A proteomics strategy of increasing importance is the systematic analysis of protein localisation in cells. A proteome scale localisation study has been performed in *S. cerevisiae* by immunolocalisation of epitope-tagged proteins (29). These experiments established the subcellular localisation of 2,744 proteins, 955 of which were of unknown function. The results obtained by this systematic analysis were integrated with previously published data and supported the thesis that there is a high correlation between protein function and localisation in yeast. Using GFP-tagged proteins, large-scale localisation studies were also performed for *S. pombe* (10) and *Drosophila* (36). Moreover, this approach was used to study the subcellular localisation of proteins in mammalian cells (54). In the future, protein localisation studies of cells will be fully automated. They will yield important insights into the subcellular organisation of cells and the interplay of proteins on a molecular level.

Protein-Protein Interactions

Besides quantity and subcellular localisation, the interactions of any given protein with other proteins provide useful insights into its function. Systematic analysis of protein-protein interactions is a key proteomics approach that will lead to a better understanding of how organisms develop, function, reproduce and age. The generation of interaction networks will also lead to the identification of new drug targets and therapeutic strategies.

Isolation and Characterisation of Protein Complexes

One attractive way of studying protein-protein interactions is to purify whole protein complexes from cell extracts by affinity chromatography (48). This can be achieved with affinity chromatography tags such as glutathione S-transferase (GST), antibodies, DNA, RNA or small molecules that specifically bind to a cellular target protein.

The human spliceosome has been purified in this way using biotinylated RNA as a “bait” (5). Its components were displayed by 2D gel electrophoresis and 19 new factors could be identified. Co-localisation studies with IF microscopy confirmed that many of the proteins were indeed associated with the spliceosome in cells. Another approach uses GST fusion proteins for the isolation of protein complexes from cell extracts. The

multi-protein complex associates with the bait, which is immobilised on beads *via* the GST tag. After washing, the complex is eluted, separated by gel electrophoresis and analysed by mass spectrometry. In a single experiment, many different components of a protein complex can be identified. Using this approach, a combination of proteins containing huntingtin, clathrin and α -adaptin was affinity purified using GST-HIP1 protein and functionally characterised by cell biological methods (59). Furthermore, epitope tagged protein, can be over-expressed in a cell. The protein is then immunoprecipitated with its interaction partners attached, by an antibody that recognises the epitope (60). This approach requires an expression clone, but no time needs to be spent on the generation of a specific antibody against the bait protein. Because full-length cDNAs for many human genes are already available, this approach will allow the systematic analysis of many unknown human protein complexes in the near future.

The analysis of protein complexes opens new lines of functional investigation. For example, a proteomics study of profilin I and II affinities using chromatography/mass spectrometry resulted in the identification of unknown signalling molecules that regulate actin polymerisation and participate in endocytosis (64). The affinity chromatography/mass spectrometry procedure was also used for systematic analysis of the entire yeast proteome (15). Tandem affinity purification (**▶TAP**) was employed to purify 589 protein complexes and determine their compositions. Comparison of yeast and human protein complexes showed conservation across species and allowed the generation of elaborate protein-protein interaction networks. Similarly, a physical and functional map of 221 molecular associations of the TNF- α /NF- κ B signalling transduction pathway was generated very recently (7).

Two-hybrid System

The **▶yeast two-hybrid** (Y2H) system has been shown to be a powerful tool for the study of protein-protein interactions (13). It is based on the molecular structure of transcription factors. Close proximity of the DNA binding domain (DBD) to the activation domain (AD) induces transcription of target genes. Proteins fused to a DBD and an AD are coexpressed in yeast. If they interact, growth (HIS3) and colour (LacZ) reporters are activated. By monitoring the growth of yeast clones on selective plates and assaying β -galactosidase activity, protein-protein interactions can be identified on a large scale. Currently, the Y2H system is used in an array based format and a library format. In the array method, yeast

clones expressing AD and DBD fusions are spotted onto selective plates and the proteins to be tested for potential interactions are screened against the entire grid by interaction mating (17). Once established, this procedure is cheap, fast and results in highly reproducible results. In the library method, one set of proteins (e.g. the AD fusions) is pooled to generate a library and the library is then screened against the DBD fusions of interest to detect protein-protein interactions. This method is relatively time consuming and requires the repeated sequencing of prey clones after each library screening experiment. Using the Y2H system, genome scale protein-protein interaction studies for *S. cerevisiae* (57), *C. elegans* (32) and *Drosophila* (16) have been performed. For the mapping of yeast interactions, both the library and array approaches were used and approximately 5,000 interactions were detected (57). The vast majority of the interactions found by Y2H screening were new. Bioinformatic analysis confirmed a certain number of the Y2H interactions on the basis of data from previous genetic and biochemical studies. However, the relevance of many others cannot be easily determined. Thus, Y2H studies allow the identification of potential interactions that have to be verified by other methods and functional assays. The main advantage of the Y2H system is that it can be performed with high throughput and in an automated manner. In the future, it will allow the generation of comprehensive interaction networks for many prokaryotic and eukaryotic organisms.

Protein Arrays and Phage Display

Protein arrays are not only a powerful tool to quantify the amounts of specific proteins in cell extracts or body fluids (see Protein Quantification section), they can also be used for global analysis of protein-protein interactions (47, 67). For interaction studies for example, 5,600 purified yeast proteins were arrayed on glass chips and screened for their ability to interact with proteins and phospholipids. Using this approach, many unknown calmodulin and phospholipid-interacting proteins were identified (67). Similarly, using a protein chip technology, pair-wise interactions among 29 human DNA replication initiation proteins were detected and characterised (47). The advantage of the protein chip approach is that a comprehensive set of individual proteins can be directly screened *in vitro* for a large variety of activities, including protein-protein, protein-DNA, protein-RNA and protein-lipid interactions, under a wide range of different conditions (69).

▶Phage display is a method where bacteriophage particles are engineered to express a peptide or protein of interest fused to a capsid or coat protein (63). It is

very efficient in screening peptide-protein as well as protein-protein interactions. Like the Y2H system, it is simple and can be performed with high throughput. Using this approach, new molecules in the epidermal growth factor (EGF)-receptor signalling pathway (70) and antigen-antibody interactions have been identified (24).

Structural Proteomics

A major challenge for post-genomic research is to assign functions to all proteins from higher eukaryotes. One of the crucial factors in the understanding of the function of uncharacterised proteins is the analysis of their experimental or modelled 3D structures. In recent years, different structural proteomics initiatives were initiated for high throughput investigation of protein structures (50). Currently, the techniques mainly used for large-scale structure determination are ►X-ray crystallography and ►nuclear magnetic resonance (NMR). Both techniques can reveal the three-dimensional structure of proteins and other biomolecules in atomic detail. X-ray crystallography uses a beam of X-rays striking a protein crystal. The diffracted (scattered) rays are detected by X-ray film. NMR spectroscopy makes use of changes in spin states of atomic nuclei that are exposed to a magnetic field. Upon absorption of electromagnetic radiation of an appropriate frequency, a transition from the lower to the upper spin state occurs. The resonance frequency of a given nucleus depends on the local chemical environment. X-ray methods give the highest resolution, but crystals are required. NMR methods, in contrast, are effective with proteins in solution, but highly concentrated solutions (~1 mM) are needed. Furthermore, NMR provides a wealth of information about dynamics. Thus NMR and X-ray techniques nicely complement each other in structure analysis. Moreover, cryo electron crystallography techniques are applied to study membrane structures. These techniques use electrons for diffraction. Since electrons are diffracted much more strongly than X-rays, very thin crystals can be studied. Accordingly, cryo electron crystallography has been applied to extremely thin, so-called two-dimensional crystals. Using this technique mainly membrane bound proteins as well as ribosomal proteins have been analysed (61).

Currently, about 16,500 structures have been deposited in public databases; however, only 300 of them are of human origin. This is due to the difficulty of human protein generation *in vitro*. Structure determination relies heavily on the high throughput production of soluble, folded proteins. Systematic expression studies have shown that only a fraction of all human proteins (20%) can be produced in soluble form in

E. coli (8). Thus, the challenge for all structural proteomics initiatives lies in the efficient production of biologically active proteins that can be used for 3D structure determination.

The knowledge of the molecule structure is a starting point for several applications, such as “►structure-based drug design”. In this iterative design process, small molecules are optimised to fit precisely into the binding site of the protein that is critical for the protein function.

Clinical Proteomics

Despite considerable advances in our understanding of the molecular basis of diseases such as cancer, substantial gaps remain in our knowledge of disease pathogenesis and the development of effective strategies for diagnosis and treatment. Proteomics approaches are used to investigate disease mechanisms and help to close these gaps. Particularly promising areas of research are altered protein expression (not only in whole cells, but also in subcellular structures), the study of protein complexes in biological fluids, the development of biomarkers for early diagnosis and the identification of new targets for therapeutic intervention.

Disease Expression Profiling

In many studies in past years, 2D gel electrophoresis was used to study protein expression in disease states. Using this approach, it has been demonstrated e.g. that leukaemias can be classified into different subtypes (22). Comparison of the protein profiles of normal human and myoepithelial breast cells allowed the detection of 170 protein spots that are differentially expressed (41). Moreover, 2D gel electrophoresis and mass spectrometry allowed the identification of proteins that are critical for the acute onset of heart disease (4).

An important recently made improvement in the 2D gel approach is the use of DIGE (see Protein Quantification section). In one study, DIGE was applied to quantify the differences in protein expression between oesophageal carcinoma and epithelial cells and a large number of proteins were found to be either up- or down-regulated in cancer cells (65). So far, mainly the most abundant proteins can be separated and analysed with 2D gels. The major challenge for future application is to reduce sample complexity prior to protein analysis. Subcellular fractionation, for example, might allow the proteome analysis of cell organelles, while protein complexes of low abundance might be enriched significantly by affinity chromatography techniques. An elegant demonstration of subproteome analysis is

the 2D gel based analysis of phagosomes, which led to the identification of over 250 proteins from this organelle (14).

One major drawback of 2D gel disease expression profiling is that it requires a relatively large amount of protein for analysis. Clinical samples especially, are generally obtainable only in limited amounts. Laser capture micro-dissection for instance, which allows defined cell types to be isolated from tissues, yields protein amounts too small to be analysed by 2D gels. Such samples need to be screened for protein expression changes using analytical protein microarrays (see Protein Quantification section).

Currently, microarray profiling studies of disease tissues are beginning to emerge. Knezevic et al. (2001) for example, analysed protein expression changes in carcinoma tissue by an antibody array approach. Using laser capture micro-dissection, specific cellular populations were studied. Differences in the expression patterns of various proteins that correlate with tumour progression were identified in epithelial cells. Most proteins were found to be involved in signal transduction pathways (27). Pawletz et al. (2001) used a reverse-phase protein array approach to quantify tissue proteins. In this, protein extracts are spotted onto microarrays and proteins of interest are quantified with antibodies. It was found that cancer progression is associated with phosphorylation of serine/threonine kinase Akt and decreased phosphorylation of extracellular signal-regulated kinase (ERK).

Another clinically relevant application of microarrays is the identification of proteins that induce an antibody response in autoimmune disorders (49). Protein arrays were incubated with patient serum and fluorescently labelled secondary antibodies were used to detect autoantibody binding to specific protein antigens in rheumatoid arthritis. Such protein arrays are powerful tools to study immune responses in a variety of diseases, including cancer.

Disease Biomarkers

There is substantial interest in applying proteomics methods to the identification of disease markers. Approaches include comparison of protein expression in healthy and diseased tissue, analysis of secreted proteins and direct serum profiling. Ostergaard et al. (1999) for example, have found the putative urinary marker psoriasin, which can be used to follow patients with bladder squamous cell carcinomas by 2D gel electrophoresis. A technology much used at the moment for serum analysis is surface enhanced laser desorption/ionisation mass spectroscopy (56). In this method, microlitre quantities of serum are applied to a protein binding surface and bound proteins/peptides

are analysed by MALDI-MS. Peptide patterns that differ between cancer patients and healthy individuals have been reported for several cancers using this method (45). Another very productive approach for the identification of cancer markers has been the analysis of serum for autoantibodies against tumour proteins. A number of antigens have been detected by screening of expression libraries with patient sera (21) or by using a random peptide-library approach (Mintz et al., 2003). Multiple proteins that induce autoantibodies have also been identified by using 2D gels to separate tumour proteins (30).

Various strategies are currently in use to identify protein complexes and protein-protein interactions (see Protein-protein Interaction section). However, these approaches have not yet been applied extensively to identify disease modulators and biomarkers. Using the two-hybrid system, a network of more than 180 interactions has recently been generated for Huntington's disease. Based on the resulting information, a potential modulator of disease pathogenesis has been identified (17). This suggests that interaction studies of diseases may lead to the identification of potential drug targets and novel biomarkers.

Proteomics and Drug Development

At present, the pharmaceutical industry is very interested in integrating modern proteomics technologies into their research programs to increase output in drug target research and lead compound development. Several studies illustrate the application of functional proteomics for identification of potential drug targets in specific signalling pathways. Lewis et al. (2000) for example, detected proteins regulated by the mitogen-activated protein kinase kinase (MKK)/ERK cascade using functional proteomics methods. Twenty-five targets were identified, only five of which had been previously characterised as MKK/ERK effectors. In another project, proteases potentially suitable for drug development have been identified in a microtitre plate-screening assay. Colorectal carcinoma biopsies were searched for protease activity and higher levels of metalloprotease expression were detected in tumours as compared to control tissue (35).

Outlook

Proteomics provides a powerful set of tools for the large-scale study of protein function. In particular, high throughput analysis of gel separated proteins by mass spectroscopy will lead to a better understanding of functional complexes and their modifications in a physiological context. We predict that proteomics in the future will move away from expression analysis

by 2D gel electrophoresis to more sensitive techniques such as protein arrays, which will allow fast and reliable quantification of small amounts of proteins in diseased and control tissues. We also suggest that systematic and hypothesis-driven protein-protein interaction, co-immunoprecipitation and co-localisation studies will be central to proteomics research in the next ten years. These studies will provide a wealth of new information concerning signalling cascades and functional protein complexes, which will have a very high impact on biological science. Because full-length cDNAs for all human proteins will be available soon, systematic proteomics studies in the coming years will focus on the human proteome. The understanding of complex physiological processes in a cell will feed into systems biology, where new hypotheses can be tested by traditional proteomics and genomics methods as well as by computational approaches.

the ratio between the rates of translation and degradation of specific proteins changes, modifying the half-life and/or the total amount of these proteins. Proteins with increased half-life become prone to post-translational modifications such as glycation, oxidation or phosphorylation; cell-signaling cascades are regulated through phosphorylation/dephosphorylation. Age-induced modifications will change the ratios between the various isoforms of a protein and reshape the network of interactions between signaling proteins, affecting gene expression in turn. Proteomics in ageing allows the detection and quantification of various proteins isoforms, based on discrimination by 2DGE and/or MS.

Characteristics

Proteomics and *In Vitro* ▶ Replicative Senescence

Human diploid fibroblasts (HDFs) divide a finite number of times in culture, counted in terms of cumulative population doublings (CPDs). Replicative senescence (RS) is due to telomere attrition, which can be accelerated by mild ▶oxidative stress. The occurrence of RS has been demonstrated for many cell types excepting embryonic germ cells and the majority of tumor-derived cells. The transcription level of many genes is altered in RS. However there is generally poor correlation between the transcription level and the abundance of the corresponding protein. Several proteomics studies compared extracts of proteins of HDFs at early, intermediate and late CPDs. Extracts of total soluble cytoplasmic, nuclear, membrane-bound and secreted proteins of relatively pure clones of morphotypes were obtained. Spots on 2DGE were found which were specific to each of these clones of morphotypes. The different age-related HDFs have been classified morphologically into 7 types called “morphotypes”. 2DGE gels were also used successfully to compare protein expression of HDFs at increasing CPDs taken from patients with ▶Werner syndrome, an autosomal recessive disease resembling accelerated ageing and from age-matched control patients (1).

Recent proteomics identified many new biomarkers in WI-38 fetal lung HDFs and rat embryo fibroblasts. For instance, the glucose-6 phosphate dehydrogenase level is decreased by 40% while the pyruvate kinase (PK) level is increased by 50% in HDFs, suggesting decreased activity of the pentose phosphate pathway and increased glycolysis. This impinges upon various

cellular functions like ATP production, DNA duplication and antioxidant defense by the glutathione reductase/glutathione oxidase system (2).

Proteomics and Stress-Induced Premature Senescence

Many normal human proliferative cell types (fibroblasts, ▶melanocytes, endothelial cells, retinal pigment epithelial cells, etc.) exposed to stress at subcytotoxic level (UVB, H₂O₂, ethanol, hyperoxia, γ irradiations, homocysteine, hydroxyurea, *tert*-butylhydroperoxide (*t*-BHP), etc.) undergo stress-induced premature senescence (SIPS) (2). SIPS covers the effects observed in proliferative cell types from 48–72 h after subcytotoxic exposure to stress, including irreversible growth arrest. An acceleration of the transition through the sequence of the morphotypes has been observed after exposure of HDFs to repeated subcytotoxic stress with UV, mitomycin C or electromagnetic fields. 2DGE run after isolation of relatively pure clones of HDFs of a given morphotype after repeated stress displayed expression changes similar to those found in RS. However further proteomic comparison indicated that, at the level of protein expression, SIPS and RS are different phenotypes sharing similarities. Thirty proteins with changes of expression level specific or common to SIPS induced by *t*-BHP or ethanol and/or RS were identified. These proteins are involved in energy metabolism, defense systems, maintenance of the redox potential, cell morphology and transduction pathways. In particular, PK was also over-expressed in SIPS. Several isoforms of the antioxidant enzyme peroxiredoxin VI displayed differential expression levels in RS and *t*-BHP-induced SIPS when compared to cells at early CPDs. There were also proteins involved in nucleus structure (1, 2). 5-bromodeoxyuridine (BrdU) and ▶5-chlorodeoxyuridine (CldU) are DNA intercalating agents that induce a senescence-like phenotype, probably due to a change in nuclear matrix structure. Nuclear matrix proteins of HeLa cells cultured with CldU were separated by 2DGE and identified by MS. Since these alterations were observed within 24 h after addition of CldU, these proteins may be involved in an early step of the senescence-like phenotype.

Proteomics and Other Biogerontological Systems

Protein profiling of the human epidermis from the elderly reveals up-regulation of a signature of Interferon-gamma-induced polypeptides that include

manganese superoxide dismutase and the p85 beta subunit of phosphatidylinositol 3-kinase.

Mouse brain proteins were isolated from five regions (cerebellum, cerebral cortex, hippocampus, striatum, cervical spinal cord) at five ages from week 10 to month 24 and separated by 2DGE. Seventeen proteins were differentially expressed in the course of ageing. A mouse brain proteome database was constructed. Another study identified modified crystallins associated with ageing of lens and produced 2DGE proteome maps of crystallins in mouse lens.

Post-translational Modifications of Proteins and Ageing

2DGE can reveal post-translational modifications inducing obvious changes in the molecular weight and/or the isoelectric point of the proteins. Specific modifications can be searched for on 2DGE with specific antibodies, staining or labeling methods. MS allows identifications of amino acids with any modification changing the molecular weight of a peptide such as phosphorylation, glycosylation or oxidation. Phosphoproteins can be enriched by immunoaffinity methods utilizing antibodies recognizing phosphoserine, phosphothreonine or phosphotyrosine (1, 3).

To investigate the occurrence of proteasome structural and functional age-related alterations, 26S proteasome was purified from peripheral blood lymphocytes of 20–63 year-old donors. An age-related decline of 26S proteasome-specific activity was found to be associated with an increased yield of post-translational modifications of proteasome subunits, while proteasome content and subunit composition were unchanged. In particular, some catalytic and assembly subunits of the 20S proteasome were preferentially modified with age by glycosylation, conjugation with a lipid peroxidation product and/or ubiquitination (4).

► ‘Drusen’ are extracellular deposits that accumulate below the retinal pigment epithelium on Bruch’s membrane. Drusen are risk factors for developing age-related macular degeneration (AMD). Liquid chromatography tandem MS analyses of drusen preparations from 18 normal donors and five AMD donors identified 129 proteins. Immunocytochemical studies localized approximately 16% of these proteins in drusen. Oxidative protein modifications were observed in drusen. This supported the hypothesis that oxidative injury contributes to the pathogenesis of AMD and suggested that oxidative protein modifications may have a critical role in drusen formation (reviewed in 3).

Clinical Relevance

Proteomics on *Ex Vivo* Cultivated HDFs

A recent study compared the proteome of *in vitro* cultured dermal fibroblasts from healthy subjects of different ages. The study identified 38 proteins

exhibiting more than three-fold reproducible variations with ageing. This investigation highlighted the role of synthetic and degradative pathways in modulating the whole cell machinery and emphasized that metabolic impairment with age could depend partly on different expression of a number of genes leading to an imbalance among functional proteins.

Molecular Scars and SIPS *In Vivo*

Molecular scars are stress-induced changes in the expression level of specific proteins. They appear several days after stress exposure to stimuli such as chemicals, UV, inflammation, ischaemia-reperfusion or ethanol abuse. The analysis of molecular scars in such conditions could help understand their pathophysiological outcome.

Cells displaying cellular characteristics of senescence are found in atherosclerotic lesions of the coronary arteries from patients who died from ischemic heart diseases, in legs of patients with venous insufficiencies, in the inflammatory context of osteoarthritis, in intestinal metaplasia from the stomach, in arteries subjected to angioplasty, in atrophic nephrons of kidneys of aged rats, in tissue surrounding liver carcinomas and in prostatic hyperplasia (2).

Future of Proteomics in Experimental Gerontology

Proteomics could be extremely valuable in gerontopharmacology and geronto-toxicology especially since the therapeutic efficiency and the possible side effects of drugs might differ greatly with age. Chemical agents can also have long-term effects on gene expression (molecular scars). Proteomics can help to evaluate how the tissues react to a particular drug with increasing age and how to match treatments with individual age classes (1).

Alteration of the mitochondrial proteome and altered mitochondrial function are involved in a variety of degenerative diseases, in heart disease, in ageing and in cancer. Based upon the human genome there are approximately 1,000–2,000 proteins constituting the mitochondrial proteome. Only about 600 mitochondrial proteins have been identified and characterized at the molecular level.

Alternative methods to 2DGE are now being employed, including different MS-based approaches following both one-dimensional SDS-PAGE and gel-free approaches, blue native gel electrophoresis (BN-PAGE), proteome simplification by subcellular fractionation and affinity chromatography (1, 3).

The findings arising from such studies will be stored and processed in gerontology-related bioinformatic databases such as the human genome and proteome resources (5).

Proteomics in Cancer

FRANÇOIS LE NAOUR
INSERM U602, Hospital Paul Brousse, Villejuif,
France
flenaour@vjf.inserm.fr

Definition

The ►**proteome** designates all the proteins expressed by a single cell at a particular moment of its life. Therefore, the proteome is more complex and dynamic than the genome. Indeed, the proteome is characterized by the expression level of the proteins as well as by their partitioning, their post-translational modifications, their molecular associations and by the regulation of their activity. The study of the proteome is called proteomics, which involves a variety of sophisticated techniques and approaches. Proteomics allows the global analysis of the proteome during physiological or pathological processes.

Cancer is a somatic genetic disease. Tumorigenesis is a multistep process involving mutations and other genetic events leading to gain of function of dominantly acting ►**proto-oncogenes** and to the loss of function of ►**tumor suppressor genes**. The modified genes have an impact in the expression of genes and proteins, thus leading to disorders in terms of cell growth and differentiation.

Characteristics

The recent intense interest in proteomics has been made possible by the sequencing of the human genome, giving access to the sequences of all the genes, as well as by the recent advances in ►**mass spectrometry** for the analysis of macromolecules (techniques for ionization and increased resolution and sensitivity). In cancer

research, proteomics provides novel opportunities to understand the tumoral process as well as to define novel markers and therapeutic targets.

Proteomics: the State of the Art

The proteome can be analyzed by ►**two-dimensional gel electrophoresis** (2DE) allowing the separation of the proteins in two dimensions. The proteins are separated according to their charge in a first dimension where they stop their migration after reaching their isoelectric point and then in a second dimension according to their molecular mass. The proteins can be visualized by different techniques of staining such as Coomassie blue or silver, and then digitalized. 2D electrophoresis is a highly resolutive technique leading to the visualization of 1000–2000 protein spots in one experiment. Therefore, 2DE allows comparative analysis of protein expression levels as well as of protein isoforms. A recent development in 2D electrophoresis has been introduced by differential labeling of proteins using dyes also called ►**DIGE** (difference gel electrophoresis). This system allows comparative and quantitative studies after mixing of two protein extracts in the same gel, which improves the sensitivity and the reproducibility of the 2D electrophoresis (1). The identification of the proteins can be performed after enzymatic digestion of the proteins in the gel followed by analysis of the resulting peptides using mass spectrometry. The mass spectrometry analysis can be performed by ►**MALDI-T** of providing a ►**peptide mass map**, which is used for database searching to identify the protein. Another type of mass spectrometry, called ►**MS/MS**, allows the identification of a protein from a single peptide after fragmenting that peptide and using the second spectrum (MS/MS or MS²) for determining its sequence or a sequence tag. This information is used for database searching. MS/MS is therefore a powerful tool for analyzing the composition of complex mixtures as well as for characterizing post-translational modifications. The most recent and spectacular advances in proteomics have been achieved by coupling ►**liquid chromatography** with mass spectrometry (LC-MS/MS). A major advantage of LC-MS/MS is that it allows the identification of basic or highly hydrophobic proteins as well as protein having extreme molecular weights, which are difficult to resolve in 2D electrophoresis. The sequential use of several types of liquid chromatography (ion exchange, reverse phase...), also called ►**multidimensional chromatography**, allows one to separate and identify complex mixtures containing thousands of peptides in experiment. In addition, quantitative analysis can be performed using LC-MS/MS after differential isotopic labeling of the proteins from two cell extracts. The advantage of this approach is that it simultaneously quantifies and identifies the regulated proteins. One of

these methods is the ►ICAT system (isotope-coded affinity tag) (2). Furthermore, the chemical derivatization of some post-translational modifications (i.e. phosphorylation, glycosylation) combined with isotopic labeling has led to the identification of peptides exhibiting these modifications in complex mixtures and their relative quantification.

Proteomics and Cancer

The first level of proteomic analysis of cancer is global protein profiling and proteome mining. Since 2DE has appeared, the technology has been applied to cancer research. This has led to comparative studies of tumors with healthy tissues. Many cancer types were investigated by 2DE leading to the characterization of novel oncogenes or proteins with clinical interest (3, 4). For example, it was demonstrated using 2DE that leukemias could be classified into their different subtypes (1). Proteomic analysis has also been combined with laser capture microdissection prior to 2DE analysis. Indeed, clinical tissues are often heterogeneous and tumor cells are often contaminated with normal stromal cells, infiltrating lymphocytes, fibroblasts and blood vessel cells. Laser capture microdissection was developed for separating tumor cells from their microenvironment. In the search for novel tumor markers, a proteomic-based approach, using 2D Western blots of sera from cancer patients, has enabled the identification of tumor-associated antigens that elicit a humoral response (1, 3, 4, 5). This revealed a high frequency of autoantibodies in sera from several types of cancer. Some of these antigenic proteins may be novel cancer markers and may have clinical applications in diagnosis as well as in determining prognosis.

Proteomics provides the opportunity to focus on cell compartments or subproteomes such as the phosphorylated proteins or the cell surface proteome. Indeed, the proteomic analysis of cell compartments has modified our knowledge of cell compartments by identifying many proteins that were not expected to be there (e.g. phagosome, mitochondria) (1). A relevant example of proteomic analysis of a subproteome is the recent study of the cell surface proteome. Indeed, there is no method so far for performing a systematic characterization of cell surface proteins, whereas they play a major role in interactions and communication of cells with their environment. In addition, cell surface proteins are low in abundance making their identification very challenging. Recent advances in proteomics combined selective chemical labeling of the cell surface proteins using biotin with specific affinity purification (based on the very high affinity of avidin for biotin) allowing the profiling of the cell surface proteome and characterization using mass spectrometry. Applied to cancer cells, this method led to the identification of many chaperone proteins expressed at the cell surface (1). This

intriguing observation raises the possibility that many proteins expressed at the cell surface are not characterized yet and that novel tumor markers might be discovered in this way.

Quantitative proteomic analysis using LC-MS/MS is still in its initial stages. However, the approaches that avoid gel separation open novel possibilities in proteomics. A recent study has focused on the modulated protein in terms of expression after transfection of the oncogene c-myc using the ICAT system followed by LC-MS/MS analysis. The approach allowed the identification, from a whole proteome, of many proteins up- and down-regulated which might be relevant to cancer, such as proteins involved in adhesion or cell growth (6). The approaches combining isotope labeling of proteins with LC-MS/MS are very promising in cancer research because they allow the identification and quantification of low abundance proteins in complex mixtures.

Future Directions

Proteomics is now moving on to the analysis of whole proteins in complex mixtures. ►Protein chips (or microarrays) are emerging as an alternative to 2DE for differential expression analysis at the protein level in oncology (7). For example, profiling of mixtures is now possible using ►SELDI-ToF mass spectrometry. SELDI-ToF (Surface-enhanced laser desorption/ionization time-of-flight) analysis enables the high throughput characterization of lysates from a very few tumor cells and may be best suited for clinical biomarker studies. Another emerging device in proteomics is ►FT-ICR mass spectrometry (ultra high resolution). FT-ICR mass spectrometry leads to obtaining precise mass measurements of proteins and information on their modifications. This approach, also called 'top down', is complementary to the analysis of peptides, called 'bottom up'. This technology is also suitable for characterizing post-translational modification by a method of dissociation (►ECD, electron capture dissociation) specific to this type of mass spectrometry. Finally, proteomics offers an unprecedented opportunity to understand protein regulatory networks. The proteins are interacting with partners and form a complicated network in the cell. A change in one node of the network can lead to changes in proteins that may not be physically associated with the initiating protein. The understanding of protein networks will help to understand pathological processes such as cancer and to determine the best therapeutic targets.

Clinical Relevance

Cancer induces disorders in term of expression of genes and proteins. In cells, the mRNA molecules are

translated into proteins that carry out the basic biological functions. The tumorigenesis process can be addressed at the mRNA level and at the protein level. Because there is no strictly linear relationship between the mRNA and the proteins in terms of the expression level, both approaches may give complementary information. Proteomics is suitable for the characterization of cell compartments and subproteomes (i.e. cell surface proteome) that might enable us to define novel markers. The characterization of post-translational modifications of proteins induced by cancer might be a promising field. The understanding of molecular networks will help to define novel targets. Finally, proteomic approaches will play an important role in the discovery of new drugs and maybe in the development of personalized medicines.

Proteomics in Cardiovascular Disease

RODNEY LUI, SEAN LAL,
CRISTOBAL G. DOS REMEDIOS
Muscle Research Unit, Institute for Biomedical
Research, University of Sydney, Sydney, Australia
crisdos@anatomy.usyd.edu.au

Definitions

► **Cardiovascular disease** (CVD) encompasses any dysfunction of the heart and its own or other blood vessels. This may progress to damage life-sustaining organs like the brain and the heart itself. The aetiology of many CVDs is not known. A number of reports have focused on the development of molecular screening tools that detect changes in gene expression or gene sequences (genomics). Only within the past decade has

► **proteomics** emerged as a practical alternative to genomics. Proteomics is defined as the study of proteins expressed in a particular condition at a particular time by a particular cell or tissue type. Proteins are involved in virtually every cellular and regulatory function and changes in either the amount or specific type of protein can lead to the development of CVD.

Characteristics

Organs express only a limited subset ($\leq 10^4$) of total possible proteins ($\geq 10^6$) encoded in the approximately 30,000 genes in the genome. ► **Proteome profiling** and ► **functional proteomics** are designed to provide molecular snapshots of the proteins that determine the structure and function of particular organs. The expectation is that this information will identify protein differences between diseased and non-diseased tissues. Proteomic studies have so far focused on the two common types of CVD, ischaemic heart disease (IHD) and dilated cardiomyopathy (DCM). These two cause more than 70% of cases of human heart failure. IHD underlies most of them.

Ischaemic Heart Disease

The primary cause is atherosclerosis, a disease of the cells that line the inner wall of arteries (endothelial cells), particularly the coronary arteries of the heart. Recently, IHD has been regarded as an inflammatory disorder (► **inflammation**) mediated by a dysfunctional immune system (1). Accordingly, proteomic research has focussed on proteins and smaller peptides associated with the immune system. This began by demonstrating elevated levels of small numbers of membrane pro-inflammatory receptors and adhesion molecules found in the membranes of ► **endothelial cells** and ► **leukocytes**. These receptors orchestrate the ► **inflammatory response** and the development of atherosclerotic plaques. Traditionally, these surface proteins were detected by immunohistochemistry or flow cytometry (FACS) using monoclonal antibodies directed against ► **cluster of differentiation** (CD) antigens on leukocytes. Expression levels of certain CD antigens may change in a way that indicates the progress of IHD. For example, there are changing levels of circulating CD11b (an adhesion molecule found on monocytes and neutrophils) and CD36 (a scavenger receptor with a high specificity for oxidised ► **LDLs**, which are the major lipid component of atherosclerotic plaques) expressed on leukocytes in IHD (2). This may be significant because leukocytes are the mediators of inflammatory responses. Pathophysiology is further complicated by the release into the circulation of cytokines (plasma proteins/peptides secreted by inflammatory cells) that activate other inflammatory cascade proteins. All of this has large effects on the cardiac tissue

Proteomics in Cardiovascular Disease. Figure 1 Dark-field images of antibody arrays that captures proteins that are expressed on the cell surface of peripheral blood leukocytes. Images illustrate the differences in both the pattern and levels of proteins expressed between (a) a non-diseased blood donor and (b) an IHD patient.

surrounding the microvasculature (3). ►Cytokines also have systemic effects by recruiting more inflammatory cells and pro-inflammatory circulating proteins from lymphatic tissues.

Dilated Cardiomyopathy

Several proteomic investigations of human heart failure have focused on DCM. In most cases the ►etiology of DCM is unknown (idiopathic DCM). Proteome analyses have largely been achieved by ►two-dimensional polyacrylamide gel electrophoresis (2-DE). More recently 2-DE has been combined with ►mass spectrometry (MS) to identify proteins based on peptide ‘fingerprints’ (resulting from the exhaustive proteolysis of isolated 2-DE protein spots), or by limited sequence analyses of proteins/peptides (MS-MS). These data have been incorporated into CVD proteome databases of which the major ones are: ►www.harefield.nthaus.nhs.uk/nhli/protein; ►userpage.chemie.fu-berlin.de/~pleiss/dhzb.html and ►www.mdc-berlin.de/~emu/heart. These

have identified as many as 100 cardiac-specific proteins from whole cardiac tissue lysates containing up to 10,000 protein spots. Significant numbers of these proteins are now known to change in the terminal stages of the disease process. However the number of mRNA changes reported from gene arrays (see below) exceeds the number detected on the protein level (4). Most of these have been categorized into three groups:

1. Defective cytoskeletal and myofibrillar proteins that are consistent with contractile dysfunctions in ►congestive heart failure (5).
2. Mitochondria-associated and energy-producing proteins consistent with impaired energetics of the myocardium.
3. Proteins associated with cellular stress responses consistent with differences in expression levels of proteins such the 27 kD ►heat shock protein (hsp27).

Until recently, most cardiac proteomic studies have been based on 2-DE separations. While this technique continues to improve, so far it has not fulfilled its promise to identify and quantify differences in protein expression between diseased and control hearts. This can be attributed to several factors including difficulties in solubilizing proteins prior to separation, failure to reproducibly detect low-abundance proteins, difficulties in separating proteins with high or low isoelectric points (pIs), and generally a limited ability of 2-DE to quantify protein expression levels. While some of these shortcomings can be addressed by the addition of MS, 2-DE is rapidly being overtaken by protein microarrays currently under development.

Protein microarrays superficially resemble the better-known gene arrays carrying oligonucleotides or cDNA fragments, except that they are based on proteins, but there are major differences. Nucleotide hybridisation relies on precise base pairing and unique probes for known genes are relatively easy to synthesize. By contrast, there are more than 20 amino acids and they lack the ability to pair precisely with synthesized probes. Protein arrays rely on the formation of high-affinity and highly specific complexes with immobilized ligands. These may – but need not – be antibodies. Furthermore, proteins are much less stable than nucleotides. In principle, proteins can be complexed to non-protein ligands including lipids or nucleic acids such as aptamers (►<http://pubs.acs.org/subscribe/journals/mdd/v05/i05/html/05ttb.html>).

Clinical Relevance

In most Western communities, the incidence of CVD continues to increase. Although the application of proteomics is still in its infancy, it is highly likely to lead to clinical therapies (6). We predict that proteomics

will not only accurately and specifically identify cardiovascular disease, but will also help to find early markers of disease and therefore identify CVD at a stage when it is eminently treatable. In addition to its diagnostic and prognostic potential, it may also identify possible drug targets and thus play a role in the development of new therapies. Given the huge range of responses to drugs in the population, we envisage that protein arrays will be used to identify and predict individual responses to drug therapies. Companies are currently developing protein arrays that will use complex diagnostic information to produce treatments that are capable of being personalized for each patient.

Proteomics in Human-Pathogen Interactions

HENGLI TANG
Department of Biological Science, Florida State
University, Tallahassee, FL, USA
tang@bio.fsu.edu

Definition

Proteomics of human-pathogen interactions investigates alterations in protein content and characteristics that happen during or after incursion of host cells by a pathogen, either in humans or in the pathogen. Changes that are revealed by these studies can aid in a wide range of research and development efforts to combat the pathogen, such as the development of ►**biomarkers** for diagnostic purposes and the discovery of novel drug targets or prophylactic vaccines.

Characteristics

Proteomics of human pathogens examines the protein expression program of the pathogen. Typically, protein contents and properties of wild type and mutant pathogens are compared to identify the underlying molecular determinants of the phenotypic differences. In addition, ►**protein expression profiling** that identifies spatial and temporal patterns of expression may correlate the potential pathogenic factors with disease progression.

Applying a proteomics approach to study changes in host cells follows the footsteps of ►**DNA microarray**-based studies of host-virus interactions. As with the ►**RNA profiling**, global changes in gene expression in response to bacterial or viral infections are measured, albeit at the protein level. Again, changes induced by wild type and mutant pathogens as well as temporal regulation of host protein expression are often analyzed.

Infectious Diseases Proteomics Technologies

Profiling of total protein contents with ►**two-dimensional gel electrophoresis** followed by identification of proteins of interest using ►**mass spectrometry** is a common theme for a proteomics project. This process can be greatly facilitated when complete DNA sequence information is available for the particular organism. Microbes, having much smaller genomes than their hosts, are especially amenable to genomics and proteomics techniques. For example, according to the National Center for Biotechnology (NCBI), there are 140 completed microbial genomes and another 180 bacterial genome projects in progress, in addition to 1506 listed viral genomes as of February 2004. The human genome, despite having approximately 3 million base pairs and being one of the largest genomes, has also been fully sequenced with only small gaps to be filled. These technological advances in the genomics field paved the way for efficient proteomics analysis of both pathogen and human host during an infection.

Proteomics databases also play an important role in studies of host-pathogen interaction. In addition to the various 2-D gel databases created by individual researchers for specific pathogens, there are also companies that specialize in establishing large, comprehensive proteomics databases. For example, the protein interaction maps (PIM) produced by Hybrigenics contain protein-protein interaction data based on whole genome information on microbes and pathogen-host cell interplay. For example, the ►**polypeptides** of hepatitis C virus (HCV) are known to interact with one another during the life cycle of the virus, thus elucidating these interactions and those between HCV and hepatic factors will probably facilitate anti-HCV drug and vaccine research. Other human pathogens

included in this PIM database are *Helicobacter pylori* as well as human immunodeficiency virus. Several 2-D PAGE databases have also been generated for Epstein-Barr virus-transformed B-lymphoblastoid cell lines (6). Most of the data in the current databases has been generated using high throughput methods. As a result, no single set of data is to be completely trusted and relied upon alone. Rather, a definitive conclusion is only reached after assimilation of all the information from different sources and validation of results with alternative methods.

Proteomics Applied to Human-Pathogen Interactions

Proteomics studies aimed at host-pathogen interactions can be divided into two main categories:

1. Proteomics of the pathogen and its adaptation to the host
2. Proteomics of the host and its response to the infection by the pathogen.

Proteomics Studies of the Pathogen

The proteomes of many bacterial pathogens have been determined by 2-D electrophoresis and mass spectrometry. These include *Staphylococcus aureus*, *Bacillus subtilis*, *Pseudomonas aeruginosa*, *Helicobacter pylori*, *Salmonella typhimurium*, *Mycoplasma pneumoniae*, *Mycobacterium tuberculosis*, *Chlamydia pneumoniae* and *Plasmodium falciparum* (1, 3). Protein profiling has been used to identify pathogenic determinants, comparing non-virulent with ►virulent strains/forms of the pathogen. For example, *Mycobacterium tuberculosis* is the pathogen that causes tuberculosis (TB) in humans, while the vaccine strain *Mycobacterium bovis* BCG is non-virulent. When the proteomes from these two strains were compared by 2-D gel electrophoresis, more than two dozen proteins were found to be differentially expressed (3). Subtle differences between isogenic mutant strains H37Rv and H37Ra of *Mycobacterium tuberculosis* revealed by proteomics analysis may also help explain the mechanism of attenuation of *M. tuberculosis* H37Ra (2). Infection of a mammalian host by *Yersinia pestis* is accompanied by a temperature change from 26°C (the temperature of the flea) to 37°C. When bacterial proteins for *Y. pestis* grown at these different temperatures were compared using a protein array approach, factors implicated in virulence were identified from the proteins that were up-regulated at the higher temperature.

Another area of microbial research where proteomics tools are useful is the molecular physiology study of pathogens. Comparative proteomics of the malaria parasite *Plasmodium falciparum* revealed distinct protein expression and localization profiles in four different stages of the life cycle, defining underlying mechanisms at the protein level for the metabolism,

►stress response and other physiological processes (1). These proteomics studies contribute to our overall understanding of the pathogens and add to our abilities to fight them by identifying potential new drug targets. Emerging antibiotic resistance in human microbial pathogens is a big concern and an area of intense research by medical microbiologists. Comparative proteomics have been used to examine the differences in protein content and characteristics exhibited by antibiotic-sensitive and resistant strains of *Streptococcus pneumoniae*, *Helicobacter pylori* and *Staphylococcus aureus*. Proteins that are up-regulated in the resistant strains were identified by mass spectrometry and their possible roles in establishing the resistance examined. Alternatively, antibiotic-binding proteins can be analyzed using a proteomics approach to study the mechanism of resistance.

