with tissue degeneration and aging, the functions and structure of Pol γ are of great clinical interest in understanding the evolution of mutations

in mitochondrial DNA. The enzyme complex consists of two subunits with molecular masses of 140 and 55 kD (p140 and p55) and synthesises DNA with high processivity. The large catalytic subunit has DNA polymerase, 3'-5' and 5'-3' exonuclease activities and can perform proofreading functions. In addition, the polypeptide shows 5'-dRP lyase activity. The small subunit binds DNA on its own and is necessary for the high processivity of the enzyme complex. Moreover, p55 stimulates the exonuclease activity of p140.

DNA Polymerase δ

Mammalian Pol δ was identified more than 20 years ago. Pol δ is implicated as one of the major DNA polymerases required for DNA replication (6, 8; see ►[Replication Fork](#)). This is mainly based on studies of SV40 DNA replication, which has served as a model for the process in mammalian cells. Consistently, the catalytic and the second largest B subunits have been found to be essential for cell viability, both in budding and in fission yeast. Mutants have a cell-cycle arrest phenotype, but surprisingly, a major amount of DNA is synthesised during replication before arrest in these mutants. Apart from its major function in DNA replication, Pol δ appears to be involved in several DNA transactions, including mismatch repair, nucleotide and base excision repair and bypass of DNA damage, as well as recombinational processes (see ►[DNA Recombination](#)).

Pol δ possesses a 3'→5' exonuclease activity in addition to its polymerase activity. The enzyme is therefore able to remove nucleotides immediately if incorporated erroneously. This proofreading greatly increases the fidelity of DNA synthesis and provides an important mechanism for the eukaryotic cell to avoid mutations. Proofreading is a feature of replicative DNA polymerases to achieve the superior accuracy in DNA synthesis that is required to duplicate large genomes. A targeted mutation in the mouse Pol δ gene inactivating proofreading causes an elevated mutation rate and mice with the proofreading defect have an increased risk of developing cancer (9). Mutations in Pol δ have also been identified in non-polyposis colon cancer cells. The clinical relevance of this finding remains unclear since the affected cell lines carry additional mutations in DNA mismatch repair factors that commonly underlie this disease (10).

Pol δ appears to be ubiquitous in all eukaryotic organisms. Apart from the catalytic subunit of approximately 125 kD, Pol δ isolated from various sources contains two or more additional smaller, structurally conserved subunits. Although these subunits appear to lack any enzymatic activity, they carry out crucial roles in maintaining the integrity of the enzyme and in mediating interactions with other proteins.

To fully understand the function of Pol δ , it has to be seen in the context of the two factors RFC and PCNA. These proteins provide the moving platform that mediates the dynamic functions of the enzyme (1; see Replication Fork). PCNA is a eukaryotic sliding clamp that is structurally and functionally related to the β subunit of *E. coli* Pol III holoenzyme. Three PCNA molecules form a closed ring able to encircle duplex DNA. Once loaded onto DNA by RFC in an ATP-dependent manner, PCNA cannot dissociate but can freely translocate on double-stranded DNA. PCNA then associates with Pol δ at the primer-template junction and supports ►[processive DNA synthesis](#) by the polymerase whilst at the same time preventing non-productive binding of Pol δ to single-stranded DNA. Pol δ in conjunction with PCNA and RFC is therefore generally referred to as the Pol δ holoenzyme.

DNA Polymerase ϵ

Pol ϵ is one of the three major replicative DNA polymerases in eukaryotic cells. It has been isolated and cloned from several species from yeast to human (11). The human enzyme consists of a 261 kD catalytic subunit and three smaller subunits of 59, 17 and 12 kD. The catalytic subunit contains DNA polymerase and proofreading exonuclease activities. Notably, it possesses a large C-terminal domain of unclear function that accounts for half of the molecular mass. Yeast homologues of the catalytic subunit and 59 kD subunit are both essential for viability. No catalytic activity has been assigned to the 59 kD subunit and its role has remained obscure. As shown with the yeast model, the two smallest subunits are not essential for viability. They possess a histone-fold and the 17 kD subunit is also an integral part of the chromatin remodelling factor CHRAC that regulates chromatin accessibility and nucleosome spacing, a process associated both with DNA replication and transcription.

Simian Virus 40 (SV40) DNA replication *in vitro* as a model of mammalian DNA replication has allowed identification and elucidation of the roles of cellular factors involved in replication, including Pols α and δ (11; see Replication Fork). SV40 DNA replication can not be utilised to study the role of Pol ϵ since it is not involved in this system. However, studies on cellular model systems have revealed that it is an essential component of cellular DNA replication machinery *in vivo*, being already involved in the initiation phase of replication (12). During elongation it seems to be supported by the same partner proteins as Pol δ , including at least RFC and PCNA. In most models presented, Pols δ and ϵ are believed to share their labour between leading and lagging strand synthesis or between elongation and maturation of Okazaki fragments. A third possibility is that the two DNA polymerases act in different regions of complex

eukaryotic chromatin, in both cases having Pol α as their sole DNA polymerase partner. Besides DNA replication, there is evidence that Pol ϵ is involved in recombinative repair, nucleotide excision repair and base excision repair. It may also be among the players in cellular response to DNA damage.

Other Eukaryotic DNA Polymerases

Apart from Pols α , β , γ , δ and ϵ , which are considered the classical cellular DNA polymerases, it became apparent that a number of additional DNA polymerases are present in many organisms (Table 2). These novel DNA polymerases can be best considered in their functional context (13, 11, 1).

One of the most prevalent roles for several of these enzymes is replicative DNA translesion DNA synthesis. Pol ζ is the first eukaryotic enzyme found capable of synthesising past a UV-induced thymidine cyclobutane dimer. This enzyme is the fourth widely distributed eukaryotic DNA polymerase related to Pol α . **Translesion DNA synthesis** by Pol ζ is error-prone and this enzyme is responsible for most of the damage-induced mutagenesis in *Saccharomyces cerevisiae*. More recent work indicates that the major importance of Pol ζ lies in its unusual ability to extend from poorly paired primer ends and to use distorted templates. One of several DNA polymerases may incorporate a nucleotide opposite to various DNA lesions. Pol ζ then uses this inserted nucleotide for limited extension beyond the lesion where the normal replication apparatus can take over again. Inactivation of the mouse gene for the catalytic subunit of Pol ζ results in early embryonic lethality. This indicates that DNA translesion synthesis may be of great importance in higher eukaryotes with large genomes.

It is probably mainly the DNA polymerases of family Y that incorporate nucleotides opposite to damaged DNA (13). Budding yeast Rev1 protein was the first enzyme of this family shown to possess DNA polymerase-related activity. Rev1 incorporates dCMP opposite to an abasic site, but appears to possess also a second, poorly understood function that is important for DNA translesion synthesis in general.

Human Pol η has been identified as the activity that prevents the sensitivity to UV light seen in cells derived from patients with the rare autosomal hereditary disorder xeroderma pigmentosum variant (XPV). The protein is encoded by the *XPV* gene that is affected in those patients. Pol η synthesises efficiently past a thymidine-thymidine *cis-syn* cyclobutane dimer, the principal damage inflicted by UV light on DNA. What is more, this translesion synthesis is apparently error-free.

Higher eukaryotes possess a second Pol η homologue, designated Pol ι . It shares several features with Pol η ,

including highly **distributive DNA synthesis** and the ability to bypass certain DNA lesions, but in contrast to Pol η , Pol ι is highly inaccurate during DNA synthesis. Translesion synthesis by Pols η and ι appears to be tightly linked to DNA replication. A fourth human DNA polymerase of family Y was recognised and designated Pol κ . As expected, Pol κ is capable of mutagenic DNA lesion bypass, but differs from other family members in that it introduces -1 frameshifts into the sequence and efficiently extends from a mispaired primer end. Crystal structures of family Y DNA polymerases reveal a conventional right hand-like architecture with domains assigned as palm, finger and thumb. Compared to other DNA polymerases, the finger and thumb domains are small, resulting in an open spacious active site that can accommodate DNA lesions and mispaired primer ends.

A process that is related to DNA translesion synthesis is **somatic hypermutation** (13). Here, mutations are intentionally introduced into certain immunoglobulin gene segments in a controlled manner. In addition to the DNA translesion polymerases, the novel Pol μ of family X is indicated for a role in this process, since it is specifically expressed in lymphoid tissues (14, 13).

Human Pol λ is an enzyme of family X related to Pol β that is involved in DNA repair. The latest, but still controversial family X DNA polymerase member is Pol σ . Eukaryotic organisms seem to possess multiple related genes for Pol σ proteins that are at least in part redundant. Pol σ enzymes execute an essential function in the sister chromatid adhesion that links the newly synthesised sister DNA strands until mitosis, but yeast as well as human Pol σ proteins apparently also have divergent functions as poly-A polymerases in the cytoplasm (13, 2, 15). Pol θ of family A is found in higher eukaryotes and is unique in that it contains a putative **helicase**, a 3'→5' exonuclease and a DNA polymerase domain in one polypeptide chain. Pol θ is probably involved in the repair of DNA interstrand cross-links.

Clinical Relevance

Human DNA replication and repair processes are highly co-ordinated and tightly controlled to maintain the stability of the genetic information. To interrupt cell-cycle progression after damage to the genome or replication stress is essential for survival of eukaryotic cells. Failure to induce a transient cell cycle arrest leads to accumulation of mutations that ultimately induce cell death or cancer. A variety of DNA lesions can damage the cellular genetic information and induce a complex set of mechanisms to repair them. The activation of these processes is the ultimate goal of the checkpoint systems. Once the integrity of the DNA is again

established, signals are sent to continue cell-cycle progression. In recent years it has become clearer that Pol α -prim and Pol ϵ appear to play a key role in co-ordinating DNA replication, DNA repair and cell-cycle checkpoints in addition to their enzyme activities during DNA replication. These replicative DNA polymerases appear to serve as sensors for the functional integrity of the replication apparatus (11, 1). In recent years, mutations of DNA polymerases such as Pols α , δ and η have been found in cancer tissues and cell lines suggesting that interference with DNA polymerase functions might cause genetic instability and then cancer. The increased cancer incidence in transgenic mice lacking the proofreading exonuclease of Pol δ and the identification of Pol η mutants as the underlying defect in xeroderma pigmentosum variant support this view (9, 13). Many DNA viruses target cellular DNA polymerases and other components of the replication apparatus to ensure viral replication. Pol α -prim, which interacts with replication factors of multiple viruses, is the major species-specific factor for polyoma virus DNA replication.

The posttranslational modifications of the central DNA replication enzyme are highly complex and only partially understood. However, the understanding of these signalling pathways will most probably allow establishment of new targets for finding new cancer drugs.

The contribution of different DNA polymerases to somatic hypermutation is not yet well understood. Mouse and cell models suggest that Pol μ and, to a lesser extent, Pol η are required for comprehensive immunoglobulin maturation (14, 13).

DNA Primase

Definition

DNA primase is a ►DNA polymerase that requires a primer in order to begin incorporation of deoxyribonucleotides into the nascent DNA strand. A DNA primase primes DNA synthesis by incorporating ribonucleotides complementary to the DNA template to generate an RNA primer. This enzyme then extends the RNA primer by incorporating several deoxyribonucleotides. Later in the replication process, other proteins remove the RNA primer and replace it with deoxyribonucleotides.

DNA Recombination

JEAN-MARIE BUERSTEDDE

Institute of Molecular Radiobiology, GSF,
Neuherberg, Germany
buersted@gsf.de

Definition

DNA recombination is a process in which specialized proteins interact with DNA to create molecules with altered base sequence content. Depending on the details of the reaction, the outcomes are deletions, duplications or simply a new order of allelic variation.

Recombination can be classified as site-specific or homologous. Site-specific recombinases recognize particular signal sequences within the target DNA molecules. In contrast, homologous recombination requires inter- or intra-molecular sequence homology to start the reaction.

DNA recombination is employed by all forms of life to change and reshuffle the genome. Whereas site-specific recombination is primarily used by viruses and **transposons** to enter and exit their host's genomes, homologous recombination enables meiotic exchanges between chromosomes and the segregation of beneficial and deleterious mutations. Most types of recombination reactions are related to **DNA repair** and require the participation of general repair factors. In return, homologous recombination helps to patch spontaneous and induced DNA damage by copying information from intact homologous **sister chromatids** or chromosomes.

Characteristics

As recombination revolves around the venerable DNA double helix, it comes as no surprise that it is itself highly conserved during evolution. Therefore, bacterial and simple eukaryotic organisms have been ideal models to explore the molecular basis of recombination reactions.

Site-specific recombination is initiated by the assembly of a multimeric protein complex around recognition sites in the target DNA, which then tightly control the timing and the directionality of the DNA **strand transfers**. The two best understood forms of site-specific recombination are **integration** and **transposition** catalyzed by tyrosine recombinases and transposases respectively.

Tyrosine recombinases are defined by a conserved catalytic domain and although their biological missions vary, the mechanism of action is unique for the whole family (1). At the beginning, the recombinase scans the target DNA for recognition sites, which consist of two

inverted recombinase-binding sites separated by a spacer. If a pair of recognition sites is detected, a tetrameric recombinase complex is assembled in which each of the recombinase subunits interacts with one of the binding sites. In the next step, a duo of coordinated strand transfers first produces a **Holiday junction** and then a complete helical exchange within the aligned spacer regions (Fig. 1). Intermediates in these tightly coordinated strand exchanges are recombinase-DNA phosphotyrosine linkages which preserve the energy of the cleaved DNA phosphodiester bonds.

Another paradigm of site-specific recombination is transposition (2). Like integration, the reaction is initiated by the assembly of a multimeric complex at the transposon DNA ends. The transposase within the complex then cleaves the 3' DNA ends of the transposon and induces a nucleophilic attack by the generated OH end groups against the target DNA. Some transposition reactions include the formation and cleavage of a hairpin at the transposon end as an intermediate. Interestingly, retroviral integration into the host chromosomes also occurs by a transposition-like mechanism.

Another variant of a transposition reaction is **antigen receptor gene rearrangement** (**V(D)J recombination**) in the immune system (3). The receptor genes are not stored in a functional form in the germline, but are assembled from families of receptor coding segments during lymphocyte development (Fig. 2). The boundaries of the rearranging gene segments are defined by conserved signal recognition sequences (SRS). Two lymphoid specific proteins, recombination activating

DNA Recombination. Figure 1 Site-specific integration catalysed by tyrosine recombinases.

DNA Recombination. Figure 2 V(D)J recombination at the murine immunoglobulin light chain locus.

gene 1 (*RAG1*) and recombination activating gene 2 (*RAG2*) recognize the signal recognition sequences and introduce a nick precisely between the coding segment and the SRS. The liberated 3' OH group of the nicked strand then attacks and hydrolyzes the phosphodiester bond of the opposite strand resulting in a double strand break at the SRS and a ▶hairpin end at the coding segment. These intermediates are further processed with the assistance of general DNA repair factors like the DNA-protein kinase (DNA-PK) and the Artemis protein, which nick the hairpins of the coding segments. The end products are coding joints between the receptor coding segments and signal joints between the removed or inverted signal recognition sequences. V(D) J recombination assures a single receptor specificity for each lymphocyte, because as a rule only one of the two light and heavy chain receptor loci successfully rearranges. A second function is to contribute diversity to the antigen receptor repertoire by the combination of segments randomly chosen from gene segment families.

First insights into the mechanism of homologous recombination (4) were gained from studies of the bacterial *RECA* gene whose mutants are severely suppressed in most forms of homologous recombination. Although *RecA* is a versatile protein with a number of functions, the best characterized activity related to recombination is a strand exchange reaction in which a single stranded DNA sequence aligns with a homologous double-stranded molecule and replaces the identical strand of the duplex DNA (Fig. 3). As long as new base pairs are formed during the strand invasion, the reaction is energetically neutral and ATP hydrolysis is only needed to proceed through areas leading to ▶mismatches. Structural analysis indicates that *RecA* coats single stranded DNA with a regularity of 3 bases per monomer and facilitates homology

DNA Recombination. Figure 3 Strand exchange catalysed by the *RecA* protein.

search and strand exchange by stretching the molecule. If two homologous double helices interact, strand exchange is often reciprocal between the aligned sequences leading to Holiday junctions. At least in theory, Holiday junctions between homologous sequences can slide back and forth with minimal energy requirements, as base pairs are broken and formed at equal rates. Nevertheless, the RuvA and RuvB proteins are recruited to Holiday junctions and most probably force the branch migration into a certain direction. In the last stage of the reaction, the RuvC protein cuts the Holiday junctions and the recombined DNA molecules are relieved of their close encounter. Studies of homologous recombination in eukaryotic models offer insight into meiotic cell division and can account for the effects of chromatin structure. Mutant screens in the yeast *Sacharomyces cerevisiae* uncovered the so-called *RAD52* genetic pathway whose mutants are characterized by high radiation sensitivity, altered recombination frequencies and a block in meiosis. The mutant phenotypes in the *RAD52* pathway can be explained by a defect in the repair of double strand breaks that initiate mitotic and meiotic recombination in yeast. The observation that the *RAD52* pathway can repair even gaps in transfected genes using endogenous genes as templates led to the influential double-strand break repair model of recombination (5) which postulates that the ends of the broken strands invade the homologous partner

DNA Recombination. Figure 4 The double-strand break repair by homologous recombination model.

sequence leading to reciprocal strand displacement, branch migration and ultimately the formation of patch and slice recombinants (Fig. 4). Although the biochemistry of homologous recombination in eukaryotes still needs to be explored in greater detail, several genes in the *RAD52* pathway encode structural and functional homologues of the bacterial RecA protein and thus probably facilitate the initial strand exchange between the donor and the target sequences.

Structural homologues of the *RAD52* pathway in the forms of *RAD51*, *RAD52* and *RAD54* genes have also been found in vertebrates and at least the *RAD54* mutant shows the expected phenotype of radiation sensitivity and homologous recombination deficiency. However, the roles of the *RAD51* and *RAD52* genes have evolved in vertebrate cells as the *RAD51* gene is essential and disruption of the *RAD52* gene which produces the most severe recombination defect in *S. cerevisiae* has only a mild effect

Clinical Relevance

Homozygous null mutations in the *RAG1*, *RAG2* and *Artemis* (5) lead to severe combined immunodeficiency (SCID) due to lack of mature T and B cells whereas *RAG* mutations which only impair the protein

function manifest themselves with the milder Omenn immunodeficiency syndrome.

Defects in the homologous recombination pathway might manifest themselves by infertility due to a block in meiosis or by cancer predisposition due to DNA repair deficiency. However, these diseases have not been associated with mutations of the *RAD52* pathway and viable *RAD54* and *RAD52* ▶knockout mice are neither infertile nor do they develop cancer. There is however evidence that the human *Rad51* protein interacts with the proteins encoded by breast cancer genes *BRCA1* and *BRCA2* suggesting that an alteration in homologous recombination causes hypermutation or chromosomal instability in breast cancer cells of affected patients.

Whereas the jury is still out as to whether human diseases directly relate to homologous recombination defects, experimental medicine has taken a lesson from Mother Nature and adapted recombination to redesign the genome of living cells. Artificial gene constructs are introduced into cells and then clones are isolated which have integrated the construct by homologous recombination. This powerful approach is now combined with embryonic stem cell technology to study gene function by disruption and to create animal models for human disease. Remarkably, site-specific recombination has also found a place in the toolbox of molecular biologists to regulate gene expression and to simulate chromosomal translocations (6). Homologous recombination offers great promise for gene therapy, because it can correct genetic defects by the targeted integration of wild type constructs. All current strategies of stable gene therapy integrate transgenes at random chromosomal positions and suffer from problems of insertional mutagenesis, variable gene expression and possible dominant effects of the causative mutation. Although the frequency of targeted integration events is still too low for *in vivo* applications, it might be possible to increase it or to expand selected stem cell transfectants for the repopulation of the patient.

DNA Relaxation

Definition

DNA relaxation designates the removal of negative or positive supercoils from DNA.

►DNA Ligases

DNA Repair

Definition

DNA repair refers to the process of identification and repair of spontaneous or induced DNA damage by enzymatic reactions. DNA repair is essential to protect the integrity of the genome, and prevents somatic mutation that can lead to cancer.

Definition

Many chemical and physical agents are capable of altering the chemistry and structure of DNA (1). DNA damaging processes occur in every cell at all times and

do not only result from environmental stress but mainly from intrinsic metabolic activities. If such lesions in DNA are not repaired, mutations may arise. In general, DNA repair reactions comprise three steps. In the first step, the damaged site is recognised and marked. The second step involves the elimination of the lesion, and during the third step, the original sequence is restored by DNA synthesis and subsequent single-strand ligation. Cells with deficient DNA-repair systems show increased levels of ►genome instability, leading to accumulations of various types of mutations (mutator phenotype). Depending on the repair mechanism affected, the mutational spectra of these cells may exhibit significant increase in spontaneous base pair substitutions, insertions and deletions, or even chromosomal rearrangements. In many cases, acquired genomic instability observed in tumour cells results from defects in the DNA repair systems, which illustrates the ►caretaker function of DNA repair genes for the maintenance of genome stability (2). These caretaker functions are also consistent with the observed phenotypes of human syndromes known to be associated with DNA repair deficiencies (see below) (3).

Characteristics

As long as only one DNA strand is damaged, the remaining undamaged strand can be used as a template for new DNA repair synthesis. Repair mechanisms that take advantage of an undamaged template include postreplicative ►mismatch repair (MMR), ►base excision repair (BER), and ►nucleotide excision repair (NER). The repair of damage that affects both strands of the DNA molecule, e.g. a double strand break (DSB) or an interstrand cross link (ICL), is more difficult. In such cases, the original sequence information can be restored by ►homologous recombination repair (HRR). If HRR cannot be used, the two sugar phosphate backbones of the double helix can be covalently closed by a mutagenic process called ►nonhomologous end joining (NHEJ) (4).

MMR

The misincorporation of deoxyribonucleotide triphosphates during DNA replication leads to mismatched base pairs. Other frequent replication errors are loop structures induced by slippage of the newly synthesised DNA strand relative to the template strand on sequences containing short repeat units in tandem (microsatellites). If not repaired, such lesions will generate either base pair substitutions (in the case of base pair mismatches) or insertions or deletions (in the case of strand slippage) in one of the daughter strands after another round of DNA replication and sister chromatid segregation. Postreplicative MMR provides a tool to remove such replication errors, because it

ensures the removal of the mispaired nucleotides exclusively from the newly synthesised strand while the parental “correct” strand remains intact and serves as a template for repair synthesis.

BER

Mutations may also arise as a consequence of chemical modification or elimination of the normal DNA bases by spontaneous deamination ($\sim 100 \text{ cell}^{-1} \text{ day}^{-1}$; e.g. cytosine \rightarrow uracil; adenine \rightarrow hypoxanthine), oxidation ($\sim 20,000 \text{ cell}^{-1} \text{ day}^{-1}$; e.g. guanine \rightarrow 8-oxo-guanine), or depurination ($\sim 10,000 \text{ cell}^{-1} \text{ day}^{-1}$; loss of adenine or guanine). In this way, base derivatives with altered base pairing properties or apurinic sites are formed. If not repaired, these types of lesions may lead to base pair substitutions in the next S-phase. Chemically modified bases are excised by DNA glycosylases leaving behind apurinic or apyrimidinic (AP-) sites. Several different DNA glycosylases exist, each of which can recognise one specific type of lesion. In the subsequent repair steps, the AP-site is recognised by an AP-endonuclease and a deoxyribosephosphodiesterase, which opens the phosphate backbone and removes the baseless sugar moiety to generate a new 3'-OH group that can prime the DNA polymerase-catalysed incorporation of one or a few deoxyribonucleotide triphosphates.

NER

Lesions in which chemical base modifications are combined with a distortion of the double helix are called bulky adducts. A typical example of this type of lesion is UV-light-induced covalent crosslinks between adjacent pyrimidines (e.g. thymine-dimers). Such bulky adducts represent major obstacles to DNA replication and transcription. They are recognised by distinct multi-protein complexes that are, depending on the state of transcription of the DNA, composed of several different polypeptides (products of the XP-, CS-, and TTD-gene-groups, see below). Lesions in the overall chromatin are repaired at a slower rate and reduced efficiency (global genome repair; GGR) as compared to the transcribed chromatin (transcription coupled repair; TCR). This ensures that active genes are repaired with higher priority than inactive genes or non-coding DNA. Both pathways share common downstream activities, characterised by incision steps on the 5'- and 3'-site of the lesion, removing a single-stranded oligonucleotide of 24 up to 32 nucleotides that contains the lesion. The remaining single-strand gap is subsequently filled in and ligated.

HRR

In cases where both DNA strands are damaged (e.g. DSB), HRR can use the undamaged sister chromatid or homologous chromosome as template and is, therefore,

capable of accurate restoration of the original sequence information. In the mitotic cell cycle, this pathway is predominantly used during the S- and G2-phase, when the sister chromatid can serve as a template for repair. The homologous chromosome is usually not used during the normal mitotic cell cycle, but becomes a template for HRR during prophase I of meiosis. HRR is initiated by the invasion of the single-stranded 3'-ends of the broken DNA molecule (recipient) in the homologous sequences of the undamaged double-strand (donor), which is catalysed by homologous pairing proteins (Rad52 and Rad51). The 3'-ends in the resulting displacement (D-) loop serve as primers for DNA synthesis on the intact DNA molecule. Downstream activities include branch migration of the resulting Holliday junction (HJ), DNA synthesis, ligation, and HJ-resolution by endonucleases.

NHEJ

Since DSB are potentially lethal DNA lesions, it is obvious, that there is a need for repair mechanisms during G1 or G0 where no sister chromatids are available to stimulate HRR. In this stage of the cell cycle, DSB are rejoined by NHEJ, an activity that can operate in the absence of sequence homology but preferentially uses sequence homology of fortuitously complementary bases whenever available. The NHEJ mechanism includes the alignment of the broken DNA ends by a protein complex and their conversion into a ligatable structure. It is obvious that such a mechanism is prone to introduce mutations, because trimming of the DNA ends often includes degradation or insertion of a few nucleotides before the remaining nicks are sealed by a DNA ligase. It is worth mentioning that the same NHEJ mechanism is responsible for the generation of the diversity of the immunoglobulins by a process called V(D)J-recombination which occurs during B- and T-cell development in the mammalian immune system.

Genetics

As outlined above, DNA repair genes have a caretaker function to maintain genome stability. A reduction in DNA repair capacity leads to an increase in the mutation rate in the affected cell; the cell develops a so-called mutator phenotype. The known accumulation of mutations in tumour cells may be explained by a two-step mechanism. First, a cell becomes deficient in a certain DNA repair function. As a result of the increased mutation rate other genes, the so-called **gatekeepers**, may be affected. Gatekeepers are represented by oncogenes and tumour suppressor genes that regulate cell division (cell cycle checkpoints), cell differentiation, and cell death (apoptosis). If mutated, these in combination with other genes promote the further development into a cancer cell. This may

DNA Repair Mechanisms. Figure 1 The figure shows repair mechanisms as discussed in the text. Double stranded DNA molecules are given as a black double-line. The Y-shaped structure symbolises the replication fork and the grey double line at the HRR mechanism indicates the homologous DNA molecule used as template for repair synthesis. In the first row, different types of damaged DNA are indicated in red. The second shows typical intermediate structures occurring during the repair process itself. The bottom line shows the repaired site with newly synthesised DNA due to repair synthesis given in blue. The bent blue line in the NHEJ mechanism indicates that this pathway is mutagenic due to loss of base pairs and mispaired bases remaining left at the junction.

explain why a common feature of many, albeit not all, human syndromes associated with defective DNA repair is a predisposition to cancer.

Information about human DNA repair genes comes on the one hand from the study of cell lines deficient in DNA repair which are derived from patients with spontaneous or inherited tumour diseases. The other approach uses the information resulting from the human genome project, to compare DNA sequences with DNA repair genes already known from simpler organisms like bacteria and yeast. Using this latter approach, about 125 genes have been identified, which are directly involved in DNA repair (5, 6).

Clinical Relevance

In humans, no disease is known so far which affects genes involved in BER. This may reflect the fact, that deficiencies in the BER system are not compatible with life. Since DNA bases are permanently chemically damaged in the normal cellular metabolism, deficiencies in BER probably cause lethality.

Deficiencies in DNA repair pathways in humans are genetically characterised by inherited syndromes with more or less distinct phenotypes. Deficiencies in the postreplicative MMR were found to be associated with **hereditary nonpolyposis colon cancer (HNPCC)**. Patients suffering from this disease are heterozygous for genes involved in the recognition of mismatches or loop structures (MLH1, MLH6, MLH1 and PMS2) generated during DNA replication. Tumours from these

patients lack MMR activity, indicating that they became homozygous due to loss of heterozygosity or a second mutation in the homologous gene. In agreement with the MMR mechanism, tumours from HNPCC patients are further characterised by microsatellite instabilities, which can be explained by the lack of repair of single-stranded loops generated during replication.

Three syndromes are associated with deficiencies in NER function, **xeroderma pigmentosum (XP)** with seven complementation groups (XP-A to XP-G), **Cockayne syndrome (CS)** with two complementation groups (CS-A and CS-B) and **trichothiodystrophy (TTD)** with three complementation groups (TTD, XP-B or XP-D). The fact, that mutations in XP-B or XP-D may cause the XP- or TTD-phenotype explains the importance of identifying the nature of the mutation causally connected with the disease. Surprisingly, cancer predisposition due to exposure to UV-light is associated with the XP, but not with CS or TTD. Another interesting point is the existence of combined phenotypes of XP and CS, caused by certain mutations in XP-B, XP-D and XP-G.

There is strong evidence, that the genes associated with familiar forms of **breast cancer BRCA1 and BRCA2** are involved in HRR. Vertebrate cells deficient in HRR have severe problems in traversing S-phase and reinitiating replication at sites where replication forks have collapsed. The mechanistic relation of these two genes with HRR is not entirely understood but may be

due to the binding of both proteins to RAD51. Like its bacterial counterpart *recA*, RAD51 is involved in D-loop formation, a key step in HRR (see above). One of the genes causing the autosomal recessive **Fanconi anaemia** (FA) (FANC-D2) was recently shown to interact with BRCA1 suggesting problems in HRR in patients with FA as well. Overall, eight FA complementation groups are known (FA-A to FA-H). FA patients are predisposed to acute myeloid leukaemia and squamous cell carcinomas.

Mutations in LIG4, an NHEJ-specific DNA ligase, are found in cells from patients with delay in growth and development combined with immunodeficiency. As well as their involvement in DNA repair, the components of the NHEJ machinery also play an important role in V(D)J-recombination, which explains the complex phenotype of these patients.

Ataxia telangiectasia (AT) is a disease caused by mutation in the ATM gene, which is involved in the sensing and signalling of DSB. It is not entirely clear, if this mutation has consequences for HRR, NHEJ, or both pathways. Interestingly, there exists another disease with a related phenotype, the **ataxia telangiectasia-like disease** (AT-LD), which is caused by a truncated MRE11 gene product. This protein is supposed to act as a nuclease in HRR and NHEJ.

DNA Replication

Definition

DNA replication refers to the duplication process by which an accurate copy of the DNA is made. The complementarity of base pairing between the two strands of the double-helix forms the basis for DNA replication. Most often, replication precedes cell division by mitosis. Notable exceptions include the DNA replication that precedes meiosis, and the

replication that occurs in cells undergoing endoreplication as a way to amplify gene copy number in a cell.

Definition

Genomic DNA, which is distributed into multiple chromosomes in eukaryotes, has to be replicated completely and only once during a single cell-cycle to maintain integrity. The necessary cell-cycle regulation is mainly executed at the initiation rather than the elongation step of DNA replication. Our knowledge of mechanisms responsible in eukaryotes largely depends on findings with budding yeast, since identification of specific DNA sequences acting as replication origins on plasmids, autonomously replicating sequences (**ARSSs**), has allowed extensive analysis of the initiation step. Several factors essential for regulation of initiation have been identified, including **ORC** (origin recognition complex), CDC6, Cdt1 and **MCM**. These players in DNA replication initiation are strictly controlled by **Cdks** (cyclin-dependent kinases). Subsequent work has suggested that the fundamental machinery for DNA replication is conserved in metazoans including mammalian cells. In this essay, current concepts of cell-cycle regulation of DNA replication in mammalian cells and their clinical relevance are summarized. For further reading, see reviews cited in the references (1, 2, 3).

Characteristics

Pre-Replication Complex Formation During G1 Phase

To initiate genome duplication, a multi-protein complex, termed the pre-replication complex (pre-RC), is generated during the G1 phase based on ORC binding to chromosomal DNA. ORC was initially identified in budding yeast as a protein complex binding sequence-specifically to ARSSs, and later found to be conserved in mammalian cells. Unlike yeast however, the interaction of mammalian ORC with chromosomal DNA is not simply determined by the primary DNA sequence and ORC localization may be influenced by high-order chromatin/nuclear structures associated with transcription (2). It is also suggested that chromatin regions

affixed to the nuclear matrix could more easily access the ORC, since functional ORC is also associated with the matrix (4). These imply a complex architecture of mammalian replication origins.

CDC6 and Cdt1 proteins are recruited to the origin possibly by physical interaction with ORC. The resultant machinery, consisting of ORC, CDC6 and Cdt1 proteins, may function as a loader for the MCM heterohexameric complex, which could function as a helicase in the initiation as well as the elongation steps. In an *in vitro* DNA replication system with *Xenopus* egg extracts, once MCMs are loaded, ORC/CDC6 is no longer required for DNA replication initiation. Therefore, replication initiates at sites onto which MCM complexes are loaded. In the case of budding yeast, these appear to be near ORCs bound to ARSs. As a consequence, the ARS acts as an initiation site as well as a *cis* element required for assembly of the initiation machinery. In mammalian cells, it appears that multiple MCM complexes are loaded beyond each ORC site (1, 3, 4). Therefore, it is possible that initiation sites are not always close to an ORC binding site. While such a broad distribution of MCMs on pre-replication chromatin seems appropriate for explaining the initiation zone observed in mammalian cells, the issue also makes the replication origin problem complicated. Finally, it is worth noting that transcription of ORC1, CDC6 and all MCM subunits is driven by the ►E2F transcription factor.

Firing of the Pre-Replication Complex During S phase

When cells enter S phase, multiple other proteins or protein complexes need to be recruited onto the pre-RCs to initiate DNA synthesis. This step is dependent on two kinases, cyclin-dependent kinase (cyclin E/Cdk2 and cyclin A/Cdk2 in mammals) and CDC7 kinase. Cdk activity is absolutely required for promoting DNA replication, yet the proteins that must be phosphorylated remain largely unknown. Cdks physically interact with and phosphorylate ORC and CDC6. However, considering that ORC and CDC6 are no longer necessary for initiation after loading MCMs, such phosphorylation is unlikely to be involved in promotion of replication. Rather, it may contribute to prohibition of re-replication (see below). Certain MCM subunits in the hexameric complexes are also phosphorylated by Cdk2 kinase, but the outcome is not clear at present (also see below).

Prior to the DNA unwinding step, CDC45, an essential replication protein, is loaded onto chromatin, probably *via* physical interaction with the MCM complex. Since the loading is dependent on both Cdk and CDC7 kinase activities and both these kinases phosphorylate certain subunits of the MCM complex, one might conclude that phosphorylation of the latter leads to stable physical association with CDC45. However, there is

no evidence of this at present. It has been reported that the MCM complex bound to CDC45 shows stronger helicase activity than when lacking CDC45. On the other hand, an *in vitro* study has demonstrated that Cdk modification of the MCM complex rather reduces its helicase activity. Whatever the case, it seems clear that Cdk and CDC7 kinase activity-dependent loading of CDC45 is a prerequisite for the unwinding of DNA. Once CDC45 is loaded, the DNA is unwound with the help of RPA, a eukaryotic single-strand DNA binding protein complex. Subsequently, many components of the DNA synthetic machinery, such as ►DNA polymerases α , δ and ϵ , are assembled onto the unwound DNA, starting DNA replication. DNA polymerase ϵ complex consists of many subunits in addition to the catalytic subunit. Very recently, it was shown in budding yeast that Cdk-phosphorylation of Sld2 protein, a subunit of the DNA polymerase ϵ complex, is essential for chromosomal DNA replication (5). This is the first protein to be clearly demonstrated to promote replication by Cdk phosphorylation. It is clearly of interest to examine whether such machinery is also conserved in human cells.

Prevention of Re-Replication by Cdks

Genomic DNA is tightly controlled so that re-replication does not occur. After functioning in DNA replication, the MCM complexes are displaced from chromatin through an unknown mechanism(s). Therefore, re-establishment of pre-RC, in other words re-binding of the MCM should be suppressed during S, G2 and M phases of the cell-cycle. Recent studies suggest that Cdks play a central role in this context. Thus, Cdk activity has a bipartite function in the cell-cycle regulation of eukaryotic DNA replication.

In mammals, cyclin E/Cdk2 and cyclin A/Cdk2 are the S phase promoting Cdks, as already mentioned, while cyclin B/Cdk1 is the mitotic Cdk. In addition, cyclin A/Cdk1 appears active during S, G2 and M phases, although the biological consequences have not been clarified. Direct evidence is lacking, but Cdk2 kinase has been suggested to prevent formation of pre-RC. The importance of Cdk1 kinase is clearly demonstrated by the fact that its inactivation results in re-binding of MCM proteins and subsequent re-replication (1). Since Cdk2 kinase activity is still maintained in cells lacking Cdk1, the latter presumably plays the primary role in prevention of re-replication. If this is the case, the main contribution of cyclin A/Cdk1 would be inhibition of re-replication in S and G2 phases.

How do Cdks prevent re-establishment of pre-RC? One means is phosphorylation of CDC6, leading to degradation in yeast or nuclear export in mammalian cells. In the latter situation, cyclin A/Cdk2 may be a responsible kinase. Cyclin B/Cdk1 can phosphorylate CDC6 as

DNA Replication Initiation. Figure 1 A model for the state of pre-replication chromatin and cell-cycle regulation in mammalian cells. Note that the phosphorylation states in this model are figurative. (A) In the G1 phase with low Cdk2/Cdk1 activity, ORC and CDC6 are associated with the matrix, together with Cdt1 and load MCM complexes onto chromatin beyond ORC binding sites. (B) and (C) When cells enter S phase, dependent on Cdk2 and CDC7 kinase activity, CDC45 and some other proteins are recruited around MCM and they unwind DNA. Then, DNA synthetic proteins are assembled on single-stranded DNA. The latter step is omitted in this model. Activated MCM plays an essential role in DNA replication, possibly as a DNA helicase and is simultaneously displaced from chromatin through an unknown mechanism. In S phase, reloading of dissociated MCM may be suppressed by Cdk2 kinase, at least through CDC6 nuclear export and ORC1 degradation (and possibly inhibition of Cdt1 function). Alternatively, cyclin A/Cdk1 kinase may be responsible for the inhibition. Geminin also prevents the MCM rebinding by sequestering Cdt1. (D) During the G2/M phase, Cdk1 kinase hyperphosphorylates CDC6 and MCM complexes (and possibly Cdt1 and ORC1), thereby prohibiting the reloading of MCM. During exit from mitosis, Cdk activity is restrained and the pre-replication chromatin structure is again constructed.

well. ORC is another target of Cdk modification. In human cells, ORC1 is degraded when cells enter into S phase. As it appears to be phosphorylated by cyclin A/Cdk2, it could be that this is the trigger leading to its degradation. In budding yeast, ORC2 is also the target of Cdk phosphorylation. Cdk modification controls the function of the MCM proteins and it has been shown that MCM2 and MCM4 in the complex are phosphorylated by Cdk1 kinase, inactivation resulting in MCM re-binding to chromatin. During exit from mitosis, Cdk activity is restrained through destruction of the cyclin by ▶APC (anaphase promoting complex) and the pre-replication chromatin structure is again constructed. As described above, Cdks appear to employ at least three redundant mechanisms, that is inhibition of ORC, CDC6 and MCM activity, to prevent re-replication. Is it necessary to block all three pathways for induction of

re-replication without inhibiting Cdk activity? In budding yeast, the answer is clearly “yes” (3). Also in mammalian cells, alteration of the regulation of the individual components, for example over-expression of the phosphorylation-deficient CDC6 mutant, fails to induce re-replication, consistent with the findings in budding yeast. Although over-expression of fission yeast CDC6 causes re-replication, it could be a consequence of inactivation of Cdk by CDC6 over-expression.

Prevention of Re-Replication by Geminin: Is It Independent of Cdk Activity?

In metazoans, ▶geminin has been identified as another inhibitor of pre-RC formation. This protein prevents the loading of MCM proteins onto chromatin by binding to and inhibiting Cdt1, appears after cells enter S phase and is destroyed during exit from mitosis in an

APC-dependent manner. Thus, geminin may contribute to prevention of re-replication during S, G2 and M phases. It has been suggested that its action is not mediated by elevated Cdk activity, which would appear favorable in some situations; even when Cdk activity is down-regulated by the checkpoint mechanism in cells undergoing DNA damage, re-formation of pre-RC could be prevented. On the other hand, it has been clearly demonstrated that inactivation of Cdk1 activity results in re-binding of MCM proteins and subsequent re-replication. Therefore, it remains possible that geminin functions are also under the control of Cdks. This point need to be further addressed in future.

Clinical Relevance

It is easily imaginable that studies of DNA replication initiation proteins will have a major impact on an understanding of cancer cell biology. However, to date, data are limited compared to those for upstream regulators such as cyclin/Cdks and E2F, whose involvement in cancer has been well established. In general, initiation proteins controlled by the E2F transcription factor like ORC1, CDC6 and MCMs, are over-expressed in tumor cells. Our group has recently found that Cdt1 protein levels are also increased in tumor cell lines. However, the biological significance of over-expression of these proteins has yet to be well addressed. Interestingly, it has now been proposed that over-expression of Cdt1 can enforce re-replication in certain tumor cell lines, suggesting an involvement in genomic instability (6 and our unpublished data). Cell responses to CDC6 over-expression are still controversial, and thus further experimentation is required.

As described above, geminin plays a negative role in regulation of DNA replication. Thus, it is conceivable that its enforced expression would inhibit tumor cell growth and a recent report provided evidence that this is indeed the case. It is also conceivable that the function of geminin might be impaired, for example by mutation of its gene, in some tumors, a possibility that should undoubtedly be addressed in future. If this were the case, geminin would be a new tumor suppressor gene.

Whatever the importance to carcinogenesis, over-expression of initiation proteins could have potential for cancer diagnostics, as shown by our group for MCM7 (7). Several subsequent studies by others support this notion. Since Cdt1 over-expression might play a role in carcinogenesis, its detection might be more significant for cancer diagnostics.

DNA Structure

Definition

DNA, desoxyribonucleic acid, consists of a long, unbranched polymer composed of four types of subunits, the deoxyribonucleotides. Each “monomer” consists of a 5-carbon sugar (deoxyribose), a nitrogen containing base attached to the sugar, and a phosphate group. The bases can be either the ►purin bases adenine (A), and guanine (G), or the ►pyrimidine bases cytosine (C), and thymine (T). The corresponding complexes with sugar residues are called ►nucleosides (adenosine, guanosine, cytidine, thymidine). The nucleotides are linked together by covalent phosphodiester bonds, that connect the 5' carbon of the deoxyribose group to the 3' carbon of the next nucleotide. In the 1950s, James Watson and Francis Crick proposed and described an hypothetical structure for DNA - the DNA double helix: while the alternating ribose sugar molecules and phosphate groups form the outer backbone of the polynucleotide strand, nitrogenous bases are “inside” like rungs on a ladder. Two of those strands of DNA wrap around each other in an antiparallel fashion and form a right-handed double helix. Adenine on one side pairs with thymine on the other by hydrogen bonding, and cytosine pairs with guanine (►complementary base-pairing). The C-G pair is stabilized by three hydrogen bonds while the A-T pair has only two hydrogen bonds, which avoids wrong pairing. The double helix has a 2-fold axis of symmetry. There is a wide (major) and a narrow (minor) groove between the backbones on opposite strands. Purine and pyrimidine rings are spaced 0.34 nm apart, and have intermolecular base-pairs in the center. The bases are stacked one on top of the other which is very important for stability.

The DNA structure model, proposed by Watson and Crick in 1953, has been verified in many different ways and its identification is recognized as one of the most significant breakthroughs in modern science, because it explains how the chain of nucleotides can encode instructions for an organism; the genetic information is carried in the linear sequence of the nucleotides and its variability along the molecule can account for the variety in the genetics code. The model also explains how the genetic information can be copied from one generation (of cells) to the next. Duplication of the genetic information occurs by the polymerization of a new complementary strand onto each of the old strands of the double helix during ►DNA replication.

One important feature of the DNA double helix regarding its function is that all the information in it is redundant. If one base is lost, the complementary base on the opposite strand still contains the information. This is the basis of one strand DNA repair. In this process a damaged or missing base is replaced using the information on the opposite strand.

Definitions

DNA topoisomerases are a class of enzymes that modulate DNA topology by the transient introduction of DNA strand breaks. Double-stranded DNA provides considerable advantages for organisms. Double stranded DNA provides critical redundancy that can serve as a template to repair damaged DNA. The finding by Meselson and Stahl that DNA replication is semi-conservative, i.e. that each daughter cell receives one parental and one newly replicated strand indicated that cells must manage to completely separate the DNA strands during the process of DNA replication and chromosome segregation. The problem of separating DNA strands after replication was better appreciated

following the discovery by Cairns that the *E. coli* chromosome is circular. While it could be imagined that the two strands of a linear double stranded DNA molecule could separate by rotation, this is impossible with a circular double stranded molecule. Although linear double stranded DNA molecules are not formally subject to topological constraints, in practice, a long (chromosome sized) DNA molecule poses the same topological problems as a circular molecule. The solution to this topological problem posed by double stranded DNA is a class of enzymes termed DNA topoisomerases. These enzymes resolve different DNA structures by the introduction of transient DNA strand breaks, and then carry out strand passage reactions that result in changes in DNA topology. This article provides a brief overview of the different topoisomerases found in prokaryotic and eukaryotic cells, their enzyme mechanisms and some of their important biological roles. Recent reviews describe enzyme mechanisms, topoisomerase protein structure and the biological roles of topoisomerases (1, 2).

Characteristics

The problem of separating replicated DNA strands was originally termed the swivel problem, since the problem was first envisioned as requiring the unwinding of parental DNA strands during replication. James C. Wang identified a protein from *E. coli* that had the ability to nick DNA but also was capable of resealing the break following a change in DNA topology. These enzymes were termed DNA topoisomerases because their principal reactions are to change DNA topology and the first discovered enzyme was named *E. coli* topoisomerase I. DNA topoisomerases were first identified in eukaryotic cells by Dulbecco and Champoux. Early studies showed that the eukaryotic enzymes had substantially different properties from the *E. coli* topoisomerase I, notably, the eukaryotic enzyme could efficiently relax both positively and negatively supercoiled DNA, while the prokaryotic enzyme was unable to relax positively supercoiled DNA. However, both the prokaryotic and eukaryotic enzymes introduced single strand breaks in DNA and are therefore termed type I topoisomerases. Since their structures and biochemical mechanisms are distinct, enzymes similar to *E. coli* topoisomerase I are termed type IA enzymes while the eukaryotic enzyme is termed a ►type IB topoisomerase. Both type IA and type IB enzymes are typically monomeric and carry out their reactions without a high-energy cofactor. Although originally found in eukaryotic cells, subsequent experiments have shown that the type IB enzyme is also encoded by some viruses such as pox viruses and is also found in many bacterial species (although not *E. coli*).

Gellert and co-workers identified a second topoisomerase from *E. coli* cells. Unlike *E. coli* topoisomerase I,

the enzyme discovered by Gellert could introduce negative supercoiling, hence the enzyme was named DNA gyrase. DNA gyrase makes double strand breaks in DNA, and is termed a type II enzyme. Type II enzymes are typically multimeric, with DNA gyrase consisting of a tetramer of two pairs of subunits termed *gyrA* and *gyrB*. The eukaryotic type II enzymes are dimers of identical subunits. Also unlike type I topoisomerases, type II enzymes require a high-energy co-factor such as ATP. Type II enzymes are also found in some viruses, including the T-even phages and are found in all eukaryotes. The type II enzymes from eukaryotes and T-even phages also make double strand breaks in DNA, but are unable to introduce negative supercoils into DNA.

More recent work has shown that eukaryotic cells also possess ▶[type IA topoisomerases](#). Hence, type IA, type IB and ▶[type IIA topoisomerases](#) are spread throughout all taxonomic kingdoms. Additionally, some unusual topoisomerases have been found in archaeobacteria, including reverse gyrase, a type I enzyme that can introduce positive supercoils in DNA and a novel type II enzyme termed Top VI. Since this enzyme has substantial structural differences from other type II topoisomerases, this class of enzymes has been termed type IIB topoisomerases. Type IIB topoisomerases have been found in plant somatic cells, and clearly play important roles. One of the subunits of the type IIB enzyme also appears in eukaryotic cells under a somewhat different guise. The ▶[Spo11](#) protein, which is required for introducing double strand breaks to initiate meiotic recombination is homologous to archaeobacterial type IIB enzymes and is thought to break DNA using a topoisomerase-like mechanism.

Reactions Carried Out by Topoisomerases

DNA topoisomerases carry out the reactions that change DNA topology by making a transient break in one or both DNA strands. DNA strand breaks are introduced by the reaction of tyrosine residue(s) of the topoisomerase with the phosphodiester backbone of DNA, resulting in the formation of a covalent phosphotyrosine bond between the enzyme and DNA, a transesterification reaction. An important aspect of cleavage *via* transesterification is its reversibility. After strand passage, a second transesterification reaction reforms the phosphodiester backbone of DNA and releases the active site tyrosine residue. Although all topoisomerases carry out a transesterification reaction with an active site tyrosine to cleave DNA, there are also clear differences between different classes of topoisomerases. The type IA and type II enzymes form 5' phosphotyrosyl linkages with DNA,

while the type IB enzymes form a 3' phosphotyrosyl linkage. Type II topoisomerases absolutely require a divalent cation in order to cleave DNA, while a divalent cation is completely dispensable for type IB enzymes. Interestingly, divalent cations are required for type IA enzyme strand passage, but are not required for DNA cleavage. Taken together, these considerations suggest important differences in the chemistry involved in DNA cleavage by different classes of DNA topoisomerases.

The introduction of DNA breaks by topoisomerases allows the enzymes to catalyze changes in DNA topology as illustrated in Fig. 1. The canonical reaction of topoisomerases, relaxation of supercoiled DNA is carried out by both type I and type II topoisomerases, although the efficiency of relaxation varies with the enzyme and the substrate. Type IA topoisomerases normally only relax negatively supercoiled DNA and are inactive against positive supercoiled DNA, while type IB enzymes are highly active against both positively and negatively supercoiled DNA. Recent elegant single molecule studies by Cozzarelli and colleagues have shown that *E. coli* top IV has much greater activity relaxing positively supercoiled DNA (3). Two enzymes have been shown to be able to introduce supercoils into DNA. As alluded to above, bacterial DNA gyrase can introduce negative supercoils in DNA. The unique ability of gyrase to introduce negative supercoils into a DNA molecule depends on the unusual DNA binding properties of this molecule. About 140 base pairs of DNA are wrapped around gyrase in right-handed orientation to produce one turn of positive superhelical turn, which is then converted into a negative superhelical turn by the strand passage reaction catalyzed by DNA gyrase. Some hyperthermic archaeobacteria carry an enzyme termed reverse gyrase, that is able to introduce positive supercoiling into DNA. Interestingly, reverse gyrase is a type IA topoisomerase, which introduces positive supercoiling by the concerted action of a DNA helicase and the type IA topoisomerase activity.

In addition to relaxation of supercoiled DNA, topoisomerases also carry out other topological changes in DNA. A reaction of critical biological importance is the decatenation of catenated DNA molecules (Fig. 1B). As described below in the section concerning DNA replication, near the end of replication, separation of replicated molecules requires passage of DNA double strands, i.e. a type II topoisomerase activity. In the absence of a type II topoisomerase, the product of replication of a circular molecule is a multiply intercatenated DNA molecule. Not surprisingly, a failure to separate such molecules before cell division prevents their proper segregation. Type I topoisomerases can also carry out decatenation reactions

DNA Topoisomerases. Figure 1 Reaction catalyzed by topoisomerases. Figure 1 shows a schematic representation of reactions catalyzed by topoisomerases. In all three panels, the solid lines represent double stranded DNA. Panel 1A shows relaxation of supercoiled DNA, a reaction catalyzed by both type I and type II topoisomerases. As indicated in the text, the reverse reaction, introduction of DNA supercoiling is carried out only by DNA gyrases. Panel B diagrams a decatenation reaction. Decatenation of intact double strand DNA can be carried out by type II topoisomerases and also by type III topoisomerases in collaboration with a *recQ* helicase (e.g., *E. coli* top III + *recQ*). Decatenation of double stranded DNA can also be carried out by type I topoisomerases provided that there is a gap in one of the two strands. Type II topoisomerases also can knot and unknot DNA (panel C).

with single strand DNA and, provided that there is a gap in one strand, type I topoisomerases can also decatenate double stranded DNA. It has recently been shown that a type IA topoisomerase in association with specific helicases of the *recQ* family can also carry out decatenation of intact double stranded DNA. An intermediate of this reaction is thought to be a hemi-catenane, a molecule in which one DNA strand of a DNA duplex is wrapped around another double strand. A reaction that is closely related to decatenation is unknotting of DNA. A knot can be considered to be an intramolecular catenane. While unknotting is useful as an assay for type II topoisomerases, knotted DNA arises only rarely in normal DNA metabolism.

Topoisomerase Strand Passage Mechanisms

There are two major mechanisms that topoisomerases use to move DNA strands during the enzyme reaction.

Type IB enzymes use a rotation, or swiveling mechanism, whereas both type IA and type II enzymes use an enzyme bridging or strand passage mechanism. Only type IB and type II enzyme mechanisms will be considered here; several recent reviews comprehensively discuss all three types of enzyme mechanisms (4, 5, 6, 7).

Type IB enzymes introduce a single strand break in DNA, through a 3' phosphotyrosine intermediate. The enzyme does not maintain tight interaction with the other end of the cleaved DNA (with a 5' -OH, see Fig. 2). The free DNA end has the potential to rotate; in general the rotation will be in the direction that results in relaxation of the supercoiled DNA. The rotation may be somewhat constrained by the enzyme, but the enzyme can relax multiple superhelical turns per cleavage cycle. After rotation, the enzyme reseals the break and can then dissociate or initiate another round of catalysis.

The reaction cycle of topoisomerase II is illustrated in Fig. 3, and is considerably more complex than the reaction cycle for type IB topoisomerases. There are several important features distinguishing the reaction mechanisms. The type II topoisomerases use a high-energy cofactor, typically ATP, however the high-energy cofactor does not directly contribute to breakage or rejoining of DNA strands, rather ATP binding and hydrolysis controls the conformational states of the enzyme. The enzyme bridging mechanism restricts the enzyme to the passage of one DNA (double) strand per breakage/reunion cycle. The reaction cycle is illustrated in Fig. 3.