Systematic identification and characterization of cell surface proteins of bacterial pathogens can lead to identification of new targets for vaccines. Based on available genome sequences, potential cell surface or secreted proteins can be identified *in silico* by a combination of computer prediction and ►homology search. These candidate proteins are expressed and purified as recombinant proteins that are in turn used as immunogens to generate ►antisera in mice. FACS staining of un-permeabilized cells confirms the cell surface exposure of these proteins. Finally, the validated antisera are tested for their ability to neutralize the pathogen in an ►in vitro infection assay. A cell surface or secreted protein that can elicit antibodies capable of suppressing infection meets the criteria for a candidate vaccine. This genomics/proteomics-based vaccine development approach, known as “reverse vaccinology” has been successfully used to identify vaccine candidates for *Neisseria meningitidis* B and *Chlamydia pneumoniae* (2, 3).

Direct analysis of ►immunogenic factors that react specifically with infected patient sera can also result in a selection of vaccine candidates for the particular pathogen. For example, 2-D PAGE was coupled with Western blotting to identify *Helicobacter pylori* proteins that were reactive to pooled patient sera; the positive spots were identified by in-gel digestion and mass spectrometry. One of the proteins identified in this study was proposed as a vaccine candidate.

An important aspect of protein function pertains to its interaction with other proteins inside a cell or a macromolecular complex. Identification of cellular factors interacting with viral proteins has been and continues to be a popular research project for molecular virologists and has produced a vast amount of useful information on virus-host cell interaction. Equally important are the interactions between microbial proteins. Traditional techniques for studying protein-protein interactions such as ►co-immunoprecipitation

and ►yeast two-hybrid can be adapted to high throughput, systematic studies. A comprehensive yeast two-hybrid analysis of all potential pair-wise combinations of the 266 vaccinia virus proteins (which total over 70,000) revealed 28 previously unidentified interactions (4). Similar studies to discover interactions between bacterial proteins have also been carried out for *Helicobacter pylori* and *Rickettsia sibirica*.

Proteomics Studies of the Host

RNA profiling (►differential display) of gene expression in a human cell pre- and post-infection by a pathogen has been done for a large number of pathogens including HIV-1. In addition to generating considerable numbers of mRNA profiles that can guide and validate the corresponding proteomics experiments, this work has also been a driving force behind the development of sophisticated ►bioinformatics tools. Comprehensive protein profiling of a human cell however, is technically more challenging, due largely to the fact that the current resolution of proteomics techniques prevents simultaneous and exhaustive analysis of the very large number of proteins. Several approaches have been undertaken to circumvent this problem and identify differentially expressed/modified proteins in infected cells or in cells manifesting a disease phenotype.

Firstly, alternative detection methods and sophisticated imaging software help increase the resolution of the 2D gels. Using computer-aided imaging analysis, Toda et al. (6) compared protein spots on silver- as well as Cypro Ruby- stained 2-D gel images from three pairs of pre- and post-immortalized Epstein-Barr virus-transformed B-lymphoblasts (LCLs). Even though no spot was found to be commonly regulated in the three cell lines pre- and post-immortalization, the expression of one protein, later identified to be stathmin, decreased dramatically in two of the three cell lines after immortalization. Importantly, the expression level of this protein in the remaining cell line is extremely low both pre- and post-immortalization, consistent with the authors' hypothesis that this change represents an early event in the immortalization process which may have already begun in the third cell line (6).

Secondly, conducting focused investigations of subpopulations of protein can cut down the number of proteins that need to be analyzed in a single study. For example, the ►"sub-proteome" of cell-surface proteins should contain most of the proteins involved in parasite receptor binding and an ►affinity purification step with phospho-specific antibodies can significantly narrow the field for an experiment aimed at detecting changes in host protein ►phosphorylation in response to infection. Alternatively, total protein samples can be interrogated with a collection of well-characterized monoclonal antibodies to discover potential changes in a group of pre-defined genes. Such a multiplex Western blotting technology was used in an

effort to define proteome changes in dermal microvascular endothelial cells (DMVEC) upon infection by Kaposi's sarcoma associated herpesvirus (KSHV) (5). Approximately 850 monoclonal antibodies recognizing ►transcription factors and cell signaling molecules (BD Biosciences) were used in Western blots to detect differential protein expression between age- and passage-matched DMVEC cell pairs with or without KSHV infection. A total of 52 proteins were found to be differentially expressed with 29 proteins up-regulated in infected cells. One of the up-regulated proteins, heme oxygenase-1 (HO-1), was characterized in detail.

Finally, using body fluids or supernatants of cell cultures as starting material can also significantly reduce the number of proteins to be analyzed. Protein profiling of body fluids from infected patients is an area of proteomics that holds great promise for biomarker and vaccine development. Coupled with high-accuracy mass spectrometry, the Proteinchip® technology offered by Ciphergen is well suited for clinical diagnostic research. Since protein separation and mass identification are done sequentially on the same surface without any gel running steps, this technology allows rapid processing of large numbers of clinical samples in parallel. It was also used to identify anti-viral factors that can inhibit HIV infection (7). Although the cell source for the factors turned out to be identified incorrectly, it nevertheless demonstrated the ability of the technology to detect and identify active anti-viral components out of a plethora of protein factors secreted by a mixture of different types of primary cells.

Clinical Relevance

Tremendous progress has been made in the proteomics study of pathogens and their interactions with the human host, fueled by advances in protein chemistry technology and the rapid expansion of genomic sequence databases. Although the majority of the current proteomics studies of pathogen-host interaction have been done with *in vitro* cell culture models of the diseases, the scientific information generated by these studies should nevertheless lead to better understanding of the complex biological processes involved in pathogenesis, host-defense and mechanisms of drug resistance of both viral and bacterial infections ►in vivo. This will greatly facilitate the development of early and accurate diagnostic markers as well as the discovery of pertinent drug targets and prophylactic vaccine candidates that promise a better outcome of disease management.

Proteomics in Microfluidic Systems

JAISREE MOORTHY, DAVID J. BEEBE
Biomedical Engineering, University of Wisconsin,
Madison, WI, USA
djbeebe@wisc.edu

Definition

► **Microfluidics** deals with transporting and manipulating small volumes (nl– μ l) of fluids within confined regions (► **microchannels**) and allows for characterizing samples in a high-throughput manner. Over the last decade, microfluidic platforms have been explored for chemical and biological studies. In molecular biology, the picture that has emerged as the central dogma is that knowledge of genes alone cannot provide the critical clues to understanding the functioning of the cell; there is a dynamic and intricate network of interactions between DNA, protein and other molecules within the cellular environment (1). Moreover, the presence, quantity and reactivity of proteins and other biomolecules inside the cell vary with time and external conditions. Characterizing the expression, structure, function and interaction profiles of proteins within the cell during different cell-cycle stages and external conditions is commonly referred to as proteomics. In order to carry out these studies in a high-throughput manner, proteomics requires improved technology to handle small volumes, to perform multiple tests and to detect molecules at low concentrations. As microfluidic systems offer these capabilities, they provide an attractive platform for proteomics.

Characteristics

Proteomics primarily involves separation, sensing (or detecting) and interaction studies. Performing one or

more of these studies is the first step towards understanding the molecular orchestration that occurs within cells. In the following sections, the basic features of microfluidic devices and their ability to perform these studies will be discussed.

Basics of Microfluidics

A typical microfluidic device consists of a myriad channels and other components such as pumps and ► **valves** to transport and manipulate fluid. The volume of fluid in a single microchannel is typically a few micro liters. Figure 1a compares the volume in one well of a microtiter plate (384-well) with that in a microfluidic channel. It is possible to carry out at least 10 assays in the microchannel for every assay done in the microtiter well. The surface area to volume ratio is very high within the channel, allowing a higher fraction of molecules in the sample volume to effectively “see” the surface. High surface area to volume ratio becomes useful when the sensor (detector) is at the surface and also for effective heat dissipation (e.g. during electrophoretic separation). ► **Laminar flow** occurs inside micron-sized channels, where the viscous properties of the fluid dominate; the flow of water through a microchannel is analogous to flow of a viscous fluid such as honey through a significantly larger channel (2). Laminar flow is smooth, steady, devoid of fluctuations (in velocity) in space and time and is predictable (Fig. 1b). Moreover, in laminar flow, two or more streams flowing adjacently mix at their interface mainly by ► **diffusion**. Slow mixing (► **Mixing Time**) can be used to advantage for separation and detection. For example, particles can be separated based on size, as larger molecules diffuse more slowly than smaller ones. A key advantage of the microfluidic platform is that the environment within the channels can be controlled in both spatial and temporal manners. This ability allows for dynamic studies that are not possible in conventional methods. For example, one can analyze cell signaling under varying external conditions or study the kinetics of biomolecular interaction.

The advantages of microfluidics include (3):

- a) ability to handle small volumes by virtue of their dimensions
- b) high-throughput, many assays can be performed in parallel
- c) quicker assays due to the larger sensing surface and better heat dissipation
- d) low evaporation and less exposure to toxins as the microsystems are enclosed
- e) occupation of less space making the devices portable for use in point of care diagnostics
- f) higher reproducibility because the sample volumes can be kept constant, as devices can be manufactured with precise tolerances

Proteomics in Microfluidic Systems. Figure 1 (a) Comparison of volumes in a microtiter well (384-well) to those in microfluidic channels. With the same amount of sample, at least 10 more assays can be performed in the microfluidic platform. (b) The viscous properties of water flowing through the channel are similar to those of honey; the flow is smooth, steady and devoid of fluctuations in velocity. Two streams flowing adjacently to each other (directions shown by arrows) mix only at their interface by diffusion, which can be slow for large molecules (e.g. proteins). However, slow mixing can be used to advantage for separation or detection as well as to define spatial regions within the channels.

- g) single cell analysis and cell based assays because the physics of transportation within micron-sized channels allow for the study of biological phenomena occurring at the same scale
- h) ability to perform experiments that require precise spatial and temporal control, which are difficult to perform in regular micro-titer plates

Fabrication

A microfluidic device consists of channels (or cavities) of a pre-defined size and is connected to other cavities. The channels can be created by either etching a surface or by forming walls. Fabrication methods have evolved from traditional silicon-based protocols to ►micro-molding and ►liquid phase photo-polymerization (LP3) (Fig. 2) using organic or biopolymers (e.g. gelatin) (4). In micromolding, a “master” containing raised features (for channels) is first fabricated, over which elastomeric polymers are cured by pouring the monomer mixture and baking for few hours. The cured elastomer is released from the “master” and sealed to form enclosed channels. In LP3, one starts with an enclosed cavity and fabricates various components *in situ* by flowing monomer solution and polymerizing channel walls and other components (eg. valve, filter) by irradiation through a mask. The mask defines the location of polymerized structures within the cavity. Using this method, the time to make a device has been reduced from days to minutes (Fig. 2). LP3 also allows the user to arrange the components in any desired location based on the assay requirements (5).

Separation

One of the most common ways to separate proteins is *via* electrophoresis. The biomolecules separate based

on their charge and mass; the presence of a protein is indicated by a band (of dyed protein) and the expression level is reflected in the intensity of the signal. By virtue of their size, separation in microchannels requires small sample volumes. Separation can be done quickly with a higher electric field because of better heat dissipation (increased surface area to volume ratio) mitigating joule heating. The microfluidic platform is well developed for capillary electrophoresis and is widely used in DNA studies. Gel electrophoresis (GE), both 1D and 2D has also been demonstrated in this platform. After separation, the proteins are usually digested into smaller peptides, further separated and detected using other techniques such as mass spectroscopy (MS). Alternatively, if the functionality of the protein is known beforehand, affinity based separations can be used to both separate and identify the proteins. Both protein digestion and affinity separations have been performed in microchannels. Moreover, separation of proteins from single cells has been performed inside microfluidic systems (6).

Sensing

Identifying a specific protein or a class of proteins is important for characterizing its functionality and to develop appropriate drugs. Increased exposure to surfaces inside a microchannel has been used to perform effective sensing on cantilever beams and surfaces. The physics of fluid flow in microchannels (slow mixing in laminar flow) has been used to develop a T-sensor, wherein biomolecules are detected by flowing antibodies in an adjacent stream (Fig. 1b); specific binding between the biomolecules was identified by tracing the diffusion of molecules at the interface of the streams (7). Analogous to DNA microarrays, protein arrays have been developed (8), wherein antibodies or fragments are immobilized on a

Proteomics in Microfluidic Systems. Figure 2 Fabrication of a microfluidic device using micromolding and liquid phase photo-polymerization (LP3). In micro-molding, elastomeric polymers are cured over a “master” and sealed to form enclosed channels (final device). In LP3 various structures (channel walls, pumps, valves, etc.) are photo-polymerized *in situ* in an enclosed cavity. A pre-polymer mixture containing monomer, cross-linker and photo-initiator is introduced into the cavity and polymerized by irradiating with UV light through the mask. Upon removing the unpolymerized mixture and washing, the final device is obtained.

surface. By using a channel network (along with protein arrays) extra dimensions in space and time can be utilized. However, unlike DNA fragments, proteins must be hydrated to maintain their functionality. A significant challenge is to keep the immobilized proteins hydrated and functioning naturally. One way to keep proteins hydrated is to position them within ►hydrogels. Another problem with protein studies is that of cross-reactions and false positives. Using channel networks, multiplexed detection (e.g. fluorescence and cantilever) can be performed to minimize false positives and non-specific interactions.

Applications

The biochemical (and biological) function of a protein is characterized by studying interactions with other proteins under varying conditions. Such studies allow for the development of an interaction map, which can help in understanding the involvement of a specific protein in various pathways and how its excess or absence can affect the functioning of the cell as a whole. Because many tests can be carried out in parallel, microfluidic devices can be used to study the parameter space (buffer type, conc. etc.) influencing the interactions in a systematic manner. Multiple interactions can potentially be studied in a microfluidic platform with the connectivity in the microchannel mimicking the signaling or metabolic pathways within the cell. The size of microfluidic systems allows for manipulating and studying a single cell and the ability to precisely control the physics of transportation inside microfluidic channels allows for manipulating the spatial and temporal environment around the cell. Takayama et al. have shown that spatial control of environment around the cell is possible by exposing a

single cell to different solutions (9). This approach can be extended to stimulate the cell at specific regions while monitoring changes (e.g. calcium waves) *in vivo* so as to elucidate signal transfer and protein interaction networks. Another area where microfluidic platforms can be useful is in crystallization studies. Finding the right conditions for crystal formation is still an art. By utilizing the capability of the platform to manipulate small volumes of fluid and to perform large number of tests in parallel, Hansen et al. demonstrated that the parameter space for crystallization could be explored quickly to find the optimal set of conditions (10).

The capabilities of traditional technologies such as 2D GE for separation and mass spectroscopy for detection of biomolecules are being improved for proteomic studies and there is growing interest in using the microfluidic platform to link multiple tools. Although microfluidic devices may quickly find applications as links between existing technologies, the strengths of these devices in handling small volumes, multiplexing and performing studies at the cellular level will drive the growth of this platform as an independent integrated system.

Clinical Relevance

Several diseases are caused by the inappropriate presence of a protein at a certain stage of cell growth, mis-folded or improper post-translation modifications of proteins, and excess (or scarcity) of a specific protein. One way to address the problem is to pinpoint the protein (►marker) that can be assayed for diagnosis and/or prognosis. As microfluidic platforms for sensing proteins are being realized, detecting a specific marker can be carried out efficiently. Multiple functionalities such as sensing, storing reagents and fluid manipulation

(pumps and valves) can be incorporated to develop portable diagnosis systems for use in remote areas (5). However, as the molecular basis of the cell is being understood, it is becoming evident that a single marker alone may not suffice; multiple markers and/or their interactions may be the cause of many diseases. In the absence of a specific marker, a fingerprint of the protein expression and interaction can be obtained. By using a microfluidic platform, the proteins expressed in the diseased cell can be quickly obtained using separation techniques and the interaction of the proteins can be analyzed. These results can then be compared with “healthy” profiles for use in prognosis and diagnosis. Other uses of the platform include high-throughput drug screening and testing for side effects of a specific drug by mapping its interaction with a set of proteins.

Proteopathies

► Defective Protein Folding Disorders

Prothrombin

Definition

Prothrombin, also referred to as coagulation factor II, is involved in the clotting cascade. The inactive precursor prothrombin is converted into the active thrombin (factor IIa) by proteolytic cleavage which is catalysed by factor Xa, the product of the preceding step of the clotting cascade.

► Polyadenylation

Protocol Mutagenesis

Definition

Protocol mutagenesis refers to the process where a practical laboratory protocol is continually modified in an uncontrolled and often unrecorded way, often rendering it useless.

► Large-Scale Homologous Recombination Approaches in Mice

Protonation States

Definition

Protonation states of the amino acids Asp, Glu, His, Tyr, Cys, Lys, and phosphorylated residue side chains can vary depending on the pH and local environment of the residue. Protonation states are derived from titration curves of proteins, and show a continuous change of total protein charge over pH ranges. However, crystal structures are commonly solved with simple assumptions regarding charges on individual amino acid residues. As hydrogen atom electrons are not usually resolved in crystal structures, assignment of coordinates to hydrogen atoms is a modeling task.

Protoplast Transformation

Definition

In general the term transforming comprises the transfer of genetic information between bacteria or RNA and viral DNA in eukaryotic cells by uptake of DNA sequences. In yeast genetics, the yeast cell wall has to be removed (remainder called protoplast) to make the cell susceptible to the uptake of foreign DNA. The uptake is usually further enhanced by chemical perturbation of the cell membrane (e.g. by the addition of polyethyleneglycol).

Protrusion

Definition

In general the term protrusion refers to anything that protrudes. In molecular biology the term describes the state that a residue protrudes the surface of a protein. It is quantified by calculating a protrusion index; this gives an absolute value for the extent to which a residue protrudes from the surface of a protein. In cell biology it is used as a general term to describe highly dynamic projections of the cell surface, like filopodia or lamellipodia, that help cells to sense their external environment.

►[X-Chromosome Inactivation](#)

Pseudogene

Definition

A pseudogene is a non-functional sequence of DNA in the genome, which is almost identical to a functional gene sequence. Pseudogenes arise by ►[gene duplication](#) (or insertion) followed by accumulation of mutations which render it nonfunctional, but in the presence of the functional original gene such mutations constitute no selective disadvantage and can persist in the gene pool. Processed pseudogenes have no introns, and are therefore thought to have arisen by the action of viral reverse transcriptase. In order to be propagated in the gene pool, the pseudogenes must have arisen early in development or in germ cells, and are therefore often associated with embryonic genes. Processed pseudogenes are abundant for embryonic simple epithelial keratins k8 and K18.

Psoriasis, Molecular Basis

KHUSRU ASADULLAH¹, WOLFRAM STERRY²

¹Corporate Research Business Area Dermatology, Schering AG, Berlin, Germany

²Department for Dermatology and Allergology, Medical School Charité, Humboldt University Berlin, Berlin, Germany
khusru.asadullah@schering.de

Definition and Characteristics

Psoriasis is a multigenic, cutaneous disorder characterized by inflammation and abnormal epidermal proliferation with a prevalence of 2–3% in the general population (1). It is defined as a clinical entity affecting skin, nails and, in approximately 5% of the patients, joints. Typical findings are ► [keratinocyte](#) hyperproliferation with hyper- and para-keratotic differentiation, epidermal influx of polymorphonuclear leukocytes and the presence of a mononuclear infiltrate in the papillary dermis and the epidermis. Based on the current pathophysiological understanding, psoriasis is considered to be a ► [T lymphocyte](#) mediated dermatosis (see below). In contrast to type 2 psoriasis, type 1 psoriasis is characterized by early onset (before age 40) and a positive family history.

Clinical Relevance Diagnostics

The observation of typical clinical features is sufficient for making the diagnosis in the majority of patients. The usual presentation of the skin lesions is that of sharply demarcated erythematous (red), hyperkeratotic (scaling) plaques of varying extent, distributed symmetrically over the skin (1, 2; Fig. 1). Histological analyses of skin biopsies show akathosis (elongation of the epidermis), abnormal differentiation and inflammatory infiltrates (Fig. 2). Molecular analyses are not necessary for the diagnosis. However, some hints of an expansion of certain T lymphocyte families expressing specific subsets of antigen recognition molecules in skin lesions has been reported, as well as an association of early onset psoriasis and a positive family history for psoriasis with the genotype ► [human leukocyte antigen](#) (HLA)-Cw6, B57 (see also below), which may contribute to a better understanding of the disease rather than have diagnostic impact.

Psoriasis, Molecular Basis. Figure 1 Typical symmetric skin lesions in a psoriatic patient.

Psoriasis, Molecular Basis. Figure 2 Typical histological findings in a psoriatic patient.

Therapy

The current options for the treatment of psoriasis are limited. Topical therapies include the use of dithranol, calcipotriol, and steroids. These, however, are usually not very successful in severe psoriasis. UV-radiation therapy is commonly used but it is associated with development of side effects like tumor induction after application over several years. The options for systemic antipsoriatic therapies include cyclosporine A, FK506, and fumaric acid esters. Yet, these treatments may also fail in certain patients and, in particular, may be of limited value due to fairly serious side effects. Consequently, these medications are only used in severe psoriasis. This situation indicates the demand for novel therapeutic strategies. New understanding of the pathophysiology of psoriasis might offer opportunities for well-targeted therapeutic interventions. Indeed several immunomodulatory approaches including intervention in the ►cytokine network or inhibition of T lymphocytes or their costimulation by antigen presenting cells as well as inhibition of T-cell infiltration are currently in clinical development (3).

Genetics and Other Pathophysiological Aspects

Psoriasis is a multigenic disorder. Genetic factors are likely to be of fundamental importance in the expression of the disease. This is supported by numerous family, twin and HLA allotype studies (reviewed in 4). Although these observations suggested that patients are genetically predisposed to psoriasis, they imply that environmental factors are also involved.

Three factors are well recognized as triggering the onset, causing new lesions or inducing a flare in the disease, stress, skin injury and infection (5). Infections seem to be of particular importance. More than 40% of psoriatic patients reported a provoking infection. Moreover, 25% of psoriatic children had the onset of their disease after an infection, commonly of the upper respiratory tract. In children already suffering from psoriasis, over 50% had a psoriasis flare within 2–3 weeks of an upper respiratory infection (reviewed in 5). The impact of bacterial infections is clinically most obvious in the frequent association of acute guttate psoriasis with streptococcal throat infection. Recent investigations suggest that this seems to result from a ►superantigen-driven process. However, the pathophysiological importance of viral infections for psoriasis has been recognized, too. Beside the association of virally induced upper respiratory tract infection with guttate flares, hepatitis C, human immunodeficiency and herpes virus infections are considered to trigger, or even to induce, the onset of psoriasis. It is likely that proinflammatory cytokines produced by infected cells or by other cells in response to the infection are involved in these processes.

The association between certain major histocompatibility complex (MHC), i.e. HLA-antigens and psoriasis and the persistence of the disease throughout life once it has appeared suggest the existence of a “memory”, and the spontaneous exacerbation and remission of disease activity is characteristic of diseases involving a chronic immune response (4). Genome-wide scans for disease susceptibility have generated evidence for a major locus situated in the MHC termed PSORS1 (for psoriasis susceptibility 1), on the short arm of chromosome 6. Subsequent studies have sought to refine PSORS1 boundaries by means of linkage disequilibrium fine mapping. Comparison between the different minimal intervals found, points to a 100 kb segment telomeric to HLA-C, and alpha-helix coiled-coil rod homolog genes. Due to methodical limitations, however, the 100 kb interval can only be considered a provisional assignment, and candidate genes lying in its proximity cannot be excluded only on the basis of their position. Studies of positional candidate genes have also been undertaken, focusing on HLA-C, corneodesmosin, and alpha-helix coiled-coil rod homolog genes. Several reports have repeatedly indicated the

HLA-Cw6*0602 allele as the most significant marker for disease prediction (6).

Several observations indicate that T lymphocytes and cytokines are of major importance in the pathogenesis of this chronic skin disease. These observations are supported by the beneficial effects of systemic administration of immunosuppressive drugs like cyclosporine A, FK506, DAB389IL-2 and fumaric acid esters, known to act on T-cells and to influence the cytokine pattern. Finally, recent investigations using SCID mice demonstrated a central role of immunocytes, in particular T cells, in the pathophysiology of psoriasis. The arguments for considering psoriasis a T-cell mediated dermatosis can be summarized as follows: (3).

- Presence of activated T-cells in the skin lesions
- Cure of the disease by bone marrow transplantation from healthy persons and transfer of the disease by transplantation of bone marrow from psoriatic patients
- Demonstration of the impact of immunocytes by SCID mice experiments
- Therapeutic effects of immunosuppressants targeting T lymphocytes (e.g. cyclosporine-A, anti-T cell antibodies)

Altogether, based on current knowledge, psoriasis is considered to be a T-cell-dependent (auto)immune disease, probably initiated by presentation of so far unknown “psoriasis-related antigens” by specialized cutaneous APC. Presentation of these antigens and/or superantigens activates T-effector lymphocytes leading to enhanced cytokine formation. These activated T-cells are considered to change epidermal growth homeostasis, leading to increased keratinocyte proliferation and abnormal differentiation. The current pathophysiological concept is shown in Fig. 3.

The cutaneous and systemic over-expression of several proinflammatory cytokines, in particular type 1 cytokines, has been demonstrated in psoriasis. This includes ►interleukin (IL)-2, IL-6, IL-8, IL-12, ►interferon (IFN)- γ and ►tumor necrosis factor (TNF)- α . IL-8 was considered to be of particular importance, since it acts as a chemoattractant in particular for granulocytes, cumulating in psoriatic lesions. Limited efficacy of anti-IL-8 therapy, however, challenged this hypothesis. In contrast, impressive effects of anti-TNF α therapy demonstrate the major impact of this proinflammatory cytokine in the disease. Considering all the data and the evidence that “classical” type-1 and type-2 patterns only mark extremes in a wide variety of motifs, the cytokine profile in psoriasis can be considered as “proinflammatory, type 1-like”. The resulting ►immunological imbalance is shown in Fig. 4. This seems to be of particular importance, since it is characteristic for an

Psoriasis, Molecular Basis. Figure 3 Model for the immunopathogenesis of psoriasis. Presentation of antigen by the antigen-presenting cells (APC), e.g. Langerhans cells, to CD4⁺ T lymphocytes leads to the synthesis of cytokines which stimulate keratinocyte (KC) proliferation and the expression of adhesion molecules by endothelial cells (EC) and keratinocytes. Keratinocytes, in turn, are stimulated to secrete their own cytokines which can act in an autocrine and/or paracrine manner to maintain the psoriatic process. In addition, expression of adhesion molecules by endothelial cells allows the extravasation of leukocytes into the lesion including skin-homing CD4⁺ memory T cells expressing the HECA-452 (CLA) antigen. These cells can also be activated in an antigen-specific manner leading to the secretion of more cytokines to perpetuate the process. Direct activation of keratinocytes by epidermal injury (Koebner reaction) could initiate a psoriatic lesion. (Adapted from a model initially developed by Baker and Fry (3) reproduced with permission from Trends Immunol).

Psoriasis, Molecular Basis. Figure 4 Immune imbalance in psoriasis. The interaction of antigen presenting cells (APC) with T lymphocytes, leading to their activation and differentiation into T-helper (Th)–1 cells is a crucial, early step in the immune activation in psoriasis. In addition, type-1 and several other pro-inflammatory cytokines are over-expressed.

ongoing cellular immune response. Remarkably, a similar cytokine pattern is found in other immune diseases, such as inflammatory bowel diseases e.g. Crohn's disease, transplant rejection and rheumatoid arthritis. Beside the regulatory effects of cytokines on inflammation, which seem to be crucial, several cytokines might directly enhance keratinocyte proliferation. It has been shown that IL-1 and IL-6 are mitogenic for keratinocytes. However, several other factors are involved in the control of keratinocyte growth as well. These include epidermal growth factors (GF), insulin-GF-1, keratinocyte-GF and hepatocyte-GF. The growth factors responsible for the increased keratinocyte proliferation might come from a wide variety of cells, including autocrine and paracrine growth factors from keratinocytes themselves. It is important to notice that there might be a special mix of factors responsible for the keratinocyte hyperproliferation and that other factors not identified so far might be involved, too.

P-Type ATPase

Definition

P-type ATPase comprise of a large protein family of transmembrane proteins, which use the energy released by hydrolysis of ATP to transport typically mono-or divalent cations across cellular membranes. However, members of a subfamily of P-type ATPases have been implicated in the transbilayer movement of lipids and bile acids. The enzymatic mechanism of P-type ATPases involves a phosphorylated intermediate, hence the name P-type.

Pulse Sequence

Definition

In NMR spectroscopy, a series of programmed radio frequency pulses are generated to irradiate NMR samples in a high magnetic field, in order to produce response signals to allow detection of correlations between different nuclei. A pulse sequence always starts with the relaxation period and ends with the detection of an FID. In-between the pulse sequence can be a varying complexity.

Pulsed-Field Gel Electrophoresis

Definition

Pulsed-field gel electrophoresis refers to an agarose gel electrophoresis method for separating large DNA fragments. Conventional electrophoresis, which separates DNA fragments by sieving (DNA has a constant charge/mass ratio), is difficult to use for fragments above 20 kbp, and fails altogether at about 100 kbp because the DNA is vastly longer than the pore size of even the softest gels, and is drawn through end-on. Shorter fragments can tumble, and thus do present a diameter to the gel that depends on their size. Pulsed-field electrophoresis techniques allows separation of DNA fragments into the tens of megabases by periodically switching the direction of electrophoresis

(various geometries), differentially retarding molecules based on their relaxation (reorientation) time, a function of length.

Quadrupole

Definition

Quadrupole is used as a mass filter consisting of four parallel electrodes. By applying combined alternate and direct voltage to the electrodes, only ions with a certain mass to charge ratio oscillate on a stable trajectory before they finally reach the detector. Stable trajectories can be calculated using Mathieu's equations. In a measurement, different voltages are used to scan a mass spectrum over a broad range of mass to charge ratios.

Quadrupole Mass Analyzer

Definition

A quadrupole mass analyser (QMA) is a device for the selection of ions of a particular mass/charge ratio (m/z) in mass spectrometers. The QMA consists of four parallel rods that have fixed direct current (DC) and alternating radio frequency (RF) potentials applied to them. Ions produced in the ion source of the mass spectrometer are passed through the QMA and selected according to their m/z by variation of the RF potentials. The mass range and resolution depends on the length and diameter of the rods. QMAs are nowadays mainly used in mass spectrometers coupled to gas- or liquid-chromatography. They were developed by Nobel Prize winner Wolfgang Paul.

Quantitative Structure-Activity Relationship

MICHAEL WIESE

Rheinische Friedrich-Wilhelms University, Bonn, Germany

mwiese@uni-bonn.de

Definition

QSAR stands for quantitative structure-activity relationship. This methodology aims to relate differences in structures of a series of molecules to differences in their biological activity through a mathematical equation, called the QSAR model. To develop a QSAR model one needs: (i) activity data, (ii) structural descriptors and (iii) an appropriate mathematical function. Activity data are biological activities of a series of related derivatives. They are usually numbers characterizing a standardized effect (binding and inhibition constants or constants related to effects like EC_{50} , LD_{50}).

Structural descriptors represent molecular properties of the investigated compounds and can be either measured or calculated. They are also expressed as numbers derived from data believed to be related to the molecular property of interest. The conversion of the chemical information into a mathematical description has to conserve the information content inherent in the molecules and should represent the changes in biological activity as a function of the changes in molecular structure. A mathematical function is required that connects changes in biological activity to changes in molecular structure. Regression techniques have been proven to be effective, but nowadays additional techniques such as artificial neural networks and genetic algorithms are also applied.

Description

A Brief History of QSAR

The earliest report on a relationship between molecular structure and biological properties comes from Crois in 1863. He observed that the toxicity of alcohols to mammals increased as the water solubility of the alcohols decreased. In 1868 Crum Brown and Fraser concluded, based on their studies of the biological effects of certain alkaloids, that the physiological (biological) activity Φ is a function of the chemical constitution C (Eq. 1).

$$\Phi = f(C) \quad (1)$$

But even today Eq. 1 cannot be applied as it was formulated; only differences in biological activities $\Delta\Phi$ can be correlated with differences in molecular structure and properties ΔC (Eq. 2).

$$\Delta\Phi = f(\Delta C) \quad (2)$$

In the end of the 19th century Meyer and Overton noted that the toxicity of organic compounds depended on their [lipophilicity](#). As a model system to determine the partitioning they proposed the olive oil/water system.

Little progress in QSAR occurred until the middle of the 1930s when Hammett observed that substituents have a similar effect on the equilibrium constants and reaction rates of aromatic compounds. He showed that equilibrium constants K and reaction rate constants k of substituted benzene derivatives can be described by Eqs. 3, 4.

$$\log \frac{K}{K_0} = \rho\sigma \quad (3)$$

$$\log \frac{k}{k_0} = \rho\sigma \quad (4)$$

K_0 and k_0 denote the equilibrium constant and reaction rate of the unsubstituted compound, respectively, while K and k refer to the substituted derivative. The parameter ρ is specific for a certain reaction. The dissociation of substituted benzoic acids was used as a reference system with ρ equal to one. The parameter σ depends only on the electronic properties of the substituent. Electron-withdrawing substituents have positive σ -values and electron-donating substituents negative σ -values. The relationships developed by Hammett are termed the linear free energy relationship (LFER) as the free energy is related to an equilibrium constant according to Eq. 5.

$$\Delta G = -RT \ln K \quad (5)$$

Such relationships are also termed “extrathermodynamic” as they are stated in terms of thermodynamic parameters, but no thermodynamic principle states that these relationships should hold.

Classical or 2D QSAR

It took another 30 years to start the modern QSAR methodology, still widely used and termed classical or 2D QSAR to differentiate it from 3D QSAR methods. Hansch is recognized as a founder of the modern QSAR. In 1964 he derived a Hammett-type equation for assigning lipophilicity values to aromatic substituents, noting that it is an additive physicochemical property (Eq. 6).

$$\log \frac{P_{R-X}}{P_{R-H}} = \pi_X \quad (6)$$

Further Hansch and Fujita combined σ and π in one equation and correlated these parameters with the biological response using multiple linear regression (Eq. 7):

$$\log \frac{1}{C} = a\sigma + b\pi + \text{const.} \quad (7)$$

where C is the molar concentration or dose that leads to a defined biological effect (for example EC_{50} , LD_{50}). This formalism, known nowadays as a Hansch analysis, provides a flexible model that is able to describe different kinds of biological activities, especially from *in vitro* experiments. Later it was extended to more than two parameters and also included nonlinear terms to describe partitioning in more complex systems like organisms (Hansch and Fujita). The first extension, also derived by Hansch, used a parabolic dependence on $\log P$ to model partitioning. However it proved to be inappropriate for describing all kinds of lipophilicity-activity relationships. Using computer simulations of drug transport, Kubinyi developed the so-called “bilinear model” that described

nonlinear relationships in a much more flexible way (Eq. 8).

$$\log \frac{1}{C} = a \log P - b \log(\beta P + 1) + \text{const.} \quad (8)$$

In the same year, 1964, Free and Wilson independently developed a model in which individual substituents X_i were additively contributing to the biological activity. It can be formulated according to Eq. 9, where a_i ($i = 1, 2, \dots, n$) are the individual contributions of all n substituents attached to the molecules at various positions and is the calculated activity of a reference compound. The presence of a given substituent is indicated by 1 and its absence by 0. Any compound can be taken as a reference and often the unsubstituted derivative is used.

$$\log \frac{1}{C} = \sum a_i + \mu \quad (9)$$

The Free-Wilson analysis can be easily applied, as no physicochemical parameters are needed. However it has several restrictions compared to the Hansch analysis. First, no information can be gained about the effects of substituents not present at a given position. Second, if a large number of parameters are involved, the regression analysis can lead to statistically insignificant contributions from many substituents and loss of useful information. This necessitates a thorough selection of the relevant substituents, which can be done by stepwise regression analysis or, more efficiently, by evolution strategies or genetic algorithms (see below). It is also possible to derive the underlying physicochemical properties from an analysis of the contributions of the substituents by a Free-Wilson analysis deriving in this way a Hansch analysis (1). Both types of analysis can be combined; positions with larger structural variation can be described by physicochemical descriptors, those with small variation by Free-Wilson indicator variables. A comprehensive overview on classical QSAR is given in (2).

Molecular Descriptors Used in Classical QSAR

Three kinds of molecular descriptors can be classified:

- based on physicochemical properties, either measured or calculated,
- based on topological properties,
- derived from quantum mechanical calculations.

Descriptors based on physicochemical properties can be largely divided into three groups: (i) electronic, (ii) lipophilic and (iii) steric (bulk). Those that characterize electronic properties are σ -Hammett values and related scales, \mathcal{F} -values that represent the inductive (field) effect of a substituent and \mathcal{R} -values that characterize the resonance effect of a substituent, spectroscopic data

like IR-frequencies of a common functional group and NMR chemical shifts. The latter descriptors are derived from the actual series of derivatives and usually describe the electronic effects of the substituents better than those derived from model systems. The drawback of such descriptors is that they are available only for derivatives already synthesized. Parameters describing hydrogen bonding could also be related to this group. Interestingly, they have been mostly neglected in classical QSAR, with the exception of the linear salvation energy relationship (LSER) developed by Kamlet and Taft and independently by Abraham. Another approach to describing hydrogen bond acceptor and donor properties has been developed by Raevsky. In the second group of parameters the logarithm of the partitioning coefficient (P) is mostly used. For the organic phase, 1-octanol is now the established standard organic phase, though it was shown that other organic phases and especially liposomes can provide better model systems. Another parameter to characterize the lipophilicity of a substituent is the π -value introduced by Hansch. Fragment values of atoms and/or functional groups are also used. There are several computational methods that aim to calculate $\log P$ solely from the molecular structure (3). None of them has been proven to be accurate in all cases, so they should be used with care, establishing that they are able to calculate correct $\log P$ differences for the series of compounds investigated by comparison of measured with calculated values for a few compounds.

Lipophilicity parameters refer to the neutral, unionized form of the compound. However, most drugs are partly ionized at physiological pH. As long as the pK_a values of the compounds under investigation do not differ too much this poses no problem in the QSAR analysis. However if the pK_a values differ significantly, the different degree of ionization has to be taken into account. Partitioning of acids and bases is pH-dependent. For bases the partition coefficient is constant at high pH and decreases with lower pH when ionization starts. When pH is further decreased the partition coefficient decreases by about one log-unit per pH unit until the $\log P$ of the ionized form is reached. The difference between the partitioning of the neutral and the ionized form has been found to be 3–4 orders of magnitude in many cases. To account for the different degree of ionization, the distribution value $\log D$, or $\log P_{app}$, can be measured at a certain pH or calculated from $\log P$. Neglecting the partitioning of the ionized form, Eq. 10 is used for acids and Eq. 11 for bases.

$$\log D = \log P - \log(1 + 10^{pH - pK_a}) \quad (10)$$

$$\log D = \log P - \log(1 + 10^{pK_a - pH}) \quad (11)$$

It is nowadays more and more recognized that membranes are an integral part of biological systems and that even passive transport across membranes can be a very selective process so that no single model partitioning system can account for transport across all kinds of membranes (4).

The third group of parameters relates to the steric (bulk) properties of the substituents. The molar refractivity MR, a measure of compound volume and polarizability is very popular. Another steric descriptor is the van-der-Waals volume V_w derived from Bondi. Both measures assume that the substituent is a sphere and neglect differences in spatial requirement in 3D space of nonspherical substituents. The STERIMOL parameters, developed by Verloop are an attempt to incorporate the shape of substituents. The substituent is described by its length (L), minimal width (B_1) and maximal size (B_4 , B_5). The major problem in this approach is that it requires up to four descriptors per substituent position, in this way necessitating a larger data set.

Soon after the start of the modern QSAR methodology many molecular descriptors based on topological properties of the molecular graphs or information indices were calculated and investigated for their use in QSAR analysis. They can easily be computed from the 2D representations of the chemical structures; however, even if a significant relationship is found, it is hard to interpret their meaning.

Quantum chemical, molecular orbital-based parameters are also used. Yet computed structural parameters may only be applicable to the set of compounds under investigation, while physicochemical characteristics of molecules can, in principle, be extended to other groups of molecules. A comprehensive summary of QSAR parameters is given in (5).

Variable Selection

The aim of a QSAR analysis is the development of a model that can fit the data, can predict the property of interest and can be interpreted to guide further synthesis and optimization of the desired properties. The availability of several hundred molecular descriptors poses the problem of selecting the “right” ones. Another problem relates to the increased risk of chance correlations by testing a large number of potential descriptors. Several statistical techniques like forward and backward elimination of variables or stepwise regression are used to cope with large numbers of potential descriptors. However, experience has shown that they often end up in a local optimum, especially if large numbers of variables are considered. Evolutionary and genetic algorithms have been proven to be superior, as they generate optimal or nearly optimal models very fast and efficiently.