Topoisomerase II interacts with two different double stranded DNA duplexes during its reaction. The enzyme generates a DNA "gate" through which a second strand can be passed. The cleaved strand is therefore referred to as the G-segment, while the duplex transferred through the break is called the T-segment. DNA cleavage occurs by the formation of phosphotyrosine bonds between a catalytic tyrosine of each enzyme subunit and the phosphodiester backbone of each strand (of the G-segment). In the case of DNA gyrase, the *gyrA* subunits carry the tyrosine involved in the transesterification reaction. DNA cleavage by type IIA enzymes results in a four base pair staggered double strand break in the G-segment, while for type IIB enzymes, a two base pair stagger occurs. In the presence of ATP, topoisomerase II undergoes dimerization of the N-terminal domains of the subunits. The enzyme forms a "closed clamp" that can trap a second DNA duplex, the T-segment. The T-segment passes through the double strand break in the G-segment, which exits the enzyme complex through the carboxy terminal portion of the enzyme (the bottom of the enzyme as illustrated in Fig. 3). Following T-segment transport, the enzyme reverses the cleavage reaction,

DNA Topoisomerases. Figure 2 Strand passage by strand rotation. Type IB topoisomerases relax DNA by a strand rotation mechanism. After DNA cleavage, the free end of the cleaved strand can rotate and alter the supercoiling of DNA. There are limited contacts between the enzyme and the cleaved strand, although recent work suggests that the rotation of the cleaved strand may be somewhat constrained. Nonetheless, multiple superhelical turns can be removed per cleavage/rejoining cycle.

and reforms the phosphodiester bonds of the G-segment. After religation of the cleaved G-segment, hydrolysis and release of ATP is required to dissociate the N-terminal domains of the subunits and restore the enzyme to a conformation where the enzyme can either dissociate from the G-segment of DNA or initiate a new catalytic cycle. For eukaryotic enzymes, the capture of a T-segment is random and will be dictated by the overall three dimensional distribution of DNA molecules.

The Complement of Topoisomerases in Cells: Genetic Studies on the Physiological Roles of Topoisomerases

The complete DNA sequencing of multiple prokaryotic and eukaryotic genomes has provided a powerful complement to the initial biochemical and genetic studies that identified many of the topoisomerases in prokaryotes and eukaryotes. There is only very limited homology among the different major classes of topoisomerases, although there are some key similarities between type IA and type II topoisomerases (8). Within each family of topoisomerases, there is significant amino acid homology. For example, determination of the DNA sequence of the gene encoding yeast Top2 revealed substantial homology with the genes encoding *E. coli* DNA gyrase. The identified homology made it possible to identify a set of residues

that are invariant within each class, making identification of topoisomerase genes relatively straightforward. All bacterial cells have at least one type IA and one type II topoisomerase. Some archaeobacteria that carry a type IIB topoisomerase do not have an obvious type IIA enzyme. Recently, type IB topoisomerases have also been found in eubacteria, however, neither *E. coli* nor *B. subtilis* carry this type of enzyme. *E. coli* cells carry two type IA enzymes (Top I and Top III) and two type IIA enzymes (DNA gyrase and Top IV). Of these four enzymes, all but Top III are essential for viability. It should be noted that in *S. typhimurum*, Top I is not essential for viability, although mutants lacking this enzyme have pleiotropic defects in gene expression and DNA repair. *E. coli* cells lacking Top I are viable provided that they also carry compensatory mutations, most commonly mutations that reduce the activity of DNA gyrase. *E. coli* cells lacking both Top I and Top III have not been identified, suggesting that the compensatory mutations do not alleviate a requirement for at least one type IA topoisomerase. These results indicate that type IA topoisomerases and type II enzymes have indispensable roles in DNA metabolism in bacterial cells. As described below, both DNA gyrase and Top IV play key roles in DNA replication and chromosome segregation.

The yeasts *Saccharomyces cerevisiae* and *Schizosaccharomyces pombe* have served as important model systems for understanding the biological functions of

DNA Topoisomerases. Figure 3 Catalytic cycle of type II topoisomerases. Figure 3 illustrates the catalytic cycle of type II topoisomerases. The enzyme first interacts with the G-segment, the strand that the enzyme will cleave. ATP binding results in dimerization of the N-terminal domain (the top of the enzyme as drawn). The dimerization of the N-terminal domain can lead to the capture of a second DNA segment termed the T-segment. A double strand break in the G-segment creates a DNA gate that the T-segment can pass through. The T-segment exits the enzyme through a C-terminal protein gate. The dynamics of the exiting of the T-segment are poorly understood. After the T-segment transits through the double strand break in the G-segment, the G-segment is religated, and the ATP is hydrolyzed. Release of ADP and Pi leads to dissociation of the N-terminal dimerization and resets the enzyme for a new catalytic cycle.

DNA topoisomerases in eukaryotic cells. Both yeasts have three topoisomerases, termed Top1, Top2, and Top3, in addition to a Spo11 (type IIB) meiotic enzyme. In both yeasts, *top1* (a type IB enzyme) null mutants are viable, indicating the enzyme is not essential for viability. *top1* mutants have relatively modest phenotypes, most notably changes in gene expression and alterations in genome stability (discussed below). The yeasts are the only known eukaryotes that do not require a type IB enzyme for viability. By contrast, null mutations in *top2* (a type IIA enzyme) are lethal. Conditional *top2* mutants have normal DNA replication and lose viability specifically at mitosis, suggesting a defect in chromosome segregation. However, the combination of a *top1* null mutation with a *top2*

mutation results in much more severe phenotypes, including defects in replication and transcription. Current models suggest that either Top1 or Top2 can perform many functions requiring a topoisomerase. *S. cerevisiae* cells lacking *top3* (a type IA enzyme) are viable, but grow extremely slowly and accumulate compensatory mutations in *SGS1*, a helicase that interacts with Top3 protein. Interestingly, *S. pombe* cells lacking *top3* are unviable unless they carry compensatory loss-of-function mutations in *SGS1*. Current studies suggest that Top3 plays a key role in genome stability, a topic discussed below.

Not surprisingly, the complement of topoisomerases in mammalian cells is more complex than that found in yeast. The known topoisomerases of mammalian cells are summarized in Table 1. Mammalian cells have one type IB, two type IA topoisomerases and two type IIA topoisomerases that are mainly localized to the nucleus. Additionally, a type IB topoisomerase that localizes specifically to mitochondria has been found. Experiments assessing the role of particular enzymes have been mainly confined to mouse gene deletion experiments. Top1, Top2 α , Top2 β and Top3 α are all required to generate viable offspring. Of these, Top2 β is of particular interest since embryos deleted for both copies of the Top2 β gene die close to birth. Therefore cells lacking this enzyme are viable and mouse embryonic fibroblasts lacking the enzyme grow and divide normally. Embryos lacking this enzyme have defective neuronal migration, resulting in abnormal neuromuscular junctions and a failure to enervate the diaphragm. The role that Top2 β plays in these processes remains to be determined. Top3 β deficient mice give rise to viable offspring, although over successive generations, the fertility of these mice decreases, accompanied by increased aneuploidy in sperm. These results suggest that Top3 β may play a role in genome stability, as has been suggested for type IA topoisomerases in other systems. Deletions of the mitochondrial topoisomerase have not yet been reported. Since deletion of many of the mammalian topoisomerases results in a complete loss of cellular viability, other experimental systems such as RNAi will be needed to dissect the role that specific topoisomerases play in various cellular processes.

Biological Functions: Replication

The main topological problem associated with DNA replication and accurate chromosome segregation arises from the winding of the two DNA strands in a double helix. At the time of chromosome segregation, the two parental intertwined strands must become completely separated. In addition to this fundamental requirement for separating replicated strands, the process of DNA replication involves the action of a replicative helicase that unwinds double stranded DNA

DNA Topoisomerases. Table 1 The topoisomerases of eukaryotic cells

Enzyme	Type	Localization	Distribution	Essential for viability in mammalian cells
Top1	IB	Nuclear	All eukaryotes	Yes
Top2 α	IIA	Nuclear	All eukaryotes	Yes
Top2 β	IIA	Nuclear, mitochondrial	Mammalian cells, absent in yeast, <i>Drosophila</i>	Yes ¹
Top3 α	IA	Nuclear, mitochondrial	All eukaryotes	Yes
Top3 β	IA	Nuclear	Mammalian cells, <i>Drosophila</i> , absent in yeast	No
mTop1	IB	Mitochondrial	Mammalian cells, absent in yeast ²	Not known
mSpo11	IIB ³	Nuclear	Most eukaryotic cells	No ⁴

¹ Top2 β $-/-$ mice do not survive to term, but embryonic cells lacking the enzyme are viable

² Mitochondrial topoisomerase I has been identified in mammalian cells, and is clearly absent in sequenced yeast genomes. Other systems have not been examined in sufficient detail to determine whether a separate mitochondrial isoform is present

³ Type IIB topoisomerases have also been found in plants, where they play additional roles besides meiotic recombination

⁴ Mice lacking mSpo11 are viable, but are defective in meiotic recombination and are sterile

ahead of the replication fork. In the absence of a topoisomerase activity, the DNA ahead of the replication fork will become highly positively supercoiled, eventually blocking further unwinding by the helicase, thereby leading to arrest of the replication fork. A topoisomerase acting ahead of the fork is able to relax the accumulating positive supercoils, and allow replication to continue. In principle, either type I or type II topoisomerases can fulfill this requirement (Fig. 4). A separate problem arises near the completion of DNA replication. Varshavsky suggested that steric hindrance might prevent a topoisomerase from acting when two replication forks converge at the completion of DNA replication. The resulting replication product for a circular DNA would be catenated. The separation of intercatenated dimers of unnicked circular double stranded DNA is a reaction that is uniquely accomplished by type II topoisomerases, suggesting that these enzymes would have to be required at the completion of replication.

The detailed steps of DNA replication in eukaryotic cells remain to be fully elucidated. Studies of replication in eukaryotes have relied on *in vitro* systems using viral origins of replication and *in vivo* studies using yeast as a model system. Replication *in vitro* requires a DNA topoisomerase, and in the absence of topoisomerase II, the products are catenated dimers. *In vivo*, yeast cells can complete replication with either topoisomerase I or topoisomerase II. Without topoisomerase II activity *in vivo*, yeast plasmids are fully replicated, but accumulate as catenated dimers. Similarly, yeast chromosome segregation fails in the

absence of topoisomerase II activity. In the absence of both topoisomerase I and topoisomerase II activities, some replication can still take place in yeast cells although replication that does occur in S phase is very limited.

Topoisomerases in Transcription

The requirement for topoisomerases during replication is clear since the two (parental) DNA strands of a replicated double stranded DNA molecule must be completely separated by the time the molecules are segregated into daughter cells. Although transcription also involves a certain degree of strand separation, the amount of strand separation during transcription is relatively limited, suggesting that DNA topology may not be an important limitation in the movement of RNA polymerase. However, DNA topology may in some instances exert effects on the process of transcription that are independent of providing a "swivel" for the movement of RNA polymerase.

Chromosome Structure and Condensation

The eukaryotic chromosomes at mitosis is a highly compacted structure, while at other points in the cell-cycle, the degree of compaction is relatively small. Therefore, during the process of cell division chromosomes undergo a condensation/decondensation cycle. A key multi-protein complex required for this process is condensin. Biochemical and genetic studies strongly suggest that both topoisomerase II and condensin are required for chromosome condensation, although the precise role of topoisomerases in this process remains

DNA Topoisomerases. Figure 4 Topoisomerases as swivels for DNA replication. Positive supercoils accumulate in front of the replication machinery (either replicative helicases or DNA polymerase holoenzymes) and must be removed for fork progression. Either type I or type II topoisomerases can act as a swivel ahead of replication forks. Topoisomerases can also effect strand separation by acting behind replication forks. Unlinking of replicated molecules at the completion of replication requires a type II topoisomerase.

to be determined. A requirement for topoisomerase II in modulating chromosome condensation suggests that this protein may be an important determinant of chromosome structure. A structure termed the “chromosome scaffold” was operationally defined as a set of proteins that remained following removal of DNA and histones from mitotic chromosomes. Topoisomerase II is one of the major components of chromosome scaffolds, although the biological roles of these structures remains to be worked out (9).

Biological Functions: Recombination and Genome Stability

DNA topoisomerases play clear roles in modulating DNA structure and also play essential roles in DNA replication. A failure to regulate chromosome structure or properly complete DNA replication might be expected to generate damaged structures that might require DNA repair processes for their rectification. It is now widely appreciated that a major function of homologous recombination is to allow restarting of DNA replication when a fork is blocked. In yeast models, a lack of any of the three topoisomerases leads to elevated recombination. Yeast cells lacking *TOP1* or carrying a temperature sensitive *TOP2* allele exhibit elevated recombination, although the hyper-recombination phenotype occurs mainly in rDNA, the locus encoding the RNA components of ribosomes. The hyper-recombination phenotype may arise from alterations in transcription, in replication or in the coordination of these two processes. Yeast cells lacking *TOP3*

also exhibit a hyper-recombination phenotype and *top3* mutants have a hyper-recombination phenotype that is not confined to rDNA. Current models suggest that topoisomerases function to suppress recombination, especially in repeated genetic elements. This may explain the elevated levels of aneuploidy observed in mammalian *top3β* deficient mutants.

Unanswered Questions and Future Directions

Work over the last few years has led to a broad understanding of the enzyme mechanisms of DNA topoisomerases. Although not described in detail in this article, protein structures determined by X-ray crystallography have made it possible to describe in substantial detail how DNA topoisomerases carry out their elaborate strand passage reactions. Studies especially in yeast and mammalian cells, have uncovered new enzymes and made assigning specific roles for the newly discovered enzymes more challenging. Topoisomerases still appear in what seem to be unlikely contexts, such as the phenotypes conferred by mouse cells lacking *top2β*.

Clinical Relevance

Topoisomerases are clearly vital for many aspects of nucleic acid metabolism. Topoisomerases also play an important role as the targets of clinically important anti-bacterial and anti-tumor agents. Fluoroquinolones are broad-spectrum potent anti-bacterial agents. The targets of fluoroquinolones are bacterial type II topoisomerases. Both DNA gyrase and top IV are targeted by quinolones. Agents acting against eukaryotic topoisomerases have

also been identified and are active, clinically used anti-cancer agents. Topotecan and irinotecan are camptothecin derivatives that specifically target topoisomerase I, while agents such as doxorubicin and etoposide target eukaryotic topoisomerase II. Fluoroquinolones, camptothecins and the topoisomerase II targeting drugs have a unique mechanism of action. The most important effect of these drugs is to block their target enzyme at a step in the catalytic cycle where the enzyme is covalently bound to DNA. Hence all of these topoisomerase-targeting agents convert topoisomerases into a form of DNA damage.

DNA-based Vaccination

REINHOLD SCHIRMBECK, MARTIN SCHLEEF,
JÖRG REIMANN

Institute for Medical Microbiology and Immunology,
University of Ulm, Ulm, Germany
reinhold.schirmbeck@medizin.uni-ulm.de

Definition

Genetic (nucleic acid or DNA) vaccination is an exciting new immunization technique with potential applications in clinical medicine. In ► [genetic immunization](#), plasmid DNA containing antigen-encoding sequences cloned under ► [heterologous promoter control](#) is delivered by techniques that lead to antigen expression *in vivo* and its immunogenic presentation. DNA vaccination has been shown to efficiently prime both humoral (antibody) and cellular (T cell) immune responses against viral, bacterial, parasite and tumor antigens in different animal species, e.g. mice, pigs, cattle, dogs, monkeys and man. A key feature of DNA-based vaccination is its potency to specifically prime ► [Th1-biased T cell responses](#), including MHC-I-restricted, cytotoxic ► [CD8⁺ T lymphocyte](#) (► [CTL](#)) responses. This makes genetic vaccination an attractive candidate for ► [prophylactic](#) or ► [therapeutic immunization](#) against intracellular pathogens and cancer. Protein antigens encoded by DNA ► [vaccines](#) are expressed by transfected cells *in vivo*, thus mimicking viral infection.

Three areas that critically influence the success of DNA vaccination are:

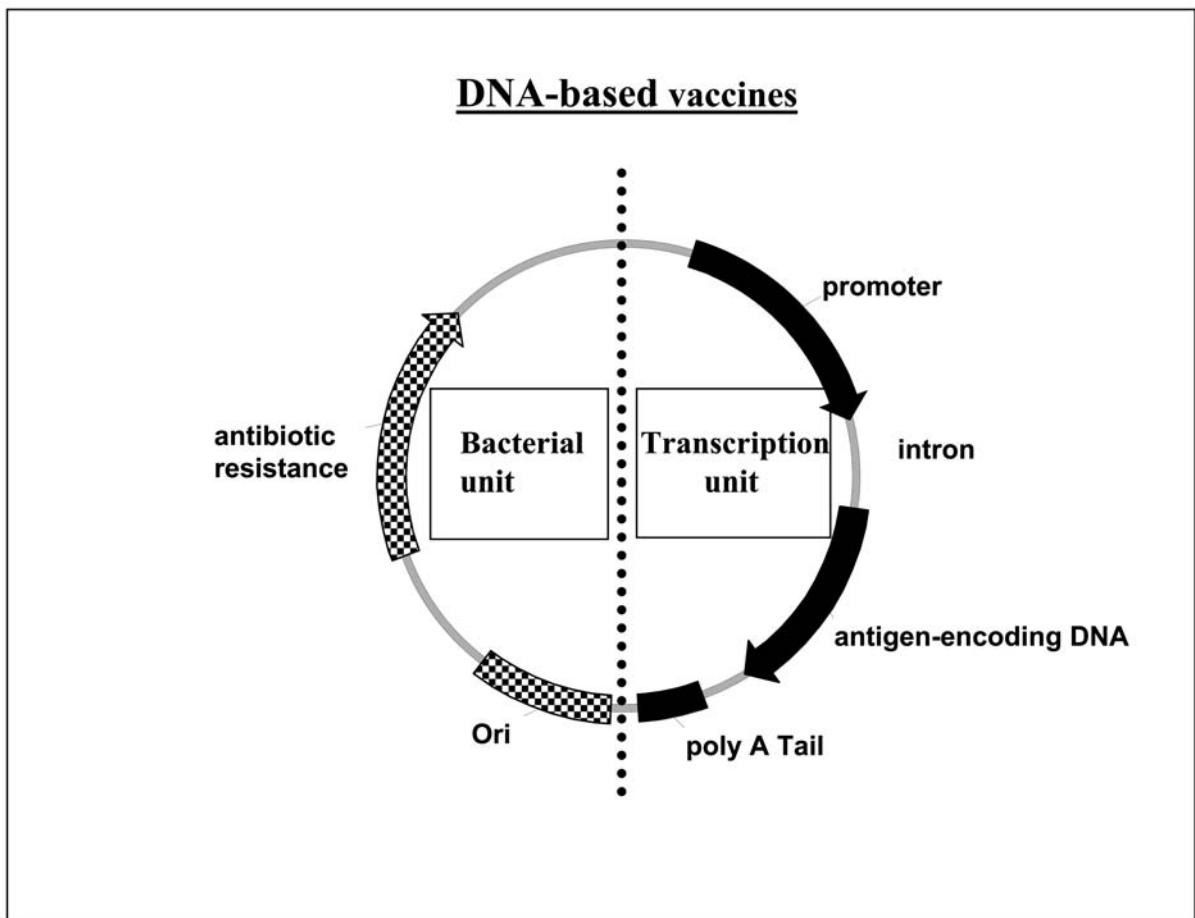

- the design of expression vectors that efficiently produce antigen(s) *in vivo*;
- the large scale production and purification of DNA vaccines;
- techniques of delivery of DNA vaccines that support a level of antigen expression that ensures immunogenicity.

Characteristics

Vector Design

The 'vaccine' delivered in nucleic acid immunization is usually plasmid DNA, though successful vaccination with antigen-encoding mRNA has been reported. The DNA vaccine contains two units, a bacterial unit (necessary for plasmid production) and a transcription unit (encoding the relevant antigen) (Fig. 1). The bacterial unit contains a bacterial drug resistance gene for selecting plasmid-containing bacteria, and an origin of replication to allow production of high copy numbers of the plasmid in appropriate bacterial strains. The transcription unit contains the antigen-encoding sequence cloned downstream from strong ► [promoter/enhancer](#) sequences that support efficient expression of the immunogenic protein in eukaryotic cells. Variables considered in the design of DNA vaccines include:

- a choice of promoter/enhancer sequences to control the level and the tissue specificity of antigen expression;
- the incorporation of innate ► [adjuvants](#) or immune modulators into the coding sequences of the DNA vaccine;

DNA-based Vaccination. Figure 1 Plasmid used for DNA-based vaccines. The plasmid contains a bacterial unit (containing sequences of the origin of replication (ORI) and the antibiotic selection marker) and the eukaryotic transcription unit (containing promoter/enhancer, intron, antigen and poly A signal sequences).

- strategies to control coexpression of different genes (either different antigens or antigen plus costimulator/▶cytokine molecules);
- strategies to target antigen to different subcellular compartments within antigen processing/ presenting cells or to facilitate antigen release from the expressing cell.

Promoter/Enhancer Sequences

Promoter/enhancer sequences used in DNA vaccines to drive antigen expression are often derived from viruses (e.g. cytomegalovirus, simian virus 40, retrovirus) or bacteria (1, 2). Because interferon- γ (IFN γ) release *in situ* during priming of immune responses by DNA vaccine injection can suppress the activity of viral promoters, mammalian cell-derived promoter/enhancer elements have been successfully used to construct DNA vaccines. These include e.g. sequences driving expression of elongation factor-1 α , desmin or metallothionein (1, 2). In addition, polyadenylation and/or

intron sequences (positioned either within the transcription unit or flanking it) can be of critical importance for the immunogenicity of DNA vaccines by stabilizing mRNA transcripts.

Coexpression of Immune Modulators by DNA Vaccines

DNA vaccines can encode cytokines, costimulator molecules, small ▶innate adjuvants or adjuvant-binding domains (2, 3). Stress proteins are potent ‘innate adjuvants’ that facilitate priming of cellular and ▶humoral immune responses. Proteins of the ▶hsp70 and hsp90 families are immunodominant antigens of many bacterial and parasite infections. Construction of DNA vaccines encoding stress proteins fused to antigen has been reported to strikingly enhance the immunogenicity of its T cell ▶epitopes.

A stress protein (hsp73)-facilitated expression system was developed in order to produce large chimeric antigens with enhanced immunogenicity for the specific humoral and cellular immune system (4). The

system is based on the observation that N-terminal sequences of the SV40 large ▶T-Ag show strong, non-covalent binding to hsp73/hsc70 because the N-terminal 77 residues of T-Ag with ▶DnaJ homology have functional docking sites for hsp73. Hence, the N-terminal T-Ag domain can dock to and regulate substrate binding of the constitutively expressed, cytosolic stress protein hsp73. Chimeric antigens constructed from such an N-terminal, hsp73-binding T-Ag domain fused to large C-terminal antigenic domains of >900 residues were efficiently expressed in an immunogenic form. The advantages of the system are:

- high expression of large amounts of chimeric proteins with a long half-life as protein/hsp complexes;
- expression of large protein antigens that bind increasing amounts of hsp with increasing length;
- codelivery of protein antigens that non-covalently bind hsp strikingly enhances and modulates its immunogenic properties.

Using DNA-based vaccination, the relative efficacy of CTL priming to a large panel of ▶MHC class I-binding epitopes processed from antigenic domains expressed either as native antigens or as chimeric antigens fused to the N-terminal hsp73-binding DnaJ domain of the T-Ag were compared. Hsp73-association greatly facilitated induction of humoral and cellular ▶immune responses to antigens or their antigen-domains targeted (4). The stable, non-covalent association of antigen with hsp73 *in situ* during its early expression thus facilitates priming of CTL. Furthermore, this system supported efficient cross priming of ▶TAP-independent and helper T cell-independent CTL responses in murine tumor models due to the codelivery of intrinsic (natural) adjuvants. In addition, priming of antibody responses to endogenous antigen was observed following DNA vaccination. This demonstrates that recombinant DNA technology can be successfully used to design DNA vaccines that codeliver 'natural' adjuvant activity with an extended range of antigenic information thereby facilitating specific stimulation of T cell responses.

Strategies for the Coexpression of Different Genes by DNA Vaccines

A key issue of DNA-based immunization is the design of polyvalent vaccines to increase the amount of immunogenic information that can be delivered by a DNA vaccine. A simple way is to mix two expression constructs before delivery. In more elaborate systems, different genes are coexpressed in complex expression constructs at stoichiometrically defined ratios from one plasmid. This is e.g. achieved by incorporating internal ribosomal entry sequences (▶IRES) between genes to

allow their coexpression under control of a single promoter. Complex expression vectors that contain multiple polycistronic expression units have been successfully designed. This approach offers the prospect of coexpressing multiple antigens, cytokines and costimulator molecules at stoichiometrically defined ratios by a single DNA vaccine. This approach may eventually allow the incorporation of the complete immunogenic information of a virus into a single DNA vaccine and its codelivery with a molecularly defined adjuvant.

Targeting Antigen Expressed by DNA Vaccines to Different Subcellular Compartments of Antigen Processing/presenting Cells or Facilitating Antigen Secretion from the Expressing Cell.

DNA-based vaccines ensure the *in situ* expression of protein antigens with correct posttranslational modifications, three-dimensional conformations or oligomerizations. The integrity of conformational epitopes that stimulate neutralizing antibody (B cell) responses is thereby maintained. DNA vaccines induce antibodies against intracellular proteins (2, 5) by a mechanism not understood. It is generally accepted that exogenous protein antigens efficiently induce antibody responses. DNA vaccines can easily be engineered to optimize the immunogenicity of encoded protein antigens for antibody induction by introducing leader and/or transmembrane anchor sequences. This programs protein antigens to be either secreted or incorporated into the surface membrane. Both modifications have been shown to enhance humoral immune responses induced by DNA vaccines (2, 5).

Production of DNA Vaccines

For manufacturing plasmid DNA of a quality acceptable for clinical use, appropriate production processes are required that have to fulfill the requirements of internationally valid guidelines and laws. Good manufacturing practice (GMP) is applied in production and quality control for pharmaceuticals. These standards are only obtained in specific manufacturing and quality control facilities. The isolation of plasmid DNA for research applications requires high quality materials and technologies to guarantee a reproducible and appropriate quality (6). The main requirements in plasmid purification are:

- the separation of plasmid DNA from contaminating substances derived from either the purification process or the bacterial host cell (e.g. cell wall residues, lipopolysaccharides, bacterial genomic DNA, RNA, proteins, lipids);
- the protection of the desired supercoiled form of the plasmid throughout the manufacturing process;
- the separation of the supercoiled form of the plasmid DNA from other DNA forms to obtain a homogenous product.

The standard process in plasmid production is the stable transformation of the plasmid vector into a defined *E. coli* host strain, its cultivation in a fermenter, the alkaline lysis of the bacterial biomass followed by filtration and chromatography steps to obtain the requirements listed above. In bacterial cultivation for plasmid productions, different plasmid forms appear. The supercoiled plasmid structure shows the most compact structure and is known to be the most active topology.

The product stability in production, storage, formulation, transport and application mainly reflects plasmid topology. The characterization of the DNA topology was for the first time possible using the technology of capillary gel electrophoresis (CGE). The CGE assay is nowadays performed as in-process control in plasmid manufacturing on a routine basis to identify and monitor sensitive process steps in which shear forces can damage plasmid DNA (e.g. sterile filtration). Recently, CGE technology was applied in process to monitor the separation of undesired topologic plasmid variants from the supercoiled fraction.

Storage and transport of DNA vaccines require defined media. Typically, a plasmid DNA solution will be frozen for long-term storage. Optimization studies ongoing in many facilities will include CGE. The use of ►gene gun or jet-injection will require further evaluation of plasmid stability and topology. Monitoring the changes in the supercoiled topology during the application, as well as optimizing the applied pressure with respect to tissue, plasmid and buffer are expected to be essential for the success of the technique.