To decide on the best QSAR models is not straightforward. The best fit can easily be checked by statistical parameters of the regression and cross-validation is often used to check predictivity. Here one compound at a time is removed from the data, the model is developed and the activity of the missing compound is predicted from the model. This process is repeated till all compounds have been left out once (leave-one-out, LOO-cross-validation). A more stringent way is to remove a larger part of the compounds temporarily from the analysis and to predict their activities from the model generated from the reduced data set (leave-group-out). Again this is repeated until all compounds have been left out and their activities have been predicted. As this procedure is not deterministic, it is necessary to repeat it several times, selecting the compounds to be left out at random, to get a valid statistical estimate. The predictive power of the model is measured by Q^2 as calculated according to Eq. 12, where y_{obs} , and y_{pred} are the observed and predicted activities and y_{mean} is the mean activity of the training set.

$$Q^2 = 1 - \frac{\sum_y (y_{\text{pred}} - y_{\text{obs}})^2}{\sum_y (y_{\text{obs}} - y_{\text{mean}})^2} \quad (12)$$

The real criterion for the validity of a model can only be its predictive ability for an external test set that has never been used in the process of model development. To select a proper test set from the available compounds is a hard problem. The test set should be representative and cover the chemical space as much as possible. On the other hand the chemical spaces of the training set used to build the model and the test set must not be too different. Often cluster or principal component analysis of the available compounds is performed in the descriptor space and from the resulting clusters one or more compounds are selected for the test set, while the others are used to form the training set. This ensures that training and test sets cover nearly the same chemical space but it can result in overoptimistic estimation because of similarity between the two sets. Another approach is to randomly select the test set from the available compounds, taking into account that the test set should span a similar range of activities as the training set. Ideally, in either case the procedure should be repeated several times, which is rarely done. The predictivity for the test set can be estimated by linear regression of the actual and predicted activities. This measure is biased as the slope of the regression line and the intercept are fitted. Q^2 can also be applied to the test set. However, Q^2 values can

be biased if the means of the activities of the training and the test set differ. Silverman has developed a new figure of merit P^2 that gives an unbiased estimate (Eq. 13), where p_i and p_j are the predicted activities, m_i and m_j are the measured activity values of the external test set and the summation runs over all pairs of compounds i and j in the test set (6).

$$P^2 = 1 - \frac{\sum_{i,j} [(p_i - p_j) - (m_i - m_j)]^2}{\sum_{i,j} (m_i - m_j)^2} \quad (13)$$

Though cross-validation is accepted as a measure of internal predictivity, it is not a reliable measure of external predictivity (7). A more reliable procedure to test the validity of the model and to avoid chance correlations is the so-called Y-scrambling. Here one attempts to correlate randomly ordered activities (Y-values) with the original descriptors. If no models of comparable fit are obtained after several scrambling runs, there is some confidence in the validity of the tested model.

Three-Dimensional QSAR

A limitation of classical QSAR is that it does not explicitly consider the 3D properties of the compounds such as shape and [conformation](#). It is therefore limited to homologous, or congeneric series of derivatives that share a common skeleton. In 1988 a method called comparative molecular field analysis (CoMFA) was published. This described molecular properties by fields around the molecules calculated as interaction energies on a regular grid (see below). The field values are correlated with biological activity values using partial least squares (PLS) analysis. A set of molecules that are assumed to act *via* the same mechanism is selected, but they need not have the same molecular skeleton. For all molecules, low energy 3D structures are generated. If rigid analogs or analogs having different conformational constraints are available this helps to define the bioactive conformations of the flexible molecules. Then an alignment is performed by superimposing all molecules according to the [pharmacophore](#) suggested. The alignment is the most difficult and important step in the analysis. However, it is not necessary to find and use the real bioactive conformations for the alignment, providing the essential pharmacophore pattern is correctly matched. For example, considering a set of molecules than can exist in an extended or folded conformation, very similar results will be obtained, as long as all molecules are modeled either in the extended or folded conformation. This follows from the way the field values are

correlated with the biological activities by PLS (see below). The overlaid molecules are put into a box that is sufficiently large and the interaction energies with a probe atom are calculated. Usually a C_{sp3} carbon with plus 1 charge is used as a probe atom. The box is divided into many cubes of a reasonable size (usually a default value of 2 Å is used), the probe atom is put on every grid point and the steric and electrostatic interaction energies between the probe and every molecule are calculated. Besides the steric (Lennard-Jones potential) and electrostatic (coulombic potential) interactions other fields like hydrogen bond donor and acceptor or hydrophobic fields can be considered. The interaction energies calculated at the grid points are unfolded to yield a table where each column corresponds to a given grid point and type of interaction and each row represents one molecule under investigation. As the interaction energies increase steeply near the molecular surface due to the form of the Lennard-Jones and the coulombic potentials, high values are truncated to a predefined cutoff (usually ± 30 kcal/mol) in order to decrease their influence on the result of the PLS analysis. PLS is a multivariate statistical technique that, like principal component analysis, extracts the maximum variance from a block of variables as fewer uncorrelated variables called principal components or latent variables. Unlike principal component analysis, in PLS the latent variables are extracted so that they cover a maximum of the variance of the X-block (structural parameters) and simultaneously are maximally correlated to the Y-block (the activity parameters). Cross-validation is used to determine the number of latent variables to be extracted. The results can be visualized by contour maps showing favorable and unfavorable regions of the different fields. The visual display can guide the decision as to in which parts of the molecules structural changes should be made to enhance biological activity. However, the contour maps are often fragmented and not easily interpreted. Additionally, the standard settings for the display of the contour maps can lead to wrong impressions. Over the years CoMFA has become the most popular 3D QSAR method. A critical review of published CoMFA results together with an overview on new trends can be found in (8).

Another popular 3D QSAR approach developed by Klebe and coworkers is the comparative molecular similarity indices analysis (CoMSIA). In CoMSIA, similarity fields, also calculated on a regular grid, are used instead of interaction fields. Gaussian functions centered at the atoms are used to describe different atomic properties and are compared to give a measure of similarity. The use of Gaussian functions eliminates the need for a cut-off and additionally, tolerates small

deviations in the molecular superposition without a significant impact on the results due to their smoother characteristics. CoMSIA contour maps are also usually smoother than CoMFA maps. In contrast to CoMFA maps that surround the regions with favorable and unfavorable contributions to activity, CoMSIA maps are directly located at the favorable and unfavorable groups and therefore easier to interpret. For an overview of CoMFA and other 3D QSAR methods see (9).

Other types of 3D approaches have also been developed that do not depend on the alignment of the molecules. The grid-independent descriptors (GRIND) are autocorrelation transforms of 3D field values that are independent of the relative orientation of the molecules (10). Another approach to describe molecular properties independent of alignment is proposed by Baumann (11).

“Multidimensional” QSAR

The limitation of 3D QSAR methods like CoMFA and CoMSIA to a single conformation is overcome by the recently proposed multidimensional QSAR. Instead of one conformation, an ensemble of conformations and alignments can be considered, inserting the “fourth” dimension in the QSAR methods (12, 13). Taking additionally into account the induced fit of the biological target, an introduction of the “fifth” dimension has also been proposed (14).

Quantum Yield

Definition

Quantum yield is defined as the yield of fluorescence photons per absorbed photons. It denotes a parameter that generally quantifies the efficiency of dye molecules to fluorescence.

► [Fluorescence Correlation Spectroscopy](#)

Quasispecies

Definition

Viruses with RNA genomes such as HIV–1 display a high level of genetic variation, and therefore exist as distributions of closely-related genomic variants, referred to as quasispecies, which evolve in response to selection pressure. The best known example is haemoglobin, consisting of 4 non-covalently associated folded chains (two alpha-chains and two beta-chains).

► [Reverse Transcriptase](#)

Quaternary Structure

Definition

The quaternary structure of a protein describes the interconnection and arrangement of polypeptide chains within a protein. Only proteins consisting of more than one polypeptide chain have a quaternary structure.

RACE

Definition

RACE stands for ‘rapid amplification of cDNA ends’ (also known as ‘anchored PCR’). It is a technique that allows for the amplification of mRNA for which partial sequence information is available. RACE is commonly used to identify the insertion site of the vector in gene-trapping experiments by amplifying the 5’ or 3’ end of the fusion transcript (a fusion of the endogenous exonic sequence of the locus and the reporter gene).

Radioactive Isotope

Definition

Radioactive isotope (radioisotopes) consists of unstable atoms with an unusual number of neutrons. This causes them to decay radioactively, during which they give off energy and subatomic particles. Radioisotopes do occur naturally, but are also artificially produced by bombarding particular elements with neutrons. Radioisotopes are used due to their chemical properties, for instance as tracers, and as sources of radiation.

- [Molecular Imaging Mod.](#)

Radioactivity/Radioactive Decay

Definition

The spontaneous disintegration of certain atomic nuclei (isotopes) is named radioactive decay. This process is accompanied by the emission of high energy radiation or particles and the energy produced during decay is the

basis for detection. The isotopes ^3H , ^{14}C , ^{15}N , ^{32}P , ^{33}P and ^{35}S are frequently used in biological experiments.

Ras Signalling

REINHOLD SCHÄFER

Laboratories of Molecular Tumour Pathology and of Functional Genomics, Charité, University Medicine Berlin, Berlin, Germany
reinhold.schaefer@charite.de

Definition

Ras proteins are critical nodal points of highly conserved signal transduction pathways, which integrate diverse extracellular ligand-mediated stimuli via a wide spectrum of cell surface receptors with the intrinsic transcriptional machinery. Ras signalling pathways regulate cytoplasmic processes as well as gene expression and cell-cycle progression. Depending on the cellular context, the phenotypic end-points of Ras signalling are proliferation, survival, growth arrest or differentiation. Mutated Ras proteins are crucially involved in tumorigenesis.

Characteristics

Identification of Oncogenic Ras Proteins by Reverse Genetic Approaches

Ras proteins are the founding members of a superfamily of small GTPases. Research on small GTPases and the signalling events associated with them was largely fuelled by the finding that the Ras proteins were encoded by viral and cellular **▶oncogenes**. Mutated and transforming versions of Ras proteins were identified in human and experimental cancers in the early 1980's. Ras proteins had already earlier been identified as **▶transforming proteins** in the genomes of RNA tumour viruses and had obtained their names from tumours in rodent cells infected by retroviruses. For example, Harvey sarcoma virus was found to encode the H-ras protein, Kirsten sarcoma virus the K-ras protein. In mammalian cells, the

transforming activity of Ras proteins was recognised in gene transfer experiments aiming at identifying cancer genes of cellular rather than of viral origin. For this purpose, genomic DNA prepared from cancer cells was transfected into normal murine recipient cells and the populations of transfectants were examined for morphologically altered cell colonies ("foci"). After cloning and further cultivation, the tumour DNA transfectants were injected into nude mice and gave rise to progressively growing, undifferentiated tumours. Comparing the transferred oncogene causing the tumorigenic conversion with the **▶proto-oncogene** present in normal cells revealed **▶point mutations** preferentially affecting amino acids 12, 13, and 61. The typical effect of Ras oncogenes introduced into immortalised, phenotypically normal rat recipient cells is depicted in Fig. 1. However, depending on the cell type, Ras proteins may exert other effects as well (Table 1). The prerequisites for an efficient oncogenic conversion of normal cells triggered by Ras oncogenes have been worked out in detail during recent years. Human cells require expression of telomerase for **▶immortalisation** and the inactivation of the TP53 and RB **▶tumour suppressor gene** pathways for Ras-induced oncogenesis (1).

Initially, Ras signalling *via* the non-mutated form of the protein was studied in genetically tractable model organisms. In *Drosophila melanogaster* the Ras signal transduction pathway controls eye development, in *Caenorhabditis elegans* the development of sex organs. In *Saccharomyces cerevisiae* the plasma membrane proteins Ras1 and Ras2 sense the nutritional status of the environment, e.g., the abundance and quality of available carbon sources. In particular, the genetic dissection of eye development in *Drosophila* allowed the elucidation of the order of protein interactions between the receptor level, receptor adapters, nucleotide exchanging factors and Ras. Protein interaction studies permitted identification of

Ras Signalling. Figure 1 The transfer of a recombinant expression vector harbouring the *KRAS* oncogene into immortalized rat ovarian surface epithelial cells results in epithelial-mesenchymal transition. Cells lose their epithelial shape and become motile. *KRAS* expression is associated with the loss of E-cadherin, a protein controlling adhesion of epithelial cells (Ref. 2).

Ras Signalling. Table 1 Selection of RAS oncogene effects mediated by forced expression in mammalian cells

Recipient cells	Phenotypic changes	Properties of cells
Mouse 3T3, rat 208F fibroblasts	Focus formation, loss of density-dependent growth control, anchorage independence, tumorigenicity	Immortal, spontaneously transformed
Rat ovarian surface epithelial cells	Epithelial-mesenchymal transition, anchorage dependence, tumorigenicity	Immortal, spontaneously transformed
Diploid rat fibroblasts	Focus formation, loss of density-dependent growth control, anchorage independence, tumorigenicity	Immortalisation by complementary oncogene required (e.g. Myc), additional genetic alterations (loss of tumour suppressor gene function)
Rat PC12 pheochromocytoma cells	Growth arrest, neurite formation	Chromaffin cell precursors
Human diploid fibroblasts	Premature senescence	Limited life span
Immortalized human fibroblasts and epithelial cells	Loss of density-dependent growth control, anchorage independence, tumorigenicity	Immortalisation by hTERT (catalytic subunit of telomerase), inactivation of tumour suppressors TP53 and RB by SV40

cytoplasmic kinases downstream of Ras in the signalling pathway. Initially it was believed that activated Ras would activate a simple linear cascade of cytoplasmic kinases in order to complete the link between the cell surface and the nucleus. However, Ras can affect multiple effector-mediated signalling pathways and is a component of a complex cellular signalling network showing mutual regulation and ►[cross-talk](#) (Fig. 2).

Biochemical Properties of Ras Proteins – Molecular Switches

The three mammalian *ras* genes encode four highly related 21 kD GDP/GTP-binding and hydrolysing proteins, which share approx. 90% amino acid identity, H-ras, K-Ras4A and K-ras4B (two alternatively spliced forms differing in their COOH-termini) and N-ras. The four Ras proteins show complete amino acid identity in regions important for interaction with several binding proteins (effectors). Ras proteins are located at the inner face of the plasma membrane. Their association with the membrane is mediated by a series of post-translational modifications, which target Ras proteins to functionally relevant micro-domains of the plasma membrane and are essential for their biological activity. This modification occurs in two consecutive steps. In the first step, the carboxyl terminus (CAAX-motif of the protein sequence) is farnesylated. Trafficking to the membrane is completed by ►[palmitoylation](#) at cysteine residues amino-terminal to the CAAX-motif of H-Ras, K-Ras4A and N-Ras. In the K-Ras4B protein, a lysine-rich sequence is responsible for membrane association.

Ras proteins exist in two functional conformations. The GDP-bound proteins are inactive; the GTP-bound forms are active. GDP can be exchanged for GTP (nucleotide dissociation) and GTP can be hydrolysed to GDP and P_i (hydrolytic GTP cleavage). Upon GTP/GDP cycling, the conformation in protein regions called switch I (corresponding to amino acids 30–38) and switch II (amino acids 59–76) changes tertiary structure. Together with the flanking region ranging from amino acids 25–45, the switch I and II regions make up the effector domain of Ras, which is responsible for binding to interacting proteins. In the GTP-bound state, a high affinity binding site is exposed. Nucleotide exchange and GTP hydrolysis on Ras proteins are facilitated by guanine nucleotide exchange factors (GEFs) and GTPase activating proteins (GAPs), respectively. Multiple GEFs and GAPs specific for Ras proteins have been identified. GEFs enhance the release of bound nucleotides and promote loading with GTP because of the higher intracellular concentration of GTP relative to GDP. GAPs enhance the rate of GTP hydrolysis and thus promote inactivation of Ras proteins. Oncogenic forms of Ras are locked in their active GTP-bound state and are insensitive to GAP activity (for review see refs 4 and 5).

Signalling Upstream of Ras Proteins

Extracellular signals that activate Ras proteins can be mediated through different types of receptors, tyrosine kinase receptors (e.g. platelet-derived growth factor receptor, PDGFR or epidermal growth factor receptor,

Ras Signalling. Figure 2 Schematic and simplified view of the cellular signalling network involving Ras proteins and some of their effectors (modified from ref. 3). Proteins marked in red have been shown to exhibit transforming activity in mammalian cells. M, plasma membrane; C, cytoplasm; N, nucleus; IE, immediate early genes.

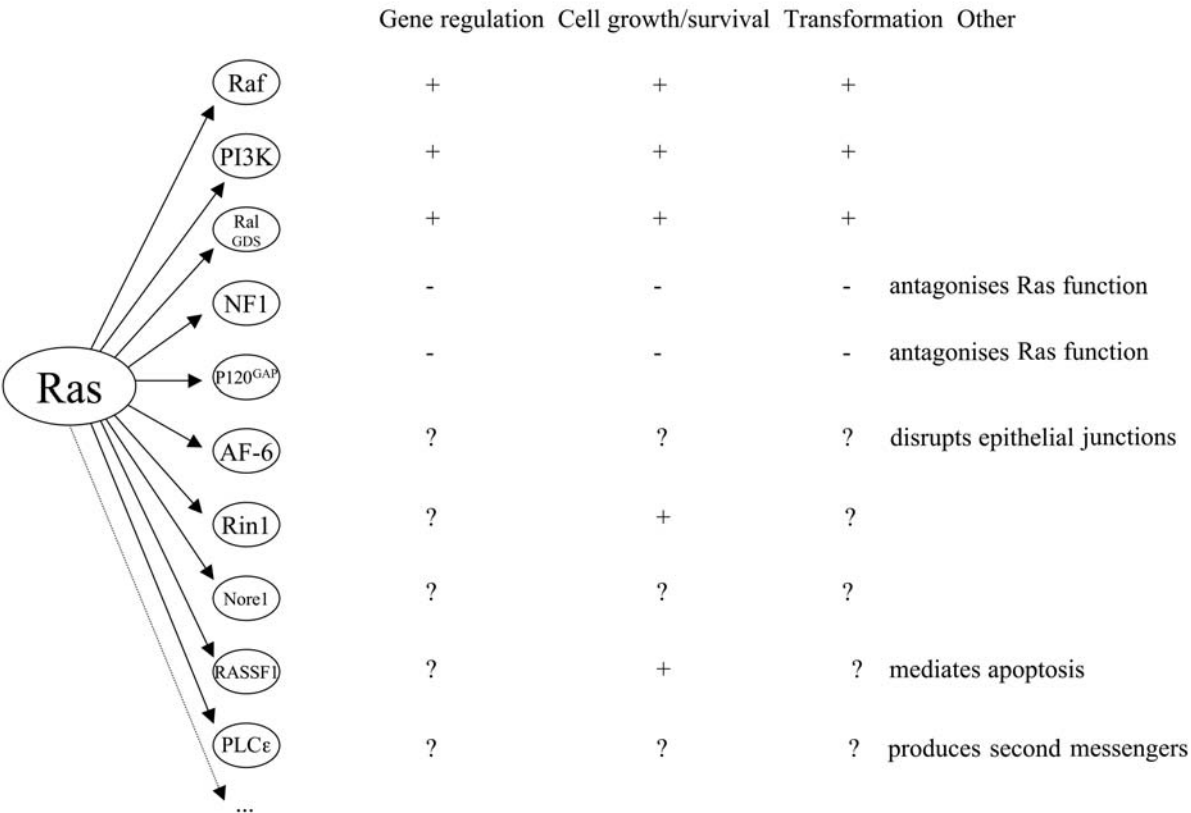

EGFR), cytokine receptors (e.g. the interleukin-2-receptor), T-cell receptors and subunits of heterotrimeric G-proteins. One of the most studied signalling processes related to Ras function is Erk activation, mediated by growth factors and tyrosine kinase receptors. Following ligand binding, Src homology domain (SH2)-binding proteins such as Grb2 or Shc bind to the phosphotyrosine residues of the activated receptor. Grb2 binds to and activates Sos, a GEF for Ras. Alternative upstream activation mechanisms involve the subunits of G-proteins or protein kinase C. The nucleotide exchange factor Sos forms a complex with Ras resulting in the release of GDP. The high intracellular GTP/GDP ratio causes replacement of GDP by GTP. The GEF then dissociates from Ras-GTP. Besides Sos, the Ras exchange factors RasGRF (cdc25Mm), RasGRP, CNRasGEF and phospholipase C- ϵ , may promote GTP/GDP exchange.

Since the intrinsic dissociation of Ras-GTP is slow and the intracellular GTP concentration is high, GAPs are required for stimulating GTP hydrolysis. Several GAPs are known in mammalian cells including p120-GAP and the neurofibromatosis type I protein (NF1).

Signalling Downstream of Ras Proteins

GTP-bound Ras proteins transmit signals down the pathway by interacting with effector proteins. A wide spectrum of proteins that interact specifically with active Ras has been isolated (Fig. 3) and it is very likely that various signals can be transduced via distinct effectors. Complex phenotypes can be achieved by the action of several signalling pathways downstream of Ras. In view of the clinical importance of permanent Ras activation, the pathways involved in tumorigenic conversion have been investigated in detail; however, the precise contribution of each effector pathway is still

Functional roles of Ras effector pathways

Ras Signalling. Figure 3 Effector proteins interacting with Ras-GTP. (+) a functional role in regulating gene expression, cellular proliferation, survival or malignant transformation has been established. (–) antagonistic function to Ras-GTP, stimulation of GTP-GDP hydrolysis and inactivation, GAPs may exert transformation suppressing function. (?) functional contribution yet unknown.

unclear. These pathways include the Raf serine/threonine kinases, Ral GEFs and phosphatidylinositol 3-kinase (PI3K). The pathways downstream of Ras have, in part, been functionally dissected by using Ras effector domain mutants. The H-Ras (12V/37G) and H-Ras (12V/40C) mutants fail to bind to Raf and activate the Ral-GDS and PI3K-pathways respectively, while the H-Ras (12V/35S) mutant preferentially activates the Raf pathway. In addition to Raf, PI3K and Ral, Ras utilises related small GTPases such as members of the Rho family to exert effects on growth and transformation (5).

Ras-GTP mediates the translocation of the serine/threonine kinases Raf (A-Raf, B-Raf and c-Raf-1) to the membrane, where other accessory factors activate the kinase function. Raf, in turn, activates the dual specificity kinases Mek 1/2. Activated MEK phosphorylates and activates ERK 1/2 mitogen-activated kinases (▶MAPKs). Phosphorylated Erk activates the cytoplasmic target p90^{RSK} serine/threonine kinase to

regulate protein synthesis and translocates into the nucleus to activate transcription factor targets such as Elk 1 and Ets family members (Fig. 2). In this way, mutated Ras proteins achieve a permanent activation of the down-stream signalling cascade and the reprogramming of gene expression. The Raf/MAPK pathway has been found to play a critical role in the control of cell-cycle progression. However, it can also protect against certain apoptotic stimuli.

In addition, Ras interacts with the p110 catalytic subunit of PI3K and stimulates its lipid kinase activity. This results in the conversion of phosphoinositides that bind to the serine/threonine kinase Akt/PkB and Rac GDP-GTP exchange factors. Akt/PkB can phosphorylate multiple targets that prevent apoptosis in various ways. One of the Akt-mediated effects is the inactivation of the AFX forkhead transcription factor. This inhibits AFX from entering the nucleus and prevents expression of the death-activating Fas ligand. Another effect is activation of IKK, which causes inactivation of

the NF κ B-inhibitor I κ B. NF κ B can translocate into the nucleus and stimulate expression of anti-apoptotic genes. PI3K also causes activation of the small GTPase Rac, which can also activate NF κ B *via* the production of reactive oxygen species. Although the PI3K/PkB/Akt pathway was initially implicated in mediating anti-apoptotic signals generated by growth factors, extracellular matrix and Ras, it can also contribute to cell-cycle progression.

Several lines of evidence suggest that RalGDS and Ral GTPase contribute to Ras-mediated transformation. Ras-mediated activation of RalGDS, like Raf activation, involves recruitment to the membrane and subsequent activation of RalA and B. Downstream of Ral, the Ral-binding protein RBP1, a GTPase activating protein, negatively regulates Rac and cdc42 GTPases. Another Ral interaction protein is phospholipase D1. The RalGDS effector pathway may affect the activity of transcription factors regulated by Rho GTPases (4, 5).

Studies on Ras-induced transformation of fibroblasts have revealed that the activity of Rho family GTPases is needed. Signalling crosstalk involves several members of the Rho family such as RhoA and B, Rac1,

cdc42 and others. A functional link between RhoA-GTP and cell-cycle regulation is established by inhibition of p21^{Waf/Cip1}. Ras and Rho pathways regulate the nuclear targets Elk-1 and SRF, respectively. These factors in turn act synergistically to activate c-Fos transcription.

Nuclear Targets of Ras Signalling Pathways

Transcription factors activated as a consequence of Ras signalling comprise Ets 1/2, Elk-1, NF κ B, SRF, c-Fos, c-Jun, c-Myc and E2F. The regulatory sequences of genes up-regulated on Ras activation harbour binding sites for these transcriptional regulators. The functional roles of these binding sites readily explain the impact of Ras signalling on the stimulation of gene activity. The up-regulation of genes exhibiting a critical function in the tumorigenic process may explain why the molecular Ras switch is of central importance for the malignant properties of cancer cells (6). More recently, the number of candidate Ras-responsive genes has increased dramatically due to comparative transcriptome analysis of normal and Ras-transformed cells. Detailed functional studies are required to find out which of these candidate

Ras Signalling. Table 2 Selection of Ras-responsive genes and their functional roles in transformation and tumorigenesis

Gene product	Function
Up-regulated upon RAS-mediated signalling	
Cyclin D1	Cell-cycle progression
COX-2 (inducible cyclooxygenase-2)	Promotion of cell survival
MMPs (matrix metalloproteases)	Destruction of extracellular matrix, invasion, metastasis
VEGF (vascular endothelial growth factor)	angiogenesis
RhoC	metastasis
Fra-1	Transformation, motility, invasion
Down-regulated upon RAS-mediated signalling	
TMs (high molecular weight tropomyosins)	Stabilisation of actin filaments, maintenance of cell shape
Lox (lysyl oxidase)	Stabilisation of extracellular matrix
Tsp-1 (thrombospondin)	Inhibition of angiogenesis
Timp-1 (tissue inhibitor of metalloproteases)	Inhibition of invasive properties
E-cadherin	Cell-cell adhesion, inhibition of invasive properties
Several transformation suppressors: WT1 (Wilms tumour suppressor) HTS1 (HeLa tumour suppressor) Lot1 ("lost in ovarian tumours", putative suppressor of ovarian carcinoma)	Tumour suppression

genes are essential for the transformed phenotype or are secondary to transformation. Gene expression profiling studies have also suggested that the number of genes down-regulated equals the number of up-regulated genes (2, 7). The mechanisms for target gene repression upon expression of Ras oncogenes are currently unknown. Some Ras-responsive genes exhibiting a critical role in proliferation and transformation are listed in Table 2.

Clinical Relevance

Ras mutations that lock the molecular switch in its active state have been found overall in about one third of all human cancers. The prevalence of mutations differs in distinct tumour types, e.g. approx. 90% in pancreatic cancer, about 50% in carcinomas of the colon, lung and thyroid. Mutations are infrequent in carcinomas of the breast, ovary and cervix (8). However, there are alternative mechanisms leading to persistent Ras activation in cancer. Over-expression of Her2/neu/ErbB2, a receptor tyrosine kinase, is prevalent in mammary and ovarian cancer. Similarly, inactivating mutations of NF1 encoding a GAP in malignant schwannomas produce high Ras-GTP levels. Moreover, the Ras-mediated signalling pathway may be activated by mutation of the downstream kinase Raf in melanoma and ovarian carcinoma. In view of the crucial role of Ras-mediated signalling in the control of proliferation and the tumorigenic phenotype, therapies targeting Ras proteins as well as active components of the signalling network such as membrane-bound receptors and cytoplasmic kinases have been developed (9) and are currently being tested in clinical trials.

Ras Superfamily of Small GTP Binding Proteins

Definition

Like all other GTPases, members of the Ras superfamily of small GTPases cycle between GDP and GTP-bound conformations. Generally, both binding and hydrolysis of GTP require assistance of accessory proteins. These include guanine nucleotide exchange factors (GEFs) which catalyze exchange of GDP for GTP, and GTPase-activating proteins (GAPs) which catalyze the hydrolysis of GTP to form GDP. In many cases, the GTP-bound conformation is membrane associated via an exposed isoprenoyl or fatty acyl anchor covalently attached to the GTPase, and interacts with specific effector proteins. Among the effector proteins of ARF-like GTPases are coat proteins, but also lipid-modifying enzymes.

► [Protein and Membrane Transport in Eukaryotic Cells](#)

Ras-Like GTPases

Definition

Ras-like GTPases belong to the large superfamily of monomeric 20–40 kDa GTP-binding proteins, which oscillate between GTP-bound (active) and GDP-bound (inactive) states. They serve as molecular switches in many fundamental cellular processes like proliferation and differentiation.

Reading Frame

Definition

During translation of a sequence of nucleotides into a protein, reading frame means reading progressively through the nucleotide sequence by grouping of non-overlapping triplets (codons). Since the codons are made up of three nucleotides, there are three possible frames; only one of them is the reading ("sense") frame, also called frame zero. If genes are not read in a multiple of three, or translation begins with a different starting point, they are considered out of the reading frame, spoiling regular translation.

Definition

Receptor serine/threonine kinases (►RSKs) are transmembrane proteins of the plasma membrane and are characterized by extracellular ligand-binding domains and cytoplasmic kinase domains. All RSKs of the human genome act as signaling receptors for members of the transforming growth factor β (►TGF- β) superfamily of secreted polypeptides (5). Accordingly, RSKs are known to play major roles in multiple physiological and pathological processes of metazoan life, including early embryogenesis, adult tissue homeostasis, atherosclerosis, tissue fibrosis and cancer (1, 3).

Rearrangement of Immunoglobulin Genes

Definition

Immunoglobulin molecules are coded by hybrid genes that are created randomly by the genomic rearrangement of DNA sequences.

►Chromosomal Instability Syndromes

Characteristics

Type I and Type II RSKs

RSKs can be divided into two subgroups, the type I and type II RSKs, based on primary amino acid sequence comparison (5). Upon ligand binding, a heteromeric complex of type I and type II receptors are formed, in which the type II RSK phosphorylates and activates the type I RSK. Type I RSKs therefore play the major role in activating downstream effectors of the signaling pathway. The type I receptors appear to have diverged more in relation to a hypothetical common ancestral precursor of RSKs. The vertebrate family includes seven type I and five type II receptors which bear multiple names in the literature. For a complete nomenclature we refer to the LocusLink database (<http://www.ncbi.nlm.nih.gov/LocusLink/>).

RSKs During Evolution

The human RSK family of 12 members is considerably smaller than the 58-membered receptor tyrosine kinase (▶RTK) family. RSK members are abundant in all metazoan species and appear even in the lowest phyla of Porifera (e.g. the sponge *Ephydatia*) and Cnidaria (e.g. the coral *Acropora*). They have been studied to various degrees in all metazoan model organisms, including *A. californica*, *C. elegans*, *D. melanogaster*, *X. laevis*, *D. rerio*, *M. musculus*, *R. norvegicus* and *H. sapiens*. Despite more than 300 receptor-like kinases identified in plants such as *A. thaliana*, counterparts of the vertebrate RSKs seem to be absent from plants and also from fungi or protists. Thus, the evolutionary emergence of the RSKs in metazoans correlates with their functional roles in mediating the physiological effects of TGF- β superfamily ligands and thus regulating cell-cell interactions and cellular movements important for the development of multilayer tissue patterns.

Invertebrates have fewer RSKs than vertebrates. Among invertebrates with fully sequenced genomes, *C. elegans* has three RSKs, one type II receptor (Daf-4) and two type I receptors (Daf-1, Sma-6) and *D. melanogaster* has four RSKs, two type II receptors (Punt, Wit) and two type I receptors (Tkv, Sax). The twelve human or mouse RSKs are commonly classified on the basis of the specific ligand they recognize or on the basis of the effector pathway they stimulate (Fig. 1A). Thus, we distinguish the TGF- β type II (▶T β R-II), the ▶activin types IIA and IIB (▶ActR-IIA, ▶ActR-IIB), the ▶BMP type II (▶BMPr-II) and the AMH type II (▶AMHR-II) receptors. On the other hand we recognize the TGF- β type I (▶T β R-I, also known as ▶ALK-5, activin receptor-like kinase 5), the activin/nodal types IB and IC (▶ActR-IB/ALK-4, ▶ActR-IC/ALK-7), the BMP types IA and IB (▶BMPr-IA/ALK-3, ▶BMPr-IB/ALK-6) and the dual specificity TGF- β /BMP type I receptors (ALK-1, ALK-2).

Structure of RSKs

All RSKs are single-span transmembrane proteins with their N-terminal ligand-binding domains extracellularly and their C-terminal kinase domains intracellularly (Fig. 1B) (5,6). The ectodomains include a primary cysteine-rich fold with a characteristic cluster of three cysteines proximal to the transmembrane domain. In addition, the extracellular domains of RSKs are glycosylated. The α helical and amphipathic transmembrane domains are important to orient the kinase domain properly in the receptor complex thereby allowing signaling. The cytoplasmic juxtamembrane domains are generally short and of divergent sequence content that may play roles in signal transduction. This is well documented for the type I RSKs whose characteristic TTSGSGSG (GS) motif immediately preceding the kinase domain plays an important role in regulation of the type I receptor kinase activity. The main part of the RSK cytoplasmic domain consists of a kinase domain that shows specificity towards phosphorylation of serines and threonines. Finally, RSKs have cytoplasmic tails which are mostly short but which in certain receptors can be longer. These tails are very divergent in sequence composition, and like the juxtamembrane domains, may contribute to propagation of signal transduction.

Molecular Interactions

Extracellular Interactions

RSKs participate in signal transduction cascades initiated by TGF- β superfamily members. Access of these extracellular ligands to the receptor complex is regulated by several ligand-binding proteins and by accessory receptors.

Ligand-Receptor Interactions

After synthesis at ribosomes of the rough endoplasmic reticulum, RSKs traffic *via* Golgi and exocytic vesicles and eventually reside on the plasma membrane as monomers or homodimers. After ligand binding, a heteromer of two type II and two type I receptors is formed (6). Whereas both type I and type II receptors are needed for high affinity ligand binding, the relative contribution differs between TGF- β and BMP receptors. Thus, the extracellular domains of T β R-II and ActR-IIA/ActR-IIB have high affinity for TGF- β and activin, respectively. In contrast, ectodomains of T β R-I or ActR-IB have weak affinity for the same ligands. Inversely, BMPr-II has weak affinity for BMP ligands, whereas BMPr-IA or BMPr-IB show stronger affinity for the same ligands.

The ligand-receptor model has recently been understood at the atomic level and provides a unifying mechanism of initiation of signal transduction by TGF- β members (7). Yet, the model cannot provide unique

Receptor Serine/Threonine Kinases. Figure 1 RSK family of TGF- β superfamily receptors. (a) Ligand-RSK combinatorial specificity. Heteromeric RSKs embedded on a lipid bilayer (double line) are shown, whereby type I RSKs (grey) pair with type II RSKs (white) and bind dimeric TGF- β superfamily ligands (light grey ovals). The receptor cartoons highlight their modular structure. The name of each RSK is shown and when multiple type I receptor combinations have been described with a single type II receptor or vice versa, the multiple receptors are listed in a consecutive acronym. The known corresponding ligands for each RSK combination are listed (light grey background). Ligand-binding proteins (white boxes) that sequester and block (inhibitory arrows) ligand release and binding to RSKs are listed on top. Nomenclature of abbreviated ligand-binding inhibitors: TSG, twisted gastrulation, DRM, drumstick, LAP, latency associated peptide. The specific Smads activated by each RSK complex are listed below the RSK cartoon. (b) Structure-function relationships of RSKs. Type I (grey) and type II (white) RSKs are drawn to highlight their modular structure. Their N- and C-termini, ligand-binding domains (light grey background), kinase domains and the glycine/serine-rich motif (GS) of type I RSKs are marked. Small black circles indicate conserved cysteine residues. Chains of grey circles indicate N-linked carbohydrates. Circled P indicates phosphorylated serine or threonine residues and curved striped arrows point to auto-phosphorylation events, while a flat grey arrow points to trans-phosphorylation events.

heteromeric pairs of RSKs for each TGF- β ligand. This is obvious since, for example, the human genome has approximately 40 TGF- β superfamily ligands, yet only five type II and seven type I RSKs occur. Accordingly, multiple ligands of the superfamily form functional complexes with the same type I/type II RSK complex. The exact mechanisms underlying signaling specificity in various cellular contexts remain to be elucidated. Thus, Fig. 1a illustrates the current knowledge of

ligand-receptor associations, which may be refined in the future. A good example of the combinatorial complexity created by the hetero-tetrameric model of the RSKs is the known use of the type I receptor T β R-I. T β R-I together with T β R-II makes the classic TGF- β receptor complex expressed in most cell types. However in endothelial cells, TGF- β signals *via* two type I receptors, T β R-I and ALK-1, and thereby transmits a dual set of signals (Fig. 1a), leading to distinct

downstream signaling cascades and physiological responses. Finally, T β R-I serves as a component of the myostatin receptor together with ActR-IIB. Thus, a single RSK can serve as a receptor subunit for multiple ligands, it can pair with multiple type II receptors and can also combine with alternative type I receptors.

Ligand Antagonists and Coreceptors

The recognition of TGF- β superfamily ligands by RSK complexes is tightly regulated in space and time. Usually, TGF- β ligands are released in a well-controlled manner leading to graded responses that can be regulated by multiple feedback loops and alternative signaling pathways that operate in the same or a neighboring cell simultaneously (5). For these reasons, a growing number of extracellular or membrane-bound factors (some of which are listed in Fig. 1a) cooperate with or antagonize the ligand-receptor interaction. Some of these proteins act negatively by sequestering ligands in the extracellular environment (6). They can be polypeptides derived from the same propeptide as the mature ligand, as is the well-documented case of TGF- β 1, whose N-terminal latency associated peptide (\blacktriangleright LAP) binds non-covalently to the mature dimeric TGF- β 1. The complex is also bound by additional proteins called latent TGF- β binding proteins (\blacktriangleright LTBPs), which constitute integral components of the extracellular matrix. Other examples are the protein follistatin that binds with high affinity activins and thus prohibits their binding to their cognate receptor complex and noggin, a BMP-specific antagonist that also traps extracellular BMPs and precludes them from binding to their receptors. Some other proteins act in a positive manner and these are usually transmembrane receptors themselves or proteins that link to the plasma membrane *via* glyco-phosphoinositide tails (5, 6). For example, the transmembrane proteoglycan receptor betaglycan and its structurally related transmembrane receptor endoglin bind TGF- β with high affinity and mediate its presentation to the signaling RSK complex, thus acting as accessory receptors. In contrast, the truncated receptor BAMBI pairs with BMP RSKs and inhibits proper signal transduction by BMPs.

Intracellular Interactions

Intracellular interacting proteins serve as direct substrates of RSK, as regulators of the kinase activity and as modulators of signaling *via* affecting accessibility of receptors to down-stream targets and *via* compartmentalization of receptors in cells. More than 30 different intracellular proteins have been found to interact with

RSKs (2, 4, 6). RSKs themselves form stable complexes with each other due to an interaction of their intracellular parts. Formation of such complexes, initiated by ligand binding, leads to activation of kinases and is the key event in initiation of the intracellular signaling.

Smads

\blacktriangleright Smad proteins are essential intracellular signal transducers of RSKs (4, 6). Smad proteins are divided into three classes; receptor-regulated Smad1, 2, 3, 5, and 8, and inhibitory Smad6 and 7 interact with RSKs, whereas common-mediator Smad4 has not been found in complex with RSKs. Receptor-dependent phosphorylation of receptor-regulated Smads is the triggering event in Smad-induced signaling. After phosphorylation by RSKs, Smads form complexes with various proteins, including common-mediator Smad4, transcription factors and co-activators; these Smad complexes then regulate gene expression. Despite structural similarity with other Smads, Smad6 and Smad7 inhibit the signaling by interacting with RSKs.

Modulatory Proteins

RSKs form complexes with modulatory proteins (2, 4, 6). As for RTKs, scaffolding, adaptor and kinase-regulating proteins regulate RSK signaling. The interaction of T β R-I with \blacktriangleright FKBP12 prevents the receptor kinase from spurious activation by stabilizing the kinase in an inactive conformation.

Proteins interacting both with Smads and with receptors serve as adaptors for Smad-dependent signaling. For example, an interaction of T β R-I with \blacktriangleright SARA enhances receptor-dependent phosphorylation of Smad2. Another protein, Dab-2, also forms a link between T β R-I/T β R-II and Smad2, thus increasing signaling efficiency. TRAP1 that forms a complex with Smad4 and with RSKs facilitates the interaction between Smad4 and receptor-regulated Smads. On the other hand, interaction of Smad3 with ARIP1 in complex with the ActR-IIA receptor results in inhibition of Smad3-dependent transcription, suggesting both enhancement and inhibition of Smad signaling by interacting proteins.

Two proteins interacting with BMPR-IA receptor, BRAM1 and XIAP, were claimed to form a link from RSKs to the TAB1 protein, thus enhancing the interaction with the TAK1 kinase (2). This link provides an example of a mechanism whereby RSKs activate the MAP kinase pathways or NF κ B signaling. Links of TGF β and activin signaling to induction of apoptosis can be provided by Daxx, which forms a complex with T β R-II and Fas receptor. Another adaptor protein, Dok-1, acts as a link

between activin receptors and the Smads; Dok-1 augments activin-induced apoptosis in B cells. An interaction of T β R-I with the B α subunit of PP2A phosphatase was shown to mediate an inhibition of p70 S6 kinase and induce cell-cycle arrest. Formation of a complex between T β R-I, T β R-II and the p85 subunit of PI3 kinase may provide a link to regulation of cytoskeletal rearrangements, whereas interaction of LIM kinase 1 with BMPR-II suggests a more direct link to regulation of the cytoskeleton.

Interactions of RSKs with caveolin-1, STRAP, Smad7, ▶Smurf1 and Smurf2 suggest biochemical mechanisms for endocytosis of RSKs into caveolin-positive vesicles and further degradation or recycling of receptors. Interaction of RSKs with proteins, such as SARA, Hgs/Hrs and Dab-2 is associated with localization of RSKs to early endosomes, where Smads can be activated in addition to their signaling from the plasma membrane. ARIP2, TLP-1, sortin nexins and dynein light chain proteins are other examples of interacting proteins which affect endocytosis and trafficking of RSKs.

A number of interacting proteins still await functional studies of their roles in RSK signaling *in vivo*, e.g., apolipoprotein J/clusterin, LXR β , farnesyl transferase α and cyclin B (2). Recent application of proteomic technologies showed that the number of RSK-associated proteins is significantly higher; for example, 33 proteins were found to associate with BMPR-II. This suggests that RSKs form distinct complexes with different signaling potentials.

Regulatory Mechanisms

Regulation of RSK by Post-Translational Modifications

Three types of post-translational modifications have been described for RSKs, phosphorylation, N-glycosylation and ubiquitination.

Glycosylation

RSKs are N-glycosylated in their extracellular domains (5). For example, the T β R-I has one and the T β R-II has three glycosylation sites (Fig. 1b). Other RSKs show rather heterogeneous electrophoretic migration patterns that suggest glycosylation to varying degrees, which depends on the specific receptor and the cell type where the receptor is expressed. The glycosylated ectodomain of T β R-II was shown to have higher affinity for the ligand, as compared to the non-glycosylated receptor. This suggests that glycosylation may enhance recognition of the ligand by receptors.

Phosphorylation

A well-characterized mechanism for regulation of RSK activity is phosphorylation (6, 7). All studied RSKs are phosphorylated on multiple sites in their intracellular domains; phosphopeptide maps showed at least 16 phosphorylated peptides in T β R-I, 17 phosphopeptides

in T β R-II and 18 phosphopeptides in BMPR-II. Many of the phosphorylation sites are due to receptor autophosphorylation or to phosphorylation by another RSK. However, phosphorylation of kinase inactive receptors has also been observed, suggesting that RSKs may also be phosphorylated by other kinases. The T β R-I kinase is activated by phosphorylation in the juxtamembrane GS-rich region located immediately N-terminally of the kinase domain (Fig. 1b). Phosphorylation of Thr185, Thr186, Ser187, Ser189 and Ser191 in the GS-region of T β R-I changes receptor conformation to the active state. A similar model of kinase activation may be valid for T β R-II, as phosphorylatable Ser213, Ser225, Ser228 and Ser229 residues are located in similar proximity to the kinase domain as the GS-region in T β R-I (Fig. 1b). The patterns of total phosphorylation of other RSKs in response to ligand stimulation are similar to those of T β R-I and T β R-II, but a detailed characterization of phosphorylation sites remains to be performed. Such studies will unveil whether the model of activation of the T β R-I kinase is valid for other RSKs.

In addition to phosphorylation sites in the juxtamembrane region, T β R-II phosphorylation was described at Ser409 and Ser416 in the kinase domain with positive and negative effects on the kinase activity, respectively. Ser551 and Ser553 in the C-terminal tail of T β R-II are also phosphorylated, the functional importance of which remains to be elucidated. There is one example of a phosphorylation that did not affect the kinase activity but rather modulated signaling; phosphorylation of Ser165 in T β R-I enhanced TGF β -dependent growth inhibition but decreased pro-apoptotic signaling.

Structural studies showed that the T β R-I kinase has certain features which are more similar to RTKs than to non-receptor serine/threonine kinases (6, 7). This observation suggested that not only serine and threonine, but also tyrosine residues might be phosphorylated by RSKs. In agreement with this notion, T β R-II was found to autophosphorylate Tyr259, Tyr336 and Tyr424 residues; mutation of these tyrosine residues inhibited the kinase activity.

Ubiquitination

Poly-ubiquitination is known to trigger protein degradation. T β R-I interaction with Smad7 in complex with the E3 ubiquitin ligases Smurf1 or Smurf2 was found to result in ubiquitination of the receptor, followed by targeting of the ubiquitinated T β R-I to degradation (4, 6). The sites of ubiquitination in the T β R-I remain to be identified, as well as whether ubiquitination occurs also in other RSKs.

Function of RSKs in Development and Human Disease

Being mediators of TGF- β superfamily signaling, RSKs are critical regulators of embryonic patterning, cell

proliferation, apoptosis, differentiation and pathogenic processes that range from tissue fibrosis and cancer to atherosclerosis and autoimmune disease.

Knockout of RSKs in Mice

The developmental role of many of the RSKs has been determined *via* genetic ablations in the mouse (1). Complete knockout of the TGF- β receptors T β R-II and ALK-5 and the endothelial TGF- β receptor ALK-1, all lead to embryonic lethality due to severe defects in vascular development. In particular, the T β R-II knockout phenocopies the complete loss of the TGF- β 1 ligand in mice. Loss of activin receptor ActR-IIA leads to partial (25%) perinatal lethality due to defects in craniofacial development and the survivors exhibit defects in fertility, whereas loss of ActR-IIB leads to perinatal lethality due to defects in left-right and antero-posterior embryonic deregulation. Similarly, loss of the activin type I receptor ALK-4 blocks early development at the primitive streak stage and causes lethality, a phenotype largely shared by three BMP RSKs, BMPR-II whose loss arrests gastrulation, ALK-2 whose loss affects gastrulation and causes defects in endoderm and mesoderm formation and ALK-3 whose loss inhibits formation of mesoderm. In contrast, knockout of the BMP RSK ALK-6 does not affect viability, but leads to defects in chondrogenesis of the limb and female-specific defects in ovarian development. Finally, knocking-out AMHR-II phenocopies loss of the corresponding ligand, [▶AMH/MIS](#), by inducing uterine development and infertility in males. The knockout of the type I receptor ALK-7 is still awaited. Based on the predominant embryonic defects that lead to early lethality by genetic ablation of most RSKs, recent attempts focus on the generation of tissue-specific (conditional) knockouts that will allow analysis of the role of these receptors in late stages of development and in adult organs. One such example is the recent hair follicle-specific knockout of the BMP type I receptor ALK-3, which supports a role of this RSK in the progenitor cell formation of the follicle. Such technologies will most certainly bring new biological links to the normal functions of the RSKs.

RSK Mutations in Human Disease

A number of RSKs have been shown to accumulate genetic mutations in humans that lead to their malfunction and subsequent development of human genetic disorders (3,). Thus, hereditary hemorrhagic telangiectasia, a severe angiogenic defect, is linked to germline mutations in the genes encoding ALK-1 or the accessory receptor endoglin. Germline mutations in ALK-1 but also in BMPR-II are linked to the development of familial primary pulmonary hypertension. ALK-6 mutations have

been uncovered in association with brachydactyly type A2, a rare disorder of the hand. The most tissue-specific of the RSKs, AMHR-II, accumulates germline mutations that lead to persistent Müllerian duct syndrome. In addition, most RSKs seem to be mutated in human cancers. Germline mutations in the ALK-3 and ALK-5 genes are known in human cancers, such as juvenile polyposis, breast, pancreatic, biliary, cervical, head and neck tumors and chronic lymphocytic leukemia, whereas somatic mutations that primarily affect epigenetic control of ALK-5 and T β R-II are abundant in the same large spectrum of human cancers, but at least in the case of T β R-II, also in atherosclerosis.

The current rapid pace of research in the RSK/TGF- β field promises to reveal additional genetic associations between RSKs and various human disorders, reflecting the function of the RSKs as mediators of signals from TGF- β superfamily members.

Receptor Tyrosine Kinases

Definition

Receptor tyrosine kinases (RTKs) are a class of transmembrane receptors for growth factors and cytokines. They contain an extracellular ligand binding domain and an intracellular catalytic domain, which

mediates ATP-dependent autophosphorylation and phosphorylation of other proteins on tyrosine residues. These residues then serve as docking sites for SH2 domain (src-homology domain-2) containing downstream effectors, such as PI3 kinase.

Receptors

Definition

Receptors are molecules that bind to a certain extra-cellular signal, initiating specific signal transduction pathways, so leading to the expression of a certain phenotype. Receptors may be located inside the cell, e.g. for steroid hormones, or at the plasma membrane, e.g. for peptide hormones. In pharmacology, a receptor is, more generically, any molecule that is a target for a drug.

Recessive Allele

Definition

Recessive allele is one of a series of terms applied to the phenotypic effect of a particular allele, in reference to another allele (usually the standard wild-type allele), with respect to a given trait. An allele “a” is said to be recessive with respect to the dominant allele “A”, if the A/A homozygote and the A/a heterozygote are phenotypically identical and different from the a/a homozygote. A recessive character, therefore, only manifests in the homozygote.

Definition

- ▶ Recombinant protein expression in bacteria requires the insertion of a DNA fragment (▶ open reading frame,

►ORF) into an expression vector, routinely a ►plasmid vector and the transferral of this vector into bacterial cells (►transformation). The cells are then cultured and induced to express the desired protein. The cells are harvested by centrifugation, samples prepared and proteins detected by ►polyacrylamide gel electrophoresis and subsequent staining of the gel with Coomassie Brilliant Blue or silver stain or by ►immunoblotting. Protein expression in bacteria is highly scalable and can be adjusted from solid growth (colony expression), to conical flasks for liquid cultures (up to 3 l), to fermentation reaction chambers (often more than 100 l volume).

Characteristics

The growing field of proteomics is resulting in an ever-increasing demand for the production and purification of recombinant proteins for structural and functional studies, as it can be very time-consuming to isolate low abundance proteins from their native source in tissue or cells. Thus, high-throughput methods for the expression and characterisation of recombinant proteins are essential to obtain sufficient amounts of protein to be used for research. An advantage of recombinant protein expression is that the selected protein can be expressed with a fusion tag such as ►His-Tag/6×His, ►GST, ►MBP etc., which can considerably facilitate the identification and purification of the protein, as well as improve both the level of expression and the solubility. The expression of recombinant proteins in bacterial cells has become the most common method for expressing large amounts of protein and *Escherichia coli* (*E. coli*) is the most frequently used prokaryotic expression system for the high-level production of recombinant proteins (1, 2).

The use of *E. coli* has many advantages, including the ease of growth and manipulation of the organism, the availability of many different vectors and host strains that have been developed over the years and the amount of information concerning the genetics and physiology of *E. coli*. However, the *E. coli* expression system also has limitations such as the inability to carry out complex posttranslational modifications, for example glycosylation, myristoylation, phosphorylation, signal sequence cleavage and extensive disulfide bond formation. Another problem can be the production of misfolded or aggregated protein in insoluble inclusion bodies or problems with the expression of “toxic” gene products. Some gene products can be toxic to the bacterial host, disrupt normal metabolism and cause bacteria to die or reduce their growth rate, making it almost impossible to generate sufficient amounts of protein for further analyses. Low levels of expression can also be due to protein degradation (3), inefficient translation (due to mRNA secondary structure in the initiation region) or eukaryotic codon usage that is not

optimal for *E. coli*. Some eukaryotic codons are rarely found in *E. coli* and can cause translation to be delayed or stopped and therefore result in severely diminished expression (2). In order to minimise some of these problems, many specialised protein expression hosts have been designed to provide for instance enhanced protein yield in T7 promoter-based systems (BL21 StarTM (DE3), Invitrogen), the tight regulation and strong expression of toxic proteins (BL21-AITM, Invitrogen) or the reduction of the basal expression of target genes via expression of T7 lysozyme (BL21 (DE3) pLysE or pLysS). Other expression hosts contain rare tRNA genes (RosettaTM, Novagen) or promote disulfide bond formation (OrigamiTM, Novagen). Thus, the decision as to which particular strain of bacteria is to be used depends on the individual application and the protein of interest.

The Cloning of DNA into a Vector

In order to express a complete protein, the exact full-length coding sequence (CDS) of the protein is required. This information can usually be obtained from databases available on the Internet such as SwissProt (►www.expasy.org/sprot/sprot-top.html), NCBI (►www.ncbi.nlm.nih.gov/) and others. The tissue, which contains the desired protein in the highest abundance, is then used to extract mRNA and in a reaction called ►reverse transcription, cDNA is generated from the many different mRNAs. The cDNA which codes for the protein of interest (open reading frame, ORF) is amplified by ►PCR using gene-specific primers and at the same time additional sequences are added, which contain restriction sites that are used to clone the DNA into a vector. Both the PCR fragment and the vector are digested using ►restriction enzymes and then joined together in a ►ligation reaction (Fig. 1). Instead of restriction enzymes, other methods can be used to clone DNA into a vector and these include the Gateway[®] Cloning System (Invitrogen) or the Creator[®] System (Clontech), both of which use ►homologous recombination and are highly efficient. Another alternative is, of course, to obtain the appropriate cDNA clone from one of the companies or institutions that distribute them; the largest of them, the RZPD (Resource Centre for Genome Research) has more than 35 mio. clones available online (►www.rzpd.de). In some cases, subcloning of the full or partial ORF is required.

There are many different plasmid vectors available for protein expression and several points need to be considered before choosing a vector, such as the type of bacterial strain which will be used, if and what kind of tag will be added to the protein, the desired level of protein expression etc. All expression vectors contain a selectable antibiotic-resistance gene, a promoter, a ►replication origin (ori), and a region into which

Recombinant Protein Expression in Bacteria.

Figure 1 Schematic representation of the steps required to obtain an open reading frame from mRNA. A mixture of many different cDNAs is produced from mRNA by using reverse transcription. With the use of gene-specific PCR, the cDNA of interest is amplified and at the same time overlaps are added to the PCR product. The overlaps contain cleavage sites recognised by certain restriction enzymes. The PCR product with the ORF is digested with these restriction enzymes, as well as the vector into which the ORF is to be cloned. Thus, compatible ends are generated in the vector and the PCR product. The ends are ligated and the ORF cloned into the vector.

foreign DNA can be inserted (known as the multiple cloning site, MCS) (Fig. 2).

The antibiotic-resistance gene facilitates the selection of positive transformants (see Transformation below). Medium is supplemented with antibiotics to kill

Recombinant Protein Expression in Bacteria.

Figure 2 Diagram of a simple expression vector. The vector contains an origin of replication (ORI), an antibiotic resistance gene (here the gene is *amp^r*, which encodes β -lactamase, an enzyme which inactivates ampicillin), a promoter, ribosome binding site (RBS), N-terminal tag, multiple cloning site (MCS) and terminator.

plasmid-free cells and maintain those that contain the plasmid with the antibiotic-resistance gene and the ORF.

The promoter is the section of DNA where RNA polymerase initiates transcription. An example is the *lac* promoter, which initiates transcription only when lactose, or the non-hydrolysable lactose analogue IPTG (isopropyl- β -D-1-thiogalactopyranoside), is added to the culture. Following induction with IPTG, the gene under control of the *lac* promoter is transcribed into mRNA, which is then translated into protein. A very popular promoter is the bacteriophage T7 late promoter (1). The T7 promoter is part of a more complicated expression system, as two levels of amplification are involved (Fig. 3). Firstly, genetically modified bacterial strains are used, which in their genome carry the gene encoding T7 RNA polymerase from the bacteriophage T7 under control of the *lac* promoter. The T7 RNA polymerase transcribes the gene under control of the T7 late promoter on the plasmid expression vector. Thus, when IPTG is added to the culture medium, the *lac* promoter initiates transcription of T7 RNA polymerase, which is translated into protein and then initiates transcription at the T7 late promoter on the expression plasmid. Thus the desired protein is produced (Fig. 3). This system leads to the synthesis of large amounts of

Recombinant Protein Expression in Bacteria. Figure 3 The two-step mechanism of protein expression with the T7 late promoter. The figure shows a section of an engineered *E. coli* chromosome, which contains the gene for T7 RNA polymerase under control of the *lac* promoter. The host also contains an expression plasmid vector with an ORF cloned into the vector under control of the T7 late promoter. When IPTG is added to the culture medium, the *lac* promoter initiates transcription of the T7 RNA polymerase gene and the mRNA is translated into protein. T7 RNA polymerase then initiates transcription at the T7 late promoter on the expression vector and the ORF is translated into the desired protein.

mRNA and results in the accumulation of the desired protein in high concentrations. The recombinant protein can represent up to 50% of total cell protein.

The origin of replication determines the approximate number of copies of the plasmid in a single bacterial cell. High copy number plasmids will yield more DNA

following a DNA preparation than medium or low copy number plasmids. High copy number plasmids also cause an increase in expression level, since the number of plasmids in a single cell correlates with the amount of protein that is expressed (when using the same promoter). However, if the desired protein is harmful to the bacterial metabolism, then a low copy vector is more appropriate, as the basal expression will be lower and thus cause less damage. Some promoters, and in particular strong promoters like the T7 late promoter, can be “leaky”, which means the protein of interest is expressed in low amounts before protein expression is induced with IPTG. This basal expression is caused by a) the high activity of T7 RNA polymerase and b) lactose in the medium. The problem can be minimised by using low copy plasmids and/or a tightly regulated promoter construct such as the arabinose p_{bad} promoter. For cloning purposes, several bacterial hosts offer advantages in particular applications. The DH10B and DH5 α strains for instance include many useful genetic markers, such as improved DNA cloning capabilities due to the *endA1* mutation (a mutation of the non-specific endonuclease endonuclease I results in reduced levels of intra- and intermolecular recombination events), which increases plasmid quality.

Transformation

Once the open reading frame (ORF) cDNA has been cloned into the appropriate vector and the strain of bacteria to be used for protein expression has been chosen, the DNA is ready for insertion into the bacterial cells. This process is called transformation.

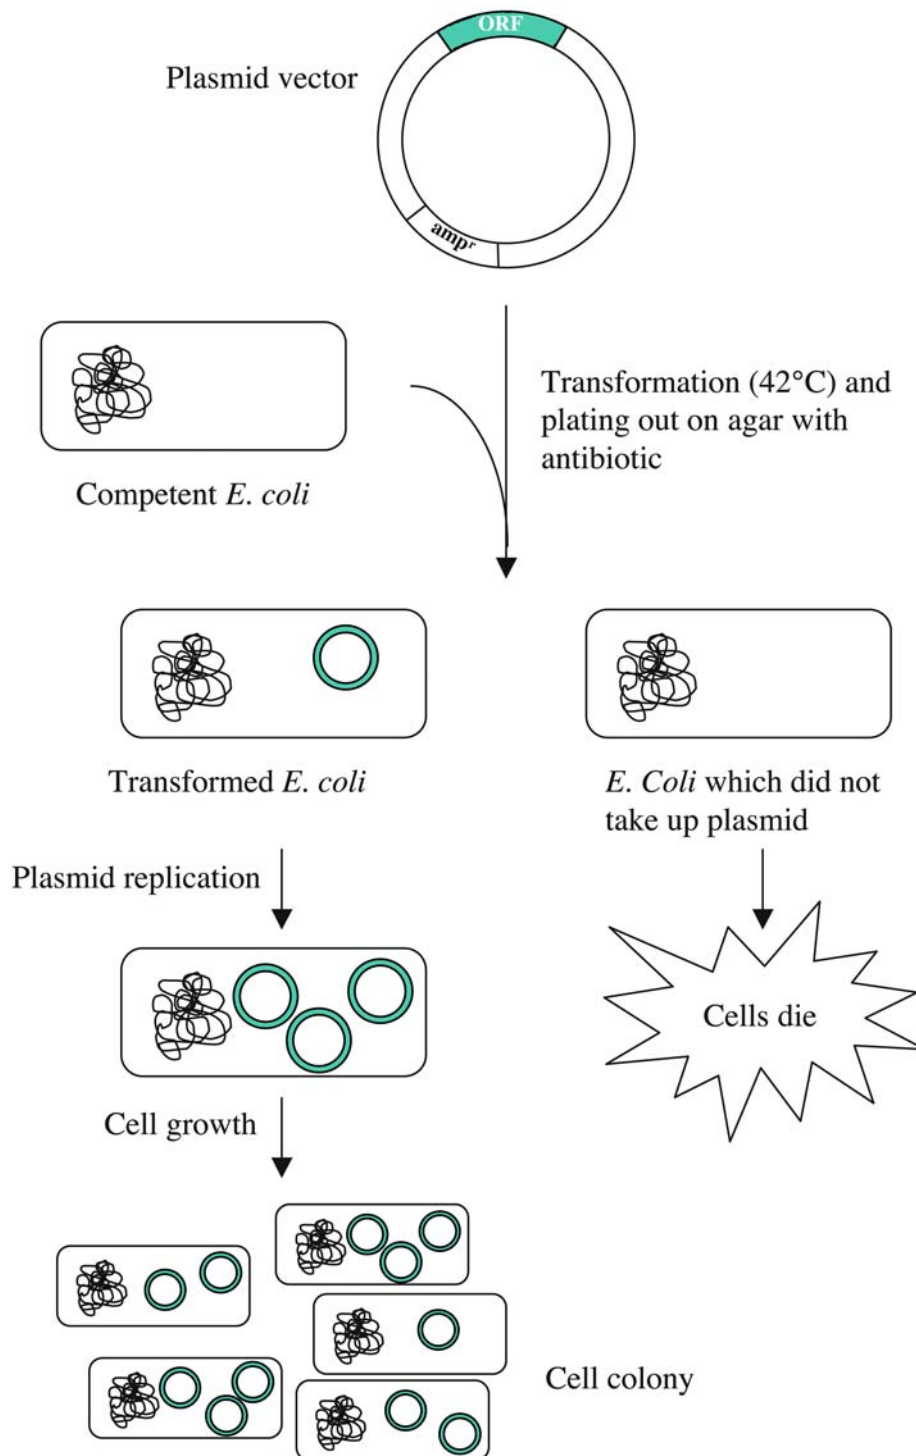

In order for a transformation to be successful, *E. coli* cells first need to be made competent i.e. permeable to foreign DNA, since normal *E. coli* cells rarely take up foreign DNA. A classical method of making bacterial cells competent is to expose them to high concentrations of calcium chloride, though the mechanism of how this is accomplished is not fully understood. In order to transform bacteria, competent cells are mixed with plasmid expression vector, briefly incubated at 42°C, grown in medium at 37°C and then plated out on a dish of agar containing an antibiotic (Fig. 4). The antibiotic is very important, as it selects for those cells, which have taken up the plasmid that contains the antibiotic-resistance gene and the ORF. All cells, which do not take up the plasmid, either die or undergo growth arrest in the presence of the antibiotic. For instance, when employing a plasmid vector that confers resistance to ampicillin, bacteria that do not take up the plasmid lack the resistance gene *amp*^R and die in the presence of this particular antibiotic. In the case of a plasmid vector conferring resistance to kanamycin, however, cells that do not contain the resistance gene *km*^R will not die, but undergo growth arrest. Thus, in order to be used in DNA cloning, a plasmid vector

should contain a resistance gene that allows for positive selection of transformants. The agar plate with the transformants is incubated overnight and colonies are picked the following day. Each colony originates from a single cell and consequently is made up of cells which all contain identical copies of the same recombinant plasmid, the expression vector with the ORF. The picked cells are incubated in medium overnight and an aliquot of the overnight culture is used to create a glycerol stock (stored frozen at –80°C) as a reference for future experiments.

Protein Expression and Analysis

For protein expression, an overnight culture is diluted in fresh medium to allow the cells to quickly return to logarithmic growth and reach the optimal cell density for induction of protein expression. The cells should be in mid-log phase when inducing protein expression, as they grow rapidly in this phase. The method of induction depends on the plasmid vector and is usually done by addition of IPTG (in the case of the T7 late promoter and many other promoters) or by temperature shift-up (in the case of the P_L promoter in combination with a specific host strain). There are different media available to culture *E. coli*, such as LB, 2YT or SOC and bacteria display different growth rates depending on the medium used. The temperature at which the cells are induced to express protein is also of importance. *E. coli* can be induced to express protein in a range of ~12°C to 42°C. The lower the temperature, the more soluble the expressed protein is likely to be, because expression proceeds at a slower rate and the protein can fold correctly and thus stay in the soluble fraction. In general, the cells are cultured for a longer time period when using a low induction temperature in order to build up sufficient amounts of protein. Thus, varying the time period and/or temperature of induction of expression is useful to elucidate the optimal conditions of protein accumulation.

Protein expression is analysed by pelleting the cells, resuspension of the pellet in ►SDS sample buffer and fractionation of the sample by polyacrylamide gel electrophoresis. The protein bands on the gel are visualised by subsequent staining of the gel with Coomassie Brilliant Blue stain (Fig. 5) or silver stain. Alternatively, if the protein has been expressed with a tag, such as a 6×His-tag or there is a protein-specific antibody available, the protein can be blotted from the electrophoresis gel onto a membrane (►Western Blot) and detected with the appropriate antibody. The solubility of the expressed proteins can be easily determined by lysing the cells, fast centrifugation and analysis of the supernatant and pellet by immunoblotting. Expressed proteins can also be analysed for function (e.g. kinase assay), but the protein may need to be purified for this purpose.

Recombinant Protein Expression in Bacteria. Figure 4 The transformation of competent *E. coli* cells. Competent *E. coli* cells are mixed with plasmid DNA, briefly exposed to 42°C (heatshock), incubated and then plated out on agar containing an antibiotic. The plasmid vector confers antibiotic resistance to those cells that have taken up the plasmid. Thus, the transformed cells survive, while the others die. The plasmid replicates independently within the cell and the transformed cells multiply to form a colony of cells all containing copies of the same plasmid.

Recombinant Protein Expression in Bacteria. Figure 5 Coomassie stained gel of protein expressions in *E. coli*. Samples were taken prior to (–) and following (+) induction of protein expression with IPTG, fractionated by gel electrophoresis and the gel stained in Coomassie Brilliant Blue stain. The molecular weight marker is indicated at the left of the figure. The gel demonstrates, how some proteins can be expressed in large amounts (lane 3 and 5), whereas others are expressed in much smaller quantities (lane 1 and 4). In lane 7, the expressed protein seems to inhibit bacterial growth, as the background staining is weaker compared to the other lanes.

Purification of Recombinant Proteins

Several vectors are available which allow expression of recombinant proteins that are fused at their N- or C-terminus to polypeptides or longer amino acid sequences. These tags can greatly facilitate purification of the expressed protein, as they bind to affinity resins. Some of the more popular tags include the 6×His tag

(which binds to ►Ni-NTA resin), GST (which binds to glutathione-Sepharose), maltose binding protein (MBP, which binds to amylose resin) or staphylococcal protein A (which binds to immunoglobulin G-Sepharose) (2, 4) (Table 1). Simple purification protocols have been devised for these and other tags, making the use of a tag one of the most common methods for cleaning up

Recombinant Protein Expression in Bacteria. Table 1 A selection of popular fusion partners and their ligands

Fusion partner	Ligand/matrix
6xHis	Ni ²⁺ -NTA
Glutathione-S-transferase (GST)	Glutathione-Sepharose
Maltose-binding protein (MBP)	Amylose resin
Galactose-binding protein	Galactose-Sepharose
Avidin	Biotin
Streptavidin	Biotin
Strep-tag	Streptavidin
c-Myc	Anti-Myc antibody
Staphylococcal protein A	IgG-Sepharose
Staphylococcal protein G	Albumin
FLAG peptide	Anti-FLAG monoclonal antibody
Dihydrofolate reductase	Methotrexate-agarose

a protein. Specific cleavage sites can be included in the sequence of the protein to allow the tag to be removed following purification (5). This is important for functional studies, since the tag can interfere with the correct folding and/or function of the protein. Proteins expressed without a tag can be purified using techniques such as gel filtration, ion exchange or hydroxyapatite, which separate samples according to protein size or charge.

Recombinant Proteins in Biomedical Research

Bacterially expressed proteins are used by researchers in order to elucidate their function and crystal structure, or to find novel interaction partners of the protein relevant for the development and progression of human diseases. Recombinant proteins can be used for a large number of different applications such as sub-cellular localisation studies using tagged proteins or antibody production. Other applications include functional assays of novel proteins or the development of protein chips in order to analyse or find interacting proteins. Protein interactions can also be studied using recombinant proteins in two-hybrid systems or bead-based assays and protein complexes can be assembled *in vitro* using recombinant proteins and thus be studied in a controlled environment. The ultimate goal of research is to learn more about the complex mechanisms involved in diseases with the purpose of eventually being in a position to treat and even cure them.

Clinical Relevance

Recombinant proteins are used in many different fields of study from apoptosis and cancer research to Parkinson, Alzheimer's and many other human diseases and some recombinant proteins are already being utilised in medicine as therapeutic agents. For instance insulin, which is essential for patients suffering from diabetes mellitus, is commonly obtained from the pancreas of pigs, but it is also produced using genetically modified *E. coli* (e.g. Huminsulin Basal[®], Humalog[®], Lilly). Drugs that modulate the immune system such as interferon alpha (treatment of chronic hepatitis B or C, leukaemia and other diseases) and interferon gamma (used in patients with chronic ►granulomatosis) are also generated using *E. coli* as well as interferon-beta 1b (Betaferon[®], Schering), which is used to treat multiple sclerosis. A relatively new compound is pegfilgrastim (Neulasta[®], Amgen), a growth factor that increases the number of neutrophils in the blood of cancer patients undergoing chemotherapy and a therapeutic agent that is still undergoing clinical trials is rViscumin (VISCUM), a genetically engineered plant protein from mistletoe. The activity of the compound is equivalent to that of the natural protein from mistletoe, which is traditionally used against many diseases including cancer.

Recombinant Protein Production in Mammalian Cell Culture

ANJA DRÖGE

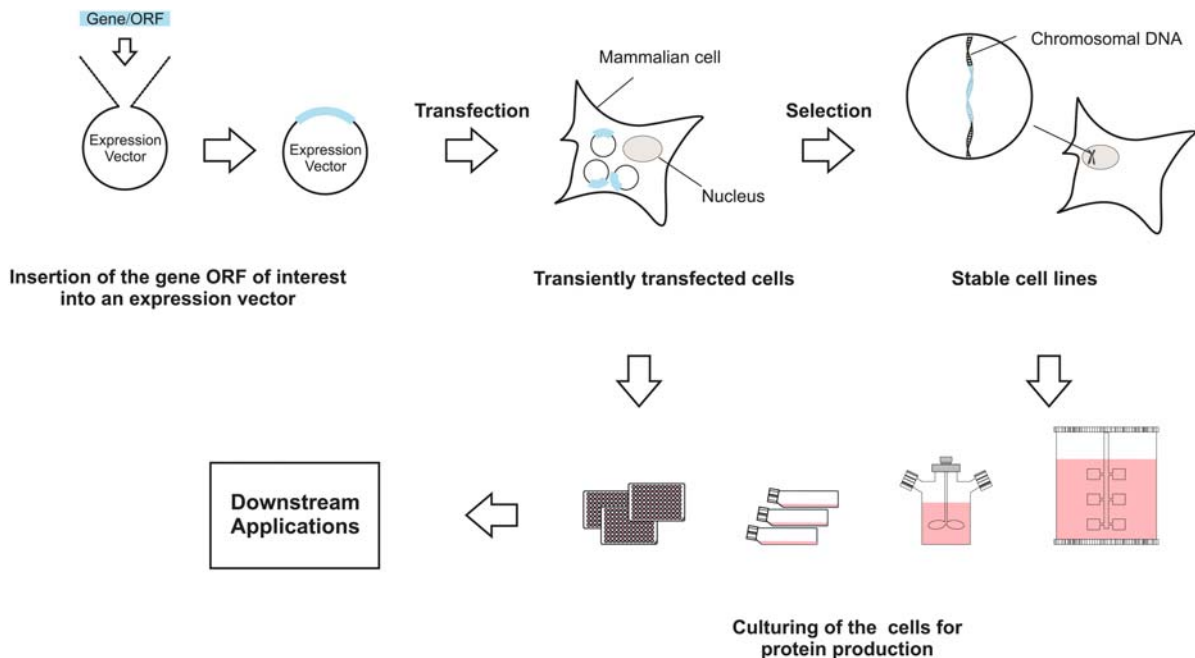

Max Delbrück Center for Molecular Medicine (MDC),
Berlin, Germany
a.droege@mdc-berlin.de

Definition

The cloning of genes in plasmid or viral vehicles and their subsequent introduction and expression in cultured mammalian cells has become an important tool for functional studies of eukaryotic proteins as well as for the industrial production of eukaryotic proteins for therapeutic use. This essay will cover the basic principles of protein expression in mammalian cell culture and summarize some of the most important applications of medical interest.

Characteristics

The production of eukaryotic proteins in mammalian cell culture offers many advantages *versus* protein production by the more economic bacterial cell cultures. One major advantage is that, in contrast to bacterial cells, mammalian cells are able to carry out proper ►protein folding, authentic ►glycosylation and a broad spectrum of ►posttranslational modifications (1). This assures the production of biologically active protein, which is required for many applications ranging from functional assays to therapeutic use. Furthermore mammalian cell cultures are ideal for studying eukaryotic proteins in

Recombinant Protein Production in Mammalian Cell Culture. Figure 1 Strategy for the production of a protein in mammalian cell culture. A DNA fragment coding for the protein of interest is inserted into an expression vector. The recombinant vector is introduced into cultured mammalian cells by transfection. For transient expression of the desired protein, the transfected cells are cultured for 24 to 96 hours. Alternatively, after transfection stable cell lines that integrated the desired coding sequence into their genome can be selected and propagated. Both transiently and stably transfected cells, can be used for various downstream applications.

convenient systems that can be experimentally manipulated but still resemble their natural environments. Using immunofluorescence microscopy and/or specific biochemical assays, essential information about the localization, the function and the interaction partners of proteins can be obtained. Such studies are of growing importance, given that after deciphering the human and other genomes, one major task is to understand the function of many so far uncharacterized proteins forming the complex proteomes of higher organisms.

Mammalian Expression Systems

The general strategy for the expression of a specific protein is outlined in Fig. 1. First, a DNA fragment that carries the **ORF** coding for the protein of interest (e.g. a **cDNA** fragment), is inserted into a **vector**, assuring its maintenance and expression. Subsequently the recombinant vector is introduced into a mammalian cell line of choice by **transfection**. Usually expression of the introduced coding sequences is seen between 12 and 96 h after transfection, depending on the vector used. Then expression decreases due to cell death or loss of the vector. This strategy often results in high levels of protein production but is transient i.e. persists only for a few days following transfection. However, transient expression systems are extremely useful for the rapid production of small quantities of protein.

For the continuous production of a specific protein e.g. for the production of therapeutics it is often advantageous to generate cell lines that permanently carry the ORF of interest. A commonly used strategy to accomplish this is to combine the relevant coding sequence with a selectable marker such as a gene conferring resistance to an antibiotic. After transfection cells are cultivated in the presence of the antibiotic to select for cells that integrated the resistance marker and the DNA carrying the ORF of interest into their chromosomal DNA. Once cells have been successfully transfected and cultured they can be used for diverse downstream applications including immunofluorescence microscopy, various biochemical assays or simply for the purification of the protein of interest.

In the following sections a survey of the most important tools and methods for mammalian expression will be given including expression vectors, transfection techniques, cell lines and cell culture types.

Vectors for Mammalian Expression

To deliver the coding sequence of interest into a mammalian cell it has to be inserted into an appropriate vector. The vector assures replication and maintenance as well as the controlled expression of the insert, which would otherwise be rapidly lost. In addition, many vectors offer the opportunity to combine the coding

sequence of interest with “tags” which code for short proteins or peptides that are fused to the target protein. For example, the hemagglutinin-tag codes for a short ▶**epitope** that is recognized by commercial antibodies allowing the immunological detection or affinity purification of the fusion protein. This is especially useful for the characterization of novel proteins for which antibodies are not yet available. Other tags like the His-tag that consists of 6 histidine residues additionally permit the convenient one-step purification of the tagged fusion protein on commercially available chromatography resins.

Numerous vectors are available for the delivery and expression of genes in mammalian cells (reviewed in 2, 3). The existing vectors can be divided into two categories, plasmid and viral vectors.

Plasmid Vectors

A broad variety of plasmid vectors is used for gene expression in mammalian cells. These plasmids contain functional elements for the replication and maintenance as well as for the efficient expression of the inserted sequence. The most important components of mammalian expression plasmids are illustrated in Fig. 2.

The sequence coding for the protein of interest is inserted into the ▶**multicloning site** (MCS) of the plasmid, which is located downstream of a mammalian ▶**promoter**, the site of transcription initiation. According to the specific requirements, one can choose among promoters for ▶**constitutive expression** or ▶**inducible expression**. Many plasmids include ▶**intron** sequences downstream of the promoter at the 5' end of the MCS, since their presence has been shown to improve expression of the usually intron-less coding sequences

(e.g. cDNA fragments). At the 3' end of the coding sequence a ▶**polyadenylation** signal is included. Polyadenylation increases the stability and the translatability of the ▶**mRNA**. To ensure correct transcriptional termination, a termination signal is placed at the 3' end of the coding sequence. This is required since eukaryotic expression plasmids usually consist of more than one transcriptional unit and continued transcription from one promoter inhibits the function of downstream promoters.

Efficient translation of the mRNA transcript in mammalian cells requires specific translational signals. The Kozak sequence CC(A/G)CCAUGG has been defined as the optimal translation initiation sequence in higher eukaryotes, with AUG being the start codon. Within this sequence the purines A/G three nucleotides upstream of the start codon and the G immediately following the start codon are most influential for optimal translation initiation. Likewise the efficiency of translational termination is modulated by the sequence context of the stop codon and is more effective if the base immediately following the stop codon is a purine rather than a pyrimidine. To allow the generation of stable cell lines as described above, most mammalian expression vectors carry marker genes suited for selection in mammalian cells such as genes conferring resistances to hygromycin or neomycin.

Last but not least, for amplification and replication of the recombinant plasmids in *Escherichia coli*, plasmids carry a bacterial origin of replication and a marker gene conferring resistance to an antibiotic. This is important because classical cloning procedures usually involve amplification of the recombinant plasmids in *E. coli*. Furthermore the recombinant plasmid-DNA can be

Recombinant Protein Production in Mammalian Cell Culture. Figure 2 Components of a mammalian expression plasmid. The functional elements depicted include signals required for bacterial (blue) and mammalian (green) replication of the plasmid, signals for correct transcription of the inserted sequence and modification of the transcript (pink) and signals assuring optimal translation of the protein of interest (orange). Abbreviations: ATB_M – antibiotic resistance gene for mammalian selection, ATB_{E.coli} – antibiotic resistance gene for bacterial selection, MCS – multiple cloning site; N-Tag/C-Tag – sequences coding for N- or C-terminal tags, respectively; Ori_M – mammalian origin of replication; Ori_{E.coli} – bacterial origin of replication; P – Promoter; pA – polyadenylation signal, TE – Transcriptional Enhancer, TrT – Transcription Terminator.

economically purified from *E. coli* cultures and used for the transfection into mammalian cells.

Viral Vectors

Viruses by their nature are efficient gene delivery vehicles and therefore excellent tools for introducing and expressing genes in mammalian cell lines. Most of the numerous different viral expression systems have in common that the structural genes that code for the proteins forming the virus capsids are deleted from the viral genome, while the gene of interest is inserted. To allow generation of infectious virus particles, these vectors are then either cotransfected with helper plasmids expressing the missing structural genes or are transfected into helper cells containing integrated copies of the required structural genes. These strategies result in the generation of viral particles that can be directly used to infect cultured cells with high efficiency but are replication-incompetent. This important feature assures the biosafety of these expression systems that are in many cases based on pathogenic viruses.

The most important viral expression systems for mammalian cells are based on Semliki Forest virus, adenovirus, lentivirus and vaccinia virus.

DNA Delivery

Unlike DNA embedded into virus particles, “naked” DNA, like other charged molecules, cannot freely pass the lipid bilayer of the eukaryotic cell membrane. Therefore tools for efficient DNA delivery have been developed (4). The choice of method depends on the cell type, the size of the culture and the required transfection efficiency. Ideally transfection should be fast and easy to perform, reproducibly yield high transfection efficiencies and cause minimal cytotoxicity. For the transfection of cultures on a large scale economic considerations can play an additional role. The methods used for transfection can be broadly classified into chemical and physical methods.

The principle of chemical methods is to complex the DNA with carrier molecules that overcome the cell-membrane barrier. These methods make use of the fact that the negatively charged nucleic acids adsorb to positively charged molecules or macromolecular complexes (the carriers) by electrostatic interaction. The carrier DNA-complexes are efficiently taken up by the cells and the nucleic acid is released within the cytoplasm or the nucleus. The first method that successfully applied this principle is the calcium phosphate method, in which DNA is co-precipitated with calcium chloride by addition of a phosphate buffer. The resulting calcium phosphate-DNA complexes adhere to the cell membrane and enter the cytoplasm. Other DNA carriers that are widely used for transfection include cationic polymers such as

DEAE-dextran, protamine, activated dendrimers and polyethylenimine polymers, liposomes and non-liposome lipids.

Several methods have been developed to deliver DNA into the cytoplasm of the target cells physically. These include the microinjection of DNA into cultured cells, the bombardment of cells with DNA immobilized onto microscopic heavy-metal particles (biolistic particle delivery) or the perturbation of the cell membranes by electrical pulses, which allows DNA entry (electroporation). The latter methods are usually not used for the routine transfection of cultured cells. Rather they are valuable tools for cells that are difficult to transfect by chemical methods or for specific applications such as DNA transfer into embryonic stem cells (microinjection), the transfection of plant protoplasts (electroporation) or the delivery of genes to cells *in vivo* (biolistic particle delivery).

Cell Hosts

Among the hosts that can be used for protein expression three major types, primary cultures, cell strains and continuous cell lines, can be distinguished. For primary cultures, cells are derived directly from excised tissue, which is typically disaggregated into single cells by enzymatic digestion with proteolytic enzymes such as trypsin. Cells are then cultured in flasks in appropriate media. The major advantage of primary cultures is that the cells have not been “modified” in any way and usually retain the distinctive characteristics they display *in vivo*. Therefore primary cells offer the opportunity to study proteins in an almost natural environment. Among the disadvantages of primary cultures on the other hand are the labor-intensive preparation of the cells and their limited life span. Moreover primary cells are much more difficult to transfect than other culture types.

Cell strains are derived from dividing primary cells by subculturing i.e. serially propagating them into cell culture dishes with fresh medium. The resulting cell strains have a finite lifetime in culture and usually die after 50–100 divisions.

Continuous cell lines have undergone genetic changes that allow them to divide indefinitely – they have “transformed” into the immortal state. Immortal cell lines can be derived from tumor cells that have undergone transformation in the organism. One example of a continuous cell line derived from a tumor is the widely used HeLa cell line that originates from a cervical carcinoma (4) and was called after the patient (Henrietta Lacks) from whom they were isolated. Continuous cell lines can also be derived from normal cell strains. Although as mentioned above these cells usually die after 50–100 divisions, variant cells that have undergone transformation arise at low frequency. Finally, transformation of cells can be experimentally

induced by treatment of normal cells with tumor viruses, chemicals or radiation. Due to the genetic modifications associated with immortalization, cell lines usually lose some of their original *in vivo* characteristics, which is a disadvantage for functional studies. On the other hand continuous cell lines have many advantages including almost limitless availability, fast growth, easy handling and consistency. Moreover continuous cell lines can be further modified by genetic manipulation and can therefore be adapted to the specific requirements of a protein production process. As a consequence most large-scale productions of mammalian recombinant proteins use continuous cell lines (1).