Delivery of DNA Vaccines

Different techniques for the delivery of low doses of DNA vaccines in immunogenic form are under development. These include the delivery of:

- ►‘naked’ plasmid DNA for injection into muscle or skin;
- ►particle-coated plasmid DNA for delivery to skin or mucous membranes by the gene gun;

The injection of ‘naked’ plasmid DNA into the muscle or skin is an efficient technique to induce humoral and cellular immune responses in mice (1, 2, 5). DNA is administered in a variety of diluents, but the most common is phosphate-buffered saline (PBS). Injection of ‘naked’ plasmid DNA into mice is usually sufficient to establish immune responses. This delivery technique is efficient in mice, but inefficient in other animal species and in man where several injections of mg amounts of DNA often elicit only marginal specific immune responses. New techniques are currently being tested to allow the delivery of low doses of DNA vaccines to a range of animals without affecting the immunogenicity of the vaccine (2).

Low doses of gold particle-coated plasmid DNA can be inoculated intradermally with the gene gun (2, 5). A single inoculation of the DNA vaccine primes readily detectable and long-lasting serum antibody responses and T cell responses. Gene gun vaccination has many advantages compared to i.m. DNA vaccination. It is an easy and reproducible way for DNA injections especially in larger animals and man.

Concluding Remarks

Since its first description in 1992, DNA vaccination has moved with amazing speed from preclinical animal models to clinical trials. Although DNA vaccination involves risks (including insertional mutagenesis, induction of low zone tolerance or autoimmune responses and immune-mediated destruction of tissue transfected *in vivo*), its potential for vaccinology is expanding. DNA vaccines have increasing appeal in the exploration of the increasing universe of molecularly cloned antigens as vaccine candidates.

Docking

Definition

In the context of protein interaction analysis or structure-based drug design, docking is the process by which the three-dimensional structures of a protein and its ligand (or drug) fit together. The energetically preferred geometry of interaction of a ligand binding to a biological macromolecule is predicted by a computational approach.

Docking (or fitting) in the context of cryo-EM refers to the positioning of atomic models of macromolecules (either as rigid bodies or in a flexible manner) into lower resolution electron density maps.

Dominant

Definition

Dominant describes the property of an allele to be expressed (phenotypically in heterozygous state; one locus on the homologous chromosomes).

Dominant Allele

Definition

The term dominant allele is applied to the phenotypic effect of a particular allele, in reference to another allele (usually the standard wild-type allele), with respect to a given trait. An allele “A” is said to be dominant with respect to the allele “a” if the A/A homozygote and the A/a heterozygote are phenotypically identical and different from the a/a homozygote.

- [Large-Scale ENU Mutagenesis in Mice](#)

Dominant Inhibitory Mutant/ Dominant Negative Mutant

Definition

Dominant inhibitory (or dominant negative) mutant is used to describe a mutation in a protein, which when expressed, is non-functional, or can interfere with the function of the normal (wild-type) protein. In classical genetic nomenclature, this type of mutation is analogous to an antimorphic allele.

► [Mouse Genomics](#)

► [Xenopus as a Model Organism for Functional Genomics](#)

Dominant Mutation

Definition

Dominant mutation characterizes a mutation that usually results in a gain of gene function and produces the mutant phenotype, even in the presence of the wild-type gene.

► [Protein Interaction Analysis: Suppressor Hunting](#)

Dominant Negative Mutation

Definition

Dominant negative mutation refers to a mutation that dominantly affects the phenotype, by means of a defective protein interfering with and inhibiting the function of the normal (wildtype) gene product in the same cell.

Donor

Definition

In Förster resonance transfer (FRET), the donor is defined as the molecule passing energy to another molecule (acceptor) causing its excitation.

► [FRET](#)

Dopamine

Definition

Dopamine (DA) is a catecholaminergic neurotransmitter of dopaminergic neurons, as well as the precursor for the synthesis of noradrenalin. Dopaminergic neurons that have their cell bodies in the ventral tegmental area (VTA) are the key players in the ► [reward system](#). They send their axons to the nucleus accumbens, the frontal cortex, and parts of the striatum. Actions that increase DA release tend to be repeated. There is evidence that the release of the neurotransmitter DA increases after repeated drug use, and is reduced during withdrawal from the drug. Loss of dopaminergic neurons is seen in Parkinson's disease, and therapies are based on ► [dopamine replacement](#) in that disease.

► [Addiction, Molecular Biology](#)

► [Parkinson's Disease: Insights from Genetic Cause](#)

Dopamine Replacement Therapy

Definition

Dopamine replacement therapy means medication that increases the stimulation of dopamine receptors in the brain. This is achieved by either directly increasing the dopamine, via administering dopamine precursors (with medications such as carbidopa/levodopa), or dopamine agonists, or by medications that inhibit the metabolism of dopamine. These treatments are currently the mainstay of therapy in Parkinson's disease.

► [Parkinson's Disease: Insights from Genetic Cause](#)

Dopamine Responsive Parkinsonism

► [Parkinson's Disease: Insights from Genetic Causes](#)

Dormancy

Definition

The term is taken from bacteriology, indicating survival of a pathogen or a population of cancer cells with minimal activity and lack of growth because of unfavourable circumstances.

► [Cancer Invasion and Metastasis: Cellular, Molecular and Clinical Aspects](#)

Dosage Compensation

Definition

Dosage compensation describes a mechanism by which organisms adjust the dose of X-chromosome-linked transcripts, in order to equalize levels of sex-chromosome products in males and females of one species. In mammals, dosage compensation operates by maintaining only a single active X chromosome in each cell, while in *Drosophila* it operates by hyperactivating the single male X chromosome.

► [Chromatin Acetylation](#)

► [X-Chromosome Inactivation](#)

Doss Porphyria

Definition

Doss porphyria is an autosomal recessively inherited disease, caused by deficiency of the δ -Aminolevulinic acid dehydratase, which leads to an acute hepatic porphyria in the compound heterozygous state.

► [Acute Intermittent Porphyria](#)

Double Mutant

Definition

Double mutant describes an individual that is carrying homozygous mutations in two different genes. In the context of mouse genetics, a double mutant is usually produced by crossing individual heterozygous for mutations in two different genes.

Definition

Faithful maintenance of the integrity of the genetic information in response to DNA damage is critical for proper functioning of all living organisms. Double-strand breaks (DSBs) in DNA, i.e. breaks occurring simultaneously in both strands of the DNA double helix, are among the most severe types of damage which, if left unrepaired, can lead to broken chromosomes and cell death. DSBs occur as intermediates in several cellular processes, including meiotic recombination in germ cells and during the assembly of ► [immunoglobulin](#) and T-cell receptor genes to form functional genes in lymphocytes by ► [V\(D\)J recombination](#). In proliferating cells, DNA replication is a major source of DSBs in the genome. DSBs can also be induced by exposure to DNA damaging agents such as ionizing radiation and radiomimetic chemicals like bleomycin, both of which are frequently used in cancer therapy.

The presence of a DSB in the genome of a eukaryotic cell triggers activation of complex and highly coordinated DNA damage response pathways, which function to restore the integrity of the genome through ► [cell-cycle checkpoints](#) and ► [DNA repair](#). Defects in these mechanisms can lead to cell death or the accumulation of mutations and ► [chromosomal aberrations](#). There is abundant evidence from cytogenetic and molecular studies that tumor development in humans is frequently associated with the formation of chromosomal aberrations such as translocations. Presumably, these aberrations arise as a consequence of DSBs and their inappropriate repair. Two main pathways, namely, homologous recombination (HR) and non-homologous endjoining (NHEJ) have evolved in eukaryotes for the repair of DSBs. While largely distinct from one another, they function as complementary mechanisms to repair DSBs. Repair through HR requires the presence of an undamaged homologous (identical) DNA sequence. Such sequence information is present not only on the homologous chromosome but also in replicating cells on the sister chromatid. The homologous sequences are used for accurate repair of the nucleotide sequence at the site of the DSB. The process of NHEJ is based on the simple rejoining of the two DNA ends of a DSB, but this process is less precise than HR.

Characteristics

Homologous Recombination

Repair of DSBs through homologous recombination (HR) was first observed in the yeast *Saccharomyces cerevisiae*. Survival studies showed that diploid yeast cells are more resistant to ionizing radiation than haploid cells. The observations that repair of DSBs induced by ionizing radiation requires the presence of two DNA copies suggested that DSBs could be repaired through HR (also called recombinational

repair). This assumption was confirmed by the isolation of ionizing radiation sensitive (RAD) mutants. These mutants belong to the RAD52 ►epistasis group and are characterized by increased sensitivity to ionizing radiation and chemical compounds capable of inducing DSBs. In addition, most of these mutants have severe defects in mitotic and meiotic recombination as manifested by the formation of nonviable spores. Homologs of these genes have been identified in higher eukaryotes including man. At present the RAD52 group in mammals encompasses 12 genes (Table 1).

The classical model for HR is based on studies in yeast and other fungi. After the induction of a DSB, the first step is the formation of 3'-single-strand ends by the action of specific nucleases. Subsequently, one of the 3'-ends invades an undamaged homologous DNA molecule leading to the displacement of one of the DNA strands (D-loop). The invading 3'-end is then used as a start for DNA synthesis. Later on, after enlargement of the D-loop, the other 3'-end can also be used as a start for DNA synthesis. Finally, the intermediate structures in recombination are resolved and repair is completed by ligation of the ends (Fig. 1).

Double-Strand Break Repair. Table 1 Proteins involved in double-strand break repair in mammals

homologous recombination		non-homologous endjoining
BRCA1	XRCC2:	Ku70
BRCA2	XRCC3	Ku80
RAD50	RAD51B	DNA-PKcs
MRE11	RAD51C	Artemis
NBS1	RAD51C	Ligase IV
RAD51		XRCC4
RAD52		
RAD54		
RAD54B		

With the exception of BRCA1 and BRCA2, proteins required for homologous recombination belong to the RAD52 group and were identified on basis of homology with yeast proteins. XRCC2, XRCC3, RAD51B, RAD51C and RAD51D are referred to as RAD51 paralogs because these proteins display 20-30% identity to RAD51. A sixth RAD51 paralog, DMC1, functions only in meiosis. In addition to the proteins known to be directly involved in HR, there are several other factors required for repair through this pathway, e.g. replication protein A, resolvases of intermediate structures in recombination, DNA polymerase and DNA ligase.

Double-Strand Break Repair. Figure 1 Schematic representation of homologous recombination and non-homologous endjoining, the two main pathways involved in repair of double-strand breaks in DNA in eukaryotes. (a) The first step in HR after the induction of double-strand breaks, is the specific formation of 3'-single-strand DNA ends at the site of the break. One of the 3'-ends invades a homologous undamaged DNA molecule leading to the formation of a D-loop. Both 3'-ends are then used to prime DNA synthesis. The synthesis of new DNA leads to restoration of DNA sequences that were lost as a consequence of the induction of a double-strand break. Finally, the intermediate structures in recombination (also called joint molecules) are resolved and repair is completed by ligation of the ends. Repair through HR results in correct repair of the break. (b) The first step in NHEJ is binding of DNA-PK (consisting of Ku70, Ku80 and DNA-PKcs) and Artemis to the site of the break. After aligning, the ends are ligated by the DNA Ligase IV/XRCC4 complex. Repair by NHEJ frequently results in mutations at the site of the break due to the removal or addition of a few nucleotides.

Proteins encoded by the RAD52 group genes have been purified and analyzed in great detail. The RAD50 protein acts in a complex containing also MRE11 and NBS1. This trimeric complex has been implicated in the formation of 3'-single-strand ends during the initial steps in HR. The RAD50 complex is also involved in cell-cycle regulation after the induction of DSBs in DNA. RAD51 is the eukaryotic homolog of the RecA protein in *E. coli* and plays a central role in recombination. Like RecA, the RAD51 protein binds to the 3'-single-strand ends at the site of the break, and is crucial in the search of a homologous template DNA and the subsequent invasion step leading to the formation of joint molecules between broken ends and the undamaged template DNA molecule. Other

proteins belonging to the RAD52 group such as the RAD52 and RAD54 proteins and the RAD51 ▶ **paralogues** act as accessory factors in this process by stimulating joint molecule formation. Much less is known about the resolution of the intermediate structures in the final stages of HR. With a few exceptions, inactivation of RAD52 group genes in experimental animals is not tolerated, indicating that HR is essential in proliferating cells. In addition to the RAD52 group genes, other factors such as the breast cancer associated proteins BRCA1 and BRCA2 have been implicated in HR in mammals (see below).

During meiosis when the homologous chromosome is used as a template, HR leads to crossing over (i.e. exchange of segments between paternal and maternal chromosomes) and plays a fundamental role in the generation of genetic diversity. In somatic cells the sister chromatid is the preferred template for HR. Therefore, HR is the predominant pathway for DSB repair in late S and G2 phase cells and is less important in G1 phase cells. Since sister chromatids are identical in sequence, HR results in precise restoration of the original sequence of the damaged DNA molecule, i.e. the HR process is error-free. However, HR involving homologous chromosomes can lead to homozygosity for certain mutant alleles present in one chromosome and not in its homolog. This phenomenon termed “▶ **loss of heterozygosity**” or LOH has been observed for various ▶ **tumor-suppressor genes** in cancers.

Non-Homologous Endjoining

DSB-repair *via* non-homologous endjoining (NHEJ) is based on ligation of the two ends of a DSB without the requirement for extensive sequence homology between the DNA ends. This mechanism was first identified in mammals using rodent cell mutants characterized by an increased sensitivity to ionizing radiation. NHEJ is important in mammals to repair DSBs generated by exogenous agents, in particular during the G1 phase of the cell cycle. In addition, NHEJ plays an essential role in V(D)J recombination in differentiating lymphocytes and defects result in severe forms of immunodeficiency in rodents as well as in humans. Biochemical and genetic studies identified six proteins, which are required for NHEJ. The DNA-dependent protein kinase complex (DNA-PK) consisting of Ku70, Ku80 and the catalytic subunit DNA-PKcs has a central role in NHEJ. Ku70 and Ku80 are abundant nuclear proteins with strong affinity for free DNA ends. Binding of Ku to DNA-ends facilitates recruitment of DNA-PKcs and the Artemis protein to the site of the break to form an activated DNA-PK complex. Activated DNA-PK phosphorylates a large number of proteins *in vitro*, but the precise role of DNA-PKcs *in vivo* remains unclear. Binding of Ku to DNA ends also facilitates binding of the ligase IV-XRCC4 complex to the site

of the break and stimulates intermolecular ligation (Fig. 1). The endonucleolytic activity of the Artemis protein is important for processing of DNA ends and hairpin structures. Opening of hairpins is a crucial step in V(D)J recombination in differentiating B- and T-lymphocytes.

Mice deficient for ligase IV or XRCC4 die during early embryogenesis as a consequence of massive neuronal apoptosis, indicating that these gene products are essential for development. However, mice lacking Ku70, Ku80, DNA-PKcs or Artemis could be generated. These animals display the SCID (severe combined immunodeficiency) phenotype and increased sensitivity to ionizing radiation. Mice deficient for Ku70 or Ku80 have reduced body weight and are also characterized by premature ageing implying additional functions for the Ku proteins. Inactivation of NHEJ has been found to be associated with increased rates of lymphomas in mice. Detailed analysis of tumor material indicated that misrepair of DSBs generated during V(D)J recombination may be one of the initiating steps in the formation of these tumors. At the cellular level, impairment of NHEJ leads to enhanced levels of fragmented chromosomes and chromosome aberrations, indicating an essential role for NHEJ in maintaining genome stability.

Clinical Relevance

A direct link between defects in DSB repair and increased tumorigenesis has come from studies of the *BRCA1* and *BRCA2* (breast cancer susceptibility) genes. Women carrying germline mutations in one of these genes have a risk for developing breast cancer of up to 85% by the age of 70. Both *BRCA1* and *BRCA2* act as tumor-suppressor genes since in tumor material the wild type allele has also been mutated. Both the *BRCA1* and *BRCA2* proteins have been found associated with the RAD51 protein, which plays a central role in the repair of DSBs through HR. In addition, *BRCA1* and *BRCA2* function in several other cellular processes. Loss of normal *BRCA1* or *BRCA2* function in mammalian cells leads to the accumulation of spontaneous chromosome breaks, accompanied by cell-cycle checkpoint-mediated growth arrest. However, a total inactivation of *BRCA1* or *BRCA2* genes is not tolerated in experimental animals. Recently, it has been found that mutant alleles of *BRCA2* are responsible for the defect in one of the complementation groups of Fanconi anemia (FA), a rare disorder with chromosomal instability and proneness to cancer. Thus, apparently, residual *BRCA1* and *BRCA2* activities are essential for cell proliferation. Both *BRCA1* and *BRCA2* are specific for higher eukaryotes and have not been identified in yeast.

Cancer-prone disorders involving genes belonging to the RAD52 group are ataxia-telangiectasia-like disease

(ATLD) and Nijmegen breakage syndrome (NBS), which are caused by ►[hypomorphic mutations](#) in *MRE11* and *NBS1*, respectively. Both human syndromes are characterized by a high incidence of cancer and at the cellular level by radiosensitivity and defects in activation of proper cell-cycle checkpoints. A similar phenotype is also observed in ataxia-telangiectasia (AT) patients, a classical human disorder with a defect in response to DSBs. The ATM kinase, defective in these patients, initiates a signal-transduction cascade, by phosphorylating several proteins, including NBS1, p53 and histone H2AX in response to DSBs. The cancer predisposition seen in AT, NBS and ATLD patients underscores the importance of ATM and the RAD50/NBS1/MRE11 protein complex in avoiding increased genome instability caused by DSBs.

Defects in NHEJ have been found in a very limited number of SCID patients. In these patients mutations in the *Artemis* gene have been identified. Cells derived from these patients display an increased sensitivity to ionizing radiation and defective V(D)J recombination. In contrast, patients defective in the *Lig4* gene show radiosensitivity but do not show severe immunodeficiency since there is only a partial defect in the gene. This suggests that the residual activity of Ligase IV is sufficient to repair the smaller number of breaks that arise during V(D)J recombination but not the larger number induced by ionizing radiation. Since the number of analyzed patients defective in NHEJ is still very limited, it cannot be concluded yet whether mutations in these genes lead to an increased cancer incidence in humans. Studies using mouse mutants, however, clearly demonstrated that defects in DSB-repair through either NHEJ or HR result in enhanced cancer incidence and underscore the importance of faithful repair of DSBs in maintaining genome stability.

Downstream

Definition

The term is used to describe the relative positions of sequences on a nucleic acid or protein molecule. "Downstream" defines the direction in which a nucleic acid or protein molecule is synthesized, i.e. on the 3' side of any given site in DNA or RNA, and on the C-terminal side of any site within a polypeptide, i.e. a protein is synthesized stepwise from its amino-terminal end to its carboxyl terminal end. With reference to the direction of genetic transcription, downstream is in the 3' direction on the non-template strand, but in the 5' direction on the template strand.

DPE

Definition

The DPE (down stream core promoter element) is a sequence motif that is commonly found in core promoters. The DPE cannot act independently, but functions along with the initiator (Inr) element.

Definition

The fruit fly *Drosophila melanogaster* has an established and successful record as a valuable genetic model system for studying complex biological phenomena. For example, several basic signaling pathways have been discovered in this organism, and a lot of progress on understanding the interconnections between the components of the signaling cascades is still made using this system. Since the completion of the sequence of the *Drosophila* genome we now know that, compared to other known invertebrate genomes, *Drosophila* has the most genes in common with humans (1). Consequently, this has increased the interest of the pharmaceutical industry in using this organism as a powerful and economical model system for target screens and drug testing. Functional genomics, the new research paradigm employing a multitude of high-throughput methodologies (2) promises to add function to the raw, pure digital blueprint of life that was assembled in recent years, by finishing the genome sequences of the human and major model organisms. By integrating results from the analyses of the transcriptome (expression profiling/microarray analysis, ► [ChIP on chip](#)), the proteome (2D-gel electrophoresis and mass-spectrometry analysis) and the interactome (two-hybrid screens, affinity tag and mass-spectrometry analysis, ► [protein chips](#)) of model organisms, it will be possible to establish a more solid understanding of the intricate developmental and

cellular networks that are at the basis of multicellular organisms. Another advantage to this approach will not only be added by the availability of classical ► [gain- and ► loss-of-function screens](#)/mutants, but also by the newly discovered phenomenon of ► [RNA interference](#) (RNAi), which for the first time allows for an easy, systematic genome-wide ► [knock-down](#) of every gene in a model organism. Bioinformatics analyses of such datasets should finally unravel, and give an overview of the underlying mesh of interwoven networks of regulatory interactions in such a comprehensive manner as was not possible before (3).

Characteristics

The main advantages of *Drosophila melanogaster* as a model organism for functional genomics can be summarized as follows:

Bioinformatic Tools

FlyBase, a database of genetic and molecular data that was introduced in 1993 is vital for today's success in *Drosophila* research. While the primary information represented is from *Drosophila melanogaster*, it also presents an increasing amount of data from the family of other *Drosophilidae*. The database includes information on genes and mutant alleles, information about the expression and properties of transcripts and proteins, information on the functions of gene products, information about natural and engineered transposons and other molecular constructs, descriptions of *Drosophila* stocks held in stock centers and research laboratories, images that illustrate *Drosophila* anatomy and development terms, a bibliography of *Drosophila* references and the complete, annotated and curated genome sequence.

Resources

Stock centers, which provide thousands of different mutant lines to labs worldwide, represent a valuable resource for *Drosophila* research. In many cases it is not necessary to produce new mutant alleles, since for most genes mutant lines are already available, or will be in the near future, as there are several large scale gene disruption projects already under way. In addition to mutant alleles, the stock centers offer ► [P-element](#) insertion lines that allow for the controlled over-expression of genes as well as enhancer- or protein-trap lines, specific for a variety of tissues or cellular structures. Likewise, there is a huge collection of cDNA libraries, a gene collection containing sequenced cDNAs for 70% of all *Drosophila* genes, genomic clones such as BACs, cosmids, P1 or YACs, as well as a vast assortment of antibodies and an increasing number of cell lines.

Genetic Tools

Drosophila melanogaster offers a multitude of exceptional genetic tools that allow a thorough and

systematic manipulation of genetic networks. Examples include the availability of a series of differently marked ▶[balancer chromosomes](#), permitting an unproblematic, stable inheritance of mutant alleles in a heterozygous state. In addition, the absence or presence of the marker can be used to trace the fate of the balancer chromosome(s) during crossings. Transgenic lines are generated using the system of P-element mediated transformation, and the mobilization of carefully designed P-elements may be used for extensive, genome-wide gain- or loss-of-function screens. Mutants from such screens are often used as a starting point for additional ▶[enhancer/suppressor screens](#). This can, for example, further deepen our understanding of interconnected signaling pathways, by identifying (all) possible genes involved in modifying a specific signal. Using the ▶[binary Gal4-expression system](#), *Drosophila* not only offers temporal and spatial control on the expression of transgenes coding for proteins but also for the expression of RNAi constructs, and thus the controlled knockdown of endogenous genes. Lethal mutations may be studied by inducing homozygous mutant cell clones in a heterozygous background by means of the ▶[FLP/FRT system](#).

Genomic Tools

In addition to providing the rich source of information on genetic networks acquired by traditional genetic approaches, *Drosophila* research has also now successfully moved into the genomic age. Based on the success of genome-wide protein interaction mapping in yeast, *Drosophila* was the first multicellular eukaryote for which a comprehensive protein interaction map was established. Using the yeast two-hybrid system, Giot et al. (4) screened most of the *Drosophila* proteome (more than 10,000 of the ~13,600 proteins) to produce a draft map of 7,048 proteins and 20,405 interactions, which was refined to a high-confidence map of 4,780 unique interactions involving 4,679 proteins. Following this pioneering work, researchers established more detailed interaction maps by focusing on genes orthologous to human cancer-related proteins, signaling proteins or cell-cycle regulators. While the information acquired so far is still limited, the enormous potential is already obvious, and these types of studies will eventually offer the complete bird's eye view on the complicated mesh spanned by all possible protein-protein contacts. Validation may come from expression profiling data and/or genome-wide RNAi experiments performed in *Drosophila* cell lines. The gene sequences on microarrays needed for such profiling experiments are already available. At the moment, scientists can choose between commercially available oligonucleotide based systems (e.g. Affymetrix, MWG, Operon, Agilent, NimbleGen), a novel

long-oligo set developed by the INDAC (International *Drosophila* Array Consortium), chips based on the BDGP cDNA collection (*Drosophila* Gene Collection, DGC) covering about 70% of all annotated ORFs, and arrays using PCR-fragments representative of every predicted gene in the genome (Heidelberg FlyArray, Eurogentec, White lab, Incyte set). For all this methodology there are a growing number of successful applications, paralleled by an ever increasing amount of expression profiling data deposited in public database, representing a perfect starting point for further data mining projects. Examples include studies on gene expression changes during the life cycle of *Drosophila*, in dorsal-ventral patterning, in mesoderm development, during ageing, in alcohol abuse, in insecticide resistance, in nutritional control, during circadian gene control and during immune responses. Studies in yeast demonstrated the value of combining gene expression analyses with a genome-wide localization of transcription factor binding using ChIP on chip methodologies. In addition to commercially developed, oligo based systems (Affymetrix, NimbleGen), the *Drosophila* research community is actively working on the generation of an array system that will contain the complete genome pursuing two approaches: (1) generation of a large oligonucleotide set for the generation of overlapping PCR fragments spanning the complete genome (K. White, S. Russell, and G. Micklem), and (2) use of the clone collection developed for the generation of the genome sequence (E. Furlong, S. Celniker, J. Hoheisel).

In contrast to mammalian cells, the simple addition of dsRNA to *Drosophila* cells gives fully penetrant phenotypes, opening up the way for systematic ▶[reverse genetic](#) approaches. After an initial, limited study (based on DGC Release 1, ~40% coverage) demonstrated the feasibility of such experiments, another study identified several hundred genes involved in cell growth/viability in different *Drosophila* cell lines (5), scanning the whole transcriptome by preparing dsRNAs to all predicted genes using the Heidelberg FlyArray PCR fragment set. Based on this pioneering work, novel RNAi facility were established at Harvard Medical School (Boston, MA, USA) and the German Cancer Centre (DKFZ, Heidelberg, Germany), not only providing unrestricted access to datasets of previous genome-wide RNAi screens and tools for the design of new, optimized dsRNAs, but also inviting researchers to propose and perform additional screens which will greatly benefit from this standardized set of reagents, and the established excellence in RNAi studies at Harvard and Heidelberg. Consequently, additional RNAi sets were developed by academic laboratories (P. O'Farrell, R. Vale, G. Davis, E. Foley, B. Eaton, N. Stuurman, S. Rogers, distributed by OpenBiosystems) and commercial sources (Ambion).

With all these tools at hand (or at least close to), *Drosophila* research is well prepared to tackle the next challenging steps in functional genomics.