Culturing Cells

Cell cultures can either grow in suspension (as single cells or small free-floating clumps) or in monolayers adherent to the surface of a tissue culture flask. Both types can be grown at various scales. Adherent cells can be grown in the wells of 384-well microtitre plates with a surface of approximately 0.05 cm² as well as in large stackable chambers with each stack providing 2.5 m² of growth area. Likewise, the volumes of suspension cultures can range from a few ml in a small flask to up to more than 10,000 l in large stirred tanks for industrial production. Independently of the culture morphology the cell density has to be carefully controlled and contaminations have to be avoided by sterile working techniques and, if possible, the inclusion of antibiotics in the culture medium.

Clinical Relevance

Recombinant protein expression in mammalian cell culture is widely used for manufacturing of recombinant human proteins for therapeutic and diagnostic use (5, 6). Among the recombinant proteins that have already been approved as therapeutics are blood factors (e.g. Factor VIII, Factor VII), anticoagulants (e.g. tissue plasminogen activator), hormones (e.g. insulin, human growth hormone, erythropoietin), interferons and interleukins. Although most of these proteins can be, and earlier have been, extracted from their natural source, only large-scale recombinant protein production made them available in amounts sufficient for their common medical use. One good example of this is erythropoietin, which in former times had been isolated in small amounts from serum and urine. The increased availability of erythropoietin due to recombinant production allowed its widespread application for the treatment of anemia in chronic renal failure, which has led to a reduced morbidity and considerable improvements in the quality of life of patients. Recombinant protein production not only overcomes problems with the availability of therapeutic proteins, but also helps to avoid safety risks associated with natural sources such as human blood, urine or tissue. Another major advantage of recombinant protein production *versus* traditional

methods for the isolation of biopharmaceuticals is the possibility of modifying and thereby improving the naturally occurring proteins e.g. by generating faster or longer acting drugs or drugs with a higher activity.

Another important group of recombinant therapeutics produced in mammalian cell culture are monoclonal antibodies (6, 7). Naturally, antibodies are produced by B-lymphocytes. Each of these cells produces antibodies of unique specificity. By fusion of mouse B-cells to tumor cells derived from a mouse myeloma, immortal 'hybridomas' can be produced, which make the same antibody as the original B-cell but have the advantage that they can easily be cultured and used for the large-scale production of antibodies. Due to their murine origin these "first generation" monoclonal antibodies often provoked severe immune reaction in patients, especially after repeated treatment. To overcome these problems, chimeric and humanized antibodies were subsequently engineered and several of these antibodies are already approved and used for the treatment of a variety of diseases.

Recombinant Protein Production in Yeast

ROLAND WEIS, FRANZ HARTNER, ANTON GLIEDER
Research Centre Applied Biocatalysis, Institute of
Molecular Biotechnology, Graz University of
Technology, Austria
glieder@glieder.com

Definition

Proteins of industrial or medical interest are often produced in very low amounts by their natural hosts. However, for almost every application they are needed in both high yield and purity in order to meet safety and feasibility demands. This implies a need for high quality recombinant protein expression in heterologous production hosts. Prokaryotic systems such as *Escherichia coli* are cheap, fast and well established, but often fail to produce proteins in the required qualities, while on the other hand, production by cell cultures is time-consuming and cost-intensive.

As an alternative yeasts combine ease of genetic manipulation with high productivity and the ability to perform eukaryotic protein processing. Moreover, the scale-up to large-scale production is well established.

Characteristics

Standard procedures for expression of a foreign gene in yeast require some basic steps: (1) cloning of the gene into an appropriate expression vector and amplification of the DNA in the prokaryotic host *Escherichia coli*, (2) introduction of the expression cassette into the yeast of choice and (3) induced or constitutive expression of the foreign gene product.

Step (1) cloning and preparation of the DNA. A generalised scheme of an expression vector for yeast is shown in Fig. 1. It has to be supplied with an origin of replication and a selection marker for *E. coli*. Essential yeast-specific features include an appropriate selection marker (either resistance to antibiotics or ►[complementation](#) of metabolism-deficiencies), a eukaryotic promoter-region driving the expression of the gene of interest and a terminator-region ensuring proper termination of the transcript. The vector is either integrated into the genome of the yeast host by homologous recombination, or kept in the cell as extrachromosomal DNA. In the latter case, an additional DNA-sequence on the plasmid called the ►[autonomously replicating sequence](#) (ARS) is responsible for correct replication and segregation.

Step (2) transformation of yeast cells. The foreign DNA is introduced into the yeast cells by ►[electroporation](#) or ►[protoplast transformation](#). For gene integration the vector is linearized by cutting it with ►[restriction endonucleases](#) prior to transformation. Free DNA ends stimulate homologous recombination at a higher rate. The advantages of integrative transformation include e.g. expression strain stability, generation of multicopy strains and control of integration site.

Step (3) expression of foreign genes. Transformed yeast cells contain at least the gene of the ►[selection marker](#) and usually also the gene which should be expressed, as long as no recombination event has taken place that separated this gene from the selection

marker. Usually several transformants have to be analysed for expression of the desired gene product.

In an ideal expression strategy a compromise must be found combining high-level expression of recombinant protein with optimal cell growth. The choice of the promoter driving the production of the desired protein can be regarded as the committing step; the first option is to take a strong constitutive promoter leading to continuous protein expression during all stages of cell cultivation. However, constitutive expression cannot be employed for cytotoxic proteins (5).

Alternatively, inducible promoters are available that are characterised by strong regulation; in the absence of inducer and/or presence of a repressing force, the gene is not expressed. Repressor depletion and/or supplementation of inducer initiate gene expression. In most cases the addition of inducer is strictly required to obtain considerable amounts of heterologous protein. Inducible promoter systems often provide highly efficient expression and the possibility of producing toxic proteins.

Employing yeasts for the expression of eukaryotic proteins usually helps to avoid difficulties with protein folding, insolubility or formation of protein oligomers due to their fully functional eukaryotic protein synthesis machinery. However, the success of recombinant protein expression depends on many experimental parameters. The decision for a specific host/protein-combination and the optimal ►[fermentation](#) process is a case-to-case choice that is dictated by an economic rationale and product properties. In both regards yeasts seem to be preferable to many other systems.

Saccharomyces cerevisiae

The yeast *Saccharomyces cerevisiae* is the workhorse for many industrial and scientific applications including heterologous protein production. Several reasons drive the extensive use of this yeast: (a) well-established, cost-effective fermentation and process technology; (b) efficient and highly developed methods for molecular manipulation and (c) its ►[GRAS](#)-status (generally regarded as safe).

Readily available expression vectors for this host organism fulfil two main requirements: high-copy-number for dosage-dependent high-level expression and mitotic stability under non-selective conditions (2). Yeast episomal vectors (YEp) can replicate independently from the yeast genome due to the presence of an ARS. Usually 30 or more copies of these vectors are present inside the cells. Vectors of the integrative-type (YIp) have no ARS sequence and are stably integrated into the genome in low copy numbers (<20). Several strategies for multiple-integration events have been developed, as e.g. targeting the recombinant DNA to the ►[LTRs](#) (long terminal repeats) of the retrotransposon Ty or the ►[ribosomal DNA](#) (rDNA) cluster.

Recombinant Protein Production in Yeast. Figure 1 Standard yeast plasmid for genomic integration or episomal replication using a yeast ARS. The “gene of interest” is inserted into the multiple cloning site (MCS); all necessary features for an *E. coli*-yeast species-shuttle vector are included (origins of replication, selection markers, promoter, terminator and MCS).

A variety of well-characterised constitutive, inducible and engineered (hybrid) promoter elements are in use to drive the expression of foreign genes. They are mainly derived from yeast genes of central metabolic pathways. Strong constitutive promoters include *ADH1* (alcohol dehydrogenase 1), *PGK1* (phosphoglycerate kinase) and *GAPDH* (glyceraldehyde-3-phosphate dehydrogenase) promoters. For inducible expression of foreign genes, the promoters of the *GAL*-system are employed. They are repressed in the presence of glucose and can be induced approximately 1000-fold by galactose (4).

Secretion of heterologous proteins is often an advantage due to simpler purification steps and in order to overcome problems with intracellular [▶proteolytic degradation](#). For several heterologous proteins effective secretion has been shown under the direction of their native [▶leader signals](#) but generally host-derived signal sequences are much more reliable. In *S. cerevisiae* the most widely used signal sequences derive from acid phosphatase (*PHO5*), invertase (*SUC2*) or mating factor α (MF α 1). The last is extensively used in a wide variety of yeasts (4).

Protein glycosylation is a [▶posttranslational modification](#) step common to all eukaryotes. While in mammalian cells highly complex N- and O-linked oligosaccharide-structures composed of a variety of sugars are produced, most yeasts contain mannose type structures lacking some typical mammalian sugar entities like galactose or sialic acid. These non-mammalian structures can result in severe problems for therapeutic applications, mainly due to their high potential for immunogenicity. To overcome these problems, efforts are on the way to humanise yeast-derived oligosaccharide structures. All eukaryotes

share the early steps of the glycosylation pathway, which produce a core structure in the endoplasmic reticulum (ER). In mammals this structure is usually trimmed by mannosidases before building the mature complex-type oligosaccharides. Yeasts do not trim the core structure to the same extent before adding further sugars, which are almost solely mannose moieties. *S. cerevisiae* especially even tends to hypermannosylate glycosylation targets. Co-expression of recombinant *Aspergillus saitoi* α -1,2-mannosidase was shown to produce human-like (Man₅GlcNAc) core structures. As an alternative the *mm9* mutant of *S. cerevisiae* can be used to avoid hyperglycosylation (1).

Non-Conventional Yeasts

During the last ten years, an increasing number of scientific studies have described the successful employment of non-conventional yeasts, especially of the methylotrophic genera, for recombinant protein production. Often higher protein yields were achieved than with any other host system.

Methylotrophic Yeasts

A limited number of yeast species is able to grow on methanol as sole energy and carbon source. They belong to the genera of *Pichia*, *Hansenula*, *Candida* and *Torulopsis*. When the cells are grown on methanol, the enzymes of the general methanol utilization pathway can account for up to 30% of total intracellular protein content.

Their genes provide strong promoters for high-level protein expression and methylotrophic yeasts can be grown to extremely high cell densities. The low level of secreted endogenous proteins allows efficient production of almost pure secreted heterologous proteins in

the culture supernatant. The massive abundance of alcohol oxidase upon induction by methanol makes this gene a preferred target for site-directed insertion of expression cassettes by gene replacement (2).

Hansenula polymorpha (*Pichia angusta*)

Standard expression vectors for this methylotrophic yeast carry the strong *H. polymorpha* *MOX* (methanol oxidase)- or *FMD* (formate dehydrogenase)- promoters. The *MOX* gene product introducing methanol into the catabolic pathway is present in high abundance in cells grown on methanol (induction). Since methanol is not strictly required for protein expression considerable amounts of protein are produced in cells grown in media supplemented with low levels of glycerol (derepression). However, upon induction by methanol, product levels are tremendously elevated. Several ▶auxotrophic *H. polymorpha* host strain/marker gene combinations as well as dominant markers are available, as described above for *S. cerevisiae*.

One observes a high frequency of plasmid integration, despite the presence of an ARS on a vector. Transformation results in mitotically stable strains containing varying copy numbers (up to 100) of expression cassettes integrated by non-homologous recombination. However, a high copy number does not necessarily confer high expression levels, since this depends also on the relative strength of the promoters involved, the 5'-untranslated region, the surrounding of the translation initiation site, the integration site and of course the nature of the heterologous gene and protein to be expressed. As for *S. cerevisiae*, Mfa1 is the preferred leader sequence for protein secretion. Glycosylation by methylotrophic yeasts does not differ from that of *S. cerevisiae* except that hypermannosylation is found to be less common. Unpredictable random integration of the expression cassette into the genome of *H. polymorpha* and the genetic instability of high copy number production strains are drawbacks for some applications (2).

Pichia pastoris

Unlike *H. polymorpha*, this species contains two alcohol oxidase genes, *AOX1* and *AOX2*, which offer different strategies for gene insertion. *AOX1* is the major enzyme for methanol-oxidation as compared to the weakly expressed *AOX2*. The lack of stable ARS-elements for *P. pastoris* raises the importance of stable gene integration for reliable usage in commercial high-level protein expression. For selection, complementation of metabolic deficiencies in the corresponding host as well as resistance to antibiotics is routinely used. The strong methanol-inducible *AOX1*-promoter (alcohol oxidase 1) and the strong constitutive *GAPDH*-promoter (both derived from *P. pastoris*) are frequently

used for protein expression. Less frequently employed are the weaker *FLD1*- (glutathione-dependent formaldehyde dehydrogenase, constitutive), *YPT1*- (gene encodes a GTPase involved in secretion, constitutive) or *PEX8*- (gene encodes a peroxisomal matrix protein, constitutive and inducible) promoters (5). The *AOX1*-promoter is tightly repressed by most carbon sources such as glucose, ethanol and glycerol and highly induced by methanol in the absence of these C-sources. Up to 20 g of heterologous protein are produced per litre of culture volume. For secreted proteins the Mfa1 signal sequence is the most frequently used, although many signal sequences from mammals and plants are functional as well. Recent publications demonstrated the feasibility of humanised protein glycosylation by *P. pastoris*. Therefore, *Pichia pastoris* can be regarded as a powerful system for the economical, recombinant large-scale production of mammalian polypeptides (1).

Fission Yeasts

The ▶fission yeast *S. pombe* diverges in some respects from the “classical” budding yeasts (e.g. *S. cerevisiae*). Apart from its asexual proliferation by cell division (fission), it shows a variety of typical properties of mammalian cells. For example, its mitochondrial genome structure, type of RNA-splicing, transcription-initiation mechanism, sugar chains of glycoproteins and posttranslational modifications resemble mammals more than fungi.

Interestingly, even though this species has been extensively studied in terms of molecular genetics and cell biology, it has not gained much importance in producing heterologous proteins yet. However, several of the features outlined above imply extraordinary beneficial capabilities of *S. pombe*, which might be exploited in the near future in the course of production of authentic heterologous polypeptides for therapeutic applications (3).

Clinical Relevance

The production of recombinant proteins in mammalian cell cultures is often difficult, error-prone and expensive, while still low yields are obtained. In addition, the assurance of virus-free products is a serious task. As an alternative, yeasts are employed efficiently for the production of therapeutically interesting recombinant proteins (Table 1), where *E. coli* cannot be used, usually due to difficulties in folding, posttranslational modification or quality demands (2, 5, 7, 8).

In order to avoid rejection or other immunological reactions, some proteins need an exactly matching mammalian glycosylation pattern. This cannot be done by native yeasts. Up to now no fully humanised, glycosylated recombinant protein has been produced in

Recombinant Protein Production in Yeast. Table 1 Recombinant therapeutic proteins produced in yeasts (all products are secreted into the culture media); HBsAg = Hepatitis B surface antigen; HSA = Human serum albumin

yeasts, but the routine generation of metabolically engineered yeast strains is getting closer. It should be mentioned however, that mammalian cell lines, which are often derived from cancer cells, also usually show some deviations from human standard glycosylation patterns. Prior to administration, many heterologously expressed and purified proteins have to be treated further to become fully active. For example, insulin is derived from proinsulin *via* cleavage by carboxypeptidase Y. Often these “secondary” modifying enzymes that process precursors of therapeutically interesting targets are also produced in yeast systems (J.M. Cregg, personal communication).

As an example for the expression of a therapeutic protein in different hosts, the production of hirudin has been chosen. Hirudin is a low molecular weight anticoagulant peptide (~7 kD) naturally excreted from *Hirudo medicinalis*. Hirudin prevents fibrinogen from clotting, in addition to inhibiting several other thrombin-catalysed reactions such as the activation of factors V, VIII and XIII, as well as platelet activation. The most important application of hirudin is the treatment of the arterial thrombosis that causes cardiovascular diseases, e.g. heart attack and stroke, in cases of heparin-induced thrombocytopenia. Originally production of hirudin in *E. coli* yielded 1 mg/L intracellular protein, with the major drawbacks that a mixture of two hirudin forms with different activities were produced and proteolysis occurred. Successful attempts to secrete the target into the periplasma increased the protein level to 200–300 mg/L.

To circumvent the folding problems and limited secretion by bacterial hosts, yeasts have been employed as an alternative. In *S. cerevisiae*, hirudin was efficiently secreted into the culture medium at up to 500 mg/L; but it turned out that in some strains two derivatives lacking C-terminal residues were produced due to C-terminal processing. In order to improve the production yield in the yeast system, *H. polymorpha* and *P. pastoris* were investigated for the expression of hirudin. The yields of secreted recombinant hirudin in these species were in the range of 1.5 g/L. In addition, C-terminal proteolysis was much less pronounced (7).

To date, the vast majority of commercial processes rely on the well-known yeast *S. cerevisiae*. Due to increasing knowledge about non-conventional yeasts, together with the apparent advantages in terms of large-scale fermentation and glycosylation issues, alternative yeasts will be employed in many cases in the near future. Some important therapeutic proteins produced by *P. pastoris*, e.g. human serum albumin (HSA), endostatin and angiostatin, are currently in clinical trials, demonstrating that this reorientation of therapeutic protein production by yeasts is in progress (5, 6).

Recombination

Definition

Recombination refers to the exchange of genetic material between different chromosomes or chromatids resulting in changes of the phenotype.

- Genetic Epidemiology
- Huntington's Disease
- Repeat Expansion Diseases

RecQ Helicase Family

Definition

RecQ helicases belong to a gene family of helicases that is highly conserved in evolution. The protoType Is RecQ of *E. coli*, a 610 amino acid protein.

- Bloom Syndrome

Recurrence Risk

Definition

Recurrence risk is the probability that a genetic disease occurs in siblings or other relatives of an affected individual.

- Cleft Lip Palate
- Heritable Skin Disorders

Redefinition of Codons

Definition

Redefinition of codons describes a recoding event in which a different meaning is temporarily assigned to a codon. All cases known so far involve stop codons in special contexts. The typical example is UGA, which is recoded to specify the twenty-first amino acid selenocystein.

- Genetic Code

Reductive Unfolding

Definition

Reductive unfolding characterizes a process by which the disulfide bond(s) of a native protein is/are reduced under strongly reducing conditions, thereby denaturing its native structure.

- Protein Disulfide Bonds

Redundancy

Definition

Redundancy defines the state when two or more genes share similar functions, and upon single gene inactivation do not display a mutant phenotype. The loss of both/all genes is required in order to reveal the genes' functions.

- Morpholino Oligonucleotides, Functional Genomics by Gene 'Knock-down'

REE, RxRE

Definition

REE, RxRE describes the region on the HIV (human immunodeficiency virus) or HTLV (human T-cell leukaemia virus) genome to which Rev or Rex bind.

- Retroviruses

Reference State

Definition

Reference state defines a thermodynamic state relative to which all state functions are measured and to which binding is determined. Usually it is the unliganded native protein, or biopolymer. In DNA studies, for instance, it could be the double helix at specified pH, temperature and salt conditions.

RefSeq

Definition

The Reference Sequence (RefSeq) collection is aimed at providing a comprehensive, integrated, non-redundant set of sequences, including genomic DNA, transcript (RNA), and protein products, for major research organisms.

- ▶ [Protein Databases](#)

Refsum Syndrome

Definition

Refsum syndrome or “Heredopathia atactica polyneuritiformis” is an autosomal recessively inherited peroxisomal metabolic disease, which is caused by a deficiency of phytanic-acid-oxidase and results in storage of phytanic acid in blood and tissues. The disease is characterized by ichthyosis of the skin, anomalies of bones, retinitis pigmentosa, polyneuropathy and cerebellar symptoms such as ataxia.

Region of Interest

Definition

Region of Interest describes an area of an image that will be photobleached or monitored during the time course of an imaging experiment.

Relaxation Techniques/Relaxation

Definition

Relaxation techniques are primarily applied for quantitative determination of reaction kinetics in extremely fast chemical or biochemical reactions. The idea is to physically disturb an equilibrated system (e.g. by pressure or temperature jumps), and temporally resolve the dynamics of relaxation back to equilibrium. In NMR experiments, relaxation describes the disappearance of magnetization after excitation. The relaxation of nuclear magnetization depends on external (spectrometric) as well as internal (sample specific) parameters. Homogeneity of the magnetic field and temperature are important examples of external parameters that influence relaxation, while internal parameters as, for example, the shape, size and composition of a molecule determine the intrinsic relaxation properties of an NMR sample.

REM (Rapid-Eye-Movement) Sleep

Definition

REM sleep is one of two distinct brain states that occur during sleep. The name is derived from the fact that during REM sleep the eyes move rapidly behind the closed lids. REM sleep, also called paradoxical sleep, is a very active brain state as indicated by a desynchronized EEG similar to wakefulness, high variability of respiration and heart rate, and other signs of autonomic activation. Dreams occur during REM sleep but are not confined to this state.

Repeat Expansion Diseases, Dynamic Mutations Cause (Neurological) Model Disorders

JÖRG T. EPPLN

Human Genetics, Ruhr-University Bochum, Bochum, Germany

joerg.t.epplen@rub.de

Definition

Repeat expansion diseases are caused by crucial extensions of naturally occurring polymorphic simple tandem DNA sequences within or in the vicinity of different human genes. A characteristic of these expanded alleles is their excessive instability in successive generations (► [dynamic mutations](#)) (4). Similarly, these alleles differ in lengths in cell populations of the same organism - mosaicism. A common clinical phenomenon in the so-called trinucleotide repeat disorders – the most abundant forms of repeat expansion diseases – is ► [anticipation](#), a clinical correlate of intergenerational repeat instability with a tendency towards further repeat elongation. Increased repeat lengths in successive generations lead to an earlier age of onset in affected individuals (and sometimes to accentuation of the symptomatology). So far, nearly two dozen human diseases with ► [Mendelian](#)

inheritance patterns have been shown to be caused by expansions of intrinsically polymorphic tandem repeats, mainly involving different trinucleotide motifs but also longer repetitive sequences up to 12mers. Interestingly, repeat expansion diseases have not been encountered thus far in animals or plants, but transgenic animal strains will be instrumental in understanding many facets of these diseases.

Characteristics

Two main categories of repeat expansion diseases are discernible on the basis of the expression of the repeats:

- **Polyglutamine disorders** are caused by moderate (CAG)_n expansions in coding regions (Table 1). The expanded trinucleotide blocks are translated into uninterrupted polyglutamine tracts.
- An even more heterogeneous group of disorders is due to large or very large expansions of (GAA)_n, (CTG)_n, (CGG)_n, (CCTG)_n, (ATTCT)_n and (CCCGCCCCGCG)_n blocks (Table 1). These repeats are not translated into protein, but whenever expanded in mutation carriers they interfere critically with the regulation of **gene expression** and/or **protein expression**.

Thus the pathophysiology of the two disease categories differs in principle.

Polyglutamine Disorders

Polyglutamine diseases are due to enlarged (CAG)_n blocks in the coding regions of a number of different genes. The (CAG)_n trinucleotide tracts are translated into polyglutamine domains within proteins. Depending on individual thresholds for the critical repeats, the resulting proteins form peptides containing β -sheet structures, accumulate in cells and are deposited as **inclusion bodies** in the cytoplasm and/or nucleus. Apparently, the **misfolded proteins** may interfere with the **proteasome** and metabolic pathways of the cell and finally lead to neuronal **cell death** (5). Polyglutamine diseases may share similar pathophysiological aspects with respect to repeat elongation, although the expansion thresholds are disease specific (Table 1). In addition, polyglutamine diseases usually present as adult onset, neurological traits with progressive neuronal dysfunction leading to **neurodegeneration** in specific brain regions. Up to now, this group comprises ten diseases, among which **Huntington's disease** (HD) is the most frequent.

The course of HD is characterized by neurological and/or psychiatric symptoms with onset usually in the 4th to 5th decade of life. On average, HD patients die after 10–20 years of disease. In contrast to the homogenous causation of HD, the genetically heterogeneous **spinocerebellar ataxias** (SCAs) are a growing group of dominantly

inherited neurodegenerative diseases with cerebellar atrophy. SCAs have a broad range of overlapping clinical symptoms with typical cerebellar signs. The disease entities SCA1–3, SCA6, SCA7 and SCA17 are based on critical (CAG)_n expansions (for further details on additional forms of SCA's see below). **Machado-Joseph disease** is the Japanese variant of SCA3 with a slightly different clinical symptomatology. **Dentatorubral-pallidoluysian atrophy** (DRPLA) is also more common in Japan and shares some symptoms of HD and the SCAs. **Kennedy disease** (**spinobulbar muscular atrophy**) is a X-chromosomal recessive trait presenting with neuromuscular symptoms and endocrine deficiency due to **androgen insensitivity**. The causative (CAG)_n expansion is localized within the **androgen receptor gene** encoded on the **X chromosome**.

Like polyglutamine disorders, (GCG)_n and (GAC)_n trinucleotide blocks result, albeit rarely, in elongated polyalanine as well as polyaspartate stretches. Yet, compared to the (CAG)_n expansions these motifs are only marginally increased in length and they do not result in neurological diseases, instead affecting bone differentiation. As a non-neurological exception among trinucleotide diseases, the autosomal dominantly inherited **synpolydactyly** has been shown to be caused by expansions of a polyalanine tract in the HOXD13 protein. Usually 15 alanine residues are expressed, whereas affected individuals harbor 7–9 extra alanine residues in the mutated allele products. In contrast to 'classical' trinucleotide diseases, the polyalanine tract in HOXD13 protein is more stable – like the polyaspartate block in **pseudoachondroplasia**. Thus these mutations appear to be products of non-reciprocal **recombination** or misalignment during recombination in contrast to the elusive mechanism(s) of the other **repeat expansion diseases** (see below).

Diseases with Repeat Expansions that Are Not Expressed on the Protein Level

Large-scale expansions of 'non-protein' coding, repetitive DNA sequences may also cause disease. Such expansions show extensive variability concerning the repeat positions in the genes, the sizes of the expanded sequence blocks and the sequence motifs concerned. Apparently similarly heterogeneous are the known pathophysiological mechanisms involved. As a common denominator, this disease group shares phenomena of reduced gene expression at the transcriptional and/or translational levels. The fragile XA and the rare fragile XE mental retardation syndromes are X-chromosomal (recessively) inherited. The (CGG)_n and (GCC)_n repeats are localized in the 5' untranslated regions of *FMR1* and *FMR2* genes, respectively. Repeat expansions entail increased methylation of neighboring (promoter) DNA sequences and lead to inactivation of *FMR* gene

Repeat Expansion Diseases, Dynamic Mutations Cause (Neurological) Model Disorders. Table 1 repeat expansion diseases: dynamic mutations cause (neurological) model disorders

expression (1) resulting in critical perturbations in regular psychomotor development.

An ▶**intronic** expansion of a $(GAA)_n$ repeat in autosomal-recessively inherited ▶**Friedreich ataxia** prevents expression of frataxin, a protein maintaining iron homeostasis and therefore mitochondrial function. Myotonic dystrophy 1 (DM1), on the other hand, is a disorder characterized mainly by muscle wasting and myotonia. It is caused by $(CTG)_n$ expansions in the 3'-untranslated region of the *DMPK* gene. ▶**Dominant** inheritance suggests a dominant negative effect of the expansion on gene ▶**transcription**, eventually influencing the expression of neighboring genes. DM2/PROMM is the first repeat expansion disease found to be caused by tetranucleotide motifs (3). Certain forms of SCAs have expansions of a $(CTG)_n$ repeat in the 3' untranslated region (SCA8), an intronic $(ATTCT)_n$ block (SCA10) and a $(CAG)_n$ tract in the promoter region of the disease gene (SCA12), respectively. The $(ATTCT)_n$ expansion in the *SCA10* gene is the sole pathogenic pentanucleotide known to date.

Theoretically, additional simple tandem repeats may also cause expansion diseases like elongated ▶**minisatellite** alleles with their longer motifs/periodicities. The ▶**multifactorial** nature of ▶**common diseases** like ▶**diabetes mellitus** and certain ▶**malignancies** includes genetic contributions of e.g. given minisatellite loci and their specific alleles (2). These common diseases characteristically lack classical Mendelian inheritance patterns with high ▶**penetrance** making the slight variations (and hence effects) of repeat allele lengths conceptually optimal candidates with the required differential properties to be responsible for genetic contributions, probably exclusively in certain combinations, together with additional, thus far elusive, factors.

Cellular and Molecular Regulation

A number of large-scale repeat expansions had previously been shown to cause cytogenetically detectable 'fragile' sites demonstrable in metaphase ▶**chromosomes**. Yet this phenomenon is not inevitably pathogenic, except for critical expansions in the abovementioned *FMR* genes. Approximately 8% of human genes bear repeat ▶**polymorphisms** and are candidates for pathogenic expansions (Wren et al., 2000). Two general mechanisms are discussed to account for repeat instability. i) 'Slippage' of DNA polymerase during mitotic and meiotic ▶**DNA replication** (Sinden, 2001). But 'slippage' explains only low degree length variations observed in the physiological polymorphism ranges of these frequent loci due to mutations of 1(-2) repeat units. It may result from imprecise DNA replication during error-prone cell divisions, especially during gametogenesis. ii) Potentially, disease-associated triplet repeats form stable 'alternative' ▶**DNA conformations** like triplex and

quadruplex helices and hairpins and promote intermediate to large range expansions during DNA replication. Finally, ineffective ▶**DNA repair** mechanisms may account for some additional instability phenomena.

Depending on repeat class, different mechanisms are responsible for disease development.

- A potential common denominator of polyglutamine disorders includes distorted degradation and/or accumulation of mutant protein complexes. Yet formally, the relevance of the microscopically visible protein inclusions and of their cellular localization etc. remains to be proven. Additional disorder-specific molecular complexities behind these rather general rules are not yet explicable for the different disease entities.
- $(CGG)_n$, $(GCC)_n$ expansions in ▶**fragile X syndromes** and the intronic expansions in *FRDA* [$(GAA)_n$] and *SCA10* [$(ATCTT)_n$, Matsuura et al., 2000] down-regulate or abolish gene expression on the transcriptional level *via* nearly complete ▶**loss of function** (1). The pathophysiological effects of these expansions appear explicable solely by the reduced mRNA levels of the affected gene.
- Additional pathomechanisms behind untranslated $(CTG)_n$ and $(CCTG)_n$ expansions in the myotonic dystrophy forms DM1 and DM2/PROMM as well as *SCA8* are only gradually being understood, like the complex sequelae of $(CAG)_n$ expansions in the 5' UTR of the *SCA12* gene. In addition to the demonstrably reduced expression of the respective genes, the apparent dominant negative effect with accumulations of mutant RNAs in nuclear foci offers a novel rational explanation. Furthermore, expression of additional neighboring genes appears to be critically affected.
- $(GCG)_n$ expansions like in the coding region of the *PABPN2* gene are translated into polyalanine tracts which may cause mutated PABPN2 peptide oligomers to accumulate as filamentary inclusions in the nuclei of certain cell populations, finally leading to the rare oculopharyngeal ▶**muscular dystrophy**. This dominant negative effect may cause the proteins to be sequestered and degraded at an increased rate.

Clinical Relevance

Molecular biological investigations into repeat expansion diseases have already revealed unprecedented insights into the genetics and pathogenesis of these ▶**disease models** in man. The ramifications for other diseases cannot be underestimated, potentially also for common multifactorial disorders, where non-Mendelian, modulating genetic effects of variant repeats are to be expected. Yet it is also likely that more repeat expansion diseases will be discovered in the future for (rare) Mendelian traits, especially with regard to expansions of the many

additional repeat motifs demonstrably present in the
► [human genome](#).

Repetitive DNA

► [Repetitive Elements](#)

Repetitive Elements (Repetitive DNA, Repeats)

Definition

Repetitive elements are DNA fragments that are present in multiple homologous copies in the genome without a clearly assigned biological function.

Replication

Definition

Replication is the duplication of genomic DNA as part of the reproductive cycle of a cell.

► [DNA Replication Initiation](#)
► [Replication Fork](#)

Replication Bubble

Definition

Replication bubble designates the appearance at the electron microscope of a portion of just duplicated DNA near a replication origin, immediately following origin activation.

► [Replication Origins](#)

Replication Foci

Definition

Replication foci are subnuclear sites where DNA replication takes place. During S-phase, the newly synthesized DNA, and most of the proteins involved in DNA replication, accumulate in these sites.

► [DNA Ligases](#)

Replication Fork

ULRICH HÜBSCHER, IGOR SHEVELEV

Institute of Veterinary Biochemistry and Molecular Biology, University of Zürich, Zürich, Switzerland
hubscher@vetbio.unizh.ch

Definition

Each mammalian cell contains about 2 meters of genetic material, called DNA. The DNA consists of four bases; adenine (A), guanine (G), cytosine (C) and thymine (T), which are attached to a pentose sugar and connected by a phosphate backbone. There are about 5×10^9 bases in each mammalian cell. Prior to cell division, the process of ► [DNA replication](#) must faithfully duplicate the five billion bases with an absolute minimum of mistakes. Less than one mistake is allowed per replication round. DNA replication is an extremely complex cellular event involving many actors to coordinate this difficult task in a very short time (usually 30 min). These actors work in a big complex called the ► [replisome](#). Part of this replisome constitutes the enzymatic machinery around the replication fork. The enzymes that synthesize DNA according to the Watson-Crick base-pairing rule A opposite T and C opposite G and *vice versa* are called ► [DNA polymerases](#). DNA polymerases, of which a mammalian cell contains more than 18 species [reviewed in (1)], can use the energy

of the four deoxyribonucleoside 5'-triphosphates to incorporate deoxyribonucleoside 5'-monophosphates onto a growing DNA strand. DNA is an **▶antiparallel** double-strand molecule with polarities of 5'→3' and 3'→5', respectively. Since all DNA polymerases exclusively synthesize DNA in the 5'→3' direction the antiparallel DNA molecule presents a logistical problem for uni-directional replication. To circumvent this problem one strand, called the **▶leading strand**, is synthesized continuously and the other, called the **▶lagging strand**, discontinuously. Discontinuity means that the lagging strand is synthesized in short pieces of about 200 bases that are called **▶Okazaki fragments**. Discontinuity furthermore involves the necessity for frequent initiations of replication (10^7 per replication round) that are coupled to the subsequent processing of the Okazaki fragments in order to obtain a completely replicated DNA molecule. Here again the complex process includes many enzymes at the replication fork. The two original strands are called mother strands onto which the two strands are synthesized. DNA replication is therefore a semiconservative process in which the final replicated product contains an original and a newly synthesized DNA strand.

Characteristics

Maintenance of genetic stability is a key issue for any form of life. Consequently highly sophisticated mechanisms for maintaining of the integrity of the genome were well established before the three kingdoms of life (Prokaryotes, Archaea and Eukaryotes) separated. DNA replication in eukaryotic cells, including human, requires a large set of proteins. In all of these events, complexes of more than 30 polypeptides appear to function in highly organized and structurally well defined enzymatic machines. It is the replisome that gives the replication fork the characteristic structure for replication of DNA. DNA replication is the event leading to the duplication of DNA in advance of mitosis (or meiosis) and cell division. It occurs *in vivo* in an ordered and highly organized way, in which all enzymes and proteins involved have their exact roles in the replisome, which itself is located in so called nuclear replication factories. Models have been proposed as to how the enzymatic machinery might be spatially arranged at replication. They are based on the idea that DNA polymerases dimerize and that the lagging strand forms DNA loops that orient the DNA in such a way that the "directionality" for the DNA polymerases is the same. If one postulates that the replisome is fixed to structures in the nuclear replication factories, the DNA polymerases would thread the DNA through itself. The assembly and the events in a replisome might occur as follows [reviewed in (2)].

An initiator protein complex called the origin recognition complex (ORC) is bound to an origin of DNA

replication. The ORC has to be activated by other proteins, such as minichromosomal maintenance proteins (MCMs) and cell division cycle proteins (Cdc6 and Cdk7/Dbf4), by mechanisms such as phosphorylation or possibly other posttranslational protein modifications. This leads to the formation of an initiation complex that is able to alter DNA structures locally, presumably by activating the intrinsic helicase activity of an MCM subcomplex or by attracting other **▶DNA helicases** to the origins. The single stranded DNA produced must be protected and stabilized by the **▶single-stranded DNA binding protein**, called replication protein A (RP-A). RP-A helps to unwind the DNA by its intrinsic unwinding activity and possibly through its interactions with DNA helicases and DNA polymerase α /primase that acts as the initiating DNA polymerase (Fig. 1). In order to initiate DNA synthesis, **▶DNA primases** must synthesize short RNA stretches of 5–15 nucleotides. The short RNA stretches serve as primers for each Okazaki fragment and moreover as primers for leading strand replication. After very limited DNA synthesis, a **▶DNA polymerase switch** from DNA polymerase α /primase to the processive form, **▶DNA polymerase δ holoenzyme** occurs. This is most probably mediated by the DNA polymerase δ auxiliary protein replication factor C. DNA polymerase α /primase itself subsequently acts at the discontinuously synthesized lagging strand, where it initiates Okazaki fragments. While the DNA polymerase δ holoenzyme (DNA polymerase δ , proliferating cell nuclear antigen and replication factor C) is engaged in processive leading strand DNA synthesis, the situation at the lagging strand is more complex. At the lagging strand, a second DNA polymerase (DNA polymerase δ or ϵ) holoenzyme is formed for completion of each Okazaki fragment initiated by DNA polymerase α /primase. DNA syntheses on the leading and on the lagging strand are probably coordinated by dimerization of the two processive DNA polymerase holoenzymes. To complete DNA replication on the lagging strand, dimerization possibly occurs either through a direct physical interaction of two DNA polymerases or *via* a clamp factor. The initiator RNA between Okazaki fragments is removed by flap endonuclease 1 and/or by the Dna 2 endonuclease. After complete synthesis the Okazaki fragments are sealed by DNA ligase I. Topological constraints are released by **▶DNA topoisomerase I** and the replicated DNA can finally be separated by DNA topoisomerase II. Proofreading activity of DNA polymerases is an absolute requirement for accurate DNA synthesis, and it can be achieved by 3'→5' exonucleases that preferentially remove incorrectly incorporated bases e.g. guanine opposite a thymine. There are more than ten such exonucleases in a mammalian cell and some of them

Replication Fork. Figure 1 The replication fork proteins and their tasks. 1: primer synthesis by DNA polymerase α /primase; 2: Replication factor C displacement of DNA polymerase α and recruitment of proliferating cell nuclear antigen; 3: elongation by the newly recruited DNA polymerase δ holoenzyme; 4: strand displacement by DNA polymerase δ ; 5: cutting of the 5' displaced flap by flap endonuclease 1. 6: sealing by DNA ligase I. are part of the DNA polymerase molecule e.g. DNA polymerases δ and ϵ [reviewed in (3)]. Cells containing a mutated 3'→5' exonuclease are prone to cancer (see Clinical Relevance).

Clinical Relevance

DNA replication is a conserved process required not only by mammals but also lower organisms such as bacteria

and viruses to replicate their DNA. Bacteria have their own replisome while viruses have evolved strategies in which they can either fully replicate their DNA (e.g. herpes viruses) or can partly do it (e.g. HI-virus, hepatitis virus) independently of a host. Although many replication proteins are extremely conserved from viruses to human, even subtle differences between the replication machineries have served as a basis for successful drug

Replication Fork. Table 1 Replication Fork Proteins

Protein	Function at the replication fork
MCM DNA helicase	Opens double-strand DNA in front of DNA polymerases
Replication protein A	Stabilizes single-strand DNA created by MCM DNA helicase
DNA polymerase α /primase	Initiator DNA polymerase, can synthesize RNA and DNA
DNA polymerase δ	Elongating DNA polymerase
DNA polymerase ϵ	Elongating DNA polymerase
3'→5' exonuclease	Proofreading for DNA polymerases
Proliferating cell nuclear antigen	Moving platform for DNA polymerases
Replication factor C	Loader of proliferating cell nuclear antigen
Flap endonuclease 1	Removes initiator RNA and DNA at the lagging strand of the replication fork
Dna2 endonuclease	Removes initiator RNA at the lagging strand of the replication fork
DNA topoisomerases I and II	Solve topological problems of the DNA in advance of and after DNA replication
DNA ligase I	Seals the remaining nick at the DNA to connect Okazaki fragments

development. It would be beyond such a short essay to cover in detail all the clinically relevant drugs; however we generate a short list below (4).

Antibacterial Drugs

Antibacterial drugs include inhibitors of DNA gyrase, a special form of bacterial DNA topoisomerase. So far these inhibitors have been used for treatment of more than a hundred million patients. Novel strategies include the development of DNA polymerase (DNA polymerase III) and DNA helicase (Dna B helicase) inhibitors.

Antiviral Drugs

Azidothymidine is the prototype of many nucleoside inhibitors that have been successfully applied as HIV reverse transcriptase (a special form of a viral DNA polymerase) inhibitors. Moreover non-nucleoside inhibitors such as Nevirapine were successfully used for recent combination drug therapy.

Anticancer Drugs

Anthracyclines are drugs that inhibit DNA topoisomerases. They have been, among other applications, used to preferentially inhibit fast replicating cancer cells. However since they also inhibit normal cells (but to a lesser extent) they are rather toxic and are far from being optimal.

Diseases due to Replication Fork Proteins

When the ►proofreading exonuclease of DNA polymerase δ is mutated in the active centre, mice containing such a mutation develop cancer much earlier than those containing the wild type proofreading activity. This suggests that DNA polymerase δ without the “Tippex” control is sloppier in DNA replication, which eventually leads to unfaithful DNA replication, to mutations of certain genes and to cancer (5). Moreover, ►haploinsufficiency of flap endonuclease 1 leads to rapid tumor progression in mice (6) suggesting that flap endonuclease 1 might act as a tumor suppressor protein.

Diagnostic

Detailed knowledge that has accumulated over four decades [the first DNA polymerase was discovered by A. Kornberg in 1956, reviewed in (1)] led to the invention in the mid 1980 of DNA polymerases that can be used to amplify DNA several million fold. This technology is called polymerase chain reaction and is known as PCR. The property of the DNA polymerase to amplify DNA is now universally used to test and to quantify viral, bacterial and parasitic infections, to test for genetic diseases and for paternity cases. Furthermore,

modern forensic medicine would be impossible without PCR.

In conclusion the detailed knowledge of the human replication fork is of paramount interest for the development of novel drugs against bacterial and viral infections. Moreover the therapy of various types of cancer will be improved because of knowledge of the replication fork. Finally, PCR diagnostics have already found their ways into practical medicine.

Synonyms

Replicator; a DNA sequence on which regulation of DNA replication occurs, origin of bidirectional synthesis.

Definitions

DNA replication occupies a central position in the cell cycle and also in the development and life of multicellular organisms. During the last 10 years, our comprehension of this important process has considerably improved. Although the mechanisms that coordinate DNA replication with the other moments of the

cell cycle are not yet full understood, it is known that the regulation of the process operates by modulating the activation of DNA ►replication origins i.e. the sites where DNA replication starts.

The Replicon Model

In the early sixties, Jacob, Brenner and Cuzin proposed the ►replicon model for the replication of the bacterial chromosome. In this model, the replicon is a genetic element replicated from a single origin of DNA replication or ►replicator, which is recognized by a specific positive regulatory protein, the ►initiator. Since then this model has been validated in numerous prokaryotic and viral systems.

Unlike the single bacterial chromosome, the eukaryotic genome is organized as several chromosomes, each formed by numerous replication units that are named, by analogy with the prokaryotic models, replicons. Each replicon (10–300 kb in length) is characterized by an origin from which two oppositely moving forks issue. Origin activation is a tightly controlled event occurring in a well defined interval of the cell cycle called S-phase. Moreover, origin firing follows a precise and reproducible spatio-temporal program; origins embedded in transcribed portions of the genome are activated in early S-phase while origins associated with heterochromatic transcriptionally silent domains fire in mid and late S-phase.

The Replication Origins

Computation of the ratio between replicon and genome sizes, as well as calculation of the rate of advancement of the ►replication fork, led to the conclusion that about 30,000 origins should exist in mammalian cells. However, less than 50 mammalian origins have been identified so far, and even fewer have been characterized in detail. Fundamental questions, such as how origins are spaced in the genome, which are their functionally essential sequence features and how they are regulated remain largely unanswered.

Historically, the first insights into eukaryotic DNA replication derived from studies of viruses that replicate their DNA in mammalian nuclei (SV40 and Epstein Barr). The genome of these viruses is organized into circular mini-chromosomes and its replication requires a number of proteins borrowed from the replication machinery of the host in conjunction with a trans-acting initiator protein encoded by the virus itself. The DNA replication origins of these viruses are quite simple, consisting of a well-defined core and of regulatory regions composed of several auxiliary elements. A completely viral origin enables autonomous replication of plasmid DNA, when the cognate initiator protein and other necessary replication factors are provided.

An invaluable contribution to the characterization of eukaryotic DNA replication origins was made by the budding yeast *Saccharomyces cerevisiae* model. DNA replication origins in *S. cerevisiae* were identified as genomic regions able to drive autonomous replication of plasmid DNA molecules and were, therefore, called *ARS* for *autonomously replicating sequences*. A complete ARS element (100–200 bp) contains a highly conserved 11 bp AT-rich sequence (*ACS*, *ARS consensus sequence*), and two or three auxiliary motifs (*B domains*) that although divergent in sequence are functionally conserved. B-domains are involved both in the assembly of the pre-replication complex and in the unwinding of the double helix that is required for the assembly of the replication machinery (►replisome).

The relatively easy identification and characterization of replication origins in viruses, bacteria and yeast raised many expectations as to the possibility of isolating the mammalian origins of replication. However, this task has proved much more difficult than expected. The main reason for the elusiveness of origin sequences in animal cells is probably related to the lack of a successful functional assay. Following the approach used for the identification of yeast ARS elements, several groups have tried to obtain autonomous replication of a reporter plasmid driven by specific mammalian DNA sequences. Despite sporadic positive reports the overall outcome of these attempts has been negative.

The lack of simple genetic assays led to the development of methods for the identification and mapping of replication initiation sites in the chromosomal context. All these methods are based on some conserved features of replication forks. Initiation of DNA synthesis generates specific structures (►replication bubbles) and proceeds bidirectionally in a semidiscontinuous manner. Thus, an origin of DNA replication can be operationally defined as the site where: i) transition between continuous DNA synthesis of the ►leading strand and discontinuous DNA synthesis of the ►lagging strand occurs, ii) nascent DNA synthesis occurs and iii) replication bubbles are created. These three features have all been utilized in recent years for origin mapping in eukaryotic chromosomes.

A partial list of identified mammalian replication origins is shown in Table 1.

Characteristics

Pre-Replication and Post-Replication Complexes

In the last few years, our understanding of the molecular events regulating origin firing has significantly improved thanks to studies in *S. cerevisiae* that led to the identification of the numerous proteins involved. According to the current model a complex of six polypeptides – ►origin recognition complex, ORC– recognizes and binds to the yeast origins. In

Replication Origins. Table 1

Region studied	Organism	Sequence properties	Method
<i>TOP1</i> gene promoter	Human	CpG tracts and AT-rich element	Interaction with Orc2 in ChIP ¹ experiments.

¹ChIP: chromatin immunoprecipitation

G1 phase, ORC proteins cooperate with the products of the Cdc6 – in *S. cerevisiae* – or Cdc18 – in *S. pombe* – genes to load a complex of six proteins – called MCMs (Mini Chromosome Maintenance). In *Schizosaccharomyces pombe* and in higher eukaryotes this process requires the activity of another protein, called Cdt1. The final result is the assembly on the origin of a pre-replicative complex. After this event ORC, CDC6 and Cdt1 proteins are no longer required. Following origin firing, the concordant removal of CDC6/CDC18 prevents the loading of MCM proteins onto the origin-bound ORC in G2, thereby preventing re-replication of DNA. The pre-replication complex formed in G1 is ready to initiate DNA replication upon the activation of S-phase promoting factors like cyclin-CDKs and CDC7/DBF4 kinases that are part of the pre-replication complex.

Interestingly the ORC, MCM, CDC6, CDC7, DBF4 and CDC45 proteins are quite conserved in evolution,

and mammalian homologues have been identified and cloned. However, very scanty evidence so far exists about the interactions of these proteins with any origin-specific sequences in mammalian DNA.

The DNA Origin Associated to the Human Lamin B2 Gene

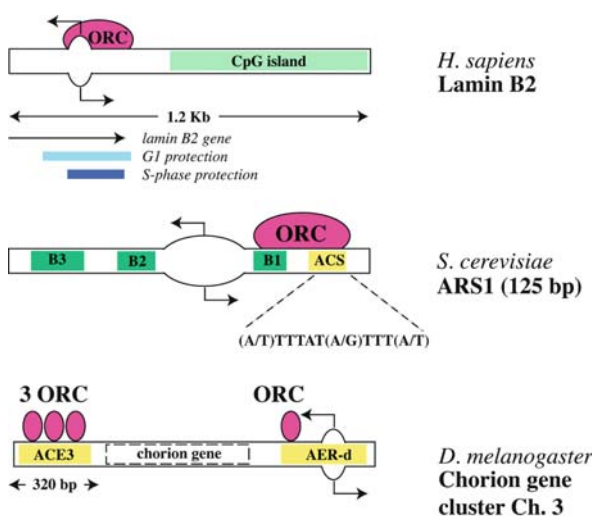

The human DNA replication origin for which most details concerning the *cis*-acting sequences involved in origin activity are currently available is the one located in a short intergenic region immediately downstream of the human lamin B2 gene.

The origin was localized using the competitive polymerase chain reaction (PCR) assay to quantify the abundance of adjacent genomic DNA fragments in the pool of newly synthesized DNA fragments. In this assay, fragments proximal to the origin are more abundant than distal ones. The origin has been mapped in an approximately 500 bp region corresponding to the

3'-end of the lamin B2 gene and the promoter of the TIMM13 gene. This origin is activated in the first two minutes of S-phase in HL-60 cells, and is active in all the cell types tested so far. A distinguishing feature of this origin, revealed by *in vivo* genomic footprinting experiments, is a prominent protected region overlapping the replication initiation site. The extension of this protection undergoes remarkable changes during the cell cycle. In quiescent cells, no protection is detectable. As the cells enter the cell-cycle a footprint appears and keeps growing throughout G1 to reach its maximal extension (over 100 bp) at the G1/S border. After origin firing, the protection shrinks to 70 bp and remains unchanged until G2/M. In mitosis, the protection totally disappears. A similar phenomenon takes place on ARS elements in yeast and reflects the assembly of the pre- and post-replication complexes. The proteins responsible for these interactions are currently the subject of intensive investigation. The precise initiation start sites of DNA replication have been recently mapped within the protected region at the single nucleotide level. Fig. 1 schematically illustrates the structure and the mode of activation of the human lamin B2 origin along with that of other dissected eukaryotic origins.

Relationship Between Origins of DNA Replication and Replicators

DNA sequences of four of the most characterized mammalian origins of DNA replication (β -globin,

Replication Origins. Figure 1 Schematic representation of three eukaryotic DNA replication origins. The positions of ORC binding sites relative to start sites of DNA replication (arrows passing through a bubble) are indicated.

lamin B2, c-myc and DHFR) have been either mutated in their original locations or cloned in plasmid vectors and stably transferred to ectopic sites of the genome. Altogether the results of these experiments support the notions that: 1) mammalian cell origins might consist of relatively short regions, the activities of which are primarily specified by DNA sequence, by analogy with all replicators from simple organisms, 2) these origins probably have a modular organization of different genetic elements and 3) the genetic elements determining replication function correspond or lie in close proximity to the initiation region. Whether origin specification by these replicators might occur by primary DNA sequence recognition by initiator proteins (most probably members of the ORC complex) or by other epigenetic features favoring the recruitment of initiation proteins (attachment to matrix? chromatin modification? transcription factors?) begs further investigation.

Chromatin Structure, Epigenetics, and Origins

The absence of common consensus motifs in mammalian origins of replication, the low sequence-specificity of binding of the ORC complex to DNA and the observation that in early amphibian and *Drosophila* embryos DNA replication can start from any DNA sequence have led to the proposal that origin specification might be influenced by epigenetic mechanisms rather than solely by DNA sequence information. The notion that chromatin conformation is a strong determinant for origin activity is unquestionable. Even in yeast, initiation activity of ARS elements in the chromosomal context depends not only on the ARS sequence but also on chromatin structure and chromosomal position. For example, origins near telomeres tend to be activated late in S phase and the activation time of early-firing origins is considerably delayed upon translocation into a sub-telomeric position.

One of the possible mechanisms by which chromatin regulates initiation of DNA replication is by restricting access of DNA to direct or indirect ORC binding. Thus, a strict correlation has begun to be envisaged between ORC proteins, origins of DNA replication and regulators of chromatin modeling in metazoan cells. In this regard, it was proposed that CG-rich regions of the chromosome, approximately 1 kb long, free of methylation and often containing transcription promoters (the so called CpG islands), might specify the location of at least a subset of DNA replication origins. CpG islands might mark chromosomal sites that are more accessible to initiation proteins (ORC) as well as to transcription factors.

Some possible modes of ORC recruitment to eukaryotic origins are depicted in Fig. 2.

Replication Origins. Figure 2 Possible modes of ORC recruitment to origins. (a) ORC directly contacts target DNA with several ORC subunits. The paradigm for this mode is the interaction of ORC to ARS sequences in *S. cerevisiae*. ORC contacts both the ACS and the auxiliary B1 element. (b) The specificity of binding is conferred only by one ORC subunit. This is the case for *S. pombe* ORC in which Orc4 has an N-terminal extension containing nine repeats of an AT-hook motif that recognizes stretches of AT-rich DNA in the ARS element. (c) Specificity of ORC binding to DNA is very relaxed in term of primary DNA sequence and the interaction is mostly determined by chromatin conformation. (d) ORC directly binds DNA but the specificity of binding is provided by the association with another factor bound to neighboring DNA sequences. This may be the case of the ACE3 element of *Drosophila* chorion genes. Here ORC binding requires transcription factor E2F.

Origins of Replication and Cell-Cycle Control

Another important topic of investigation is related to the understanding of the molecular events linking cell-cycle control, replication regulatory proteins such as ORC, CDC6 and MCMs and origins of DNA replication. As in budding yeast so also in mammalian cells, the proteins involved in origin regulation are most probably the targets on which cell-cycle control mechanisms converge. This was indirectly suggested by the study of protein-DNA interactions at the lamin B2 origin, which showed a cell-cycle regulated pattern and by experiments in which *Xenopus* egg cytosol was used to stimulate hamster nuclei to enter S phase, which demonstrated that origin specification occurs at a distinct time in G1 phase. The existence of a specific network of interactions between cell-cycle regulation and origin activation can be also inferred from the elucidation of the mechanisms of S-phase checkpoint in yeast cells. In *S. cerevisiae*, the induction of DNA damage by genotoxic agents or the stalling of replication forks are sensed by the Rad 53

protein and DNA replication is blocked by specifically preventing late origin firing. Similarly, in *S. pombe* ORP2, the homologue of *S. cerevisiae* ORC2, is required for the response to checkpoint signals, preventing progression of the cell-cycle after DNA damage. Most probably, these biochemical and functional interactions requiring replication initiation proteins will also turn out to be conserved in higher eukaryotic cells.

Clinical Relevance

The definition of DNA replication origins and their timely and coordinate activation are key factors in the faithful replication of genomes and in the maintenance of their integrity. Regulatory circuits controlling cell proliferation and differentiation must generate signals that dictate origin activation/inactivation through the cell-cycle. It is to be expected that alterations of the programmed activation of origins of replication might have pathological consequences. Evidence of this is

starting to emerge. These issues, however, are greatly complicated by the realization that in higher eukaryotes initiation of DNA replication does not simply depend on sequence elements, but also on additional elements such as chromatin structure, transcriptional activity and possibly also the sub-nuclear location of DNA domains. The elucidation of the interplay between replication factors, transcription factors and proteins modulating chromatin structure and nuclear architecture remains one of the major challenges in molecular biology. A thorough understanding of the positive and negative elements regulating this process will offer essential insights into the modulation of DNA proliferation, assuring the harmonious development and differentiation of tissues and organs from the fertilized oocyte to the healthy adult organism; furthermore, a definition of the structural and mechanistic details of the molecules involved and of the reactions they perform may offer in the future indications for the production of drugs capable of interfering specifically with the uncontrolled cell proliferation typical of cancer.

Replicative Senescence

Definition

Normal human cells exhibit a restricted replicative lifespan when propagated in culture. This replicative barrier is called replicative senescence or mortality stage 1 (M1).

- ▶ Proteomics of Aging
- ▶ Telomerase

Replicator

Definition

The DNA sequence corresponding to the origin of DNA replication is called replicator.

- ▶ Replication Origins

Replicon

Definition

In prokaryotes, replicon defines a DNA molecule capable of autonomous replication; in eukaryotes, replicon denotes a DNA sequence (100 to 300 kb long) organized in tandem with other replicons on the chromosome, which contains in its middle a replication origin that is activated by specific proteins during the S phase of the cell cycle.

- ▶ Replication Origins

Replisome

Definition

Replisome is a multiprotein complex performing the advancement of semi-conservative DNA synthesis at a replication fork (e.g. *E.coli* DNA Polymerase III holoenzyme is composed of at least 17 polypeptides).

- ▶ Replication Fork
- ▶ Replication Origins

Repolarization

Definition

Repolarization is the phase of the action potential that reconstitutes the resting membrane potential.

Reporter Genes

Definition

Reporter genes are used as genetic tools to visualize transgene expression. When introduced into a genomic locus via homologous recombination, reporter genes are under the transcriptional control of the mutant gene, which allows assessment of its spatio-temporal expression pattern (knock-in). Commonly used reporter genes are LacZ encoding β -galactosidase gene from *E. coli*, GFP Green Fluorescent Protein gene from marine jelly fish, and hPLAP human Placental Alkaline Phosphatase gene.

Resolution

Definition

In X-ray structure analysis, resolution describes the degree of order of the crystal that determines the maximum angle of diffraction from the crystal, and from Bragg's law, the level of detail resolvable by the diffraction data. The accuracy of the structure is typically much higher than the resolution of the diffraction data, depending on the applicability of chemical geometry information used to refine the crystal structure. In mass spectrometry, resolution (R) is defined as the differentiation of two neighbouring masses with $R=m/\Delta m$. In chromatography, resolution is the differentiation of two neighbouring co-eluting peaks.

Respiratory Burst

Definition

Respiratory burst describes a sudden rise in oxygen consumption of phagocytes upon contact with micro-organisms or stimulation with, e.g. anaphylatoxins, immune complexes or proinflammatory cytokines. It is the physiological equivalent to superoxide anion production by NADPH oxidase and is essential to initiate the killing reaction during phagocytosis. Any inability to adequately respond with respiratory burst leads to inefficient clearance of pathogens (chronic granulomatous disease). Ubiquitous strong and persistent activation of the respiratory burst contributes to the pathology of septicemia.

- [Free Radicals](#)

Residue Interface Propensity

Definition

Residue interface propensity quantifies the preference for certain amino acids to be in the interface site of two interacting molecules.

- [Protein-Protein Interaction](#)

Respiratory Chain

Definition

The respiratory chain consists of five enzyme complexes embedded in the mitochondrial inner membrane. The respiratory chain produces ATP through the process of oxidative phosphorylation, and its function is dependent on both nuclear and mtDNA-encoded protein subunits.

- [Mitochondrial Myopathies](#)

Response Elements

Definition

Response elements are precise sequences of nucleotides recognized by transcription factors. In nuclear receptor action, they are recognized by the receptor. They are pairs of half sites that may be arranged palindromically, or as tandems, or as reverse tandem repeats or even singly.

► [Nuclear Hormone Receptors: Regulators of Gene Transcription and Cellular Signaling](#)

REST

Definition

Repressor element-1 silencing transcription factor (REST), also known as neuron restrictive silencer factor (NRSF), is a C₂H₂ zinc finger protein that is related to the Gli-Krüppel family of transcriptional repressors. In non-neuronal tissues, REST/NRSF is part of a transcriptional repressor complex that binds to the neuron restrictive silencer element (NRSE), effectively silencing neuronal genes in non-neuronal tissues. Huntingtin interacts with REST/NRSF to modulate the transcription of NRSE-controlled neuronal genes such as BDNF or proenkephalin.

► [Transcriptional Repression](#)

Restriction Enzymes

Definition

Restriction enzymes (also called restriction endonucleases) in nature are part of a bacterium's antiviral defense system. These enzymes recognise four to eight base pairs in a DNA strand (recognition site), and then cleave both strands of DNA at or close to that specific site (restriction site). In the molecular biological laboratory these enzymes are a key tool for analysing DNA; they are used to cleave DNA at defined sequences. The cleavage sites are used as landmarks and the sizes of fragments give the distance between them, allowing physical maps to be built up.

► [Recombinant Protein Expression in Bacteria](#)

► [YAC and PAC Maps](#)

Restriction Fragment Length Polymorphism

Definition

Restriction fragment length polymorphisms (RFLPs) are variations between individuals in DNA fragment sizes after cutting by specific restriction enzymes. RFLPs are usually caused by mutation at an enzyme's cutting site. If even one nucleotide within a cutting site is altered (by mutation) then the enzyme will no longer cut the target DNA at that point. The resulting restriction fragments will be of a different length. RFLPs are a quick way to differentiate two alleles by the size of DNA fragments.

► [Common Diseases, Genetics](#)

► [Spinal Muscular Atrophy](#)

Restriction Mapping

Definition

Restriction mapping displays a physical mapping technique in which the position and spacing of restriction sites is deduced, often as an aid to construction of clone contigs. This can be applied to genomic or cloned DNA. Key techniques used are multiple enzymes singly and in combination, partial digestion with a single enzyme, and Southern transfers.

► [YAC and PAC Maps](#)

Restriction Point

Definition

Restriction point is a critical point in the G1 phase of the cell cycle when a growth factor has committed a cell to cell proliferation.

Retinal Pigment Epithelium

Definition

The retinal pigment epithelium (RPE) is a monolayer of cells loaded with melanin granules. The RPE is located

just outside the retina between Bruch's membrane (basal side) and the photoreceptors (apical side). The RPE are important for phagocytosis of photoreceptors, transport and storage of retinoids, regulation of extracellular ion concentration, and protection of the photoreceptive system from short-wavelength light.

►Retinitis Pigmentosa (RP)

Retinal Protein

Definition

Retinal protein refers to a protein in which retinal is covalently bound as a prosthetic group via a Schiff base.

►Photoreceptors

Retinitis Pigmentosa

ezrenner@uni-tuebingen.de

Definition

The term "retinitis pigmentosa" (RP) comprises a large group of genetically heterogeneous and clinically similar hereditary retinal dystrophies and degenerations (prevalence of 1:3000–1:5000). The term was coined by the Dutch ophthalmologist F.C. Donders (1855), implying an infectious disease, which turned out to be wrong. The term "retinitis pigmentosa" is the most common one; synonyms are retinopathia pigmentosa, photoreceptor dystrophy, hereditary retinal degeneration or tapeto-retinal degeneration. Due to the excessive clinical variability of RP and its enormous genetic heterogeneity, it has become common in recent years to differentiate these retinal diseases according to the gene symbol and its chromosomal locus (examples see Table 1). They can be classified according to their inheritance: autosomal dominant, autosomal recessive, x-chromosomal recessive and mitochondrial. Additionally there are numerous cases where different mutations in the same gene cause clinically quite heterogeneous patterns, stationary or progressive or where clinically similar terms have been applied to patients with

different mutations in different genes (1, 2). In all cases, the functions of retinal photoreceptors (rods or cones) or of the ►retinal pigment epithelium ("RPE" or "tapetum") or of structures supporting these cells (choroid, glial cells, inter-photoreceptor matrix) are primarily affected. There are spontaneous animal models and generated mouse mutants that suffer from several forms of "retinitis pigmentosa" due to mutations also found in man.

Characteristics

The typical clinical characteristics of RP are:

1. Bilateral involvement with onset in the first three decades of life.
2. Loss of peripheral vision if ►rods are primarily affected or central vision if ►cones are involved first.
3. Progressive loss of photoreceptor function, as assessed by electroretinography, a process that may last several decades.
4. Alterations at the level of the pigment epithelium.

At the stage where rod function deteriorates, the corresponding visual symptoms comprise night blindness or delayed adaptation to dim light, impaired orientation caused by the loss of visual field, abnormal sensitivity to glare and, eventually, difficulties with color discrimination as well as a decrease in visual acuity. Many patients become legally blind in the late stages of the disease.

Morphological Findings

There are characteristic clinical signs of typical RP (3, 4), yellow, wax-colored optic disks, narrowed blood vessels and almost always changes in the ►macula, such as wrinkling of the inner limiting membrane, diffuse atrophy or cystoid macular edema. In most cases, changes are found in the mid-peripheral retinal pigment epithelium, beginning with depigmentation, followed by dark pigments in a typical "bone spicule" configuration, reflecting an intraretinal pigment migration. Vitreous changes are always found at least in later stages and myopia is very frequent. In middle-aged patients subcapsular posterior cataract is very common. There are atypical cases without pigment changes or with localized deposits only. Additionally, there are a number of syndromes that may involve extra-ocular structures and functions.

Mendelian Genetics

In about 25% of patients, autosomal dominant inheritance can be established; autosomal recessive inheritance is found in approximately 20% and x-chromosomal recessive inheritance in about 8% of the cases. In the majority of all affected patients, no heredity is provable;

Retinitis Pigmentosa. Table 1 Genes involved in retinitis pigmentosa

Phototransduction			
Symbols	Location	Diseases;Protein	Comments
RHO , RP4	3q22.1	dominant RP; dominant CSNB; recessive RP; protein: rhodopsin	accounts for 30 to 40% of autosomal dominant RP; more than 100 distinct mutations but RhoPro23His causes 10% of adRP
PDE6B , CSNB3	4p16.3	recessive RP; dominant CSNB; protein: rod cGMP phosphodiesterase beta subunit	same as retinal degeneration in the <i>rd</i> mouse, <i>r</i> mouse and <i>rcd1</i> Irish Setter dog; accounts for 3 to 4% of recessive RP; photoreceptor rescue with calcium-channel blocker in mouse but not dog
RPGR , RP3	Xp11.4	X-linked RP, recessive; X-linked RP, dominant; X-linked CSNB; X-linked cone dystrophy 1; X-linked atrophic, recessive; protein: retinitis pigmentosa GTPase regulator	mutations are found in 70% of RP3 cases, with dominant mutations in ORF15; exceptionally heterogeneous, retina-specific alternate splicing; protein is similar to RCC1, and binds PDE-delta and RPGRIP1 with species-specific colocalization (rod/cone outer segments in humans, connecting cilia in mice)
Cation Channel			
CNGA3 , ACHM2, CNCG3, RMCH2	2q11.2	recessive achromatopsia; protein: cone photoreceptor cGMP-gated cation channel alpha subunit	total color blindness and other cone-related abnormalities (rod monochromacy); CNGA3 accounts for 20–30% of achromatopsia cases
CACNA1F , CSNB2, CSNBX2	Xp11.23	X-linked CSNB, incomplete; protein: L-type voltage-gated calcium channel alpha-1 subunit	CACNA1F mutations are found in 60 to 90% of X-linked incomplete-CSNB patients; retina-specific expression with synaptic localization of protein
Disc structure			
RDS , RP7	6p21.2	dominant RP; dominant MD; digenic RP with ROM1; dominant adult vitelliform MD; protein: peripherin 2	dominant mutations; accounts for 5% of dominant RP; same as <i>rd</i> s mouse; photoreceptor rescue in mouse model
Rhodopsin transport			
TULP1 , RP14	6p21.31	recessive RP; protein: tubby-like protein 1	protein localizes to developing and adult rods and cones; possibly involved in transport of rhodopsin from inner to outer segment; a similar gene in <i>tub</i> mouse causes obesity, deafness and retinal degeneration
RP1	8q12.1	dominant RP; protein: RP1 protein	causes 5 to 10% of adRP; highly variable expression; two common mutations, Arg677X and 2280del4; protein is photoreceptor-specific,
Retinoid cycle			
RPE65 , LCA2, RP20	1p31.2	recessive Leber congenital amaurosis; (LCA) recessive RP; protein: retinal pigment epithelium-specific 65 kD protein	accounts for 2% of recessive RP and 7 to 16% of LCA; protein is necessary for production of 11- <i>cis</i> -vitamin A; 9- <i>cis</i> -retinal restores visual function in mouse model; successful gene therapy in dog; in same pathway as LRAT

Retinitis Pigmentosa. Table 1 Genes involved in retinitis pigmentosa (Continued)

Phototransduction			
Symbols	Location	Diseases;Protein	Comments
ABCA4 , ABCR, RP19, STGD1	1p22.1	recessive Stargardt disease, juvenile and late onset; recessive MD; recessive RP; recessive cone-rod dystrophy; protein: ATP-binding cassette transporter - retinal	may be involved in age-related macular degeneration; expressed in rod outer segment and foveal cones; ABCA4 mutation may increase severity of STGD3; flippase for all- <i>trans</i> retinal and N-retinylidene-PE
LRAT	4q32.1	recessive RP, severe early-onset; protein: lecithin retinol acyltransferase	gene is expressed in RPE; protein catalyzes first step in visual cycle transforming vitamin A into 11- <i>cis</i> -retinol; same pathway as RPE 65
RBP4	10q23.33	recessive RPE degeneration; protein: retinol-binding protein 4	RPE atrophy with night blindness and reduced visual acuity; carrier protein for serum retinol
RDH5 , RDH1	12q13.2	recessive fundus albipunctatus; recessive cone dystrophy, late onset; protein: 11- <i>cis</i> retinol dehydrogenase 5	stationary night blindness with subretinal spots and delayed dark adaptation; protein is an RPE microsomal enzyme involved in converting 11- <i>cis</i> retinol to 11- <i>cis</i> retinal; extremely delayed rod and cone resensitization in null mutation
Ciliary Structure			
MYO7A , DFNB2, USH1B	11q13.5	recessive Usher syndrome, type 1; recessive congenital deafness without RP; recessive atypical Usher syndrome (USH3-like); protein: myosin VIIA	MYO7A, an unconventional myosin, is a common component of cilia and microvilli; same as <i>sh1</i> shaker-1 mouse (but no RP) and <i>mariner</i> zebrafish; possible digenic deafness with USH3A
Phagocytosis			
MERTK	2q13	recessive RP; protein: c-mer protooncogene receptor tyrosine kinase	human ortholog of the mouse <i>Mertk</i> gene; causes defective phagocytosis of photoreceptor outer segments by the RPE and retinal degeneration in the RCS rat; successful gene therapy in rat; expressed in multiple tissues including RPE/sclera
Extracellular Matrix			
USH2A	1q41	recessive Usher syndrome, type 2a; recessive RP;	usherin is a basement membrane protein, with laminin, EGF and fibronectin type III domains, found in many tissues, in retina and inner ear; Cys759Phe mutation found in 4 to 5% of recessive RP without hearing loss
Transcription Factor			
CRX , CORD2	19q13.32	dominant cone-rod dystrophy; recessive, dominant and <i>de novo</i> Leber congenital amaurosis; dominant RP; protein: cone-rod otx-like photoreceptor homeobox transcription factor	meiotic drive suggested; CRX also activates pineal genes; interacts with NRL; <i>Crx</i> -deficient mice have diminished circadian entrainment; causes approximately 3% of LCA

Retinitis Pigmentosa. Table 1 Genes involved in retinitis pigmentosa (Continued)

Phototransduction			
Symbols	Location	Diseases;Protein	Comments
Splicing			
PRPF31, RP11, PRP3	19q13.42	dominant RP; protein: human homolog of yeast pre-mRNA splicing factor	high frequency in British Isles (21%); highly variable severity, protein is a highly-conserved, ubiquitously-expressed member of the U4/U6-U5 tri-snRNP particle complex
Upstream metabolisms			
CHM	Xq21.2	choroideremia; protein: geranylgeranyl transferase Rab escort protein 1	ubiquitously expressed protein (REP2 can substitute); attaches isoprenoids to Rab proteins

CSNB, congenital stationary night blindness; MD, macular dystrophy

these isolated cases are simplex patients, some of which may be autosomal recessive cases. Heterozygotes can be identified quite often by tapetal reflexes, scattered discrete pigment atrophy or in ERG recordings, especially in the flicker electroretinogram.

The Natural Course of the Disease

According to Massof and Finkelstein (1987), the loss of visual field in typical RP occurs in two stages (5). Stage 1 is characterized by very slow progression up to a critical age, which is 32 years in the autosomal dominant form and about 20 years in the x-linked type, with autosomal recessive forms lying somewhere in between. After this critical age, the rate of visual field loss follows an exponential function, so that every year about 20% of the remaining visual field is lost. Various clinical studies suggest two forms of autosomal dominant RP with different natural courses.

Type 1 is characterized by a relatively early diffuse loss of rod sensitivity with increasing concentric visual field impairment, but cone function is preserved for a long time.

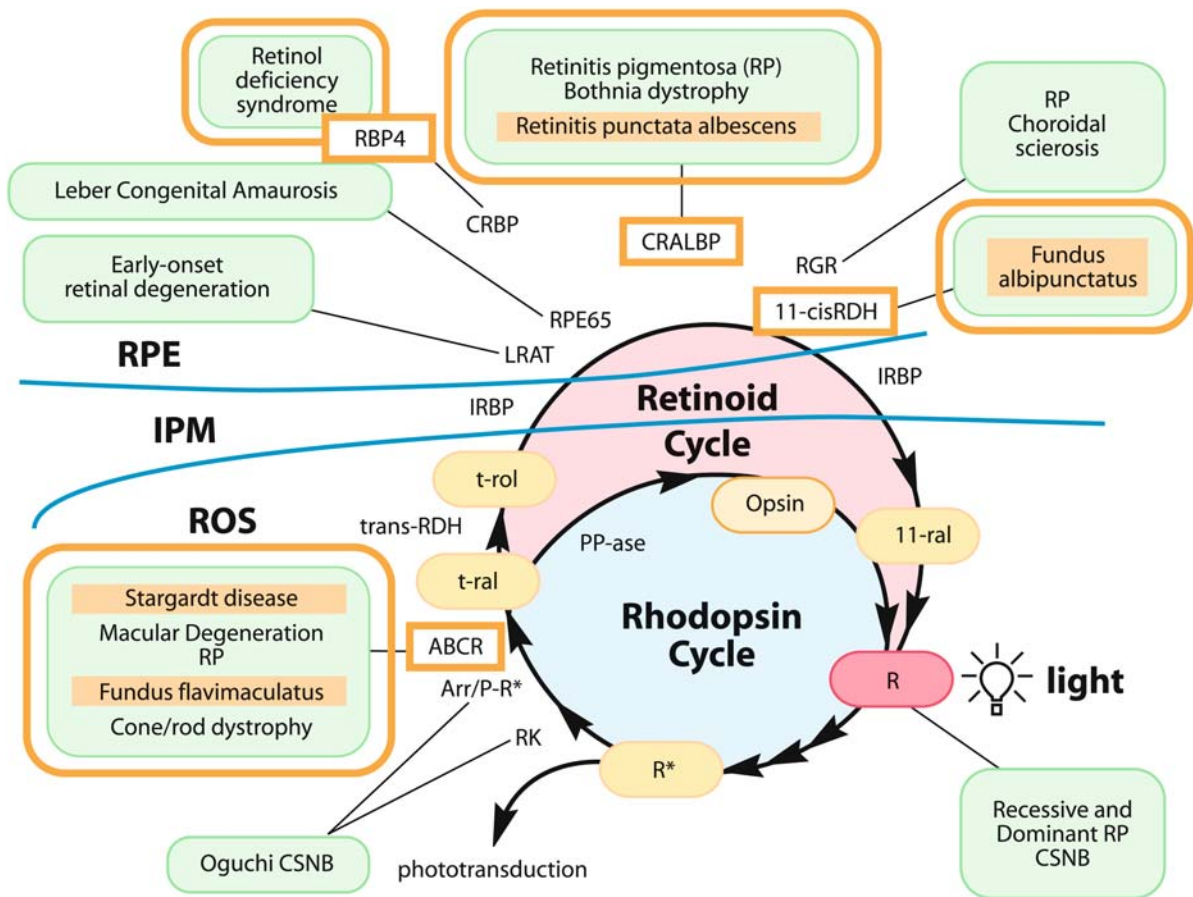

Type 2 is characterized by a more regional simultaneous loss of rod and cone function; the onset of night blindness occurs late and the loss of peripheral visual field progresses relatively slowly (6). A more refined differentiation is however possible only by molecular genetic differentiation. There is a large variation in the degree of function loss from very serious at birth to very mild at an advanced age.

Other Retinal Degenerations Related to RP

- ▶ **Choroideremia** is an x-linked disease, which manifests characteristic fundus findings of diffuse

choroidal and retinal atrophy. Its pattern of visual function loss is quite similar to that of typical x-linked retinitis pigmentosa.

- ▶ **Cone-rod dystrophies** differ clinically from RP in that photophobia, decrease in color vision and visual acuity loss occur before the onset of peripheral visual field loss and impaired dark adaptation. There are special forms of hereditary macular dystrophies that form an entity of their own (e.g. Stargardt's disease, Best's disease). They can be differentiated at an early stage by electroretinography (ERG) in conjunction with typical fundus appearances.
- ▶ **Leber's congenital amaurosis** (LCA) denotes a heterogeneous group of inherited retinal dystrophies which cause severe visual loss with non-recordable or a largely reduced ERG response either congenitally or in very early childhood. The fundus findings may be indistinguishable from those seen in typical RP.
- ▶ **Atrophia gyrata** is a rare autosomal recessive disorder with clinical signs similar to those seen in RP; it is however characterized by sharply defined garland shaped areas of chorioretinal atrophy. An elevation of plasma ornithine level caused by an ornithine aminotransferase deficiency is involved in this disease.
- Syndromic diseases with retinal dystrophy may be marked by typical or atypical RP. Frequent symptoms associated with RP are sensory neural hearing loss such as in Usher syndrome or various kinds of neurological involvement such as mental retardation, ataxia or other signs of degeneration of the central or peripheral nervous system, e.g. Laurence-Bardet-Biedl syndrome or Refsum's disease. Various metabolic disorders can occur together with retinal

Retinitis Pigmentosa. Figure 1 Hereditary retinal diseases can be caused by many different, usually monogenic mutations in either the phototransduction process and its support mechanisms ("Rhodopsin Cycle") or by involvement of the Retinal pigment epithelial cells that are important for the metabolic steps of visual purple regeneration ("Retinoid cycle").

degeneration such as paroxysmal disorders, mucopolysaccharidosis or abetalipoproteinemia.

- Phenocopies can mimic retinitis pigmentosa by their very similar fundus appearance in several non-genetic acquired disorders. Drug exposure, especially binding to melanin or neurotoxic drugs, as well as malnutrition and infectious diseases such as syphilis can mimic RP as well.

Genetic Differentiation

To the present at least 150 cloned and/or mapped genes causing retinal dystrophies and degenerations have been found (for surveys see 7). They are listed in specialized data banks such as RETNET: ► <http://www.sph.uth.tmc.edu/retnet/disease.htm>

At this Internet site the OMIM numbers, the genetic location, the known diseases and/or proteins, the mapping method and the reference given for each chromosome and for the mitochondrion are given. Table 1 shows the more common cloned genes of

hereditary retinal dystrophies and their contribution to such dystrophies.

Cellular and Molecular Mechanisms

In the following, only a subgroup of hereditary retinal dystrophies in which cellular and/or molecular mechanisms have been elucidated to some degree is discussed.

As also shown in the subheadings in Table 1, RP symptoms can be caused by mutations in practically every component of the phototransduction process from rhodopsin (RHO) to subunits of transducin, phosphodiesterase (PDE), the cyclic nucleotide gated cation channel (CNG3) or arrestin, to name just a few common examples. Thus the generation of an appropriate photoreceptor signal is hampered or a slow toxic increase of metabolic products is induced, leading finally to cell death, as can be studied in spontaneous animal models or generated mutants (Fig. 1).

Another set of causes for retinal dystrophies involves structural proteins responsible for the integrity of the membrane (e.g. ROM 1, cadherin etc.)

A third chain of events involves retinal pigment epithelium (RPE) cell function by mutations that disturb the photoreceptor pigment renewal performed in the retinoid cycle as shown in Fig. 1. The ►[retinoid cycle](#) is closely related to the ►[rhodopsin cycle](#) and involves the transport of retinoids from the rod outer segment (ROS) across the interphotoreceptor matrix (IPM) to the RPE and *vice versa*. Numerous clinically different retinal diseases, as shown in Fig. 1 stem from mutations in the various proteins involved in this cycle, especially enzymes such as retinol-kinase (RK) retinol dehydrogenase (RDH), lecithin-retinol-acetyltransferase (LRAT), isomerase controlling proteins (RPE 65), retinol binding proteins (RBP) and cellular retinol binding protein (CRALBP) serving as carrier for RDH5. Some mutations cause flecked retinal diseases by yellowish deposits of products of the altered visual cycle (disorders are marked by frames in Fig. 1). Other genes (TULP1) involve the ciliary structure, important e.g. for rhodopsin transport or the phagocytosis (MERTK) necessary for photoreceptor renewal. Transcription factors can also be affected (CRX) or splicing mechanisms (PRPF8) besides not fully upstream metabolisms such as the geranylgeranyl transferase in choroideremia.

Clinical Relevance

The fact that retinitis pigmentosa is the most common cause of blindness in early life and the fact that initial successful gene therapy approaches have been performed in dogs suffering from early onset RP (LCA, RPE65) make clear that the understanding of the various molecular mechanisms is a most important prerequisite for targeted therapeutic strategies in these diseases that are not yet curable.

Details and references can be found in the continuously updated RETNET data bank (see above).

Retinoid Cycle

Definition

Absorption of light by rhodopsin or cone pigments in photoreceptors triggers photoisomerization of their universal chromophore, 11-cis-retinal, to all-trans-retinal. This photoreaction is the initial step in phototransduction that ultimately leads to the sensation of vision. The process that restores rhodopsin and counterbalances the bleaching of rhodopsin, is called the retinoid cycle. In this process, visual pigments are regenerated by enzymatic isomerization of all-trans-retinal to 11-cis-retinal. Regeneration begins in rods and cones when all-trans-retinal is reduced to all-trans-retinol. The process continues in adjacent retinal pigment epithelial cells (RPE), where a complex set of reactions converts all-trans-retinol to 11-cis-retinal. A number of enzymes is involved in the transport, storage, and transformation of vitamin A and its derivatives; mutations in the genes encoding these proteins leads, in many cases, to retinal diseases, either cone-rod dystrophies or tapetoretinal degenerations of the retinitis pigmentosa group.

► [Retinitis Pigmentosa](#)

Retinopathy

Definition

Retinopathy is a disease of the retina in the eye. Retinal capillaries that provide blood to the retina are destroyed. With the onset of retinopathy, retinal capillaries weaken or bulge with microaneurysms that may hemorrhage, leaking blood or fluid into surrounding tissue. When new blood vessels grow on the retina

(and into the vitreous) they can cause blurred vision and even temporary blindness. Ultimately, scar tissue may form, detaching the retina from the back of the eye and often causing permanent loss of vision. Chronically elevated blood insulin and glucose levels can induce retinopathy.

Retroviruses

JOHN M. COFFIN

Department of Molecular Biology and Microbiology,
Tufts University, Boston, MA, USA
john.coffin@tufts.edu

Definition

Retroviruses are a group of viruses that is widespread in nature, and contains members, identifiable as either infectious transmissible agents or as germline remnants of past infections, in all vertebrate species as well as many invertebrates. Related elements can also be found as ►retrotransposons in the genomes of plants, yeast and many other eukaryotic organisms. Effects of different retroviruses on the infected host vary greatly from asymptomatic infection to severe diseases such as immunodeficiency, malignancy, neurological disease and many others. Despite their wide distribution and diverse biology, retroviruses form a monophyletic group, in that all are more closely related to one another than any is to any other type of virus or transposable element.