Clinical Relevance

An increasing number of researchers have tried to exploit the power that the *Drosophila* genetic system offers, to dissect pathways of disease pathogenesis and

identify targets for therapeutic intervention (6). The knowledge that 75% of all known human disease genes are conserved in the *Drosophila* genome (7) and the experimental advantages of the *Drosophila* system (8) formed the basis for several investigations, trying to decipher the normal and pathogenic functions of genes implicated in, for example, neurodegenerative diseases. Consequently, a multitude of transgenic models were

produced to analyze disease pathways including Parkinson's disease, Alzheimer's disease, Huntington's disease, and several spinocerebellar ataxias in an *in vivo* model. Information gained from these models implicate protein folding and degradation pathways in Parkinson's disease and the polyglutamine repeat disorders, as well as kinases and apoptotic pathways that may modulate neurodegeneration in tauopathies. Functional genomics in *Drosophila* will therefore contribute substantially to the elucidation of complex disease pathways/networks, and speed up the process of target identification as well as target validation. Finally, there is an increasing interest in the *Drosophila* system as a basis for drug screens, phenotype screens, which circumvent the classical target identification process and directly aim for lead substances that qualitatively improve the disease phenotype in the fly model. Drosophila as a Model to Study Cardiac Disease Genes

ROLF BODMER, ETHAN BIER
UCSD and The Burnham Institute, La Jolla, CA, USA
rolf@burnham.org

Definition

The fly *Drosophila melanogaster* is an invertebrate model system that is exquisitely suited to genetic

studies (<http://flybase.net>). For more than 100 years, genetic methods in *Drosophila* been developed and refined. These powerful tools have provided detailed mechanistic insights into a variety of widely applicable biological problems, including creation of the first genetic maps, discovery of sex-linkage, elucidation of genetic recombination, demonstration of induced mutation by radiation and more recently, a nearly complete understanding of the initial embryonic patterns and the molecular logic of setting up the [primary body axes](#). The insights gained from these studies provided the fundamental concepts for unraveling the genetic basis of vertebrate development and [organogenesis](#).

Characteristics

Human, mouse, *Drosophila* and many other genome sequences have now been completed. As a consequence, a comprehensive cross-genomic analysis was conducted between *Drosophila* and all human disease genes known to have at least one mutant allele listed in the Online Mendelian Inheritance in Man (OMIM; <http://www.ncbi.nlm.nih.gov/omim>) using an interactive database called Homophila: <http://homophila.sdsc.edu> (5). Of the current 2400 human disease genes, 74% have homologs in *Drosophila* and nearly a third of them are as highly conserved as genes known to be functionally equivalent. These *Drosophila* genes include homologs of genes causing a broad spectrum of human diseases, including neurological disorders, cancer and cardiovascular disease. Here we concentrate on genes involved in [congenital heart disease](#) (CHD). Many genes have been identified which can lead to CHD or susceptibility to cardiac dysfunction when mutated. Among them are genes encoding factors involved in cardiac development (e.g., [transcription factors](#)), cardiac muscle contraction (e.g., cytoskeletal proteins), and conduction of electrical signals (e.g., [ion channels](#)). Although many genes causing CHD have been identified, it is estimated that most of the suspected genetic factors have yet to be identified. An important challenge in elucidating the genetic basis of CHD is to identify new genetic loci and to understand how allelic variants interact combinatorially to cause a genetic risk for cardiac arrest and failure.

Of the CHDs, [cardiomyopathies](#) typically result from defects in genes encoding contractile proteins, whereas many conduction defects result from malfunctioning mutations in ion channels and the genes encoding them (Table 1). In addition, genes controlling early stages of heart development have been highly conserved between vertebrates and invertebrates (1), indicating that the common ancestor of flies and humans had already invented the basic contractile fluid pumping organ from which all hearts in the animal kingdom eventually evolved. Thus, there is good reason to believe that

many of the *Drosophila* homologs of human cardiac disease genes will function similarly to their human counterparts, and that new genes that are identified in *Drosophila* that interact with these disease gene homologs will themselves be candidate cardiac disease

genes. Mutations already exist in many *Drosophila* homologs of human disease genes, and transgenic constructs can be readily introduced into flies to mis-express genes of interest in various spatially and temporally specific patterns using the [▶UAS-Gal4](#)

Drosophila as a Model to Study Cardiac Disease Genes. Figure 1 The UAS/Gal4 Expression System: (1) Cross UAS-cDNA stock to Gal4 driver stock. (2) Gal4 transcription factor activates UAS-cDNA in progeny in the pattern dictated by the tissue-specific enhancer driving Gal4.

system (2). More sophisticated GAL4-dependent mis-expression schemes have also been devised, which allow for conditional mis-expression of genes in certain tissues and for rapid isolation of dominant alleles of a gene of interest (3, 4). *Drosophila* is therefore ideally suited for analysis of gene function through loss-of-function genetics and mis-expression studies. In contrast to this efficient manipulation of genes in flies, knocking out human disease-related genes in mice is costly, time consuming and frequently results in very modest mutant phenotypes. It also is non-trivial to mis-express transgenes in mice in regulated temporal and tissue specific patterns. Given the limitations of model systems and the conservation of principle control functions that extends to insects, the genetic versatility of *Drosophila* is a viable alternative to mammalian experimental assay systems such as mice for studying the function of human disease genes. Furthermore, *Drosophila* is currently the only simple model system for examining heart function, since other invertebrate genetic models such as *C. elegans* lack a heart.

An important type of genetic scheme in *Drosophila* is the so-called second-site enhancer-suppressor screen. The idea of this type of screen is to start off with a partial loss-of-function mutation in one component of a pathway and then search for ▶heterozygous mutations in other genes that greatly increase or decrease the severity of the phenotype resulting from this first mutation. The ability to pick such ▶synergistic interactions in rapid F1-generation screens allows the researcher to survey the entire genome for mutations in genes that interact in a common process. Classically, comprehensive genetic screens in *Drosophila* make use of relatively random chemical or radiation mutagenesis methods. More recently, large-scale mutagenesis by transposon insertion has offered several advantages over point mutagens. An insertional mutant greatly facilitates the molecular characterization of the nearby gene and, in addition, enhancer-trapping transposon vectors have been designed that report on the expression of genes next to the site of transposon integration. A growing number of transposon insertions

have been recovered in major genomic loci in *Drosophila* (▶<http://flybase.net>), which greatly facilitates mutant analysis. The UAS-Gal4 system has also been applied to phenocopying loss-of-function mutations by mis-expressing constructs that lead to transgenic RNA interference (▶RNAi).

▶Evolutionary Conservation of Heart Formation

The discovery of the ▶homeobox transcription factor Tinman in *Drosophila* and its conservation in vertebrates provided the first evidence that heart development was controlled by homologous pathways in the animal kingdom. The elucidation of conserved regulatory genetic networks involved in cardiac specification led to molecular models of cardiac diseases in humans (6). Remarkably, basic aspects of cardiac morphogenesis have also been conserved during evolution. Despite the reversal of the dorsal-ventral axis between vertebrates and invertebrates and obvious differences in terminal morphology, the cardiac progenitors in all heart-forming creatures originate from bilateral symmetrical mesodermal tissues located most distally from the axis of gastrulation, which then fuse into a primitive heart tube at the midline (1). Over the past decade has work in *Drosophila* provided a detailed molecular understanding of the complex interplay between positional cues provided by inductive factors secreted from the ectoderm (Wnts and TGF-βs) and transcription factors expressed in the mesoderm (homeodomain protein Tinman, GATA factor Pannier and T-box proteins), which specify and position the heart field within the embryo. The key determinants of ▶cardiogenesis in the fly also play fundamental roles in early cardiac specification in vertebrates and they do so in similar ways. For example, in flies and vertebrates Dpp/BMP signals cross germ layers to maintain Tinman/NKX2-5 expression. A similar relationship exists between Tinman/NKX2-5 and Pannier/GATA-4. Moreover, mutations have been identified in humans in many of these conserved heart-specifying genes, such as NKX2-5, GATA-4 and TBX-5, which cause various forms of

***Drosophila* as a Model to Study Cardiac Disease Genes.** Figure 2 Performance assay using an electrical pacing paradigm. Flies are arranged touching foil electrodes (left) and the heart failure rate (right) is measured following a 30-second pacing protocol at 6 Hz in one week old flies (left bar: 1) and five week old flies (right bar: 5). Note the three- to four-fold increase in failure rate with age (20-80% failure rate) (see also ref. 7).

CHD. This deep conservation of genetic control mechanisms makes *Drosophila* a versatile genetic model system to identify interacting combinations of candidate genes responsible for CHD.

Drosophila as a Model for Cardiac Function

The fly heart offers a number of advantages as a screening device for genes involved in CHD. In addition to the general efficiency and versatility of performing genetic experiments in flies, the fly heart is a simple and highly ordered linear tube in which morphological changes can easily be detected (1). It consists of two major cell types: the inner contractile myocardial cells, which form a central cavity, the lumen of the heart and the outer, non-myogenic pericardial cells. Importantly, insects have a tracheal system; thus, the heart is not needed for distributing oxygen within the body, which bypasses the problem of early lethality in vertebrates due to cardiac malfunctions. In contrast to our understanding of *Drosophila* heart development, not as much is known yet about how cardiac physiology is controlled. Nevertheless, mutations in ion channels, gap junctions and other membrane proteins involved in ionic homeostasis influence the *Drosophila* heart rate and/or rhythm as they do in humans. Moreover, a large-scale screen revealed dozens of mutants that affect the fly's heart function, and a majority of the corresponding genes have human homologs, which may very well turn out to be candidate CHD genes (R.J. Wessells and R.B., unpubl.).

A number of methods have recently been developed to examine heart function in *Drosophila* larvae and adults, which include measuring the rate of the heartbeat using an edge tracing system, the rhythmicity of the heart beat using an autocorrelation analysis, and

the rate of heart failure (cardiac arrest or fibrillation) in response to stress provided by external [▶electrical pacing](#) to increase the heartbeat frequency (Fig. 2) (7). Using these assays, it is now possible to target UAS-transgenes of interest or UAS-RNAi constructs exclusively to the heart, in order to determine the heart-autonomous effect of mis-regulated or compromised function of one or more genes on cardiac performance. This approach is particularly useful for heart-specific screens for genes involved in cardiac performance and senescence.

Drosophila is an Essential Gene Identification Tool in the Post-Genomic Era

Nearly complete genome sequences are available for humans and a number of model organisms. An important goal in the genomics field is to identify genes that interact to cause complex phenotypes such as human heart disease. It is likely that *Drosophila* and other model systems will play an increasingly important role in the functional analysis of candidate genes involved in [▶polygenic disorders](#). The advantage of these model organisms is that it is possible to survey large numbers of interacting genotypes, which may potentially be involved in CHD. To study the nature of polygenic traits these model systems can be used as *in vivo* test systems to identify small sets of interacting genes for further analysis in a vertebrate model.

Using Model Systems to Identify Gene Functions Involved in Polygenic Traits

One of the challenges of complex traits is to determine which genes among several plausible candidates at multiple loci contribute most to a phenotype in question. Interactions among human disease gene

homologs involved in cell autonomous functions have been successfully identified in yeast. For example, genes required for mismatch repair of DNA cause cancer. Some of these proteins are indispensable for mismatch repair while others function redundantly to assemble or execute the function of complexes binding to mismatched bases. Another example is provided by congenital disorders of glycosylation, which affect consecutive steps in the synthesis of carbohydrate chains. In this case, based on mutant analysis in yeast and rescue of the defect by the human homolog, a screen was devised to identify other genes acting in the same glycosylation pathway in yeast. Subsequently, it was found that mutations in human homologs of these newly identified yeast genes caused disorders of glycosylation. Thus, model genetic systems can be viewed as first pass *in vivo* filters or as “genetic bioassays” to search for relevant genetic interactions among a potentially large set of genes. Interactions among this more manageable set of genes can then be rigorously tested in a vertebrate system such as the mouse or zebrafish. Yeast is ideal for determining genetic interactions between conserved gene networks acting within single cells, but *Drosophila* is the simplest genetic model for studying polygenic traits involved in heart function.

► **RNA profiling** experiments provide an important post-genomic source of information regarding function of organs such as the heart. Initial datasets of this kind identify several hundred genes whose levels change in a statistically significant fashion. If one considers a subset of these genes whose levels change by more than 10-fold, the number often drops to 1–2 dozen genes. This is a manageable number of genes to examine in all pair-wise combinations for genetic interactions in *Drosophila*. If a small subset of interacting combinations is identified, one can then test for synergistic interactions involving more genes. Experiments of this scale are impractical in any vertebrate model system. Once a key subset of interacting genes have been identified in the *Drosophila* genetic model system, synergistic interactions can then be tested in a suitable vertebrate model system.

How do multiple genes contribute to a complex trait such as CHD? When the activities of two or more genes that function in a single genetic pathway are reduced, mutant phenotypes may be observed. This is a classic condition that experimental geneticists often create when screening for second site mutations that enhance the effect of a reference mutation. In simple situations of this kind, complete loss of function of two different genes in the pathway leads to the same phenotype, which may be similar to the combined reduced function of both genes. Another common basis for multigenic effects is in cases where duplicated genes provide overlapping activities. As the vertebrate genome has

expanded by rounds of large-scale duplication, such ► **genetic redundancy** is often encountered as is well exemplified by the overlapping functions of four nearly complete copies of the HOX gene cluster, which is present in only a single copy in *Drosophila*.

Synergistic interactions can also occur between genes acting in different pathways or performing diverse cellular functions, which need to be coordinated to accomplish a biological process. For example, normal cell migration involves genes functioning in signal/pathway recognition, regulated cytoskeletal reorganization, target identification and terminal differentiation. Evidence for the existence of such cooperation between heterologous genetic pathways is provided by contiguous gene syndromes, in which the gene dose of several structurally unrelated but neighboring genes are altered by either deletion or duplications of small chromosomal regions. In Down syndrome (DS), for example, small duplications of regions of chromosome 21 have been associated with CHD and deletions of small chromosomal intervals have been implicated in cardiac phenotypes caused by DiGeorge and Williams syndromes. A possible explanation for the coordinated function of adjacent structurally unrelated genes is that they are co-regulated by a shared cis-regulatory element. Indeed, several genes associated with CHD in DS, or genes contained within the deleted interval of DiGeorge syndrome are co-expressed in the heart. Regarding DiGeorge and other syndromes, there has been some doubt as to whether these diseases result from misregulation of multiple contiguous genes or from one gene alone, even though human *TBX1* and *ELASTIN* have been identified as causing CHD phenotypes similar to those observed in DiGeorge or Williams syndromes, respectively. There is also evidence, however, that phenotypes resulting from monosomy of small deletions encompassing these genes are considerably more severe than those due to the single mutations. Furthermore, mutations in another gene (*CRKL*) within the DiGeorge critical deletion also cause CHD in mice, suggesting that both *TBX1* and *CRKL* may participate in manifestation of the full syndrome.

Clinical Relevance

Because homologous genes control early developmental events, as well as functional components of the *Drosophila* and vertebrate hearts, the fly is the simplest model system for assaying genes involved in human CHD. The wide variety of genetic tools available to *Drosophila* researchers offers many technical advantages for rapidly screening through large numbers of candidate genes. Therefore, an important future direction is likely to be the use of *Drosophila* as a vehicle for analyzing polygenic traits. Indeed, this may be the most important long-term use of *Drosophila* as an aid in human genetics. One can anticipate a time in the not too

distant future when mutant lines exist for every gene in vertebrate systems such as mice and zebrafish. However, one of the enduring problems not easily addressed by such resources will be the tracking of complex traits defined by polygenic variants. For this level of genetic analysis, simple model genetic systems including yeast, *C. elegans* and *Drosophila* will undoubtedly play a crucial ongoing role. Among them, *Drosophila* will be critical for examining gene networks and interactions involved in organogenesis and clearly the system of choice with regard to cardiac development, function and aging since it is the only one with a fluid pumping heart.

Duchenne Muscular Dystrophy

ERYNN S. GORDON, ERIC P. HOFFMAN

Children's National Medical Center, Washington, DC, USA

ehoffman@cnmcresearch.org

Definition

Duchenne muscular dystrophy (DMD) is an X-linked recessive neuromuscular disorder that shows progressive weakness of skeletal muscle. DMD primarily affects males, with symptoms generally presenting by four years of age. Muscle biopsies from individuals with Duchenne muscular dystrophy show a complete absence of the protein ►[dystrophin](#). A milder form of DMD is ►[Becker muscular dystrophy](#) (BMD), in which there is a decrease in, but not loss of, dystrophin. Patients with BMD typically have a later onset and a slower disease progression than patients with DMD.

Duchenne muscular dystrophy (DMD) is the most common form of muscular dystrophy, making it one of the most common inherited lethal disorders (►[incidence](#) 1/3,500 males). Although DMD affects all populations equally, the incidence has decreased in developed countries in recent years due to genetic counseling and prenatal testing. The high incidence of DMD is in large part due to the high ►[mutation rate](#) in the dystrophin gene with a new mutation occurring in 1/10,000 eggs and sperm. Patients with Duchenne muscular dystrophy (as well as patients with other types of dystrophinopathies) show marked elevation of serum ►[creatinine kinase](#) levels (CK), a blood marker for muscle damage.

Characteristics

Boys with Duchenne muscular dystrophy generally start to show noticeable symptoms between four and six years old. In families where an individual has already been diagnosed with Duchenne, parents may notice symptoms earlier. The main symptoms reported by parents include delayed walking, and difficulties in walking, getting up from the floor and walking up stairs. Additional symptoms noticed by parents include learning and speech problems. The first muscles affected by DMD are those closest to the body (proximal muscles). Weakness in the pelvic area can cause boys to appear to waddle in their walk. In order to rise from the floor, boys use the classic Gower's maneuver, which entails using hands on the floor and then the knees to push oneself into the standing position.

Over time, strength is lost and the ability to walk is lost. In general, boys with DMD become wheelchair bound between seven and fifteen years of age, with the

average being eleven years of age. However, the use of steroids in the treatment of DMD has been proven to slow the disease progression and may in time significantly alter this time frame. Along with weakness of the muscles, patients with DMD may develop ►**cardiomyopathy** (weakness of the heart muscle). Finally, patients often die of respiratory failure in their early twenties. The respiratory problems in DMD are caused by weakness of the muscles between the ribs that aid in breathing. Throughout the disease progression the muscles of the face as well as muscles controlling speech are not affected. Although mental retardation is not associated with DMD, in general, boys with Duchenne muscular dystrophy have a lower IQ than average; the mean IQ for boys with DMD is about 85, while the general population mean is 105. In addition, specific learning disabilities, such as listening comprehension difficulties are common in boys with DMD.

Manifesting Carriers

Women, unlike men, have two copies of the X chromosome. Therefore, women carrying a disease causing gene change in the dystrophin gene on one of their X chromosomes, are not generally affected by DMD because the second X chromosome compensates for the non-working copy of the gene (instructions). Females who are symptomatic are known to have ►**skewed X inactivation**. Since women have two copies of the X chromosome, and men only have one copy, women turn off one copy of the X chromosome in each of their cells. In general, we expect each female cell to decide randomly which X they will turn off, resulting in random X-inactivation. In some cases, cells of a woman always turn the same X chromosome off (skewed X-inactivation), if the X chromosome with a non-working copy of dystrophin is the one left active, a woman will show symptoms of Duchenne. Although symptoms are not common in female carriers of DMD, some women may have muscle cramping and others may show abnormalities on electrocardiogram. It is therefore important to identify carriers of DMD in a family with an affected individual both for the purposes of genetic counseling and potential medical complications.

Cellular and Molecular Regulation

The dystrophin gene is the largest gene identified to date. Genes are made of four different base pairs repeated in a meaningful code. At about 2.5 million base pairs, the dystrophin gene is nearly ten times bigger than the next largest gene. Genes have different sections referred to as ►**introns** and ►**exons**. When a gene is being converted to a protein the introns are cut out, while the exons are used as the instructions. The majority of the dystrophin gene sequence is in non-coding introns (about 200 base pairs of intron for every

base of exon, over a total of 79 exons). The complete protein coding sequence is about 11,000 base pairs and encodes a large protein that weighs 427 kD. The protein product, named dystrophin, is completely absent in patients with DMD and is present but abnormal or reduced in patients with BMD. Although it is the lack of dystrophin in muscles that causes the disease symptoms, different forms of dystrophin have also been detected in the eyes, liver, and other neurons.

All Duchenne muscular dystrophy patients show a complete loss of function of the dystrophin protein. The most common type of gene change in both disorders is a deletion of one or more exons of the gene. Because of the large size of the introns, relative to exons, nearly all deletion mutations start and end in an intron. There are two deletion hot spots, one in the region of exons 44–50, and a second near the beginning of the gene (exons 2–13). On a molecular level, the main difference between DMD and BMD is the ►**reading frame** of the gene. Genes are read in groups or “words” of 3 base pairs. When a mutation in a gene alters the 3 base pair “word” to 2 base pairs, then the reading frame is put out of phase, and the protein reading frame becomes incorrect (frame-shift). In general, patients with DMD have deletions that shift the reading frame, while patients with BMD have deletions that keep the reading frame intact. There are also other key regions of the gene that can affect how severe the disease will be. Approximately 45% of DMD patients and 30% of BMD patients do not have deletions but instead have duplications or point mutations. Duplications, accounting for 5% of cases of DMD or BMD, follow the same reading frame rules as deletions.

Clinical Relevance

There are many reasons for narrowing a diagnosis from the general, muscular dystrophy, to the specific, Duchenne muscular dystrophy. This information is needed for providing families with the appropriate prognosis, treatment, and genetic counseling. Currently genetic testing is available for Duchenne muscular dystrophy, however due to the enormous size of the gene it remains difficult to detect the specific gene mutation in all families. The gold standard for testing is still considered to be the lack of dystrophin protein on muscle biopsy.

Genetic counseling and prenatal diagnosis has reduced the number of families with multiple relatives with Duchenne muscular dystrophy in the USA. However, the high new mutation rate of the Duchenne muscular dystrophy gene in all eggs and sperm means that the disease will always occur at a relatively high rate. If parents have a single child with Duchenne muscular dystrophy, and no other affected family member, there is a 66% chance that the mother is a carrier of the disease, and a 33% chance that she is not a carrier (the

mutation happens in just a single egg in the latter case). For women who are defined as definite carriers for Duchenne muscular dystrophy 50% of male pregnancies will be affected with the disease, and 50% of female pregnancies will be carriers. For those individuals concerned about being carriers or passing the disease on to future generations, DNA testing, prenatal diagnosis and ►[assisted reproduction](#) are options currently used by some families.

Dynamic Range

Definition

Dynamic range defines the range of signal intensities that can accurately be quantified; more technically this refers to the range of signal amplitudes over which an electronic communication channel can operate within acceptable limits of distortion. The range is determined by system noise at the lower end, and by the onset of overload at the upper end. In protein chemistry, this refers to the variation of the copy number of proteins present in a cell, reaching from a few copies to several hundred thousands of copies. The dynamic range also describes the concentration range between lower and

upper limits of detection, which can be used for quantitative analysis of pre-defined metabolites.

Dystroglycan

Definition

Dystroglycan is a receptor that binds to multiple basement membrane proteins. Dystroglycan is composed of an extracellular, highly glycosylated α -chain, and a β -chain spanning the cell membrane. These two chains are encoded by a single gene. Protein sequence comparisons suggest that dystroglycan is a single unique molecule in that it is not member of a family. The α -chain and β -chain core elements are associated with several other proteins, forming a large dystroglycan complex. This receptor system found in muscle, epithelium and some other tissues, links the cytoskeleton to the extracellular matrix. Binding of extracellular ligands to dystroglycan activates signalling pathways, gene transcription and modifies cell behavior. Mutations in the gene encoding dystroglycan lead to severe developmental anomalies.

Dystrophin

Definition

Dystrophin is a large, rod-like cytoskeletal protein found at the inner surface of muscle fibers. It provides structural support to the cellular membrane in muscle

cells. Dystrophin is also found in cells of cardiac tissue, brain tissue, liver and other tissue types. Defects of the dystrophin gene cause progressive muscular dystrophy. Dystrophin is missing in Duchenne Muscular Dystrophy (DMD) patients or reduced in amount or changed in shape, respectively, in Becker Muscular Dystrophy (BMD) patients.

Electron Multiplying CCD Camera

Definition

Charged coupled devices (► [CCD](#)) read noise increases proportional to the readout speed. This disadvantage is overcome in the electron multiplying charge coupled devices (EMCCDs). They use a special extended register, the so-called multiplication register, to provide a high gain before image readout. Electrons are accelerated from pixel to pixel in the multiplication register by applying higher-than-typical CCD clock voltages, thus generating secondary electrons via an impact-ionization process. The probability of electron generation is small (around 0.01). Although this number is small, the overall gain may be very high (above a factor of 1000) due to a large number of pixels in the multiplication register. EMCCDs amplify low light signals above the read noise floor of the CCD, which otherwise defines the detection limit for the system. This enables performance with effectively zero read noise at extremely high frame rates. Their low noise, high speed, high quantum efficiency and robustness to over-exposure make them ideally suited to single particle tracking applications.

Electron Tomography

MANFRED AUER

Laboratory of Sensory Neuroscience, The Rockefeller University, New York, NY, USA
 auerm@mail.rockefeller.edu

Definition

► [Electron tomography](#) is a transmission electron microscope-based imaging technique, ideally suited

for the three-dimensional (3-D) structural determination of cellular volumes at molecular resolution. The 3-D structure of molecular machines in their natural surrounding of a cell can be revealed, even if the cellular complex is neither abundant, robust, homogeneous nor arranged in a regular array. A series of 2-D projection images of the tilted specimen is recorded, aligned and reconstructed into a 3-D volume, also known as a tomogram.

Although still an expert technique, setups for data collection and 3-D reconstruction are becoming widely available. Visualization of tomographic data is less straightforward due to its 3-D nature, low signal-to-noise ratio, ► [macromolecular crowding](#) and the complexity of cellular volumes. Novel 3-D data visualization and exploration, noise reduction, automated ► [segmentation](#) and ► [skeletonization](#) approaches have been developed, which in combination with interactive model building assist in interpretation of cellular tomograms.

Further developments including virtual reality approaches, real-time annotation and automated model structure fitting, together with biochemical ► [tagging](#) and ► [labeling](#) approaches are needed to achieve high-throughput of this powerful method in cellular proteomics. Automated high throughput electron tomography will enable the comparison between healthy and diseased tissue on the level of proteins and will lead to the understanding of molecular pathogenesis at a structural level.

Electron tomography in combination with other structural techniques will allow the 3-D visualization of the architecture of cells and tissues and their cellular machines at a molecular level.

Description

2-D Electron Microscopy and Sample Preparation for EM

Microscopic imaging has been critical for the understanding of healthy and diseased cells and tissues. Fluorescence confocal light microscopy dominates biological imaging, due to its ability for real-time, non-invasive imaging of cellular events, using genetically encoded fluorescence reporter molecules. Electron microscopy (EM) reaches beyond the diffraction limit of light microscopy and has led to a detailed understanding of the ultrastructure of cells and tissues. EM requires thin sectioning of the specimen and imaging under high vacuum conditions, due to the strong interaction of accelerated electrons with matter. For this reason, tissue samples are embedded into a plastic resin, which is then polymerized to ensure successful sectioning using an ultramicrotome. The hydrophobic nature of most plastic resins requires an exchange of cellular water with an organic solvent prior to embedding, and hence the

cellular components are usually chemically fixed in order to avoid protein denaturation and extraction. In addition, heavy metal salts are added throughout the tissue processing procedure to obtain a better contrast upon EM imaging. Not only is this protocol tedious and lengthy, it is also vulnerable to sample preparation artifacts, such as denaturation, aggregation, component rearrangement and extraction. Considerable efforts have been made to minimize such sample preparation artifacts, including the introduction of instantaneous cryo-immobilization methods, such as high pressure freezing or slam-freezing, as well as low-temperature solvent substitution methods, such as freeze-substitution and progressive lowering of temperature dehydration. Moreover, a number of embedding resins with specific hydrophilicity profiles are commercially available and can be polymerized by heat, chemical cross-linkers or UV light. A truly artifact-free sample preparation is the fast immobilization (freezing) of the cellular components, sometimes referred to as cryo-fixation, followed by observation of the unstained, frozen-hydrated specimen using **►cryo-EM** imaging. While this method has been very successful for the tomographic imaging of very thin specimens, cells and tissues have to be sectioned in their frozen-hydrated state. Cryo-sectioning, once it becomes a routine technique, could revolutionize the art of sample preparation and avoid artifacts altogether.

Electron Tomography – Taking EM to the Third Dimension

Although sections for EM imaging are very thin, they still exceed the dimensions of individual molecules by at least one magnitude and since electron microscopes project a 3-D volume onto the 2-D plane of a recording device such as film or **►CCD**, the information about the third dimension is lost; all features along the electron path are superimposed. Among the cryo-EM 3-D reconstruction techniques used for the study of macromolecular complexes (1), electron tomography is the most general method, since it doesn't require the complex to be abundant, robust, homogeneous or arranged in a regular array. 3-D information can be obtained by recording projection images of the specimen from different angles; the images then need to be aligned and combined into a 3-D volume, e.g. by **►weighted back-projection** or algebraic reconstruction techniques (for a thorough introduction to all aspects of electron tomography see ref. 2). The principle of electron tomography is similar to that of **►CAT** scan medical imaging, however the microscope stays stationary and the EM specimen is rotated to discrete angles (Fig. 1).

Years of pioneering work both on the hardware as well as the software side have resulted in commercially available setups for semi-automated data collection.

Electron Tomography. Figure 1 Principle of electron tomographic imaging. Projection images of a 3-D object are recorded, aligned and then back-projected into a 3-D volume, which can then be inspected by suitable computer graphics. The 3D volume can be rendered, rotated and analyzed to reveal the architecture.

The stability and accuracy of electron microscope stages, as well as the sensitivity of detection devices such as CCD have been significantly improved, along with software for low-dose imaging and automated data acquisition, minimizing the electron dose that is spent on tracking and focusing of the image (3). Due to the radiation sensitivity of biological material, automation has played a crucial role because the dose has to be kept to a minimum. The tilt range is usually restricted to $\pm 75^\circ$ due to the thickness of cell slices at high tilt angles and the limitations introduced by the specimen support (EM grid), resulting in an incomplete sampling of the projection space (missing wedge). Whole cells and tissues could, in principle, be reconstructed by combining tomograms of neighboring areas or serial tissue sections, but the size of the resulting 3-D data set would be gigantic.

Visualization of 3-D Data

While data collection and 3-D reconstruction are becoming routine tools, the further development of visualization tools is crucial for the study of increasingly larger and more complex 3-D volumes. Tomographic 3-D volume can be inspected slice by slice, especially when supported by non-orthogonal slicing and slice averaging methods. However, the 3-D nature of the tomographic data is better appreciated by

►**rendering** methods, such as volume or surface rendering.

Volume rendering retains the volume data and sums it from back to front with appropriate weights (ray casting). The information of each volume element (voxel) is incorporated, resulting in a transparent, ghost-like impression of the electron density.

Surface rendering creates the illusion of depth by the removal of hidden surfaces, as well as the use of perspective, lighting options, shading, color and texturing effects. Such 3-D scenes are more familiar to our brain and therefore often preferred for display of the 3-D data. However, surface rendering shows the object only at a certain chosen density threshold and is often not very helpful for highly complicated objects with internal cavities. For a photorealistic impression, ray tracing is the method of choice, but it is computationally very expensive, since it follows the paths of each individual light ray as it interacts with the surface of the object. Hence, ray tracing cannot be achieved in real-time and is therefore not suited for data inspection, but for data presentation and publication.

Stereo display techniques as well as a looped video animation of the rendered object, particularly when rotated around an axis, can substantially ease the understanding of structural detail.

Physical models, although out of fashion, are a powerful alternative to computer graphics display and even complicated models can – in principle – be produced by stereolithography.

Noise Reduction

The poor signal-to-noise ratio usually observed in tomograms complicates automated feature extraction, as well as the visualization of the volume. Since averaging techniques cannot be applied to unique cellular 3-D volumes, other methods for signal enhancement such as median ►**filtering**, wavelet filtering, bilateral filtering and nonlinear anisotropic diffusion filtering are often used.

Data Exploration

The study of cellular volumes resembles the exploration of uncharted territory and, while the individual protein components may be familiar, there is often no preconception of the architecture of cellular machines. Real-time rendering of whole tomograms is therefore key for interactive data exploration and has recently been implemented using multi-resolution interactive geometry. Further developments towards a cellular “flight simulator” are needed, which would allow 3-D navigation through the densities, zooming up and down in scale from individual proteins to the whole cell,

as well as interactive, semi-automated fitting of candidate protein structures to the density envelopes and validation of the fit. Such a virtual-reality-based program would be of enormous value in the analysis of tomographic data.

Data Simplification: Interpretation of Tomograms Through Segmentation, Skeletonization and Model Building

Tomograms of cellular volumes contain thousands of individual proteins, all densely packed and mostly organized into cellular machines. This macromolecular crowding complicates the analysis and therefore the complexity of the scenery needs to be reduced to allow biological interpretation. Segmentation methods can electronically extract multi-protein complexes from their cellular surrounding, allowing an unobstructed view into the machinery’s architectural organization.

While manual segmentation is still widely used, automated segmentation methods are desirable due to the labor-intensive and somewhat subjective nature of manual segmentation. Robust automated segmentation algorithms based on density thresholds (watershed immersion (4)) and density gradients (boundary segmentation, see ref. 5) have been proposed and allow fast and more objective segmentation of cellular volumes.

Skeletonization approaches (5) have been developed in order to simplify a complex 3-D density pattern into a stick model, as a cartoon is a simplified version of the real world. Skeletonization also allows quantitative analysis of the object including distances and angles.

Model building has long been the key in interpreting biological structures and has led to a level of insight that was not available from the obtained density distribution alone. If the exact molecular makeup of a complex is known and the resolution is sufficient, protein structures can be fitted into the density maps, either manually using interactive 3-D graphics or semi-automatically. Another approach, ►**template matching** has been proposed for data exploration and analysis. It seems particularly well suited for segmented volumes, whereas it may be problematic in cases where the features are not sufficiently separated from one another or not distinctly shaped.

Molecular Component Identification: the Quest for a ►GFP for Electron Microscopy

Due to the complexity of a cell and its unknown exact molecular composition, the localization of an individual protein molecule within the tomographic volume is not a straightforward task. In other words, cellular volumes do not come annotated. In some cases, the cellular location and association with easily identifiable features, such as actin filaments, as well as the size and shape of the densities may give clues to the identity of a

protein, but even a good fit of a likely candidate protein to the density is no proof.

What is needed is a widely applicable reporter system that recognizes the protein of interest, ideally through a genetically encoded tag. This reporter system must provide sufficient contrast to be unambiguously detected in the electron microscope, be small enough to ensure access to the protein, be stable throughout the sample preparation, show a high affinity, yet be specific for its target to avoid false-negative and false-positive signals, respectively.

The recent development of stable and small, but recognizable immuno-gold-cluster labels is certainly a step in the right direction. However, for each epitope, a suitable antibody must be found, which can be a rather tedious endeavor and may sometimes fail altogether.

In contrast, an ideal method would be based on a genetically encoded tag that is recognized by an electron-dense label. The labeling protocol would only have to be worked out once and would then be applicable to all systems, provided the tag-modified protein is expressed and functional. In the ►[FlAsH/ReAsH](#) system a small genetically encoded tag is recognized by a non-toxic membrane permeable dye, resulting in a steep increase in fluorescence. The use of the fluorescence photooxidation technique allows ►[correlative microscopy](#), meaning that a system can be first studied by confocal fluorescence microscopy and subsequently processed for EM (6). The only but important downside of this approach is that the stain is not localized to one point but is rather diffuse. For the exact 3-D localization of a candidate protein, an electron-dense point label would be desirable. The commercially available Ni-NTA-Nanogold may become such an ideal labeling system. It is designed to recognize hexa-histidine tags genetically engineered onto the protein of interest. Once in place, such a system based on tags and labels would allow the exact 3-D-localization of proteins within a cell and therefore become a central part of cellular proteomics approaches.

Electrospray Ionization Mass Spectrometry

Definition

Electrospray ionization (ESI) is the most commonly used method for “soft” ionization of peptides and proteins in quadrupole, ion-trap, or time-of-flight mass spectrometers. The ionization is performed by application of a high voltage to a stream of liquid emitted from a capillary. The highly charged droplets are shrunk, and the resulting peptide or protein ions are sampled and separated by the mass spectrometer.

ELISA

Definition

ELISA defines a method that uses an antibody to detect an antigenic molecule in a sample. In a typical ELISA, plastic wells with sticky walls are used to immobilise molecules of a biological sample. A specific antibody is covalently linked to an enzyme and is added to the wells, where it is retained on the walls if immobilised antigenic molecules are present. This is detected by a color-change reaction catalysed by the linked enzyme (Linked Immuno-Sorbent Assay), converting a colourless substrate into a coloured reaction product.

Embryonic Stem Cell

Definition

Embryonic stem (ES) cells are derived from the inner cell mass of mammalian embryos, usually mouse embryos. An ES cell self-renews and has the potential to develop into all or nearly all of the tissues in a mammal, maintaining its ability to contribute to the germline of an organism. ES-cells can be indefinitely maintained in culture. When introduced into another embryo, ES-cells can contribute to the host tissues. ES-cells that efficiently contribute to the germline of the host have so far only been established in mice.

5' End/3' End

Definition

A single stranded molecule of DNA will have an orientation determined by its sugar-phosphate backbone. The links between the nucleotides in the molecule are through the 5' and 3' carbons in the ribose moiety. In a double stranded DNA molecule, the strands are antiparallel, so that at a break in the molecule, the 5' end of one strand will be the 3' end of the complementary strand. Nucleases (including restriction endonucleases) cleave DNA leaving a 5' phosphate group and a 3' hydroxyl group.

Endocytic Pathway

► **Endocytosis/Endocytic Pathway**

Endocytosis

Definition

Endocytic pathway/endocytosis comprises of a series of trafficking steps through which materials are internalized into eukaryotic cells, without passing through the plasma membrane, and are then transported to endosomes, ► **endosomal compartment** and/or ► **lysosomes**. The plasma membrane folds around material outside the cell, resulting in the formation of a sac-like vesicle into which the material is incorporated, often in a highly concentrated form. The best characterized mechanism of such internalization involves the coat protein clathrin in conjunction with the adaptor complex AP-2.

Synonyms

Transcription enhancer, transcriptional enhancer

Definition

An enhancer (transcription enhancer, transcriptional enhancer) is a regulatory DNA segment of about 200 base pairs that is typically found in multicellular eukaryotes. It can strongly stimulate (“enhance”) the transcription of a linked ► [transcription unit](#), i.e. it acts *in cis*. An enhancer can activate transcription over very long distances of many thousand base pairs, and from a position upstream or downstream of the site of

transcription initiation. Enhancers have a modular structure by being composed of multiple binding sites for transcriptional activator proteins. Many enhancers control gene expression in a cell type-specific fashion. Expression of one and the same gene can be controlled by several remote enhancers. Conversely, a given enhancer may also serve to activate more than one gene.

Characteristics

Viral Enhancers as Harbingers of Cellular Enhancers

The first enhancer was described in 1981 in the genome of a small DNA virus, simian virus 40 (SV40) as a DNA segment that was not only essential for viral early gene expression but in experimental conditions was able to stimulate the expression of a heterologous gene linked to it more than one hundred fold (1, 2). Naturally this enhancer is located between 100 bp and 300 bp upstream of the transcription initiation site for the viral “early” messenger RNA. In experimental situations it was able to stimulate the expression of the reporter gene over long distances of several thousand base pairs, both from positions upstream or downstream of the site of transcription initiation. Other enhancers were discovered soon thereafter in both DNA viruses and retroviruses.

Already at this early stage it was proposed that enhancers were not a viral peculiarity but that similar enhancers would also be associated with cellular genes (1). The discovery of an enhancer associated with immunoglobulin (Ig) heavy chain genes marked another breakthrough in the understanding of eukaryotic gene regulation, mostly for two reasons. First of all, it was active only in B lymphocyte-type cells and thus represented the first genetic element of eukaryotes to control cell type-specific gene activity. Furthermore, this enhancer is located in the second intron, i.e. within the transcription unit, and thus demonstrated that enhancers can indeed be located downstream of the transcription initiation site in a natural setting (3, 4) (Fig. 1 a, b, c, d). Over the following years, many other cellular enhancers were discovered, some close to the ►promoter/transcription initiation site, others tens, if not hundreds of kilobases away from the gene to be activated (strictly speaking, the term “gene” should be replaced here by “transcription unit” because even a very remote enhancer is, by definition, an integral part of the gene). Enhancers are widespread in nature; in all multicellular eukaryotes from worms to mammals, control of gene activity *via* enhancers seems to be the rule rather than the exception. Most enhancer studies so far have involved genes transcribed by RNA polymerase II, but enhancers have also been described for ribosomal RNA genes, which are transcribed by RNA polymerase I.

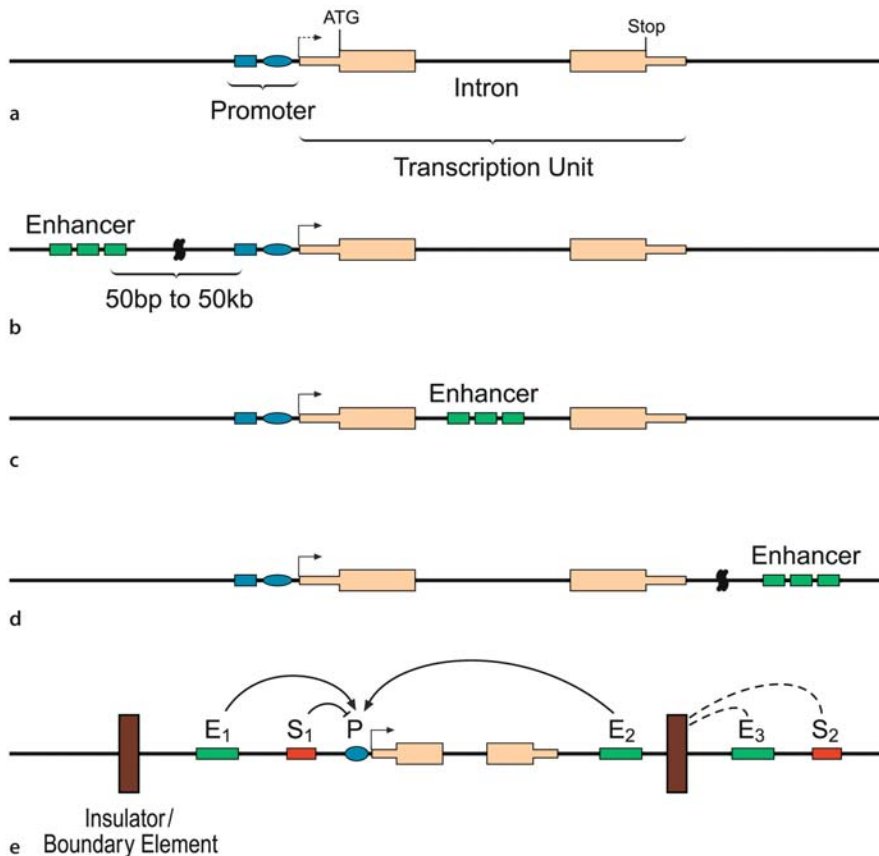

For stage- and cell type-specific gene expression, one and the same gene may rely on multiple enhancers. The immunoglobulin heavy chain genes are no exception; besides the originally discovered enhancer in the second intron, this locus contains another B-lymphocyte-specific enhancer far downstream of all IgH transcription units, as well as additional cytokine-inducible enhancers which play an important role in the so-called heavy chain “class switch” during an immune response. The most extensive studies on this topic have been carried out in the fruit fly *Drosophila*. There, genes for specific developmental regulators are known to be controlled by multiple enhancers in most cases. For example, the seemingly simple stripe pattern of the fly embryos is not controlled by one enhancer, but multiple enhancers are needed to form but one of the stripes. One of the key regulators of *Drosophila* development are ►transcription factors of the Pax family. The most extensive enhancer study so far was done with the Pox neuro gene that controls multiple steps in development (5) (Fig. 2).

In baker's yeast (*Saccharomyces cerevisiae*), a unicellular eukaryote of simpler organization than most other eukaryotes, regulatory sequences that are functionally equivalent to enhancers of higher eukaryotes have been discovered. These are called “upstream activating sequences” (UASs) and also serve as binding sites for transcriptional activators. The UASs also activate transcription of a linked transcription unit independent of their orientation and over distances of up to approx. 1000 bp (6). However, UAS motifs are usually in close proximity to the initiation site of transcription and do not activate from a position downstream of the transcription unit. Even in prokaryotes, long-range effects of regulatory DNA elements were found (7), but unlike the situation in higher eukaryotes, enhancer effects appear to be the exception rather than the rule, in prokaryotes.

Enhancers Have a Modular Structure

A typical enhancer is about 100 bp to 300 bp long (or longer) and consists essentially of a string of binding sites for DNA-binding activator proteins or transcription factors. Each cell of a higher organism harbors hundreds of different such transcription factors. A transcription factor contains a DNA-binding domain to recognize a short DNA-sequence motif of approx. 10 bp and an “activation domain”. The latter establishes contacts with other components of the transcription apparatus and consequently raises the rate of transcription of the corresponding gene. At least some activation domains also facilitate, most probably indirectly, the process of transcription elongation by ►RNA polymerase II.

Unexpectedly, and despite the eukaryote's larger genomes compared to the ones of prokaryotes, the

Enhancer. Figure 1 Possible positions of enhancers in eukaryotic genes. (a) A gene without enhancer that would merely contain a promoter consisting of one proximal binding site (green box) for a transcription activator protein, a TATA box and an Inr (initiation region) would be poorly, if at all, transcribed (dotted arrow). (b–d) An enhancer (c) green boxes schematically indicate the multiple binding sites for activating transcription factors) can be located at different positions: near the promoter region, or overlapping with the latter, as is the case in different viral genes, as well as metallothionein genes (b); far upstream of the transcription unit, as in the albumin gene; d), within a gene, usually as part of an intron, such as in immunoglobulin (Ig) genes (c); or even far downstream of the transcription unit, as, e.g., in T-cell receptor and Ig genes (d). (e) Enhancers, promoters, silencers and boundary elements control gene expression. Similarly to enhancers (simplified as a single green box), silencers (red box) can influence gene activity over long distances. They also consist of an array of binding sites, but for transcription repressor proteins. A gene flanked by so-called boundary elements (= insulators) is protected from undesired effects of neighboring enhancers or silencers. In this scheme, one might envision a situation where two enhancers (E1 and E2) activate transcription from the promoter (P, in blue) in two different cell types. In a third cell type, the gene is completely repressed by the silencer S1. Neither the nearby enhancer (E3) nor the silencer (S2) can exert any effect because the gene is bracketed by a pair of insulator/boundary elements (brown).

selectivity of DNA recognition by eukaryotic transcription factors is often less pronounced than that of bacterial regulators. This deficiency in specificity, however, is compensated by a greater number of binding sites and factor interactions; while bacterial, and even some yeast genes are regulated by a single activator, most eukaryotic enhancers have to interact with multiple factors to become active. By serving as a platform for the binding of specific transcription factors, enhancers thus ensure correct development in all multicellular organisms (5).

Although a typical enhancer contains binding sites for several different transcription factors (8), synthetic enhancers can, in accordance with the concept of a modular structure, readily be generated by linking together multiple copies of one and the same DNA sequence motif. From this point of view, every binding site for a transcription protein (or a protein dimer) can be considered a minimal enhancer unit, even though on its own it would have low, or even no activity (9). Multiple binding sites however show a strong synergy in transcriptional activation. At least in some cases, the

Enhancer. Figure 2 Many enhancers control cell fate in embryonic development and cell differentiation. Genes in control of embryonic development tend to be regulated by particularly complex patterns of enhancers, silencers and boundary elements. Shown here is the multitude of enhancers regulating the expression of a paired-box transcription factor-gene, *pox neuro* in the fruit fly *Drosophila*. Various enhancers are required for ensuring gene activity at a multitude of specific stages, in different tissues/cell types (5).

minimal functional unit consists of a larger DNA segment of some 60 bp, on which multiple transcription factors stereospecifically interact with each other and the DNA, with the assistance of structural (“architectural”) proteins, which suitably bend the DNA. Such a superstructure has been termed an **enhanceosome** (10) (Fig. 3).

In bacteria, RNA polymerase directly recognizes the promoter, and this interaction may be facilitated by the nearby binding of an activator protein. In contrast, in eukaryotes not even the DNA-bound transcription factors are able to directly bind and thereby recruit RNA polymerase II for transcription initiation. Rather, they only bind indirectly *via* mediator proteins (adaptor proteins) that are part of large multiprotein complexes. Because of the multiple layers of interactions and because of their sheer size, such protein complexes are relatively insensitive to the exact position of their DNA-binding partners. This explains why a whole enhancer, or parts of it, and in many cases even single binding sites for transcription factors, can be inverted relative to other DNA-sequences in an enhancer or a promoter without loss of activity. This remarkable orientation independence is a general attribute of eukaryotic regulatory DNA sequences and was first documented for the enhancer/promoter region of a histone gene in the sea urchin, a DNA-segment of –100 to –300 from the transcription start dubbed the “modulator” (11).

Mechanism of Action: Certainly Recruitment – but How?

Unlike bacterial RNA polymerases, eukaryotic RNA polymerase II is unable to recognize the naked DNA of a promoter; rather, the promoter has to be “tagged” by DNA binding proteins. However, there are additional layers of complexity in that not even such DNA-binding proteins are able to recruit the polymerase to the promoter; they in turn bind to a multitude of intermediary proteins, referred to as co-activators, mediator complex, adaptors or SRB proteins, which are organized in large multiprotein complexes, and on their part recruit the RNA polymerase II to the initiation site (12) (Fig. 3). For example, many genes depend on the closely related, large adaptor proteins CBP and p300. These proteins were originally identified as binding partners of the DNA binding transcription factor **CREB**, but this turned out to be but one of many interactions with transcription factors. DNA-binding transcriptional activators may also interact with the general transcription factors (GTFs) that include the promoter-proximal TFIIB, the TATA-box-binding protein (TBP) and/or so-called TAF-proteins, which are complexed to the latter. The question as to how transcription from a given promoter can be dramatically induced by a remote enhancer has been a source of speculation ever since the discovery of the enhancer effect. Several models have been proposed to explain

Enhancer. Figure 3 Enhancer-binding transcription factors: recruitment and DNA looping. (a) A typical DNA-binding transcription factor (= transcriptional activator = transactivator) contains a DNA binding site to dock onto the enhancer or upstream promoter site, a so-called **NLS** (nuclear localization sequence) for transport to the nucleus, an activation/effector domain which interacts with the co-activator/mediator proteins and often an additional domain for homo- or hetero-dimerisation. (b) Superstructures composed of a stereospecific array of DNA sites and transcription factors, aided by “architectural protein” HMG I(Y) which bends the DNA to facilitate assembly of this complex, are found in the enhancer/upstream region of interferon beta genes. Such superstructures act as functional entities and have been referred to as enhanceosomes (10). (c) The transcription factors bound to both enhancer and promoter, including the generally used TATA-box binding protein (TBP) and TFIIB, recruit further general transcription factors, as well as adaptor and mediator proteins via multiple protein-protein-contacts. The mediator complex helps to recruit RNA polymerase II to the initiation site, resulting in the formation of the extremely large initiation complex. Besides RNA polymerase, several other enzymatic activities are associated with this initiation complex, including protein kinases and acetyl transferases. The latter primarily acetylate histones, resulting in a loose chromatin structure permissive for transcription.

the mode of activation, three of which were most often considered, namely, (i) today’s most popular “looping” model, (ii) the “linking” (or “oozing”) model and (iii) the “polymerase scanning” model. Regarding the looping model, several experiments support the concept of DNA-looping between enhancer and promoter (13, 14). Most probably, the enhancer-bound transcription factors bind indirectly, *via* a multitude of cofactors, to the ones bound in the promoter region and thereby form a large initiation complex, with the intervening DNA being looped out (Fig. 3). Under experimental conditions in a cell-free system, a promoter on its own can establish such an initiation complex, but *in vivo*, on a native chromosome, it depends on the assistance of

the enhancer. The linking model (also known as “oozing”) has recently gained momentum. The linking model proposes that the binding of certain activating proteins to the enhancer regions causes a modified chromatin structure, which thereafter spreads along the DNA in either direction until ultimately a transcriptionally competent promoter is encountered and included in the “open” configuration (15). A combination of the two models can also be envisaged, whereby DNA looping between enhancer and promoter is not permanent but rather a transient on-off phenomenon. Even though in some cases RNA polymerase II is also found associated with an upstream enhancer, where it may or may not initiate a low level of transcription,

there is hardly any evidence for a sliding, or scanning by the polymerase from there until it reaches the “real” promoter.

DNA-bound factors, the mediator proteins and the transcription apparatus synergize in the recruitment of chromatin “remodeling” complexes such as SWI-SNF. The concept of local or long-range modification of chromatin structure, starting at an enhancer and extending until the promoter is reached, is also supported by the findings that several transcription-associated proteins contain, among other enzymatic activities, ►**histone acetyltransferase** (HAT) activity. This serves to acetylate specific residues on histones and transcription factors. Acetylation of histones generally loosens chromatin structure and makes the DNA more accessible to the transcription apparatus. An obvious indication of this is the increased sensitivity of such chromatin on treatment with DNase I. Transcribed “active” DNA generally is DNase I sensitive, so this condition correlates with DNA being packaged into acetylated histones. On top of this general sensitivity, enhancer and promoter regions are, as a consequence of the binding of transcription factors, hypersensitive to DNase.

Enhancer Shuffling, Enhancer Rearrangements

In higher eukaryotes, genes which control embryonic development and other traits are usually controlled by multiple enhancers. It has been argued that DNA rearrangements leading to the displacement of enhancers within the genome (“enhancer shuffling”) are a major driving force in evolution to generate new expression patterns of genes. Besides such “shuffling”, enhancers themselves can undergo alterations, as is most dramatically shown in the evolution of viruses. Selection for a new cell type specificity was shown to be accompanied by extensive alterations in the enhancer DNA sequence and relatively small changes in protein-coding sequences. Gross deletions/duplications of enhancer subsegments are most commonly observed (16 and references therein). Duplications of enhancer regions, which indicate relatively recent changes in gene expression, have also been found in some cellular enhancers and may contribute, for example, to variation in disease resistance. While an enhancer translocated to a new position in the genome can result in a new gene expression pattern, not every arbitrarily chosen enhancer-promoter combination is functional, since promoter and enhancer can co-evolve for optimal function. There are well-documented cases of exclusive enhancer/promoter-specificity (17). On the other hand, novel enhancer-promoter combinations that interact productively have been found from yeast to mammals and may be the rule, rather than the exception. In a similar way, displacement of an enhancer in somatic cells by chromosome translocation

can result in over-expression of cell growth-promoting genes and thus contribute to malignant cell transformation. The same dire consequences can result from the insertion of a retrovirus with a strong transcription enhancer near a regulatory gene. Due to the long-range activity of enhancers, the insertion site might well be located dozens, if not hundreds of kilobases away from the affected cellular gene.

Enhancers in the Context of Eukaryotic Gene Regulation

Thanks to a combination of genetics, specific mutagenesis and biochemistry, many aspects of eukaryotic transcription control have been elucidated – but a number of questions remain. One of these concerns the mode of activation; does an enhancer affect a gene in an all-or-none fashion whereas the fine-tuning of transcription is left to the promoter, or do enhancers of different strength confer gradual levels of transcription to an individual gene? The latter possibility seems more plausible at first sight, but at least in particular cases, such as in hemoglobin genes, there is evidence for an all-or-none “switch” of individual genes whenever the concentration activating transcription factors reaches a critical level. In the latter case, gene expression in the beta-globin locus is controlled by a cluster of no less than five enhancer-type DNA segments that are collectively referred to as the LCR (►**locus control region**) and that are 20–50 kb away from the beta-globin family members. The LCR ensures the complete stage- and cell-type-specific expression of the different beta-chains (18). Facing the possibility of an activation over such distances of dozens of kilobases, the question arises whether activation can only occur on a contiguous DNA molecule (“*in cis*”), or whether an activation *in trans*, from one DNA to another, is also possible. Although enhancers typically exert their activity *in cis*, cases of an activation *in trans* have been reported. This phenomenon, called ►**transvection**, is of particular importance in *Drosophila*, where the homologous chromosomes remain paired in somatic cells, allowing an enhancer to influence the corresponding allele on the homologous chromosome.