Characteristics

Despite their wide distribution and varied biology, all retroviruses share a set of defining characteristics:

A ►virion (Fig. 1) consisting of:

- An inner core of uncertain symmetry made up of about 1500 copies of at least 3 proteins: ►MA (matrix); ►CA (capsid); and ►NC (nucleocapsid), products of the ►gag gene
- At least 3 viral enzymes: ►PR (protease) a product of the ►pro gene; ►RT (reverse transcriptase) and ►IN (integrase), products of the ►pol gene
- An ►envelope, derived from a cell membrane modified by the insertion of the trimeric combination of the ►SU (surface) and ►TM (transmembrane) proteins, products of the ►env gene

A genome (Fig. 2) with the following properties:

- Two identical molecules of plus (mRNA)-sense RNA molecules, 7–12 kb in length, which are capped and polyadenylated like cellular mRNA's
- Four genes, always in the order: *gag* (encoding internal structural proteins); *pro* (encoding the protease necessary for maturation of virions); *pol* (encoding reverse transcriptase and integrase) and *env* (encoding the virion SU and TM proteins

necessary for entry) as well as additional genes in some genera

- Associated molecules of a tRNA, specific for each virus group, which serve as primers for the initiation of ►reverse transcription.

A replication cycle (Fig. 3) that includes:

- Entry mediated by interaction with a host-cell receptor
- Reverse transcription of the RNA genomes into a single molecule of double stranded DNA characterized by ►long terminal repeats (LTRs) of about 0.5–1.5 kb
- ►Integration of viral into host cell DNA at more-or-less random sites to form the ►provirus
- Transcription of the provirus to yield new genomes as well as spliced and unspliced mRNAs that encode virion and (in some groups) regulatory proteins
- Assembly of the newly-made genomes and ►poly-protein precursors for internal (Gag), and enzymatic (Pro and Pol) proteins into capsids
- Budding of virions from the cell membranes and release into the extracellular space
- Proteolytic processing of the internal Gag, Pro and Pol proteins to yield mature, infectious virions

Based on details of genome organization and molecular relationships, retroviruses are classified into 7 genera (Table 1). All these genera have currently active members; some are also represented as ►endogenous proviruses, which are remnants of infection of the germ line of the host dating from recent times to 30 million or more years ago. In humans, there are about 80,000 such elements, as compared to about 30,000 genes. These proviruses constitute a valuable record of ancient host-virus interaction, as well as subsequent evolution.

The nature of retrovirus genome structure and replication has made them valuable as models for disease, particularly cancer, as well as vectors for gene delivery in both experimental and therapeutic settings. These virtues result from the facts that cis-acting signals for replication are found at the ends of the genome and that, in general, virus-encoded components necessary for replication are found in the virion. Therefore, genomes with non-viral sequences replacing some or all viral genes can be packaged into infectious virions when expressed in cells that express a full set of virion proteins.

Molecular Interactions

The replication cycle is characterized by a large number of interactions between and among viral and cellular proteins and nucleic acids, many of which are still

poorly characterized. Those central to the replication cycle are discussed here.

Entry

Entry of all retroviruses into cells involves fusion of virus and cell membranes after interaction of the Env protein with one or more specific receptors on the cell surface. This interaction is highly specific and a large number of different proteins is used as receptors by

different viruses. The distribution of appropriate receptors is the most important determinant of retrovirus species and tissue tropism. For example, HIV-1 recognizes only the CD4 protein found on the T helper cells, macrophages and a few other cell types and then only the CD4 of humans and chimpanzees, limiting its infection to these specific cell types and species. Following binding of a specific site on the SU to the receptor, rearrangement of the SU and TM proteins

Retroviruses. Figure 1 A typical retrovirus virion.

Retroviruses. Figure 2 Minimal (simple) retrovirus genome, provirus and mRNAs. Symbols: R, a short terminally redundant sequence. U5, a unique sequence near the 5' end of the genome. U3, a unique sequence near the 3' end of the genome; PB, a site complementary to the 3' end of the RNA primer that provides the priming site for minus strand DNA synthesis. PP, the polypurine tract, which provides the initiation site for plus strand DNA synthesis. D, A donor and acceptor splice sites.

Retroviruses. Figure 3 The retrovirus replication cycle.

Spumavirus	Human Foamy V. (HFV)	Complex	No

leads to exposure of a hydrophobic region of the TM protein that is buried in the native trimer. This region, known as the ►fusion domain, interacts with the target cell membrane and folding of two separate regions of the TM protein trimer into a coiled coil draws the membranes together until they fuse, causing the capsid to be introduced into the cytoplasm of the target cell. Although these steps are common to all retroviruses, different groups of viruses use different mechanisms to link receptor interaction to membrane fusion. With many viruses, including ►Gammaretroviruses like

MLV, fusion is activated by receptor binding itself, with no apparent intermediate steps. ►Alpharetroviruses (like ALV), by contrast, require endosomal uptake and the consequent reduction in pH for entry to occur. Unlike other viruses that use this pathway, Alpharetroviruses require receptor binding to activate the Env protein for low-pH mediated fusion, thus preventing infection of cells lacking receptors by chance endocytosis. ►Lentiviruses, particularly HIV and related viruses, require interaction with 2 cell surface molecules, the CD4 receptor and a ►coreceptor

molecule, usually one of the chemokine receptors CCR5 or CXCR4. Interaction with the receptor leads to rearrangement of the SU, exposing the binding site for the coreceptor, binding to which leads to rearrangement of the TM protein and fusion.

DNA Synthesis

Following entry into the cytoplasm, the viral RNA is copied into a double stranded DNA molecule by the action of the RT present in the virion. This process is covered in another chapter (Wainberg) and will not be discussed in detail here. It is important to note that reverse transcription takes place in a structure derived from the capsid and leads to a double stranded DNA containing long terminal repeats (LTRs) derived by copying the U3, R, and U5 regions at the ends of the RNA genome twice (Fig. 2).

Nuclear Transport

Following reverse transcription, the DNA-containing structure, often referred to as the **▶preintegration complex (PIC)**, must find its way to the nucleus. The process by which this transport happens is unclear and controversial and also seems to vary from virus to virus. MLV, for example, appears to have no active process for nuclear uptake of a structure as large as a PIC and requires breakdown of the nuclear membrane at mitosis to gain access to chromosomal DNA. This restriction imposes a requirement for division of the infected cell on the process of MLV replication. HIV, by contrast, can access an active cellular transport mechanism (which one is still unclear) for nuclear import of the PIC and therefore can infect many kinds of nondividing cells.

Integration

The covalent joining of viral to cell DNA is the central and defining event in the retrovirus life cycle. It is carried out in the context of the PIC, containing the viral DNA, IN, RT and most probably some capsid proteins as well as some cellular protein cofactors. Integration proceeds in 3 steps, the first two of which are carried out by IN: (1) removal of two bases from each 3' end of the viral DNA to expose a conserved CA-OH dinucleotide; (2) attack of the 3' OH at each end on internucleotide phosphates spaced 4–6 bases apart in the target DNA; (3) repair of the resulting gapped intermediate to join the opposite strands and create a characteristic 4–6 base pair duplication using cellular DNA repair systems. Although some viruses (including HIV) seem to exhibit a clear preference for integration into transcribed regions of host DNA and integration targets display a modest sequence preference, integration events are very widespread in the host genome and can, for many purposes, be considered to be randomly distributed.

Transcription

All retroviruses use host cell RNA polymerase and transcription factors for expression of the integrated provirus. For this reason, they must provide sites for transcription factor binding upstream of the initiation site of transcription at the U3-R border. Thus the U3 region of all retroviruses contains a complex combination of such sites and binds a number of transcription factors. As discussed in the next section, the pattern of transcription factors used by a virus can make an important contribution to regulation of retrovirus expression in certain cell types and certain differentiation states. Simple retroviruses, as a rule, do not actively participate in this process and all important functions are carried out by cellular machinery acting on viral DNA signals. Complex retroviruses encode **▶transactivating proteins** (e.g., **▶Tat** in HIV, **▶Tax** in HTLV) that are necessary for efficient transcription, yet work in very different ways. The role of these factors in regulation of the replication cycle is discussed below.

RNA Processing and Export

Retroviral transcripts are capped and polyadenylated by the same cellular systems as for cellular mRNAs. In addition, all viruses encode at least one gene (*env*) that must be expressed from a spliced mRNA. In the case of some complex viruses like HIV, many variously completely and partially spliced mRNA's are required for expression of all virus genes. Thus unlike most cell mRNAs, for which complete splicing is required to license RNA for transport, genome and *gag-pro-pol* mRNAs must be exported from the nucleus in an incompletely spliced form. Retroviruses use one of two mechanisms for this purpose. Some viruses encode a specific protein (**▶Rev** in HIV, **▶Rex** in HTLV) that binds to a highly structured region in the RNA and mediates its export in the absence of splicing. Other (simple) retroviruses contain a sequence (sometimes called the constitutive transport element, or CTE) that interacts directly with nuclear export machinery to bypass splicing of a fraction of genomes.

Translation

Translation of the *gag-pro-pol* mRNA takes place on free polysomes, while *env* mRNAs are translated on membrane-bound polysomes and cotranslationally secreted into the endoplasmic reticulum. A special feature of retroviral translation is the mechanism of synthesizing Gag, Pro, and Pol protein precursors from the same mRNA. Depending on the virus, there are terminators at the end of *gag* and/or *pro* that can be bypassed by either causing ribosomes to shift into the –1 reading frame (**▶frameshift suppression**), or by insertion of an amino acid opposite the termination codon (**▶read-through suppression**). Whatever the

mechanism, the result is the synthesis of Gag and Gag-Pro-Pol polyproteins at a ratio of 1:10 or so, as required for efficient assembly of virions with the correct ratio of structural proteins and enzymes.

Assembly

Synthesis of the viral gene products as polyproteins at relative amounts determined by efficiency of suppression of termination allows for efficient assembly of virions, since the sites required for the appropriate interactions need be present only once. Although a few retroviruses are assembled in the cytoplasm and subsequently associate with the plasma membrane, most retroviruses assemble at the plasma membrane, in a process involving simultaneous interaction between viral mRNA and proteins, viral proteins with one another and viral proteins and the cell membrane. Sites for Gag-Gag interaction are found on the NC and CA domains, for Gag-RNA interaction on NC, which contains both basic domains and zinc fingers essential for recognition of genome RNA and for Gag-membrane interaction on MA, which is usually myristoylated at its N-terminus. Assembly also requires RNA; genomes are preferentially packaged as a result of interaction of NC with a packaging (ψ) sequence near the 5' end of the genome. In the absence of genomes, cell RNAs are nonspecifically incorporated into virions. Pro and Pol proteins are included in proportions equal to their representation among the primary products of translation.

Release

As assembly proceeds, the envelope is formed by wrapping of the cell membrane, modified by insertion of the Env trimer, around the growing capsid. This process is apparently passive, driven only by association between the respective components. By contrast, the final step in budding – the release of virions from the cell surface by sealing of the neck attaching the nearly complete virion to the cell – requires the active participation of the cellular ►ESCRT machinery, normally involved in the formation of multi vesicular bodies by enabling budding of endosomal membranes. All retroviruses contain motifs that interact with various members of the ESCRT pathway, including tsg101, NEDD4 and AIP1 among others. All of these motifs are in the Gag protein, albeit in different locations in different viruses.

Processing

As budded, the immature virions are noninfectious, and require processing by the PR molecule initially embedded in an inactive form in the Gag-Pro-Pol polyprotein. Delay of processing and maturation until after budding ensures both that all gene products

remain in the virion and that infectious virions cannot find their way back into the already infected cell. PR is an aspartic protease whose active form is a dimer, with the active site formed by the dimer interface. Apparently, dimerization of the protein from within the precursor is a very slow step, accounting for the delay in processing, but once the first active dimer is formed, processing of the remaining polyprotein molecules occurs very rapidly, in a chain reaction, so that intermediates in virion maturation are not observed. The Env precursor also must be processed for infectivity; this step is accomplished by action of a cellular protease (►furin) found in the Golgi.

Regulatory Mechanisms

Simple Retroviruses and Passive Regulation

Regulation of the replication process for many retroviruses is accomplished in a passive manner determined by the specificity of the virus-host interaction. For example, the distribution of receptors for a given virus determines its target cell specificity. Another important type of passive regulation is the cell-type and temporal specificity determined by the pattern of transcription factor binding signals in the U3 portion of the LTR. For example, mammary tumor virus (►MMTV) is transmitted naturally from mother to newborn mice in milk. Soon after transmission, it establishes an infection in mammary gland tissue, where the provirus remains quiescent until lactation, at which time both the loss of negative control and the appearance of positive control elements, including glucocorticoid hormones, ensure expression at the correct place and time for efficient transmission, with minimal risk of collateral damage due to induction of transformation of other infected cell types (B and T cells, for example) by integration of active LTRs near oncogenes.

Complex Viruses and Active Regulation

In addition to these mechanisms, complex retroviruses like HIV have developed a mechanism for regulating expression of the provirus involving the transcriptional activator (Tat) as well as the RNA transport protein (Rev). Since both these proteins are translated from fully-spliced RNA's, their expression does not depend on the presence of the transport protein and a small amount of constitutive transcription from the newly integrated provirus in the absence of Tat can lead to expression of both Tat and Rev. Tat, through its binding to a region (TAR) near the 5' end of the nascent RNA and activation of phosphorylation of the C-terminal domain of RNA pol II, causes a large increase in transcription of the provirus, allowing expression of itself and other products of fully spliced mRNAs to be

rapidly ramped up in the absence of virion proteins, all of which are translated from partially-spliced RNAs. When concentrations of Rev increase to adequate amounts, nuclear export of Gag-Pro-Pol and Env mRNAs can occur and the synthesis of these “late” proteins commences. This control scheme permits a phased replication cycle in which the “early” proteins Tat and Rev set the stage for high level expression of the “late” virion proteins. HTLV exhibits a very similar pattern of regulation involving the analogous Tax and Rex proteins.

The benefit of such regulation to the virus is at least two fold. First, it prevents exposure of most virus antigens to the immune system until expression is maximal, permitting a rapid burst of virions to be produced before the infected cell is detected and killed. Second, it allows a means of balancing expression of virion proteins with other proteins depending on their mode of expression. HIV, for example, encodes several other proteins that help to overcome roadblocks thrown in its way by the cell and the Tat-Rev system allows them to be expressed in proper proportion to virions.

Synonyms

Rett disorder

Definition

Rett syndrome (RTT) was first described by Andreas Rett in German in 1966 and in English in 1985. He described a distinctive nonprogressive, neurodevelopmental disorder in girls associated with a variable hyperammonaemia and characterised by deceleration of psychomotor development and the subsequent loss of acquired cognitive and motor skills. It is an X-linked dominant disorder, affecting 1 in 10,000 to 1 in 15,000 females and possibly 1 in 100,000 males, making it one of the most common causes of profound intellectual disability in girls. The clinical features and natural history of classical RTT have been well described. It is often associated with mutations in the *MECP2* gene located at Xq28. Variant or atypical RTT is a term used to describe cases with some, but not all of the features of classical RTT; this is much less commonly associated with *MECP2* mutations. RTT can occur without mutations in *MECP2* and not all those with mutations in *MECP2* have RTT.

Characteristics

Clinical Features

Rett syndrome is essentially a clinical diagnosis that is supported by mutational analysis of the *MECP2* gene in ~85% of patients with classic features of RTT. An international working group published modified guidelines in 2002 to aid the clinical diagnosis of RTT (Table 1). The phenotypes associated with mutations in the *MECP2* gene range from healthy, unaffected carrier females to severe neonatal ▶encephalopathy in males.

Classical RTT syndrome is described in those who have a normal prenatal and perinatal history and apparently normal development in the first 6 months of life. Subsequently there is a period of regression, with onset between the ages of 6 months and 3 years of age, with the loss of acquired motor skills and the development of hand stereotypies. There is postnatal deceleration of head growth. Profound cognitive impairment becomes apparent. In addition there are a number of supportive features including seizures, growth retardation, ventilatory irregularity and other features of autonomic dysregulation (Table 1). A variable hyperammonaemia and lactic acidosis have sometimes been reported.

Four stages in Classical RTT have been identified:

- stage 1 (first 6–18 months) hypotonia, disinterest in play.
- stage 2 (age 6 months up to 3 years) a period of agitation, withdrawal and rapid regression, often with some features resembling those found in autism.
- stage 3 (2–10 years) post-regression stabilisation with seizures, cognitive impairment, hand stereotypies, hyperventilation, air swallowing and teeth grinding

Rett Syndrome. Table 1 Revised diagnostic criteria for Rett Syndrome¹

Necessary criteria
1 Apparently normal prenatal and perinatal history
2 Psychomotor development largely normal for the first 6 months or may be delayed from birth
3 Normal head circumference at birth
4 Postnatal deceleration of head growth in the majority
5 Loss of achieved purposeful hand movements between ages 6 months-2 ½ years
6 Stereotypic hand movements such as hand wringing/squeezing, clapping/tapping, mouthing and washing/rubbing automatisms
7 Emerging social withdrawal, communication dysfunction, loss of learned words and cognitive impairment
8 Impaired (dyspraxic) or failing locomotion
Supportive criteria
1 Awake disturbances of breathing (hyperventilation, breath-holding, forced expulsion of air or saliva, air swallowing)
2 Bruxism (teeth grinding)
3 Impaired sleep pattern from early infancy
4 Abnormal muscle tone successively associated with muscle wasting and dystonia
5 Peripheral vasomotor disturbances
6 Scoliosis/kyphosis progressing through childhood
7 Growth retardation
8 Hypotrophic small and cold feet; small thin hands
Exclusion criteria
1 Organomegaly or other signs of storage disease
2 Retinopathy, optic atrophy or cataract
3 Evidence of perinatal or postnatal brain damage
4 Existence of identifiable metabolic or other progressive neurological disorder
5 Acquired neurological disorders resulting from severe infections or head trauma

- stage 4 (10 years+) scoliosis, rigidity, increased feeding difficulty, less mood disturbance, reduction in seizures and improved eye contact.

Variant RTT is used to describe those with some, but not all of the features of classical RTT. There are some more specific phenotypes within this category, congenital-onset RTT, the preserved speech variant and the delayed onset variant. The clinical diagnosis of variant RTT is based upon a person meeting 3 of 6 main criteria and 5 of 11 supportive criteria (Table 2). Congenital RTT is sometimes used to describe those whose development was never normal, but who have many features of the Rett disorder. However it is important to note that there are developmental problems in all RTT

girls, present from birth, but these are subtle and often missed. Delayed onset variant is used to describe those with regression occurring later than 3 years, and subsequently developing features consistent with variant Rett disorder. Preserved speech variant (PSV) describes those with Rett who are able to speak. They may only have a few words or even be able to converse. These patients are mildly affected and frequently have a previous diagnosis of atypical autism and speech delay. The Angelman syndrome-like RTT phenotype is seen in both males and females with RTT; the characteristic facial features include a long face, wide mouth and widely spaced teeth. Apart from this, and a few exceptional cases associated with various malformations,

Rett Syndrome. Table 2 Revised delineation of variant Rett phenotypes¹

Inclusion criteria	
1	Meet at least 3 of 6 main criteria
2	Meet at least 5 of 11 supportive criteria
Six main criteria	
1	Absence or reduction of hand skills
2	Reduction or loss of babble speech
3	Monotonous pattern to hand stereotypies
4	Reduction or loss of communication skills
5	Deceleration of head growth from first years of life
6	RS disease profile: a regression stage followed by a recovery of interaction contrasting with slow neuromotor regression
Eleven supportive criteria	
1	Breathing irregularities
2	Bloating/air swallowing
3	Bruxism (harsh sounding type)
4	Abnormal locomotion
5	Scoliosis/kyphosis
6	Lower limb amyotrophy
7	Cold, purplish feet, usually growth impaired
8	Sleep disturbances including night screaming outbursts
9	Laughing/screaming spells
10	Diminished response to pain
11	Intense eye contact/ eye pointing

the dysmorphology of RTT is subtle. Features described in females include a short, broad face, wide nasal bridge, hypotelorism, low hanging columella, short philtrum, everted upper lip and full lower lip. Most affected cases do not have a dysmorphic appearance.

The problems of RTT change with time. In teenage years and adult life, progressive scoliosis, feeding difficulties and hypertonia become increasingly prominent. Early features such as hyperventilation, seizures, poor eye contact and mood fluctuations improve. Most girls with RTT survive to adult life. However, the death rate is reported to be 1.2% per annum. Approximately 95% of affected women survive to 25 years. Early death occurs most commonly in those with severe RTT who are in a wasted state. Severe epilepsy or causes unrelated to RTT may also cause early demise. However, some deaths are

completely unexpected and may be related to the autonomic disturbance in RTT.

Males

The classical RTT phenotype arises in males most commonly in association with Klinefelter syndrome or with somatic mosaicism for a typical RTT-causing mutation in *MECP2*. When affected males arise in families with at least one affected female, the phenotype is often not typical – it is often more severe than in classical RTT and can range from classical RTT to neonatal encephalopathy. A small number of males have been reported with RTT-associated mutations in the *MECP2* gene. These often present with severe neonatal encephalopathy, hypotonia, seizures and apnoeic spells and usually die in early childhood. Dysmorphic features have been described in association with the encephalopathic presentation, as has bilateral perisylvian polymicrogyria.

Other mutations in the *MECP2* gene – apart from those associated with RTT in females – may be associated with X-linked recessive phenotypes in males, although it remains difficult to be certain whether some missense changes reported in association with non-syndromic mental retardation in males have any functional or pathogenetic significance. A phenotype of X-linked mental retardation with progressive spasticity is recognised. Developmental delay, hypotonia, sialorrhea, relatively large head circumference and complicated spastic paraparesis were apparent in affected males. Compared with cases of classical RTT, the features of growth retardation, the loss of hand skills and the acquired microcephaly are absent. Similarities with classical RTT include sialorrhea, spasticity, tooth grinding, ataxic gait and absence of speech. See below for discussion of A140V.

MECP2 Mutations

Mutations in *MECP2* are identified in more than 80% of classical RTT and up to 40% of less typical RTT. The low frequency of mutations in variant RTT suggests that this group may be heterogeneous. Given that at least 20% of classical cases do not have a mutation in the *MECP2* coding region and that there is a lower chance of identifying a *MECP2* mutation in families with affected sibs, it is likely that RTT is genetically heterogeneous. Some patients with features of Rett and onset of epilepsy or infantile spasms before 3 months of age have mutations in a second gene: *CDKL5* (cyclin dependent kinase like 5). In fact, a mutation in *MECP2* has not yet been reported in any patient with infantile spasms.

The *MECP2* gene has a very high mutation rate, perhaps 4×10^{-5} , as evidenced by the predominantly sporadic nature of RTT and its relatively high incidence

in the population. Sib recurrence risks are generally quoted as less than 1%. Mutations commonly arise at CpG hotspots and result from spontaneous deamination of methylated cytosine residues. There are eight recurrent mutations, which account for 70% of reported mutations and these arise at eight different CpG dinucleotide locations (Fig. 1).

The female preponderance of RTT was previously thought to be the result of *in utero* lethality for affected male foetuses, but an additional factor is now known to operate – the origin of most mutations in spermatogenesis. This has been demonstrated by haplotype analyses indicating that over 95% mutations are paternally derived. This is consistent with other diseases where mutations tend to arise at CpG hotspots. Male germ cells are highly methylated and this, in combination with the increased number of mitotic divisions, may explain the largely paternal origin of *de novo* mutations.

Genotype-Phenotype Correlation

Many studies have been carried out to look at genotype-phenotype correlation in Rett syndrome. Two studies have shown that those with early truncating mutations are associated with a more severe phenotype than those with missense mutations. A recent study has shown that females with the missense mutation R133C have a relatively mild phenotype, with

better-preserved hand use, better ambulation and an increased likelihood of being able to use speech. The preserved speech variant (PSV) is associated with milder *MECP2* mutations i.e. missense and late truncating mutations. More recently large deletions of *MECP2* have been described, and it may be that deletions extending beyond the gene are associated with additional features.

X chromosome inactivation has an important role in modulating the phenotype of Rett syndrome. This is most clearly demonstrated in monozygotic twins, discordant for the Rett phenotype. In addition, clinically normal mothers with the same pathogenic mutation as their affected daughters have been described, in whom there has been highly skewed X-inactivation. There are some genotype-phenotype studies that have included X-inactivation and suggest that severe skewing is usually associated with a milder phenotype. Conversely, skewed X-inactivation has been associated with either a milder or more severe phenotype. Most girls with Rett Syndrome have random skewing and it is possible that those with severe skewing arose by chance. Further understanding of the influence of X inactivation on disease phenotype will require a knowledge of the parent of origin of the mutation and the phase of X inactivation. Since X-inactivation has recently been shown to be a leaky process, the development of functional analyses of the

Rett Syndrome. Figure 1 Site and nature of mutations in the *MeCP2* gene in Rett Syndrome.

MECP2 gene or MeCP2 protein may prove to be more revealing than X-inactivation studies.

The *MECP2* mutation, A140V was previously thought to be a benign variant, as it had no clinical effect in females. A number of phenotypes have now been reported in males with this mutation, mental retardation, childhood onset schizophrenia, mental retardation with abnormal gait and speech delay and PPM-X (a syndrome characterised by manic depressive psychosis, pyramidal signs, macroorchidism and mental retardation). This suggests either that the A140V mutation has a less severe effect on MeCP2 function than other mutations, or perhaps that it is a marker for a nearby genetic disorder.

Cellular and Molecular Regulation *MECP2*

Mutations in the *MECP2* gene were identified as the major cause of RTT in 1999 by Amir et al. This gene spans 76 kb, lying between the IRAK and rhodopsin loci at Xq28 and is subject to X-inactivation. It has four exons that are transcribed from telomere to centromere. It contains a 1461 nucleotide coding sequence within exons 2–4, translating a 486 amino acid protein. The MeCP2 translational initiation site was originally identified in exon 2. A second site has recently been identified in exon 1 which yields a new and predominant MeCP2 isoform. The MeCP2 protein contains a methyl binding domain, a transcription repression domain, two nuclear localisation signals and a proline rich C-terminal. The nuclear localisation signals are important for transporting MeCP2 to the nucleus. The C-terminus has a binding domain specific to nucleosomal DNA and may suggest that this domain reduces binding to methylated DNA and enhances protein stability.

Expression

MeCP2 protein is widely expressed throughout embryonic and adult tissues. Expression is low during early embryonic development. Levels of mRNA do not correlate well with MeCP2 protein levels in cells, suggesting that there may be tissue specific factors regulating MeCP2 expression. Recent studies show that MeCP2 follows the path of neuronal maturation.

MeCP2 Function

MeCP2 was first described in 1992 and has a role in gene regulation through methylation-dependent transcriptional repression and histone deacetylation. It binds symmetrically methylated CpG dinucleotides with its corepressor mSin3A. Histone deacetylases are recruited to the transcription repression domain,

contributing to the corepressor complex and play an important role in chromatin remodelling. Deacetylation of histones allows DNA to wrap more tightly around these proteins, preventing access of the transcription machinery to the promoter sequences. MeCP2 can act as a transcription repressor independently of histone deacetylases, again acting through its transcription repression domain. For example, MeCP2 binds to TF11B, a component of the basal transcription machinery.

MeCP2 also associates with pericentromeric heterochromatin. Consequently the loss of MeCP2 function may destabilise the process of cell division and possibly contribute to the disease phenotype. MeCP2 has a putative role as a matrix attachment protein, retaining silenced heterochromatin areas within the matrix. The flanking regions loop away from the matrix where they are more accessible to regulators of gene expression and chromatin structure. It is uncertain whether MeCP2 plays this matrix attachment role within neurons.

In the somatomotor cortex of RTT patients many genes involved in neuronal signal transduction show reduced expression and there is an increase in transcription in glial cells. Surprisingly, there has been no evidence of a generalised dysregulation of gene expression in animal models. The hypothesis that loss of MeCP2 function results in a generalised derepression of transcription in neurons is not supported by the available evidence.

Relationships are now being explored between *MECP2* and other genes with a role in brain growth and function including *BDNF*, *UBE3A*, *GABRB3*, *MAP2*, *NING1* and *DLX5*. That Ube3a expression is disturbed in patients with Rett is particularly interesting, since, in the early stages, those with RTT and Angelman can be difficult to clinically distinguish from one another.

Neuropathology

Brain weight is reduced but stable in RTT and histological studies show a reduction in neuronal size and increased cell packing density. There is a generalised reduction in both grey and white matter, but with regional differences. While forebrain areas are often markedly affected, the cerebellum is relatively spared. The substantia nigra is hypopigmented with reduced dendritic branching of the pyramidal neurones. It was believed that RTT was a neurodegenerative disorder, but more recently it has come to be thought of as a disorder of neuronal maturation and synaptogenesis.

Clinical Relevance

Rett syndrome is a distinctive and relatively common cause of profound intellectual disability, usually in

girls. Following the identification of the *MECP2* gene, the broad range of phenotypes associated with mutation in this gene is being elucidated. Study of the *MECP2* gene and the pathogenesis of RTT is likely to yield important insights into gene regulation and transcription repression through chromatin remodelling and other mechanisms.

Rev, Rex

Definition

Rev and Rex designate proteins of HIV (human immunodeficiency virus) and HTLV (Human T-cell

leukemia virus (HTLV), respectively, which interact with specific regions of the viral RNA to promote the export of incompletely spliced RNAs from the nucleus.

► [Retroviruses](#)

Rev-Erb

Definition

The orphan nuclear receptor Rev-erb-alpha is a major component of the circadian clock. While Rev-erb-alpha influences the period length and affects the phase-shifting properties of the clock, it is not required for circadian rhythm generation.

Reverse Genetics

Definition

Reverse genetics is an approach to discover the function of a gene. It begins with a cloned segment of DNA, or a protein sequence, and uses this knowledge to introduce programmed mutations (through directed mutagenesis) back into the genome in order to investigate gene and protein function. This is opposed to forward genetics, which begins with a mutant followed by a chromosomal mapping, and molecular identification of the gene by positional cloning.

Definition

Reverse transcriptase (RT) is an ►enzyme that catalyzes the conversion of single-stranded RNA to double-stranded DNA. This process is known as reverse transcription or RNA-dependent DNA polymerization. RT is essential for the replication and evolution of all retroviruses that contain RNA genomes including the ►human immunodeficiency virus type-1 (HIV-1). In this essay, HIV-1 RT will be exemplified in order to discuss some important characteristics with regard to the structure and function of this enzyme and its role as a viral target for the development of antiretroviral drugs used for the treatment of patients with HIV infection.

RT is one of three enzymatic activities that is encoded by the HIV-1 ►polymerase (*pol*) gene open-reading frame. In mature viral particles, RT exists as a heterodimer that is made up of two protein subunits referred to as p51 and p66. The p51 subunit contains only the first 440 amino acid residues encoded by the RT gene. The larger p66 subunit includes the entire p51 amino acid sequence and, unlike the latter, contains all of the 560 amino acids normally found in the HIV-1 RT (1). The active site for the RNA- and DNA-dependent DNA ►polymerase catalytic activities of RT is partly contained within a tyrosine-methionine-aspartate-aspartate amino acid sequence between positions 183 and 186 in both the p51 and p66 subunits. This region of the RT enzyme is known as the YMDD motif and has been found to be highly conserved among most polymerases. However, in the p51 subunit, the active site is present in a catalytically incompetent conformation, and consequently only the p66 subunit is able to participate in the reverse transcription reaction. The carboxyl-terminal end of this subunit also contains the ribonuclease H (RNase H) domain, which is essential for retroviral DNA synthesis (1). Furthermore, phylogenetic studies have shown that the RT catalytic site is relatively well conserved among the different HIV-1 subtypes.

The three-dimensional structure of HIV-1 RT has been elucidated from X-ray crystallographic studies performed with a complex consisting of RT bound to

nevirapine, a non-competitive inhibitor of this enzyme. Interestingly, the molecular topography of RT has been described as resembling the structure of a right hand, and accordingly the major functional regions of RT are known as the fingers, palm, thumb and connection sub-domains. These sub-domains are present within the p51 and p66 subunits of RT (1).

Characteristics

The Reverse Transcription Process

Reverse transcription is a complex and highly regulated process that requires coordinated interaction between the enzyme's polymerase and RNase H activities with both RNA and DNA substrates in order to replicate the single-stranded RNA viral genome into double-stranded proviral DNA which is then integrated into host cell chromosomes. Briefly, reverse transcription is initiated with a cell-derived tRNA^{Lys3} primer, which provides a free hydroxyl group (-OH) that is required to covalently bind the incoming nucleoside triphosphate (dNTP). The primer-dNTP complex then binds to a primer-binding site (PBS) located in the genomic viral RNA strand and synthesis of the first product of the reverse transcription reaction, i.e. minus strand strong-stop DNA, then proceeds along the 5' direction. Contemporaneously, the RT-associated RNase H degrades the genomic RNA and, as a result, generates purine-rich RNA fragments that serve as primers for plus strand strong-stop DNA elongation using the minus DNA strand as a template for this second round of DNA synthesis. Both polymerization steps are also associated with strand transfer reactions that are needed in order to complete the production of a proviral pre-integrative complex which is later integrated into the host cell genome by integrase, another retroviral enzyme, which like RT, is also encoded by the HIV-1 *pol* gene (1).

Reverse Transcriptase and HIV-1 Genetic Variability

It is interesting to question whether the gains associated with the multifunctional nature of HIV-1 RT might come at the expense of some other important property such as the fidelity or error rate of this enzyme during DNA synthesis, although from an evolutionary perspective this may also be advantageous for HIV-1. A wide array of studies has confirmed the low fidelity of ►wild-type (WT) RT, which among other factors, is thought to be an important determinant for the high rate of spontaneous mutagenesis in HIV-1. Genotypic analyses of HIV-1 DNA have detected several types of mutations including base substitutions, additions and deletions. The frequency of spontaneous mutation for HIV-1 can vary considerably as a result of differences among viral strains studied *in vitro* and the specific methodology employed. In several studies, the forward

mutation rate for WT HIV-1 has been frequently estimated to be approximately 10^{-4} per nucleotide. The high level of genetic variation in HIV-1 has been largely attributed to the absence of 3'→5' exonuclease proof-reading activity in RT and the short viral generation time, although several other interdependent factors that include enzyme processivity, fitness, viral pool size and availability of target cells for new rounds of infection have also been shown to be important in this regard (2). Furthermore, as a result of the error-prone replication of HIV-1, resistance-conferring mutations to all known classes of **antiretroviral agents** (ARVs) arise spontaneously, and, in addition, are selected both *in vitro* and *in vivo* by pharmacological pressure. Therefore, it follows that the development of HIV-1 drug resistance can be considered to be both a consequence and limitation of antiretroviral therapy.

Clinical Relevance

Competitive and Non-Competitive Inhibitors of HIV-1 Reverse Transcriptase

In view of the central role that RT plays in the retroviral life cycle, this enzyme was the first major target for inhibition of HIV-1 replication to be identified and has been extensively exploited for the development of potent antiretroviral drugs for the treatment of HIV/AIDS. Two categories of antiretroviral agents (ARVs) have been developed to block RT; these are the nucleoside analog RT inhibitors (NRTIs) and the nonnucleoside RT inhibitors (NNRTIs) (3). These compounds are important components of highly active antiretroviral therapy (HAART) where their use in combination with other classes of ARVs such as the protease inhibitors (PI) has been associated with significant reductions in HIV/AIDS morbidity and mortality. Important aspects of the pharmacology and mechanism of action of both types of RT inhibitors will be discussed below.

NRTIs are pharmacologically inactive in their administered form and are phosphorylated to their active triphosphate form by host cellular kinases. These compounds are analogs of naturally occurring dNTPs and can effectively compete with these substrates for binding to RT and incorporation into proviral DNA (4). However, unlike dNTPs, NRTIs lack a 3'-hydroxyl group in their sugar moiety that is required for DNA polymerization and hence the mechanism of action underlying the antiviral activity of these compounds is based on premature termination of viral DNA strand synthesis (4). Zidovudine (ZDV, AZT), an NRTI, was the first antiretroviral drug to be licensed for the treatment of patients with HIV-1 infection and presently, including ZDV, there are seven NRTIs i.e., didanosine (ddI), dideoxycytidine (ddC), stavudine

(d4T), lamivudine (3TC), abacavir (ABC) and emtricitabine (FTC) that are commercially available for use in antiretroviral combination therapy regimens (3). Recently, tenofovir (TDF, PMPA), a novel antiviral drug from a related class of compounds known as nucleotide analog reverse transcriptase inhibitors (NtRTIs), has also become available for the treatment of HIV/AIDS. As is the case with NRTIs, TDF also functions as a chain terminator of DNA strand elongation. However, this new drug has a reduced requirement for metabolic activation because of the presence of a phosphonate group. This in turn is believed to impart certain advantages to TDF such as heightened antiviral potency and longer intracellular half-life compared to most existing NRTIs (4).

NNRTIs are non-competitive inhibitors of HIV-1 RT. The basis for their antiviral activity is not completely understood but is known to involve the binding of these compounds to a hydrophobic pocket (i.e. NNRTI binding pocket) that is located adjacent to the active site of RT in the p66 subunit. The NNRTI binding pocket also contains a few amino acid residues from the RT p51 subunit. It is thought that the inhibition of HIV-1 replication by NNRTIs may be mediated through allosteric effects that cause the RT active site to assume a configuration that is incompatible with DNA polymerization. NNRTIs are particularly active at template positions at which the RT enzyme naturally pauses. There are presently three NNRTIs, i.e. nevirapine (NVP), delavirdine (DLV) and efavirenz (EFV) that have been approved for use in antiretroviral combination therapy regimens (3).

Resistance-conferring **mutations** in RT can precede the initiation of antiretroviral therapy because of spontaneous mutagenesis and/or sexual and other forms of transmission. In addition, resistance-conferring **mutations** in RT are selected in patients following treatment with NRTI- or NNRTI-containing regimens. These mutations encode amino acid substitutions in RT at codons that are responsible for reduced antiviral susceptibility to these inhibitors and, in general, are also predictive of worse virological responses to antiretroviral therapy (5, 6). Drug resistance to NRTI and NNRTIs has been shown to be mediated by different mechanisms. For example, some resistance mutations in RT are associated with increased drug discrimination, a situation where the binding and/or incorporation of antiviral drugs by the mutated RT is significantly attenuated (5, 6). Other RT mutations known as **thymidine analog mutations** (TAMs) mediate resistance to ZDV and d4T as a result of increased levels of nucleotide primer uncoupling. With this mechanism, ZDV- or d4T-monophosphate is excised from the terminus of blocked primer templates by RT harboring TAMs, thus permitting DNA polymerization and HIV-1 replication to continue in the

presence of these antiviral drugs (1, 5, 6). Tables 1 and 2 illustrate important mutations in RT that are known to confer resistance to NRTIs/NtRTIs and NNRTIs, respectively.

Resistance Mutations in Reverse Transcriptase and HIV-1 Fitness

It has been demonstrated that HIV-1 variants that harbor drug resistance mutations in RT display diminished fitness or replication competence compared to drug-sensitive viruses (7). Without antiretroviral pressure, WT virus is the fittest and most prevalent HIV-1 [▶quasispecies](#) in the replicating viral pool. The eventual outgrowth of drug-resistant variants arises due to their fitness advantage under conditions of selective drug pressure. Therefore, both the mutation rate and selection forces (i.e. drug pressure and/or immunological selection) are important factors for the evolution of HIV-1 quasispecies (2, 7). It has been shown that HIV-1 variants containing the M184V mutation in RT, which confers high-level phenotypic resistance to 3TC (i.e. 500–1000 fold increase in IC_{50}), demonstrate marked impairment of replication capacity relative to

WT viruses (8). In addition, M184V-mutated viruses also appear to have a lower propensity for further mutational accumulation and in addition exhibit several other alterations in RT function that may be associated with improved therapeutic outcomes (8). Interestingly, this situation with M184V may represent a unique case in which it may be advantageous to preserve a drug resistance mutation in therapeutic regimens; further research on this topic is required.

Reverse Transcription

Definition

Reverse transcription refers to the synthesis of a strand of DNA from RNA, which is used to make a complementary DNA copy of sample RNA. In retroviruses, reverse transcription refers to the process of copying the RNA genome into double-stranded DNA by the retrovirus enzyme transcriptase (a product of the ►[pol](#) gene).

Reward System

Definition

One of the major targets of all drugs of abuse is a brain circuit called the reward system. The activation of this neuronal assembly reinforces behaviours. Responses of midbrain dopaminergic neurons represent learning signals. Rather than signaling pleasure, dopamine highlights significant stimuli and their motivational significance, suggesting that drug addiction might be a dopamine-dependent associative learning disorder.

Definition

Rheumatoid arthritis (RA) is a chronic autoimmune inflammatory disease of unknown aetiology. However, current thinking favours the hypothesis that an interplay between genetic factors, sex hormones and possibly an infectious agent or another immune activating agent initiates an autoimmune pathogenic mechanism that culminates in a disease with inflammatory and destructive features.

To date there is no diagnostic test specific for rheumatoid arthritis. Revised classification criteria for the diagnosis of RA were formulated by the American College of Rheumatology (1) based on a hospital population of patients with established, active disease.

These criteria combine a constellation of clinical, serological and radiological features and have become widely accepted for epidemiological and clinical studies. By emphasising key features of the disease, the criteria help to differentiate RA from other forms of inflammatory arthritis with a diagnostic sensitivity and specificity of about 90% for active disease. However, these requirements have a much poorer sensitivity for a diagnosis of RA in the early stages of presentation at which time there may be an insufficient number of the features required to satisfy the classification criteria.

Characteristics

Once established, RA is characterised by deforming symmetrical polyarthritis of varying extent and severity, associated with synovitis of joint and tendon sheaths, articular cartilage loss, erosion of juxta-articular bone and, in a majority of patients, the presence of IgM ►**rheumatoid factor** in blood. In a proportion of patients systemic and extra-articular features may be observed during the course of the disease (and rarely prior to joint disease). These include anaemia, weight loss, vasculitis, serositis, nodules in subcutaneous, pulmonary and sclera tissues, mono-neuritis multiplex and interstitial inflammation in lungs as well as in exocrine salivary and lacrimal tissue. However, these systemic manifestations occur relatively late in the disease progression.