Because of its property of causing a loose, permissive chromatin structure, an enhancer can be exploited for additional activities. A particular stage of development can be associated with the emergence of a new origin of DNA replication. During immune cell maturation, an immunoglobulin gene enhancer can cause cytosine demethylation in CG-dinucleotides, sequence-specific DNA-rearrangement (VDJ joining), and “class switch recombination”. Furthermore, the amazing process of local immunoglobulin gene hypermutation in B-cells is dependent on an active transcription enhancer.

Besides transcription enhancers, the immunoglobulin gene locus harbors so-called “matrix attachment regions” (MARs). These are [A+T] rich DNA-segments, which do

not necessarily enhance transcription on their own, but in an experimental situation can facilitate enhancer activity over long distances in transgenic animals, apparently by counteracting the formation of transcriptionally inactive chromatin.

The transcription enhancer's counterpart is referred to as a ►[silencer](#). This term defines DNA segments that are able to inactivate genes *in cis* over long distances (19) (Fig. 1e). Instead of activators, a silencer interacts with repressor proteins, which unlike bacterial repressors do not necessarily have to bind to the promoter region, but inactivate corresponding genes through different mechanisms, recruitment of histone deacetylases, specific histone methylases and co-repressors that in turn can block the activity of the basal transcription apparatus. Enhancers and silencers were originally described as completely different entities. But especially in the control of cell-cycle and embryonic development, situations have been described where in the absence of an activation signal, one and the same DNA-binding transcription factor can bind a co-repressor instead of a co-activator, such that the distinction between enhancer and silencer becomes ambiguous. Therefore, an enhancer in one stage or cell-type would act as a silencer in other circumstances. In other cases of overlapping enhancer/silencer functions, binding sites for activator and repressor proteins are not the same but are rather interdigitated in a given segment of DNA. However, such overlaps do not seem to be the rule, and in most cases, enhancers and silencers have been described as separate entities.

Wherever activation or repression over long distances is possible, there also must be mechanisms to limit undesirable effects on noninvolved genes. The so called boundary elements or insulators serve this purpose, namely, to protect a gene from the effect of a neighboring enhancer or silencer or from negative effects of heterochromatin (20). Insulators are again DNA segments with an array of binding sites for specific regulatory proteins. For optimal insulation from neighboring elements, a gene has to be bracketed by a pair of ►[insulator/boundary elements](#) (Fig. 1e). Experimental deletion of an insulator can leave an undefined transition between inactive heterochromatin and active euchromatin; the border is then settled more or less randomly in every individual cell. Once such a border is established in early embryonic development, it is retained throughout following cell divisions, which leads to clonal patches of cells that may or may not express a particular gene in the border region. Such patchy gene expression patterns are referred to as PEV (position effect variegation) and have been most extensively studied in the fruit fly, e.g., as “mottled” eye color.

Finally, to avoid confusion of terms, it should be mentioned that during the process of RNA-splicing, certain RNA sequences, especially in exons, bind specific proteins that facilitate splicing at a nearby site. Such ►[“splice enhancer”](#) sequences thus allow for the usage of an otherwise suboptimal splice site. Splice enhancers play an important role in the regulation of alternative splicing. Fundamental differences from transcription enhancers (and, accordingly, from silencers) are that splice enhancers consist of (single stranded) RNA, rather than DNA, and thus are not active in reverse orientation and that they act over only a short distance (dozens of base pairs) to facilitate splicing.

Enzyme Catalyzed Post-Translational Hydroxylation of Proteins

Definitions

The hydroxylation of proteins as catalyzed by dioxygen dependent enzymes is now established as an important ►post-translational modification. The importance of the oxidative hydroxylation of amino acid residues in collagen biosynthesis has been long recognized, but the role of post-translational hydroxylation in signalling and degradation pathways has recently become clear. Whilst the full extent of post-translational hydroxylation relative to other modifications, including phosphorylation, glycosylation, acetylation and methylation, has yet to be established, the results arising work on the hypoxic sensing pathway in animals suggests that hydroxylation may be significantly more extensive than previously perceived. Manipulation of post-translational hydroxylation offers prospects of new therapies for the treatment of cancer, cardiovascular diseases and diseases associated with connective tissue.

Characteristics

Types of Protein Hydroxylation

Initially it was thought that the oxygen of post-translationally introduced alcohols was derived from water, however pioneering work by Hayaishi and contemporaries demonstrated that it originated from dioxygen. Oxidative hydroxylation, i.e. the conversion of a C-H bond to a C-OH (alcohol) group, must be mediated via a ►reactive oxidizing species (ROS). In principle protein hydroxylation may be mediated either by 'free' ROS, e.g. superoxide, peroxide radicals or macromolecular bound ROS, i.e. enzymes. Protein hydroxylation via 'free' ROS has been proposed to occur in oxidative responses involved in stress and aging and it is also known to be involved in the inactivation of oxidizing enzymes. However, whilst 'free' ROS may well mediate specific post-translational

modifications such as disulfide formation and the oxidation of tyrosine residues, evidence for their involvement in the selective hydroxylation of unactivated C-H bonds is lacking. Given the activation energy barrier for hydroxylation of an unactivated C-H bond it would seem unlikely. The oxidation, including hydroxylation, of nucleic acids by free ROS has been more thoroughly studied and has been plausibly linked with tumour development.

The involvement of protein ►hydroxylases in the biosynthesis of 4-hydroxyprolyl residues was first demonstrated in the 1960s. The following post-translational modifications involving oxygenase-mediated hydroxylation of an unactivated C-H bond have been identified: (Fig. 1)

1. Prolyl residues to 4*R*-(*trans*)-hydroxyprolyl residues (in collagen biosynthesis and transcription factors involved in hypoxic sensing),
2. Prolyl residues to 3*S*-(*trans*)-hydroxyprolyl residues (in collagen biosynthesis),
3. Lysyl residues to 5*R*-hydroxylysyl residues (in collagen biosynthesis),
4. Aspartyl residues to 3*S*-hydroxyaspartyl residues (in epidermal growth factor-like [EGF-like] domains),
5. Asparaginyl residues to 3*S*-hydroxyasparaginyl residues (in EGF-like domains and transcription factors involved in hypoxic sensing),
6. Formation of α -hydroxylated derivatives of C-terminal glycyl residues in protein amidation. (Fig. 12)

Characteristics of Protein Hydroxylases

To date, the enzymes identified as catalyzing oxidative post-translational hydroxylations of C-H bonds in side-chains of protein residues belong to a single superfamily termed the 2-oxoglutarate (2-OG) dependent oxygenases. Almost all members of this family employ ferrous iron [Fe(II)] as a cofactor and 2-oxoglutarate and dioxygen as cosubstrates (Fig. 2). [Hydroxylation of C-terminal peptidyl glycine residues is catalysed by different enzymes and is discussed below]. These enzymes are widespread and, in addition to post-translational modifications, catalyze many reactions in metabolic and regulatory processes including the hydroxylation of free amino acids, steps in the biosynthesis of antibiotics in microorganisms and plant signalling molecules, fatty acid metabolism and DNA repair. Although the 2-oxoglutarate oxygenases catalyze a range of oxidative reactions including desaturation and oxidative cyclizations, their most common reaction is hydroxylation, either of small molecules (e.g. gamma-butyrobetaine) or macromolecules including proteins and DNA.

Crystallographic and sequence analysis studies have revealed that many 2-oxoglutarate dependent oxygenases, including most of those involved in post-translational

Enzyme Catalyzed Post-Translational Hydroxylation of Proteins. Figure 1 Known post-translational hydroxylations catalyzed by Fe(II) oxygenases: (i) prolyl (Gly-Pro-Pro) to (2S, 4R)-4-hydroxyprolyl; (ii) prolyl (Gly-Pro-Pro) to (2S, 3S)-3-hydroxyprolyl; (iii) lysyl to (2S, 5R)-5-hydroxylysyl; (iv) aspartyl to (2S, 3S)-3-hydroxyaspartyl; (v) asparaginyl to (2S, 3S)-3-hydroxyasparaginyl.

hydroxylation, contain a core of eight beta-strands arranged in a double-stranded beta helix (or jelly roll) motif. In the light of the crystallographic data, spectroscopic and kinetic analyses suggest that many, but not necessarily all of the family share closely related mechanisms in which the enzyme-Fe(II) complex first binds 2-OG followed by substrate. Binding of the latter triggers the enzyme for reaction with dioxygen. Subsequently, a ferryl [$\text{Fe}(\text{IV})=\text{O}$] \rightleftharpoons $\text{Fe}(\text{III})-\text{O}^\bullet$ intermediate, which acts as the ROS, is produced by oxidative decarboxylation of 2-oxoglutarate (Fig. 3).

For some 2-OG oxygenases, e.g. procollagen prolyl-4R-hydroxylase, catalytic activity is highly dependent upon the presence of ascorbate. In other cases, the role of ascorbate can be substituted by other reducing agents and/or the addition of ascorbate makes little difference to the catalytic rate. One role of ascorbate is to complete 'uncoupled' reaction cycles in which a ferryl [$\text{Fe}(\text{IV})=\text{O}$] intermediate is generated by reaction of 2-oxoglutarate and oxygen either in the absence of (protein) substrate or in the presence of a substrate that is incorrectly bound to enable hydroxylation (Fig. 4).

In this process the ascorbate is oxidized (either to dehydroascorbate or semi-dehydroascorbate) and the reactive intermediate is reduced to Fe(II) enabling the

Enzyme Catalyzed Post-Translational Hydroxylation of Proteins. Figure 2 The stoichiometry of a 2-oxoglutarate catalyzed hydroxylation reaction.

Enzyme Catalyzed Post-Translational Hydroxylation of Proteins. Figure 3 Outline mechanism for a 2-oxoglutarate catalyzed hydroxylation reaction, illustrated for factor inhibiting HIF (FIH).

Enzyme Catalyzed Post-Translational Hydroxylation of Proteins. Figure 4 A role for ascorbate (vitamin C) in completing 'uncoupled' reaction cycles by 2-oxoglutarate oxygenases.

initiation of another catalytic cycle. In the absence of ascorbate, or other appropriate reducing agents, the enzyme-bound ferryl [Fe(IV)=O] intermediate or an oxidizing species derived from it can cause inactivation *via* oxidative processes including self hydroxylation or proteolytic cleavage. However, the *in vitro* dependence of 2-oxoglutarate oxygenases on ascorbate is highly variable and there is some evidence that in the case of enzymes that have a strict requirement, ascorbate may be involved in forming a productive enzyme-substrate complex.

Post-Translational Hydroxylation and Collagen Biosynthesis Overview

Collagen is one of the most abundant and important structural proteins in animals. Genomic analyses also

suggest that collagen related structures are present in most major organisms including plants and viruses. The limited occurrence of collagen type proteins in lower eukaryotes and their absence in archaeobacteria suggests that horizontal gene transfer may account for their presence in lower organisms. In plants, the collagen-like macromolecules – including extensins, proline-rich proteins, lectins and arabinogalactan proteins – function structurally within cell walls. The hydroxyprolyl residues of these plant macromolecules are often glycoacceptors and sugar attachment is critical to their ability to provide tensile strength to the cell. Three post-translational hydroxylations have been identified in animal collagen, 4*R*-hydroxy-*L*-proline, 3*S*-hydroxy-*L*-proline and 5*R*-hydroxy-*L*-lysine, while in plants the main modification appears to be 4*R*-hydroxy-*L*-proline. In animals, 4*R*-hydroxy-*L*-proline is the most common modification followed by 5*R*-hydroxy-*L*-lysine and the rare 3*S*-hydroxy-*L*-proline.

Collagen is structurally distinctive due to the presence of domains possessing an unusual triple stranded tertiary structure. This comprises three parallel left-handed strands wound around a central axis to form a triple helix with a right-handed pitch. This is present in the *ca.* 20 different types of collagen of which the most abundant is Type I collagen which contains *ca.* 300 repeating Gly-Xaa-Yaa triplet motifs, which are critical to the tertiary structure and thermostability of collagen. The packing of the collagen triple helix requires every

Enzyme Catalyzed Post-Translational Hydroxylation of Proteins. Figure 5 Views of collagen. Left, the triple helix is shown in cartoon form with the 4*R*-hydroxy-*L*-prolyl residues displayed. Right, a view along the axis of the triple helix, with the 4*R*-hydroxy-*L*-prolyl residues shown (oxygen in red, nitrogen in blue).

third residue to be glycine. The Xaa residue is often *L*-proline and the Yaa residue 4*R*-hydroxy-*L*-proline. The tertiary structure of collagen enables it to form strong and flexible supramolecular fibrils that can be cross-linked.

Types and Roles of Collagen Hydroxylations

The hydroxyl group of the 4*R*-hydroxy-*L*-proline residues of the triplet motifs was once thought to confer stability on the structure by its involvement in intra-helix hydrogen bonding and/or by stabilising a network of water bridges. However, structural work and studies employing the systematic substitution of the triplet residues are consistent with stabilisation by 4*R*-hydroxy-*L*-proline in the Yaa position occurring at least in part *via* a stereoelectronic effect termed the gauche effect. This arises from the propensity of electronegative groups on adjacent carbons to adopt a gauche relationship (Fig. 6). As a consequence the presence of an electron-withdrawing group at the 4*R*-position of proline stabilizes a particular conformation (or pucker) of the proline pyrrolidine ring (*Cy-exo*) such that the main chain torsion angles (omega, phi, psi) are preorganised to favour the collagen structure. Central to the development of this proposal was the observation that substitution of 4*R*-fluoro-*L*-proline at the Yaa position [of the (Gly-Xaa-Yaa) collagen triplet] resulted in collagen that was even more stable than that with 4*R*-hydroxy-*L*-proline at this position.

Fewer studies have been carried out on the role of the rare 3*S*-hydroxy-*L*-proline residues on collagen stability. In contrast to 4*R*-hydroxy-*L*-proline, it appears to effect a slight destabilization in its natural Xaa position, an effect that is increased when it is in the unnatural Yaa position.

Although details remain to be resolved, the available evidence implies that the pattern and extent of lysyl hydroxylation in the non-triple helical domains of

Enzyme Catalyzed Post-Translational Hydroxylation of Proteins. Figure 6 The conformation of (2*S*, 4*S*)-4-hydroxyprolyl residues in collagen. The favoured conformation is proposed to maximise overlap between the C-O (σ^*) antibonding orbital and the two adjacent C-H (σ) bonding orbitals. This preorganises the fixation of the bond angles ω , ϕ and ψ at the ideal values for triple helix formation.

collagen are important in determining collagen cross-linking pathways that are tissue specific. Hydroxylysine is essential for the formation of the covalent pyridinium cross-links pyridinoline and deoxypyridinoline (among mature collagen molecules). Pyridinoline derives from three hydroxylysyl residues, whereas deoxypyridinoline derives from one lysyl and two hydroxylysyl residues. These and other cross-links tune the properties of collagens to specific roles, e.g. hydroxylysyl-pyridinoline is a typical cross-link of skeletal tissue and it is also thought to play a major part in the hardening of sclerotic tissue. The patterns of lysyl hydroxylation may be regulated by expression of different lysyl hydroxylase genes.

The Enzymes of Collagen Hydroxylation

The expression of both the prolyl-3- and 4-hydroxylases has been shown to be dependent on the oxygen tension and, in the case of the prolyl-4-hydroxylases, shown to be mediated by HIF1 α . (See below)

Procollagen Prolyl-4-Hydroxylase (EC 1.14.11.2)

The substrates for both procollagen prolyl-4-hydroxylase and prolyl-3-hydroxylase are repeated amino acid triplets in procollagen, with (-Gly-Pro-Pro)_n being the natural substrate for the prolyl-4-hydroxylases. The (-Gly-Pro-4Hyp)_n generated by this reaction is in turn the prime substrate for the prolyl-3-hydroxylases. It has been shown that the prolyl-4-hydroxylases only act on procollagen that has not formed a triple helical structure, and also that helical and nonhelical procollagen are secreted from the cell at different rates.

Studies on the quaternary structure of collagen prolyl-4-hydroxylases have shown that they can adopt different oligomerisation states but that the active enzyme exists in vertebrates as an $\alpha_2\beta_2$ heterotetramer. The α subunit exists in various isoforms [$\alpha(I)$, $\alpha(II)$ and $\alpha(III)$] and contains the residues directly involved in prolyl hydroxylase activity.

The β subunits have been identified as protein disulfide isomerase (PDI) and are essential for both catalytic activity and productive folding of the α subunits. The PDI/ β subunit is typically expressed in 10–100 fold excess over the α subunits in most cells and tissues and also functions in different pathways independently of them. It has been proposed that there is no mixing of the α subunits within tetramers, i.e. there are [$\alpha(I)_2\beta_2$] and [$\alpha(II)_2\beta_2$] complexes which form the Type I and Type II prolyl hydroxylases respectively.

The prolyl-4-hydroxylases are widely expressed, and of the two types ($\alpha(I)$ and $\alpha(II)$) it is the Type I enzymes which are believed to contribute most towards the total *in vivo* prolyl hydroxylase activity in humans – estimated at 60–90%. Prolyl-4-hydroxylases have been identified in many vertebrates as well as bacteria, plants and viruses and play a critical role in correct development of structural proteins across species. In humans, prolyl-4-hydroxylases are expressed in a wide variety of tissue and cell types and Type I prolyl-4-hydroxylase is the main form in most cell types, including skeletal myocytes and smooth muscle cells. Type II prolyl-4-hydroxylase is the main form in chondrocytes, capillary endothelial cells and cultured umbilical cells, as measured using immunofluorescence and Western blotting. The subcellular location of prolyl-4-hydroxylase α subunits is predominantly in the endoplasmic reticulum, although PDI is more widely distributed.

Procollagen Prolyl-3-Hydroxylase (EC 1.14.11.7)

Prolyl-3-hydroxylases are less common than the prolyl-4-hydroxylases and have been less extensively studied. They have only been definitively identified in vertebrates and evidence for their existence in plants and viruses is lacking. The substrate of prolyl-3-hydroxylase is the prolyl residue in the repeated amino acid sequence (-Gly-Pro-4Hyp-) of procollagen. Little structural information on the prolyl-3-hydroxylases has been reported but gel filtration has indicated its molecular weight to be roughly 160 kD. The tertiary and quaternary structures are not known at this time and so far it has not been cloned and expressed *in vitro*.

Procollagen Lysyl-5-Hydroxylases (EC 1.14.11.4)

The substrate of procollagen lysyl-5-hydroxylase is procollagen and contains the sequence (-Gly-Xaa-Lys-). Lysyl hydroxylation is involved in the formation of all the different types of collagen, as it is critical for both

the crosslinking and attachment of sugars to the collagen chain. In addition to hydroxylase activity, one human lysyl hydroxylase has recently been shown to possess both glucosyl- and galactosyl-transferase activity, and hence has the ability to generate glucosylgalactosylhydroxyllysyl residues. There are three isoforms of lysyl hydroxylase in humans (LH1-3), with subunit weights of *ca.* 82 kD, one of which has two different splice variants (LH2a and LH2b). LH1 has recently been cloned and expressed in a eukaryotic cell line (CHO-K1).

The three human lysyl hydroxylase isoforms are found in a wide variety of tissue types including brain, heart, spleen, artery and liver. LH1 is constitutively expressed in the widest range of tissues while LH2b is expressed at different levels in different tissue types. The subcellular localization of LH1 is known to be in the lumen of the endoplasmic reticulum but nothing is known about the other isoforms.

Protein Hydroxylation and the Hypoxic Response

When the tissues of multicellular organisms are subjected to conditions of low oxygen tension, e.g. by travel to high altitude or impaired blood supply, there is a physiological reaction known as the hypoxic response. Critical to this response is the transcription factor HIF (hypoxia-inducible factor) which is a heterodimeric protein comprising HIF1 α and HIF1 β . HIF is conserved in a wide range of organisms ranging from *C. elegans* to humans. Whilst HIF1 β is a constitutive nuclear protein (identical in sequence to the aryl hydrocarbon receptor nuclear translocator) and is unaffected by oxygen tension, levels of HIF α are highly sensitive to dioxygen levels. Under normoxic conditions (sufficient oxygen), HIF α is not normally detectable, but under hypoxic conditions levels of HIF α rise and enable transcription of the array (>100 in humans) of genes involved in the hypoxic response.

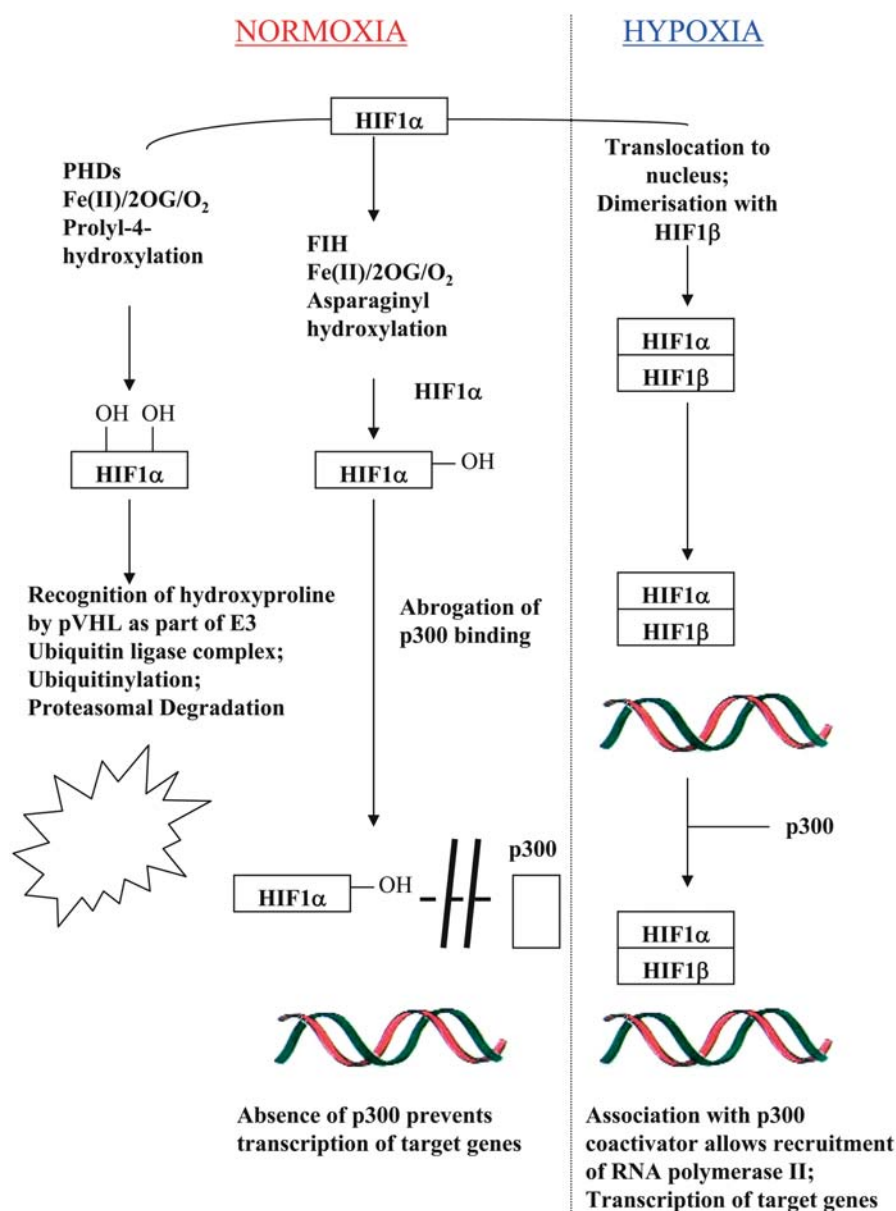

Three human variants of HIF α encoded by different genetic loci have been identified, two of which, HIF1 α and HIF2 α , are closely related. Both HIF1 α and HIF2 α possess a central oxygen dependent degradation domain that is absent in HIF1 β . The oxygen dependent degradation domain is composed of two sub-domains each of which can independently enable degradation of this HIF subunit.

Under hypoxic conditions, HIF1 α translocates to the nucleus where it heterodimerises with HIF1 β to form functionally active HIF1 $\alpha\beta$. The HIF1 $\alpha\beta$ dimer then recruits the transcriptional coactivator p300, that together with other proteins recruits RNA polymerase II to initiate transcription. Target genes that are up-regulated by HIF include those involved in glycolysis, [angiogenesis](#), vasculogenesis and erythropoiesis. Modulation of the hypoxic response in order to enable selective expression of hypoxically regulated genes

thus offers the possibility of new therapies for cancer and cardiovascular disease.

Recent work has demonstrated that post-translational modification, catalysed by a set of 2-oxoglutarate dependent oxygenases, is responsible for two separate mechanisms enabling the oxygen sensitive regulation of HIF α activity. Under normoxic conditions, HIF1 α can be hydroxylated by three closely related prolyl hydroxylases (PHD1-3, prolyl-hydroxylase domain-containing proteins) and an asparaginyl hydroxylase (factor inhibiting HIF, FIH). As shown in Fig. 7, both the stability and the transcriptional activity of HIF1 α are regulated by its hydroxylation.

The PHDs catalyse hydroxylation of two critical prolyl residues, Pro402 and Pro564 (using the human numbering system) in the oxygen dependent degradation domain of HIF1 α . Hydroxylation of HIF1 α in this manner enables it to form a complex with the von Hippel-Lindau tumour suppressor protein stabilised *via* two buried hydrogen bonds involving the new hydroxyl group. Since pVHL is the recognition subunit of an E3 ubiquitin ligase complex, this enables degradation of ubiquitin-tagged HIF1 α *via* the 26S proteasome. FIH enables its control of HIF α activity through the hydroxylation of an asparaginyl residue (Asn803 in human HIF1 α) in the C-terminal transactivation

Enzyme Catalyzed Post-Translational Hydroxylation of Proteins. Figure 7 Schematic of the hypoxic response.

Enzyme Catalyzed Post-Translational Hydroxylation of Proteins. Figure 8

The structure of a peptide corresponding to the C-terminal oxygen-dependent degradation domain (C-ODD) of HIF1 α after prolyl hydroxylation, complexed to pVHL. The hydroxyl group of Hyp564 (red, arrowed) forms hydrogen bonds with the side chains of His115 and Ser111 of pVHL, thus allowing pVHL to specifically recognise hydroxylated HIF.

domain (CAD) required for its transcriptional activity; this transactivation domain binds to the CH1 (cysteine/histidine rich) domain of p300/CREB binding protein. Hydroxylation at the β -position of Asn803 blocks the interaction between CAD and the p300/CBP coactivator.

The relative importance to the hypoxic response of hydroxylation of the two prolines (HIF1 α P402, P564) in the ODDD compared to the Asn803 of the CAD is not yet fully resolved and it may be that PHDs and FIH are tissue and/or substrate dependent allowing selective regulation.

Crystallographic analysis of FIH has revealed that, like other 2-OG oxygenases, it contains a single Fe(II) coordinated in an octahedral manner. His199, Asp201 and His279 provide side-chains that bind the iron in a facial triad (Fig. 11). The 2-OG cosubstrate binds to the iron in a bidentate manner *via* its 1-carboxylate and 2-oxo groups. In the absence of HIF substrate, a water molecule is also ligated to the metal.

In contrast to many 2-OG oxygenases in which a Ser/Thr residue and an Arg residue (on the eighth strand of the DSBH), bind the 5-carboxylate of 2-OG, in FIH the residues that form electrostatic interactions with the 2-OG side chain are the side chains of Lys214 (on the fourth strand of the DSBH), Thr196 and Tyr145. This and other structural features identify FIH as a member of a distinct subfamily of human 2-OG dioxygenases. Furthermore, since FIH contains a JmjC homology region, the sequence of FIH defines it as one of the jumonji transcription factors. It is of current interest to define the functions of the JmjC proteins that are related to FIH. Members of the JmjC transcription factors family have been implicated in cell growth and heart development and possess a conserved motif present in the 2-OG oxygenases, suggesting that, like FIH and the PHD isozymes, some of them might be iron oxygenases involved in transcriptional regulation or another type of signalling.

Other Protein Hydroxylases

Vitamin K dependent proteins, including some coagulation factors, are modified by post-translational modification at the β -position of specific aspartyl and asparaginyl residues in their epidermal growth factor domains. Although the modified residues may be involved in calcium ion binding, the available evidence suggests that their hydroxylation does not seem to affect their affinity for the metal. The biological significance of these hydroxylations has not been elucidated, and they may be related to signalling since

Enzyme Catalyzed Post-Translational Hydroxylation of Proteins. Figure 9 (i) Schematic of the topology of a double stranded beta helix (DSBH) fold; (ii) An example of the formation of the DSBH motif fold found in most 2-OG dioxygenases. The figure shows the DSBH of FIH.

Enzyme Catalyzed Post-Translational Hydroxylation of Proteins. Figure 10 View from the crystal structure of FIH complexed with the C-terminal transactivation domain of its substrate HIF (in yellow). The double stranded beta helix motif in the centre of the enzyme is coloured in red and the iron is in grey-brown. Note that Asn803 of HIF1 α is adjacent to the iron.

Enzyme Catalyzed Post-Translational Hydroxylation of Proteins. Figure 11 Active site residues of FIH showing the side chains of the Fe-binding residues, Asn803 of HIF which is hydroxylated at its β -carbon and N-oxalylglycine (a 2-OG analogue used for crystallization) binding Fe in a bidentate manner.

EGF-like (epidermal growth factor-like) domain substrates occur in blood clotting factors and other proteins such as Notch. Recent results have showed that EGF Asp/Asn hydroxylase null mice crossed with APCmin, an intestinal tumour model, develop more and larger intestinal polyps than hydroxylase WT/APCmin mice. Although previous work has shown

increased levels of the hydroxylase in some tumour tissues, this finding suggests that loss of hydroxylase function may promote tumour formation.

The EGF hydroxylase has been isolated and shown to be a 2-oxoglutarate oxygenase. Sequence alignments suggest that it probably does not contain the typical $\text{HXD}\dots\text{H}$ motif for iron binding and is likely to form a new structural sub-group. The substrate selectivity of the human epidermal growth factor hydroxylase contrasts with FIH since it accepts both Asp and Asn residues within sequence motifs as substrates, whereas FIH is limited to the latter.

Hydroxylation of C-Terminal Peptidyl Glycine Residues During Amidation

Protein hydroxylation is also involved in signalling pathways mediated by peptide hormones and neurotransmitters due to the prevalence of C-terminal amides in these molecules. Amidation is effected in a two-stage process originally thought to involve a one step mechanism but now known to require two catalytic domains within a bifunctional enzyme. The enzyme is known as peptidyl glycine α -amidating monooxygenase (PAM) and consists of two separate catalytic units: peptidyl glycine α -hydroxylating monooxygenase (PHM; EC 1.14.17.3), which converts the C-terminal glycyl residue to a hydroxyglycyl intermediate, and peptidyl hydroxyglycine N-C lyase (PHL), which cleaves it to produce a C-terminal amide and glyoxylate. The C-terminal part of the protein contains transmembrane and hydrophilic domains. The entire protein is encoded by one gene and the translated precursor protein formed can be processed to form the two subunits by proteolytic cleavage.

Crystal structures of a hydroxylase have revealed two copper ions complexed by separate jelly roll motifs. Like the 2-OG oxygenases, these enzymes use molecular oxygen as a cosubstrate, but do not use 2-OG. Instead they employ two molecules of ascorbate to effect 2-electron reduction of the dioxygen producing a reactive oxidizing species and two molecules of semidehydroascorbate. It is unclear whether the disproportion of semidehydroascorbate to ascorbate and dehydroascorbate is enzymatically controlled (a semidehydroascorbate reductase is known) or non-enzymatic.

There has been interest in PAM due to the stimulation of neuronal survival and olfactory neurogenesis by pituitary adenylyl cyclase-activating polypeptide (PACAP38), an amidated neuropeptide. It was observed that Mottled (Brindled) mice lacking a functional ATP7A copper transporter (hence providing a partial loss-of-function PAM knockout) had reduced levels of amidated PACAP and a concomitantly decreased number of olfactory neurons. Other neurotransmitters that rely on C-terminal amidation for their biological activity include adrenomedullin, galactin and allatostatin.

Enzyme Catalyzed Post-Translational Hydroxylation of Proteins. Figure 12 C-Terminal amidation of peptide hormones and neurotransmitters. The first step is abstraction of the *pro-S* hydrogen from α of the glycyl residue, followed by hydroxylation. The second step of the process comprises cleavage of the hydroxylated peptide to yield a C-terminal amide and glyoxylate.

Future Prospects

Until recently protein hydroxylation was thought to be a relatively specialized structural post-translational modification with the only widespread example occurring in collagen biosynthesis. The recent discovery of the role of protein hydroxylation in the HIF signalling pathway and its role in C-terminal amidation, combined with genomic analyses has raised the possibility that post-translational hydroxylation may be much more widespread than once thought. Whilst it is probably unlikely that the extent of post-translational hydroxylation will rival those of phosphorylation or glycosylation, it seems probable that, as with acetylation and methylation, protein hydroxylation will play an extensive role in signalling pathways. To date the comparative lack of studies on hydroxylation and other oxidative modifications including desaturation may reflect the lack of appropriate methodology for their detection, a problem that is being addressed by modern proteomic techniques.

Clinical Relevance

Clinical Relevance of Collagen Hydroxylation

Scurvy is a famous connective tissue disease with symptoms including haemorrhaging due to capillary degradation, breakdown of dentin and gum tissue (leading to loosening and loss of teeth) and joint pain. Unlike specific diseases associated with lysyl-5-hydroxylase (see below), the underlying cause of scurvy is deficiency of ascorbic acid (vitamin C) which causes procollagen prolyl-4R-hydroxylase to malfunction leading to a lack of mature collagen. Scurvy is treated directly by ascorbate or by application of a diet rich in ascorbate. The latter approach was famously undertaken by the British Navy upon the advice of

Sir Gilbert Blane in the 18th Century, following observations by James Lind that a daily ration of lemon juice was effective in combating scurvy.

Several subtypes of Ehlers-Danlos syndrome involve defects in collagen, and they occur at a frequency of *ca.* 1 in 20,000 people. Ehlers-Danlos syndrome Type VI is an autosomal recessive connective tissue disease with symptoms including muscular hypotonia and ocular problems. It is characterized by defects in collagen and is caused by mutations to procollagen lysyl-5-hydroxylase leading to deficient hydroxylation of lysine residues in tissue collagens, particularly those of the skin. The ratio of collagen cross-linking amino acids, hydroxylysyl pyridinoline and lysyl pyridinoline is biased towards the latter in Ehlers-Danlos syndrome Type VI patients and an abnormal ratio is used to diagnose the condition. Vitamin C has been tried as a therapy for the treatment of Ehlers-Danlos VI but, while in some cases it may be effective, it is not a standard treatment. Vitamin C stimulated production of pyridinoline and deoxypyridinoline in fibroblasts from patients with EDS VI has been observed and may reflect the stimulation of the activity of an alternative lysyl hydroxylase activity or that some mutations only partially inactivate the known procollagen lysyl-5-hydroxylase.

Bruck syndrome, also associated with lysyl hydroxylase, is a very rare genetic disease, the symptoms of which include bone fragility due to aberrant bone collagen formation. Bruck syndrome is associated with a deficiency in a telopeptide bone-specific lysyl hydroxylase (TLH), which has recently been identified as PLOD2, one of the lysyl hydroxylase isoforms, by identification of two missense mutations in exon 17 of the gene encoding PLOD2. There is also evidence that increased mRNA levels of PLOD2 correlate with

the increased crosslinking of collagen observed in fibrotic diseases and hence the link between hydroxylation and disease states is beginning to be understood. Chronic fibroses of major organs, commonly occurring after tissue damage, are significant clinical problems ranging from skin disfigurement to liver cirrhosis and can lead to progressive disability and death. For many of these diseases there are no effective therapies. These diseases characteristically involve overproduction of extracellular matrix material (such as collagen) and hence the specific inhibition of collagen hydroxylases may be a viable therapy. The inhibition of enzymes that are responsible for collagen biosynthesis and its regulation are thus of pharmaceutical relevance. Significant efforts have been made to produce inhibitors of collagen hydroxylases, in particular procollagen prolyl-4R-hydroxylase. As yet no compounds are in clinical use and the side effects of inhibiting the biosynthesis of mature collagen may be significant.

Clinical Relevance of HIF Hydroxylases

von Hippel-Lindau disease is a heritable cancer syndrome associated with a germline mutation of the VHL tumour suppressor gene on the short arm of human chromosome 3. It occurs in about 1 in 36,000 live births and its inheritance leads to a high individual risk of disease involving various benign and malignant tumours of the central nervous system, kidneys, adrenal glands, pancreas and reproductive organs. Although other factors may be involved, the lack of pVHL in patients is thought to disrupt the degradation of HIF α via the PHD/pVHL pathway leading to an uncontrolled hypoxic response. In VHL disease sufferers, the regulatory action of FIH may be disproportionally important and boosting FIH activity, e.g. *via* gene or protein therapy, may be a possible avenue for therapeutic evaluation. Levels of HIF α are increased in ischemic tissues and other diseased tissues including the pre-eclamptic placenta, the hypoxic retina and inflamed joints. Stimulation of the natural HIF mediated response may be useful in the treatment of important diseases including limb ischemia, heart attack and stroke. Regions of tissue that have died or are compromised as a result of oxygen starvation (e.g. after ischemic insult such as a heart attack) could potentially be revascularised *via* stimulation of HIF mediated transcriptional activity. Additionally, up-regulation of HIF activity may be used to induce expression of hypoxically regulated genes of medicinal importance such as **erythropoietin**, a recombinant form of which is currently used on a widespread scale for the treatment of anaemia. Perhaps the most attractive target for stimulation of the HIF activity is small molecule mediated inhibition of the PHDs and FIH, but

alternative targets for small molecules include blocking the interaction between HIF1 α and pVHL.

Modulation of the HIF system is also a potential target for cancer treatment. Growing tumours characteristically contain an oxygen tension gradient due to poor vascularisation and resulting regions of hypoxia within the tumour. As a consequence HIF α levels can be up-regulated to enable vascularisation of the tumour. Inhibition of the HIF transcriptional activity may thus be useful in the treatment of tumours. This might be achieved by small molecule mediated blocking of the interaction between HIF and p300 or gene therapy approaches that modulate the activity of the HIF system including the use of the HIF hydroxylase genes.

Enzyme Linked Immuno-Sorbent Assay

►ELISA

Enzymes

Definition

Enzymes are complex proteins produced by living cells, which promote a specific biochemical reaction by acting as catalysts. Enzymes accelerate, enable or control chemical reactions in living systems without being consumed in the reactions. Enzymes are typically composed of a protein part (apoenzyme) which confers specificity, and a nonprotein part (coenzyme) which is necessary for activity.

Epidermal Growth Factor Receptor

Definition

Epidermal growth factor receptor (EGFR) refers to a transmembrane glycoprotein receptor of 170 kD (also called HER1/ErbB1) which belongs to the EGFR family of receptors, containing an intracellular tyrosine kinase domain. It can be activated by various ligands including epidermal growth factor (► [EGF](#)) and transforming growth factor- α (TGF α).

Epidermis

Definition

The epidermis is the outermost, keratinizing layer of the skin and provides the first barrier of protection from the invasion of foreign substances into the body. The principal cell of the epidermis is the ► [keratinocyte](#). The epidermis is subdivided into the basal layer, the spinous layer, the granular layer and the cornified layer. Only keratinocytes in the basal layer are able to proliferate, subsequently they gradually migrate from the bottom to the surface, thereby losing their proliferation capacity. The dead cells are finally sloughed off. This process is called terminal differentiation.

Epidermolysis Bullosa (Simplex)

Definition

Epidermolysis bullosa (EB) is a group of genetic skin disorders, in which the tissue is rendered fragile by the presence of mutations in one of a range of structural proteins that normally contribute to the resilience of the skin. Clinically, they all show splits or breakdown of the epidermis (epidermolysis) with fluid-filled blister formation (bullosa). They are distinguished microscopically by the plane of cleavage of the skin. Epidermolysis Bullosa simplex (EBS) shows an intra-epidermal split, and is caused by mutations in basal cell keratins. Junctional EB splits within the basal lamina due to mutations in laminin 5 genes or basal cell integrin genes. Dystrophic EB (the most serious type) shows a sub-epidermal split below the basement membrane, and is caused by mutations in type VII collagen.

Epigenetic (Epigenetics)

Definition

Epigenetic describes any modification of gene activity during development of the organism from the fertilized

egg to the adult without directly affecting its DNA sequence. An epigenetic modification may indirectly influence the expression of the genome. Epigenetic changes can, for instance, be caused by DNA methylation, chromatin remodeling, the inactivation of one X chromosome in females, or by gene silencing processes (epigenetic silencing). Epigenetic changes that occur in somatic cells are difficult to distinguish from rare mutations at the genetic level.

“Epigenetics” aims to describe heritable changes in gene function that occur without a change in the sequence of the DNA.

Epigenetic Determinants

Definition

Epigenetic determinants are factors that are inherited, but not coded for, in the DNA.

- ▶ [Centromeres](#)

Epigenetic Modification

Definition

Epigenetic modification denotes a covalent modification of the protein, or the DNA that composes the chromatin, but is independent of the DNA sequence. The known modifications include acetylation, methylation, phosphorylation, poly(ADP-ribosylation), and ubiquitination. The usual targets are histones, but DNA can also be modified by methylation. Epigenetic modifications influence the stability of the chromatin. These marks differentiate the active and inactive genes in the genome, and play a role in the transmission of the activity of the genes during cell division. Epigenetic marks are sometimes heritable even through meiosis.

Epiglottis

Definition

Epiglottis describes a thin cartilaginous flap that covers the entrance to the larynx during swallowing, and prevents food from entering the trachea.

- ▶ [Bone and Cartilage](#)

Epiphysis

Definition

Epiphysis designates the ends of the long bones.

- ▶ [Bone and Cartilage](#)

Epistasis

Definition

Epistasis refers to the interaction of genes, where particular alleles of one gene interfere considerably with the phenotypic expression of other genes. A gene is said to be epistatic when its presence suppresses the effect of a gene at another locus.

Epistasis Group

Definition

Epistasis group comprises of a group of genes that operate in the same pathway. Classification of genes in epistasis groups is based on the analysis of single and double mutant strains. If the phenotype (e.g. increased sensitivity to ionizing radiation) of the double mutant is the same as that of the single mutants, the two genes are assigned to the same epistasis group. When the double mutant shows additive or synergistic effects relative to both single mutants, the genes are placed in different epistasis groups.

Definition

Cystic Fibrosis

Cystic fibrosis (CF) is the most frequent lethal inherited disorder among Caucasians, having a ►prevalence of 1:2,500 newborn; it is inherited as an autosomal recessive trait. The prevalence of ►carriers in the population is about 1:25. The disease is due to alterations in the cystic fibrosis transmembrane regulator (►CFTR) protein (1). The protein is encoded by the *CFTR* gene that maps on chromosome 7q31.2, contains 27 ►exons and encompasses 230 ►kb. The heterogeneous clinical expression of the disease seems to be modulated by genes that could exert epistatic effects and that are inherited independently of the *CFTR* gene (1).

Epistasis

The term “epistasis” was coined by Bateson, about a century ago (2). When expressed as a specific allelic variant, an epistatic locus/gene “masks” the alleles of another locus/gene. Epistasis has recently been reviewed particularly as regards the statistical procedures used to evaluate its effect in humans (2). The clinical expression of various genetic diseases seems to be influenced by the epistatic interaction of genes; the most notorious example is inhibition of “sickling” in homozygotes for sickle cell anemia, exerted by the alpha thalassemia concomitant genotype (3). Epistasis is also involved in such other diseases as diabetes and immune deficiencies.

Characteristics

Modifier Genes of the CF Phenotype

More than 1,000 *CFTR* gene mutations have been detected in CF patients. About 85% of CF patients have ►pancreatic insufficiency; the pancreatic status of CF patients depends on the *CFTR* mutation and a set of

mutations specifically associated to pancreatic insufficiency has been identified (1). In contrast, there is no general consensus about correlations between the *CFTR* genotype and the pulmonary, liver and gastrointestinal expression (►meconium ileus) of the disease. A different clinical expression of the disease has been observed in CF patients bearing the same *CFTR* genotype and in patients who are homozygotes for nonsense mutations (1). Furthermore, a discordant ►phenotype has been observed in CF siblings (1, 4). These data suggest that environmental factors do not play a major role in CF and that epistatic genes other than *CFTR* modulate the CF phenotype (1). A locus that modulates gastrointestinal expression was identified in mice and subsequently in humans. We suggested that this locus had a dominant effect in 9 CF patients discordant for meconium ileus (1). Among the putative epistatic genes of CF pulmonary expression, genes encoding proteins of the surfactant layer of the respiratory apparatus may play a relevant role. Antimicrobial proteins, e.g., human beta defensins 1-2 (hBD1 and 2), lactoferrin, lysozyme, histatin and cathelicidin are salt-sensitive antibacterial peptides of the airway layer that are said to belong to the innate immune system. Thus, the severity of lung expression in CF and the susceptibility of these patients to opportunistic infections could depend on the levels of sodium and chloride in the airway layer. However, findings about sodium and chloride levels at the airway surface of CF patients are discordant and other studies, possibly with more standardized techniques, are necessary to resolve this issue. The beta-defensins (hBD) 1-4 have been proposed as modulators of airway infections in CF patients. These small salt-sensitive peptides are expressed at normal levels in sputum from CF patients, but hBD2 was found to be enhanced in the bronchoalveolar fluid of CF patients. This suggests that hBD2 expression can be induced by inflammation, whereas hBD1 appears to be involved in the innate defense system and is expressed independently of bacterial stimulation. Beta-defensin antibacterial activity depends on the levels of salt in the medium. Thus, it is possible that these proteins are normally secreted but their activity is reduced in CF patients. In a collaborative study led by Dr. J.J. Cassiman in Leuven, we recently demonstrated (unpublished data) a higher rate of ►polymorphisms in *hBD1*, 2 and 4 genes in both CF patients and normal subjects as compared with most other human genes. We are now examining these polymorphisms in relation to the biological activity of beta-defensins and to the pulmonary phenotype of CF patients. More recently, a study of 34 CF sibling pairs (4) with a discordant or concordant clinical expression revealed a novel locus at the 3' end of the *CFTR* gene that could modulate the CF phenotype (stature, food intake and energy homeostasis). Genes involved in local

innate and adaptive immunological defense and inflammation could also act as epistatic genes in CF patients. A severe pulmonary expression was observed in CF patients bearing anti *P. aeruginosa* IgG3 polymorphisms associated with high protein expression and in CF patients with a polymorphic allele in the promoter region associated with enhanced production of the pro-inflammatory cytokine TNF-alpha. The latter allele is also associated with an increased risk of chronic bronchitis in non-CF patients. Pulmonary oxidative stress plays a relevant role in the pathogenesis of lung damage in CF patients. *Glutathione transferase* is involved in detoxifying hydroperoxides resulting from oxidative stress and gene polymorphisms associated with low levels of the enzyme thereby give rise to a more severe pulmonary phenotype in CF patients. A more severe pulmonary expression was reported in CF patients who expressed a polymorphic variant with low levels of mannose binding protein, a lectin involved in bacterial [opsonization](#) and [phagocytosis](#).

A body of evidence suggests that epistatic genes also influence the risk of liver expression in CF patients. Mutations of the *mannose binding lectin* gene are associated with a higher risk of severe liver disease in CF patients. In a multicenter study led by Dr. K. Friedman (1), we found that Z or S mutations of the *alpha-1 antitrypsin (A1AT)* gene confer a 3- to 7-fold higher risk of severe liver disease in CF patients.

Alpha-1 antitrypsin has been implicated in the pulmonary expression in CF patients. A better pulmonary function was reported in CF patients bearing the S and Z alleles of the *alpha-1 antitrypsin* gene, but the study was biased because it did not include CF patients who had died in early childhood from severe pulmonary disease (1). The same group of researchers retrospectively analyzed DNA from blood spots of CF patients who had died in early childhood from severe pulmonary disease and confirmed that A1AT deficiency is not associated with a more severe pulmonary disease (1). Finally, a less severe pulmonary phenotype was described in CF patients bearing polymorphisms of the A1AT enhancer. These data contrasted with the higher risk of opportunistic colonization reported in CF patients carrying mutations of the *A1AT* gene, although the pulmonary expression of the disease was not significantly different. Thus, multicenter studies of large numbers of CF patients are required to establish the role of *A1AT* as a modulator of the lung phenotype.

Cellular and Molecular Regulation

CFTR Gene and Mutations

Protein CFTR is an anion channel protein belonging to the [ATP-binding cassette \(ABC\) transporter](#) family, and is widely expressed at the apical side of cells bearing polarized [epithelia](#) involved in secretory/absorption

activities. The anion channel acts as a regulator of chloride levels across the cell membrane and may be involved in the regulation of other membrane conductance pathways. CFTR is activated by beta-2 adrenoreceptor stimulation followed by cAMP activation. *CFTR* mutations are grouped into four classes based on the molecular alteration at the protein level. Class 1 mutations (i.e., nonsense mutations, frame-shift mutations due to deletions or insertions and mutations that cause altered splicing) typically alter protein synthesis. The *CFTR* W1282X, R553X and G542X class 1 mutations each have a frequency of >2.0% among CF chromosomes within most populations studied. Class 2 mutations (including DF508, the most frequent *CFTR* mutation) alter *CFTR* protein processing. The protein is mostly degraded in the endoplasmic reticulum; it does not reach the epithelial membrane to express its normal function. Class 3 mutations include G551D, which is frequent in Northern Europe. These mutations affect the regulatory domains of the *CFTR* protein. Class 4 mutations (usually missense mutations) alter the ionic conductivity of the chloride channel and so reduce the time of channel opening and ionic flux. In summary, mutations of different classes produce different effects on the *CFTR* protein: class 1 and 2 mutations have a more dramatic effect because they are related to the absence or to an altered localization of the *CFTR* protein, whereas class 3 and 4 mutations are associated with residual *CFTR* activity. However, as previously indicated, the genotype-phenotype correlation in CF patients is not clear and epistatic genes are probably involved in modulation of the clinical expression of CF. In any event, the altered protein usually causes dense mucous epithelial secretions and thus a clinical expression that typically involves the gastrointestinal tract with the pancreas and liver, the pulmonary apparatus and the reproductive tract.

CF Polymorphisms

Several *CFTR* gene polymorphisms have been related to reduced synthesis of the channel protein. A case in point is IVS8 poly T, in which the 5T allele gives rise to alternative splicing of the mRNA. The 5T allele is more frequently observed in patients bearing atypical CF forms, where the prevalent clinical expression concerns the reproductive system and in patients with only chronic pancreatic insufficiency or symptoms not related to the main pulmonary or gastrointestinal system. In addition, third-base polymorphisms (not producing changes in the amino acid) within the coding regions of the *CFTR* gene could derange the splicing and thus reduce the levels of the *CFTR* protein (5).

Clinical Relevance

Clinical cases of CF range from death in early infancy from meconium ileus or respiratory complications to a mild form of the disease where patients live into their

40s. Pulmonary, liver and gastrointestinal expression (meconium ileus) can be observed in CF patients. Respiratory expression is responsible for about 95% of CF mortality, but the severity of pulmonary expression varies among patients. Pulmonary expression is typically due to mucous obstruction and recurrent infections resulting from the altered mucous composition and the consequent reduced mucociliary clearance. Several opportunistic bacteria gradually damage the lungs, essentially by stimulating the release of proteinases. Pulmonary function tests, i.e. forced expiratory volume (FEV) and forced vital capacity (FVC), are used to monitor pulmonary function in CF patients and to classify the severity of CF expression. The prevalence of liver involvement in CF patients ranges from 4.0% to 25–30%. The pathogenesis of liver expression is not clear, but intrahepatic biliary ducts are probably obstructed by inspissated bile, gradually leading to hepatic fibrosis and focal biliary cirrhosis. Multilobular cirrhosis with portal hypertension occurs in only 2–7% of CF patients. Biochemical markers have little predictive value for the development of severe liver disease in CF patients and specific CFTR mutations have not been linked to this outcome. Consequently, it is not yet possible to predict which CF patients will develop severe liver disease. Meconium ileus is present in 15%–20% of CF patients. It could be due to the dehydration of fetal intestine. The distal intestine obstruction syndrome (DIOS), present in about 5% of CF patients, is considered to be an adult equivalent of meconium ileus. Attempts have been made to relate the occurrence of meconium ileus or DIOS to the CFTR genotype but the question is still open. The data reported herein suggest that a number of epistatic genes contribute to produce the highly varied CF phenotype. The study of these genes could have an impact on the prognosis and care of CF patients, i.e. patients at high risk for pulmonary or liver expression could be monitored and treated with specific therapies before irreversible damage is produced. Multicenter studies on large numbers of cases with homologous genotypes and well-defined phenotypes will give more reproducible and definitive data.

Epithelia

Definition

Epithelia are the sheet tissues of the body surrounding organs and lining body cavities. They are single layered (simple epithelia) or multilayered (stratified) and have no intraepithelial blood vessels. Epithelia are clearly polarised, bounded on one side by an acellular space, and on the other side by a specialised carpet of ►[extracellular matrix](#) that defines their orientation. By definition, they occur at interfaces between two dissimilar environments, and the cells in epithelia are usually steadily turned over. Cells are held together by ►[adherens junctions](#) and ►[desmosomes](#), which are connected across each cell's cytoplasm by actin and keratin filaments.

boulan@med.cornell.edu

Definition

An epithelium is a layer of cells that lines body cavities and tubular structures and forms a physical barrier between the organism and the external world. Epithelial cells are tightly packed into two-dimensional sheets, which rest on basement membranes. A major subdivision is into stratified (e.g. skin) and simple epithelia. A distinguishing feature of simple epithelial cells is the polarized phenotype, i.e. the apical or luminal surface is structurally and functionally distinct from the basolateral or serosal side. By virtue of their specialized intercellular junctions, epithelial cells form selective permeability barriers between tissue compartments and maintain cellular homeostasis. Epithelia play a crucial role in tissue and organ morphogenesis during embryonic development. Based on their predominant functions, simple epithelial cells can be classified into absorptive (kidney tubules and intestine), exchange (lung and capillary endothelium), secretory (hepatocytes and cells of the thyroid gland and pancreas) or protective (skin). The rest of this article will deal with simple transporting epithelia.

Characteristics

Polarized epithelial cells are characterized by a) specialized intercellular junctions, b) cohesive interactions between the cells and the basement membrane,

c) asymmetric distribution of cytoskeletal elements and d) differential sorting of proteins to the apical and basolateral plasma membranes. Figure 1 depicts a simple transporting epithelium and the organization of a polarized epithelial cell.

Intercellular Junctions