The clinical presentation of RA is heterogeneous with a wide spectrum of age of onset, degree of joint involvement and severity. Similarly, the disease course of RA is variable. This ranges from a brief, mild, self-limiting ►**oligoarticular** illness with minimal joint damage to a sustained ►**polyarticular**, synovial inflammation resulting in relentlessly progressive cartilage destruction, erosion of bone and ultimately changes in joint integrity with corresponding functional impairment. Up to 90% of patients with aggressive synovitis have radiological evidence of bone erosion within 2 years of diagnosis, despite treatment with traditional, so-called disease modifying agents (such as methotrexate, sulphasalazine and gold). The majority of patients with a more aggressive disease evolution become clinically disabled within 20 years. For those with severe disease or extra-articular features the mortality is equivalent to that of patients with three vessel coronary artery disease or stage IV Hodgkin's lymphoma.

Cellular and Molecular Regulation

Cellular Pathology

RA is characterised by chronic inflammation of synovial joints with synovial proliferation and infiltration by blood derived cells, in particular, memory T cells, macrophages and plasma cells, all of which show

signs of activation. Luxuriant vasculature is a prominent feature of RA synovitis, observed as a fine network of vessels over the rheumatoid synovium at arthroscopic inspection of RA joints. ►**Angiogenesis** is evident on microscopic examination of synovial biopsies from the earliest stages of disease development. Formation of new blood vessels permits a supply of nutrients and oxygen to the augmented inflammatory cell mass and so contributes to the perpetuation of synovitis. In the chronic phase of disease, capillaries and post capillary venules are particularly evident in the synovial sublining region. In histological sections mononuclear and polymorphonuclear leukocytes can sometimes be found in close apposition to vascular endothelium, probably in the process of margination and adhesion prior to migration into the inflamed tissue. The synovial tissue becomes markedly hyperplastic and locally invasive at the interface of cartilage and bone with progressive destruction of these tissues in the majority of cases. This invasive tissue is referred to as '►**pannus**', comprising mainly lining cells with the appearance of proliferating mesenchymal cells with very little sublining lymphocytic infiltration. The accompanying destruction of bone and cartilage is thought to be mediated principally by ►**cytokine**-induced degradative enzymes, notably the matrix metalloproteinases. In most cases the major manifestation of rheumatoid disease is in the synovial joint, but there is also evidence of systemic involvement, for example the up-regulation of acute phase proteins and, in severe cases, involvement of other organs.

Human Leucocyte Antigens

Genetic factors were originally implicated in the aetiopathogenesis of RA following the discovery that in population studies there is a slight increase in the frequency of RA in first-degree relatives of patients with this disease, especially if they are ►**seropositive** for rheumatoid factor. In hospital-based population studies of identical twins concordance rates of disease are around 30%, compared with 5% in non-identical twins. The figures are lower in community-based studies and although still supportive of the concept of a genetic contribution, argue against the proposition that RA is the result of a dominant single-gene disorder. These and other epidemiological studies have led to the conclusion that RA is a polygenic disease and that non-inherited factors are also of great importance (2).

Genes encoding particular class II human leucocyte antigens (►**HLA**) are among candidates for involvement in predisposition to RA. This discovery came about with the observation that 60–70% of Caucasian patients with RA are HLA DR4 positive by cellular or serological techniques compared with 20–25% of control populations. Furthermore, patients with more severe RA, especially those with extra-articular

complications such as vasculitis and Felty's syndrome, are even more likely to be HLA DR4 positive than patients with less aggressive disease confined to joints. The immunological significance of HLA class II molecules, expressed on the surface of antigen presenting cells, lies in their key role in presentation of processed linear peptide antigens of at least nine amino acids to T cells. Antigen is bound to the HLA antigen-binding cleft formed by the α and β chains of the HLA class II molecule. This trimolecular HLA-antigen complex binds in turn to the variable portion of the T-cell receptor.

Several laboratory techniques have been used in an attempt to define the amino acid sequences of HLA class II molecules common to all RA patients, including those expressing class II molecules other than HLA DR4. These include at the genetic level, for example, genotyping of DNA and nucleotide sequencing, use of the polymerase chain reaction and enzymatic digestion for restriction fragment length polymorphisms. At the level of expressed cell surface proteins, HLA epitopes have been sought by using monoclonal antibodies and alloreactive T-cell clones. Overall, these studies support the concept that susceptibility to RA is related to expression of a 'shared epitope' on the HLA molecules.

Nucleotide sequencing of HLA DR β , exons coding amino acid residues 70 to 74 has revealed that HLA DR4 subtypes Dw4, Dw14, and Dw15 share similarities with each other (with a conservative substitution of glutamine for lysine at position 71 in Dw4) and with HLA DR1. The sequence predicts susceptibility to RA and is associated with RA in 83% of Caucasian patients in the United Kingdom. In contrast, negative associations are observed in individuals who are DR4w10, in whom the charged basic amino acids glutamine and arginine in positions 70 and 71 are replaced by the acidic amino acids aspartic and glutamic acid. In Dw13 individuals, in whom a negative association is also observed, arginine is substituted for glutamic acid in position 74. Molecular modelling studies suggest that amino acid residues 70–74 are located in the α -helix forming the wall of the peptide-binding groove and thus likely to be involved in antigen binding and subsequent interaction with T-cell receptors. Acidic substitutions could profoundly alter protein structures and thereby alter affinity for peptide antigens. Serotyping with alloantisera and monoclonal antibodies as well as reactivity with homozygous T cells and T-cell clones support the prediction that protein structures on the HLA molecule are important in susceptibility to RA. However, molecular mechanisms accounting for susceptibility to RA remain to be elucidated. Possibilities include permissive binding of specific peptides such as those on autoantigens or on environmental antigens, initiation of disease by specific binding of

superantigens to HLA molecules or modulation of the T-cell repertoire by selection or tolerance.

However, the evidence that Dw4/Dw14 heterozygotes are more likely to develop RA than are Dw4 homozygotes and the evidence that individuals expressing DR4 (and not DR1) are more likely to have severe disease, challenges the concept that sequences 70–74 are the only HLA-D regions that influence disease expression. This is despite the sequence identity of DR1 and DR4w4 in these positions, and a conservative substitution in Dw14. It has been hypothesized that the severity of disease and extra-articular complications are related to homozygosity and the density of disease-associated MHC molecules that critically influence the selection of the T-cell repertoire and tolerance to antigens.

Other Candidate Genes

HLA genes are estimated to account for one-third of the genetic component of RA. To identify susceptibility genes outside the HLA region, studies have been undertaken using genome-wide microsatellite analyses in affected sibling pair families (3). Significant levels of linkage are reported at chromosomes 1, 4, 12, 16 and 17. In seropositive patients there is evidence of linkage with a locus on chromosome 12 at a level of significance comparable to the HLA locus. This marker lies within 10 cM of the tumour necrosis factor receptor 1 (*tnfrsf1*) locus. Differences in the findings of linkage analyses between study cohorts may reflect ethnic bias and genetic heterogeneity. However, common linkages at 16q24.1 are reported in American and European populations and at 17q22 in American and UK populations. Candidate genes mapping to the 17q22 locus include intracellular adhesion molecule-2 (ICAM-2) and platelet endothelial cell adhesion molecule-1 (PECAM-1).

Cytokines

Cytokines are small, short-lived proteins and important mediators of local intercellular communication. They play a key role in integrating responses to a variety of stimuli in immune and inflammatory processes. By binding their cognate receptors on target cells in their immediate vicinity, these molecules participate in many important biological activities including cell proliferation, activation, death and differentiation. In experimental systems, some cytokines are proinflammatory, such as ▶interleukin-1 (IL-1) and TNF α ; others, such as interleukin-10 (IL-10) and transforming growth factor β (TGF β) exert predominantly anti-inflammatory effects. However, it is now known that many cytokines, for example, interferon γ (IFN- γ), with chiefly proinflammatory activity can also in some instances have anti-inflammatory properties. Similarly, IL-10 and TGF β may also exhibit proinflammatory

properties under certain experimental conditions. Interleukin-6 (IL-6) does not have a classical pro-inflammatory action but has been implicated in the process of erosion of bone in inflammatory arthritis. ►Paracrine or ►autocrine pathways involving cytokines with either pro- or anti-inflammatory activity form complex networks determining whether chronic inflammation results.

Role of Cytokines in the Pathogenesis of RA

Cytokines derived from macrophages and fibroblasts are abundant in the rheumatoid synovium. These include IL-1, TNF α , granulocyte-macrophage colony stimulating factor (GM-CSF), IL-6 and numerous chemo-attractant cytokines known as chemokines (4). Many of these factors are of importance in regulating inflammatory cell migration and activation. By contrast, given the extent of synovial inflammation and lymphocytic infiltration, factors produced by T cells, for example, IFN γ , interleukin-2 (IL-2) and interleukin-4 (IL-4) are surprisingly sparsely expressed. However, there are a number of cytokines that cause costimulation of T helper cells including interleukin (IL)-7, IL-12, IL-15 and IL-18. There is a predominance of ►Th1 cell activity, as defined by IFN γ production and low ►Th2 cell activity as defined by IL-4 production.

Tissue expression of an extensive range of pro-inflammatory cytokines in human synovial samples, regardless of differences in donor disease duration, severity or even drug therapy, has been confirmed in studies from a number of laboratories. These observations imply that there is prolonged expression of cytokines in the rheumatoid joint, contrasting with the transient production induced by mitogenic stimulation. This hypothesis was confirmed when it was observed that proinflammatory cytokines are produced over several days in dissociated RA synovial membrane cell cultures in the absence of extrinsic stimulation, a finding suggesting that one or more soluble factors regulating prolonged cytokine synthesis were present within the RA synovial membrane cell cultures. These cultures comprise a heterogeneous population of cells producing numerous cytokine and other non-cytokine molecular messengers. A key observation to emerge employing these RA dissociated synovial cell culture systems was that addition of anti-TNF antibodies strikingly reduced the production of other pro-inflammatory cytokines, including IL-1, GM-CSF, IL-6 and IL-8. Furthermore, using the same RA synovial cell culture system, blockade of IL-1 by means of the IL-1 receptor antagonist results in reduced IL-6 and IL-8 production but not that of TNF α . These observations led to the concept that TNF α occupies a dominant position at the apex of a pro-inflammatory cytokine network. At the same time, in the early 1990's TNF α was known to be a pleiotropic cytokine with biological

properties including enhanced synovial proliferation and production of prostaglandins and metalloproteinases as well as regulation of other proinflammatory cytokines.

In support of the concept of a cytokine disequilibrium within the chronic inflammatory situation in rheumatoid synovium is the observation that multiple anti-inflammatory mediators are also upregulated, but at a level insufficient to suppress synovitis. Examples include the abundant expression of IL-10, IL-13 and TGF β both in latent and active form. Naturally occurring cytokine inhibitors, such as interleukin-1 receptor antagonists (IL-1ra) and soluble TNF receptors, the specific inhibitors of IL-1 and TNF α respectively, are also upregulated in the rheumatoid joint.

The predicted clinical success of anti-TNF therapy in RA was based on the demonstration of RA synovial tissue expression of TNF α and its receptors, in *in vitro* experiments employing dissociated synovial cell cultures and pre-clinical *in vivo* studies (5). A number of independent *in vivo* studies demonstrated that antibody therapies blocking bioactivity of TNF α , administered either during the induction phase of murine collagen-induced arthritis or, more importantly, after the onset of disease, were able to ameliorate clinical symptoms and prevent joint destruction. Furthermore, in a murine model, the over-expression of a human TNF α transgene modified at its 3' end to prevent degradation of its mRNA, was associated with the development of a destructive form of polyarthritis four to six weeks after birth. This could be prevented by administration of a human TNF-specific mAb.

Clinical Relevance

The treatment approach to rheumatoid arthritis has undergone a major evolutionary change in recent years. In part this is a consequence of a growing appreciation of the severity of this condition. For example, there is now evidence that treatment intervention with disease-modifying combination therapy early in the course of RA results in improved remission rates and sustained attenuation of the rate of radiographic progression and that this benefit is independent of subsequent anti-rheumatic therapy. However, the major impetus for development of new treatment paradigms has come from advances in molecular technology that have facilitated identification of cell subsets and cytokines contributing to the inflammatory and destructive components of the disease. These new insights have prompted development of specific targeted therapies directed at relevant disease molecules (6).

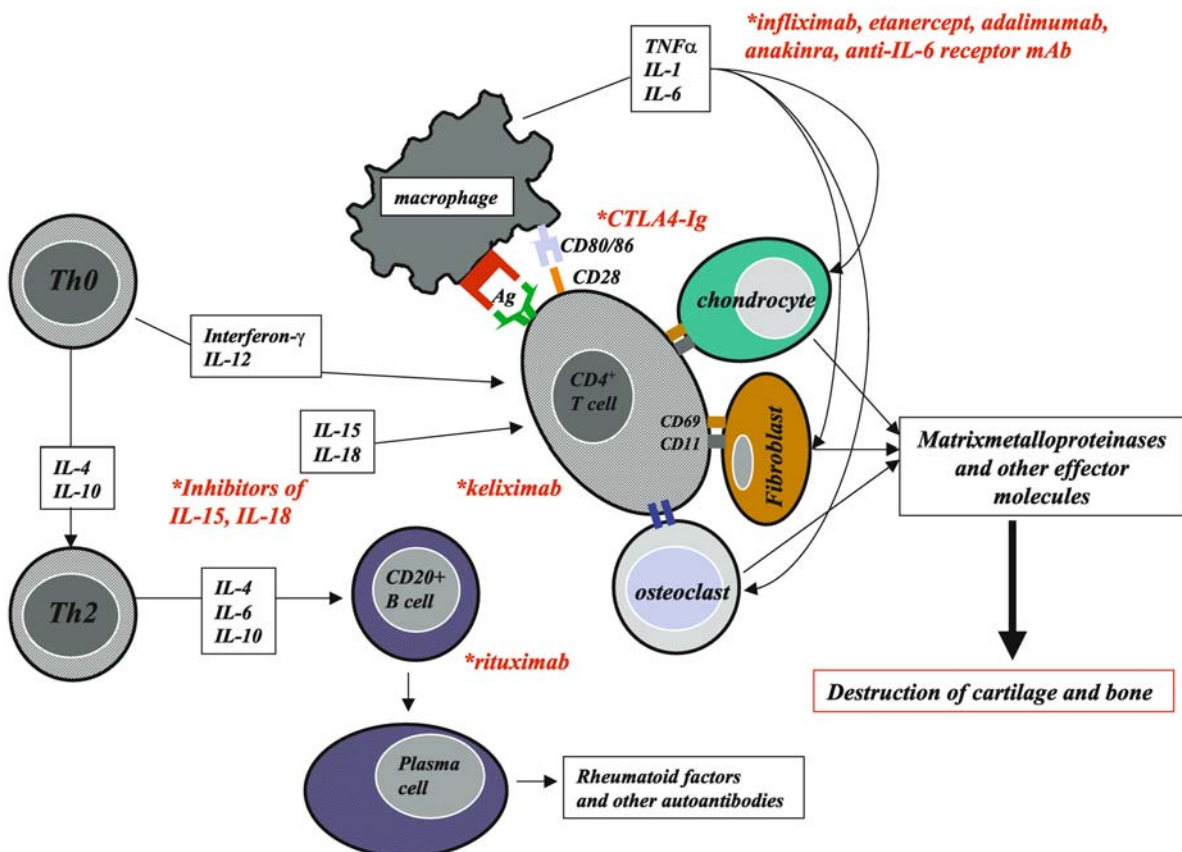

Very considerable progress in understanding the important role of cytokines in the immunopathogenesis of RA has led to two potential approaches to cytokine

modulation of rheumatoid synovitis; inhibition of dominant proinflammatory cytokines such as TNF α or IL-1 or augmenting the inadequate anti-inflammatory activity of certain cytokines or naturally occurring cytokine inhibitors as, for example, by administration of soluble TNF receptors or IL-1ra. It is now established that the long-term use of several biological agents targeting TNF α gives rise to sustained improvements in symptoms and signs of rheumatoid disease. It has recently been confirmed that anti-TNF therapy protects joints from structural damage as judged by a change in the rate of deterioration in radiographs of the hands and feet, assessed by a scoring system that assesses cartilage and bone loss separately; these two components are summed to give a total damage score. One year of combined therapy with methotrexate and the anti-TNF α antibody infliximab prevented the progressive joint damage characteristic of rheumatoid inflammation with zero median progression in joint damage over this time period. Furthermore, there was actually a reduction in the joint damage score in

40–55% of patients irrespective of whether a clinical response was achieved or not. In contrast, joint space narrowing and erosions progressed as anticipated in recipients of methotrexate alone.

Although anti-TNF α agents are well tolerated and have a good overall safety profile, pitfalls in the use of these drugs apparent with increasing clinical experience include infective complications and in particular, reactivation of tuberculosis. To date, no statistically significant increased rate of tumour occurrence over that expected has been noted although cases of lymphoma have been rarely reported in patients treated with TNF α blockade.

Clinical trials of interleukin-1 receptor antagonist show relatively modest anti-inflammatory efficacy but radiographic evidence indicative of retardation of joint damage. Several other pro-inflammatory cytokines represent potential therapeutic targets including interferon- β , interferon- γ , IL-6, IL-15, IL-17 and IL-18 and many biological interventions targeting these molecules are in clinical trials. For example, preliminary

Rheumatoid Arthritis. Figure 1 Cartoon illustrating the major cell types and cytokine pathways thought to be involved in the destruction of bone and cartilage, mediated by IL-1 and TNF α , within the rheumatoid joint. The various therapies discussed in the text target molecules marked by *.

data for blockade of the biological effect of IL-6 by means of intravenously administered antibodies to the IL-6 receptor demonstrate efficacy for reduction in symptoms and signs with acceptable safety.

In contrast to the dramatic success of TNF blockade as a new approach to RA therapy, early randomised, placebo-controlled clinical studies exploring the potential of biological therapies targeting T cells in the treatment of RA have had generally disappointing results. Some anti-T cell agents were non-efficacious whereas other preliminary trials demonstrating some clinical efficacy were terminated due to adverse events, particularly prolonged and profound T cell depletion. However, the primatized monoclonal anti-CD4 antibody keliximab results in dose-dependent clinical responses when administered once weekly over 4 consecutive weeks and the clinical response correlates with CD4⁺ T cell coating with keliximab rather than T cell depletion.

An alternative approach seeks not to deplete or inactivate T cells, but to modulate their function in such a way as to reduce their pathogenicity. For example, CTLA4-Ig, which blocks the interaction between the B7 receptor on antigen presenting cells and CD28 on T cells, has shown efficacy in the established phase of murine collagen-induced arthritis and clinical trials are underway in patients with rheumatoid arthritis. Preliminary reports indicate that in RA patients with an inadequate response to methotrexate, addition of CTLA4-Ig results in significant dose dependent clinical responses. Similarly, in patients with an inadequate response to the anti-TNF agent etanercept, addition of CTLA4-Ig therapy resulted in significant improvements in clinical and health related quality of life measures. It remains to be seen whether any of these biological agents targeting T cells have disease-modifying capability.

The potential of B lymphocyte depletion as an approach to therapy is under investigation using an anti-CD20 mAb, rituximab with encouraging preliminary data. The clinical benefit following antibody administration and time to disease relapse may be related to circulating antibodies, an interesting observation as immune complexes may be a regulatory factor in the production of TNF α .

In summary, recent years have seen the emergence of encouraging data for antibodies in clinical development that are directed against pro-inflammatory cytokines, inflammatory cells or accessory molecules. In particular, anti-TNF α therapies have set a new standard for symptom control in RA. Furthermore, by significantly retarding the rate of structural damage to joints, it is envisaged that long-term administration of biologics targeting TNF α in RA patients will preserve physical function.

Rheumatoid Factors

Definition

Rheumatoid factors (RF) are autoantibodies that recognize the Fc portion of an IgG molecule as their antigens. Many conditions associated with chronic inflammation are associated with positive RF. In patients with rheumatoid arthritis, RF is an important predictor of a poor prognosis.

Definition

► [Rheumatoid arthritis](#) (RA) is a chronic inflammatory disorder of mainly unknown etiology. It predominantly affects the joints and leads to their progressive destruction. Considering that the prevalence of RA in adults is estimated to be as high as 0.5–1% and that

work disability affects as much as half of the patients 10 years after onset of the disease, both the costs for public health systems and the social consequences for the individual patient are enormous.

The current model for RA pathogenesis proposes interaction between chronic inflammation, altered immune responses and synovial hyperplasia (previously called pannus). Synovial fibroblasts release large amounts of matrix-degrading enzymes and are thereby cellular key players in cartilage and bone destruction. The complex pathophysiology of joint destruction is still only partially understood, which limits the generation of specific therapies. Thus, the exponential development of new techniques in the field of molecular biology during the past decade has been a further milestone in our approach to understanding and treating RA. In particular, screening approaches such as gene arrays enable the fast and precise identification of genes that are differentially expressed in rheumatoid arthritis compared to the normal synovium and that might be of functional importance for the progression and perpetuation of the disease.

Characteristics

► Functional Genomics

With the accomplishment of the ►human genome project, researchers are challenged by identified sequences of approximately 30000 human genes, most of them coding for biological functions that remain so far undiscovered. The functional characterization of these genes in normal physiology as well as in the pathogenesis of diseases remains the main issue for biomedical research in the next few years.

The term “functional genomics” is defined as the use of molecular screening methods for the systematic analysis of the expression of a large number of genes. Since screening methods in general tend to generate a high number of false-positives, their results need to be confirmed by independent methods such as ►real-time polymerase chain reaction (real-time PCR) or Northern blot. The detection and quantification of differentially expressed genes in certain experimental conditions leads to the generation of a hypothesis as to their possible role in the pathogenesis of diseases. The postulated functions then have to be verified independently *in vitro* as well as *in vivo* on a functional level by using appropriate disease models. The typical procedure from the initial screening steps through the verification to the functional characterization is outlined in Fig. 1.

It is unquestionable that molecular screening procedures have the potential to identify key pathogenic pathways and, more generally, to lead to an exponential acceleration of biomedical research. Conversely, the highly sophisticated techniques and the specific

knowledge required from various scientific fields such as molecular biology, biophysics, medicine and bioinformatics carry the danger of exploitation and misinterpretation of data.

Screening Methods

Generally, a large number of molecular-biology-based screening methods have been developed including ►microarrays, subtractive ►hybridization, serial analysis of gene expression (SAGE) and RNA arbitrarily primed polymerase chain reaction (RAP-PCR). Among them, ►suppressive subtractive hybridization (SSH) and, in particular, microarrays are most often used to identify genes related to the pathogenesis of rheumatoid arthritis. Both methods are screening tools that are very useful for defining the differences in gene expression between any two related types of cells, or, more specifically, to distinguish between the expression profiles of cells derived from the rheumatoid synovium and the pattern of their healthy counterparts.

From mRNA to cDNA

The preparation steps are similarly performed in both screening methods. They consist of the extraction of messenger RNA (mRNA) from the cells or tissue of interest and the subsequent production of ►complementary DNA (cDNA).

In cell physiology, mRNA is transcribed by distinct enzymes from DNA and gets translated into functional proteins. The cytoplasmic levels of mRNA reflect the genes that are currently expressed. Normally, the proportion of expressed genes in a particular cell does not exceed 10–15%. After being transcribed, the pre-mRNA gets its final structure by the addition of a polyadenylate tail. This post-transcriptional modification converts the mRNA into its mature form, which is also referred to as Poly(A)⁺-RNA.

In a first step of the screening, total mRNA or Poly(A)⁺-RNA is extracted from the cells. The quality of the isolated RNA is critical for a successful experiment. The isolation of undamaged RNA from tissues may be especially challenging. The extracted RNA should be tested for integrity, e.g. by gel-electrophoresis, before continuing with the experiments. After isolation of mRNA molecules, cDNA copies are produced by the enzyme reverse transcriptase.

Human genes usually consist of short coding sequences (exons) and longer noncoding sequences (introns). The production of mRNA entails the removal of all introns in a process called splicing. Thus, cDNA generated from mRNA by reverse transcription contains only those regions of the genome that have been transcribed into mRNA. This is a major difference from genomic DNA, which mirrors a random sample of all DNA sequences in an organism and is indistinguishable

Rheumatism Related Genes, Identification. Figure 1 Classical procedure in molecular screening. Identification of differentially expressed genes (screening), followed by verification with independent methods and characterization of identified key molecules on a functional level (adapted and modified from Distler, *Molekularmedizinische Grundlagen von rheumatischen Erkrankungen* 2003).

between different cells. As the cells of different types of tissues produce distinct sets of mRNA, different cDNAs are obtained and can be used in further steps of the screening.

Suppressive Subtractive Hybridization (SSH)

This method is technically based on the polymerase chain reaction (PCR). Generally, the cDNA population in which differentially expressed sequences will be detected, is termed tester cDNA (e.g. cDNA from rheumatoid synovium), whereas the cDNA population that acts as reference (e.g. cDNA from normal synovium) is named driver cDNA. The differentially expressed cDNAs are present in the “tester” but are absent (or present at lower levels) in the “driver”.

The underlying principle of subtractive hybridization consists of the hybridization of sequences that are expressed both in the test-probe (tester cDNA) as well as in the reference-probe (driver cDNA). The cDNA molecules in the test-probe are hybridized with a large excess of cDNA from the reference-probe and the double-stranded hybridized sequences are removed. Those cDNA sequences from the test-probe that fail to find their reference counterpart represent genes that are expressed exclusively in the cell type or tissue of interest.

The application of SSH was first described by Diatchenko and coworkers almost ten years ago. The molecular details of SSH are shown in Fig. 2. Briefly, the tester and driver double-stranded (ds) cDNAs are first digested with restriction enzymes. The tester cDNA fragments are then divided into two samples (1 and 2) and ligated with two different adapters (adapter 1 and adapter 2), resulting in two populations of tester, (1) and (2). The SSH technique uses two hybridization steps. First, an excess of driver is added to each tester population. The samples are then heat-denatured and allowed to anneal. In the second hybridization, the two samples from the first hybridization are mixed together. Only the remaining subtracted single-stranded (ss) tester cDNAs are able to reassociate to give (b), (c), and

new (e) hybrids. Addition of a second portion of denatured driver at this stage further enriches fraction (e) for differentially expressed genes. The newly formed (e) hybrids have an important feature that distinguishes them from hybrids (b) and (c) formed during first and second hybridizations. This feature is that they have different adapter sequences at their 5'-ends, one from sample 1 (adaptor 1) and the other from sample 2 (adaptor 2). The two sequences allow preferential amplification of the subtracted fraction (e) using PCR and a pair of primers, P1 and P2, which correspond to the outer parts of adapters 1 and 2 respectively. In all PCR cycles, exponential amplification can only occur with type (e) molecules, because intramolecular annealing of longer adapter sequences is both highly favored and more stable than intermolecular annealing of the much shorter PCR primers. This is the suppression PCR effect (suppressive subtractive hybridization). Furthermore, only type (e) molecules have different adapter sequence at their ends, which allows them to be exponentially amplified by PCR. The resulting cDNA library is highly enriched for differentially expressed genes and can be cloned and sequenced using standard protocols.

Subtractive hybridization offers the possibility of identifying yet unknown genes or genes with indefinite function. The creation of a complete expression profile by this method, however, is expensive in both money and time. Dependent on cell types or tissues used for the experiment, 300–500 cDNA clones have to be analyzed to obtain all the differentially expressed molecules. Many clones get picked multiple times showing a certain level of redundancy in the use of SSH. Since this hybridization technique uses probes from just a single patient and his healthy control, the differences in expression of the identified genes must be confirmed in additional samples to obtain definite conclusions. Finally, the efficiency of the SSH decreases rapidly if heterogeneous tissues with many different cell populations such as the highly heterogeneous synovium of rheumatoid arthritis are used.

Microarrays

The further development and optimization of gene-array technology is one of the most important technical achievements of the past few years. In principle, microarray technology allows scientists to detect the expression of numerous genes in the same sample simultaneously. By determining expression profiles with gene arrays under different experimental conditions, this technique can, for instance, be used to define biological features of genes with yet unknown functions. In addition, gene arrays are often used to search for key pathogenic molecules by comparing the expression profile of samples derived from patients (e.g. synovial fibroblasts derived from patients with rheumatoid arthritis) with the expression profile of samples derived from normal tissue (e.g. synovial fibroblasts from normal synovium).

Expression microarrays are devices containing up to tens of thousands of short DNA probes of known sequence, arrayed in a systematic fashion and bound to a flat surface, commonly a nylon membrane or a glass slide. Each spot on the array corresponds to a particular probe, and each probe corresponds to a short section of a gene. The hybridization of cDNAs present in the experimental sample to their corresponding sequences/DNA probes spotted on the array is the core reaction of microarray analysis. The complete experimental procedure, includes the making of the chip (microspotting, which is performed mechanically by a robot, a so-called arrayer), sample preparation, probe hybridization and finally analysis and interpretation of the data. Figure 3 shows the detailed procedures of a microarray experiment. Nowadays, a large number of different microarrays are commercially available and ready to use for probe hybridization.

In microarray experiments, the difficulty no longer lies with the technology, but rather with the handling and analysis of the large amount of data generated. In order to interpret these data, measurement of the raw data, ►normalization for different amounts of cDNA loaded on the array, strategies for the reduction of false-positive results and statistical analysis of the large amount of data have to be standardized in each experiment depending on the scientific question. For example, signals with low intensity (e.g. less than two-fold above background signals) representing genes with very low expression levels are often excluded from further analysis during raw data analysis, since results with these genes show a high variability and often cannot be reproduced. Normalization corrects for

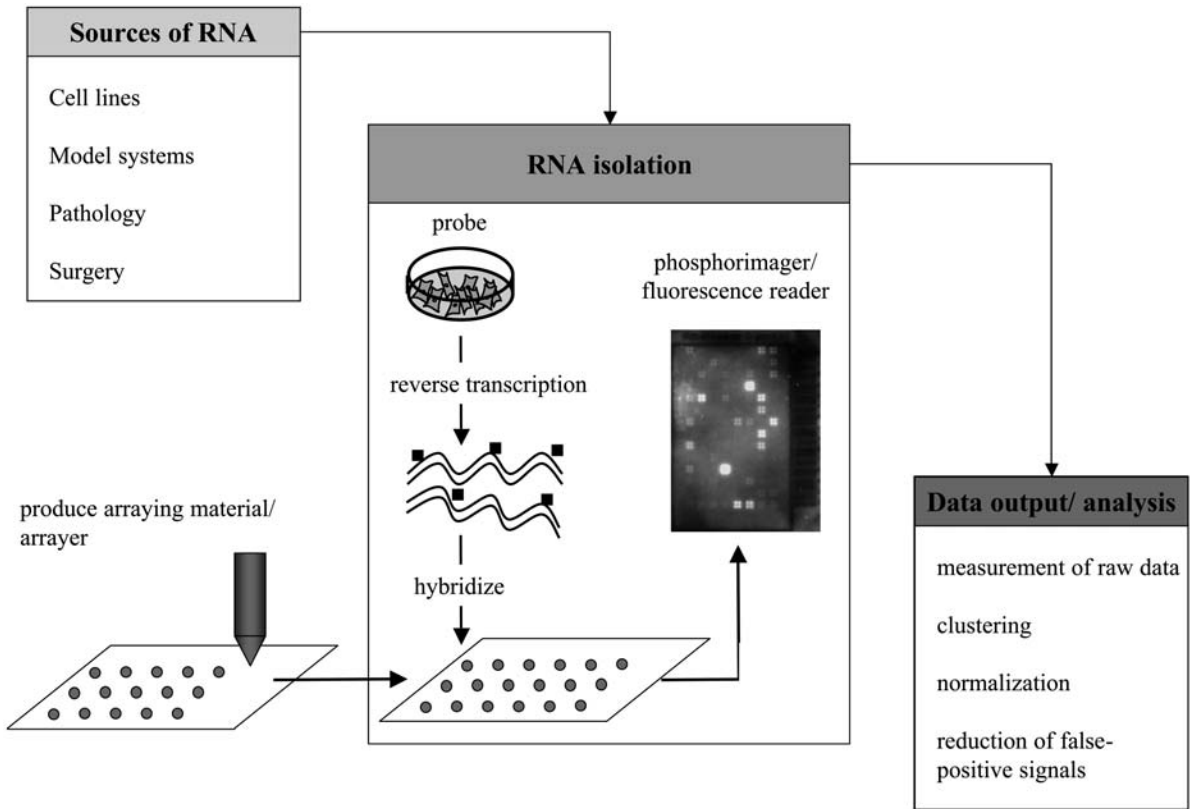

the different amounts of total cDNA in the samples that are compared. This can be achieved by measuring the signal intensity of so-called housekeeping genes, which are usually expressed at a stable level in all cells, independently of external factors. Differences in the expression levels of these housekeeping genes between two samples therefore represent differences in the amount of total cDNA extracted from the tissue/cells. To allow comparison between two samples, the expression levels of all non-housekeeping genes have to be corrected for the differences observed in the expression of housekeeping genes in the two samples. For the reduction of false-positive signals, genes with a less than two-fold difference between two samples are often excluded from further analysis (threshold-method). Although there are some limitations (e.g. genes with smaller differences in the expression level are automatically excluded from the analysis independent of their biological significance), this strategy is based on the fact that there is a strong inverse correlation between the percentage of false-positives and the level of differential expression. Finally, statistical methods need to be chosen to enable an efficient analysis and interpretation of the large amounts of expression data derived from the arrays. Among the various statistical methods available, cluster analysis is one of the most often used instruments. With this method, genes with a similar expression pattern under different conditions are grouped together to allow conclusions on similar biological functions or similar mechanisms of regulation between the clustered genes.

Microarray experiments can require significant costs, which often limits their academic use. Moreover, without bearing in mind the difficult interpretation and analysis of the microarray data, there is the danger of uncritical use of the technology. Guidelines have therefore been published for its utilization in rheumatology. These guidelines deal with the identification of false-positive results, the statistical analysis and the confirmation of differentially expressed genes by independent methods (7, 8).

Verification

Depending on the individual experiment, a major problem is the generation of false positive results. The proportion of these false positive results increases both when the number of differentially expressed molecules is low and when the quantitative differences of expression between the samples are small. Thus, the identified differences in the expression of key genes

Rheumatism Related Genes, Identification. Figure 2 Molecular details of suppressive subtractive hybridization The SSH technique uses two hybridizations between the driver and the tester cDNA. Nested PCR primers corresponding to the initially ligated adaptors allow preferential amplification of the subtracted fraction (adapted and modified from Diatchenko, Biochemistry 1996).

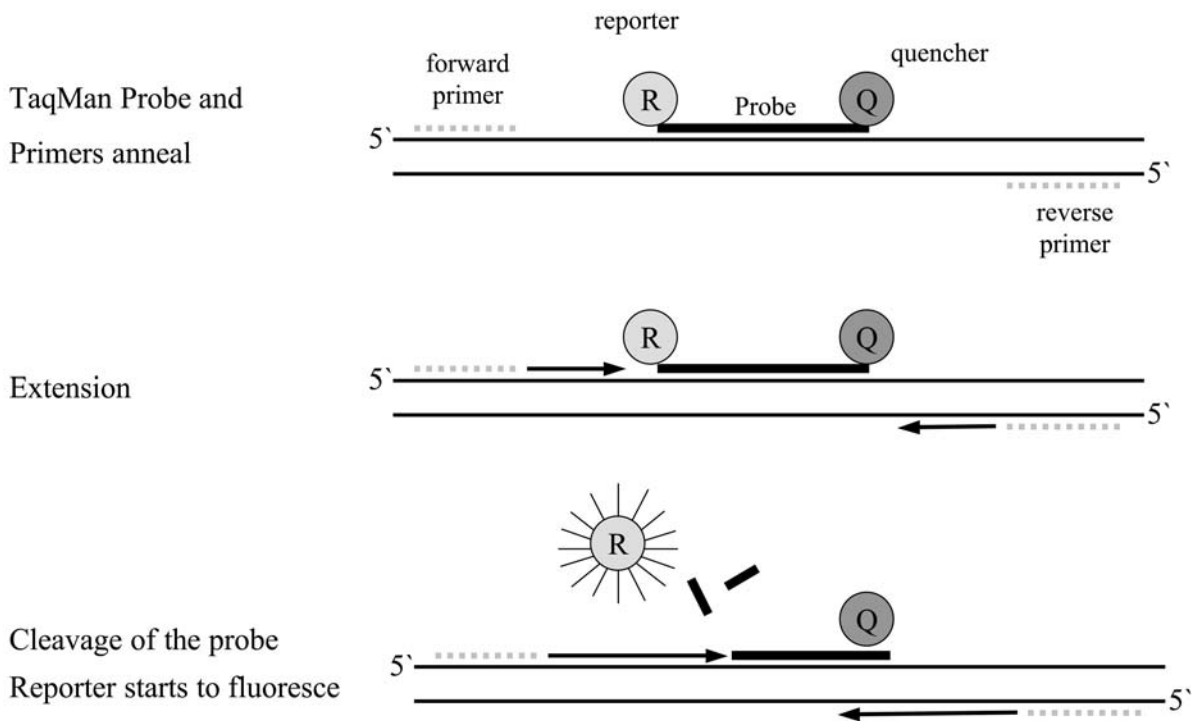

Rheumatism Related Genes, Identification. Figure 3 Details of the microarray technology Flow path scheme of the interacting components required for RNA-expression analysis using DNA – microarrays that are commercially available or generated by robotic arraying (adapted and modified from Bowtell, Nature Genetics Supplement 1999).

must be verified by an independent method. In addition to the conventional tools such as Northern blot or reverse transcriptase polymerase chain reaction (RT-PCR), the quantitative real-time PCR (e.g. TaqMan real-time PCR) is the new gold standard. Additionally to the forward and reverse primers that are used in normal PCR, in TaqMan real-time PCR another probe is introduced that binds specifically to the molecule of interest. It is labeled with a fluorogenic dye at its 5' end and with a quencher at its 3' end. The quencher suppresses the emission of the fluorogenic signal as long as the probe is intact. If the target sequence is present, the probe anneals downstream from one of the primer sites and is cleaved by the 5'-nuclease activity of Taq DNA polymerase as this primer is extended. The cleavage of the probe separates the reporter dye from the quencher dye and thus increases the reporter signal. Additional dye molecules are cleaved from their respective probes with each cycle, resulting in an increase in the fluorescence intensity proportional to the total of amplicons produced. The number of cDNA molecules produced within a single cycle of the

exponential phase of the PCR is directly correlated to the numbers of molecules in the starting solution, thereby allowing quantitative conclusions on the mRNA expression of the specific molecule. The principle of TaqMan-PCR is outlined in Fig. 4.

Functional Characterization

The term "functional genomics" includes the characterization of previously identified and verified genes at a functional level. Dependent on the experimental question, a gene can be over-expressed or inhibited by using for instance expression vectors or antisense constructs. It can then be investigated further for its biological functions in an appropriate disease model. The SCID-mouse coimplantation model that is highly disabled in its cellular immune response is such a model and is widely used in RA research. In this model, synovial fibroblasts that have been transfected with the expression vector or the anti-sense construct directed against the gene of interest are coimplanted with human cartilage under the renal capsule. After 60 days, the invasion of synovial fibroblasts into the cartilage can be

Rheumatism Related Genes, Identification. Figure 4 Principles of quantitative real-time PCR
 TaqMan real-time PCR is the most sensitive method available at the moment. It is based on the use of sequence-specific probes that are labeled with a fluorogenic dye. The amplification of the specific sequence cleaves the dye to emit a fluorogenic signal (adapted and modified from Distler, *Molekularmedizinische Grundlagen von rheumatischen Erkrankungen* 2003).

analyzed in a semi-quantitative fashion. In general, fibroblasts from RA patients show a strong invasion into the coimplanted cartilage, whereas synovial fibroblasts from healthy controls show no relevant invasiveness. The modulation of the invasion by transfection with expression vectors or with anti-sense constructs allows conclusions on the functional role of the gene of interest in cartilage degradation.

Clinical Relevance

The new molecular biology-based screening methods are a useful tool to identify target molecules for novel therapies in rheumatoid arthritis. While subtractive hybridization has been successfully used to identify yet unknown sequences and key molecules with yet unknown functions, microarrays are a powerful technique to obtain expression profiles of certain cell types or tissues under specific conditions within a comparatively short time. With both techniques, a significant number of false-positives are produced. The differential expression of key molecules identified by these methods therefore needs to be confirmed by independent methods such as real-time PCR. The term

“functional genomics” includes the functional characterization of the identified key molecules in appropriate disease models.

Rhizomelic Chondrodysplasia Punctata

Definition

Rhizomelic chondrodysplasia punctata (RCDP) is a rare peroxisome biogenesis disorder characterised by proximal shortening of the extremities, punctate calcifications in cartilage, mental retardation and dwarfism. Symptoms are usually present at birth or appear in the first few months of life. The majority of patients do not survive the first decade of life.

Type 1 RCDP (OMIM 215100) results from a defect in the PEX7 gene. In type 2 RCDP (RCDP2; OMIM 222765), patients show deficiency of the enzyme acyl-CoA: dihydroxyacetonephosphate acyl-transferase. RCDP3 (OMIM 60012) is caused by mutations in the alkyldihydroxyacetonephosphate synthase gene.

proteins, including Rac1, Cdc42 and RhoA that cycle between an active GTP-bound and inactive GDP-bound states. They are involved in a variety of cellular processes such as cytokinesis, morphogenesis, cadherin-derived cell-cell contacts, polarity, transformation, cell-substratum contacts and migration. All are primarily controlled through modifications of the actin cytoskeleton.

Definition

Rho ► [GTPases](#) form a subfamily of the Ras superfamily of small guanosine triphosphatases (► [GTPases](#)) and are molecular switches that control a wide variety of signal transduction pathways in all eukaryotic cells (1). Of the 20 members identified in mammals, RhoA, Rac1 and Cdc42 have been most widely studied and are best known for their role in regulating the actin

Rho GTPases

Definition

Rho stands for Ras homology. Rho GTPases are members of the Ras superfamily of GTP-binding

cytoskeleton, thereby affecting cell morphology and movement. However, they are also important regulators of cell-cell and cell-substratum adhesion, ►endocytosis, vesicle trafficking, ►phagocytosis and gene transcription. Furthermore, Rho GTPases play a role in a number of pathological processes, such as inflammation, cardiovascular diseases, bacterial/viral infection and epithelial tumour progression.

Characteristics

Cytoskeletal Rearrangement, Polarization and Migration

Rho proteins are key regulators of the actin cytoskeleton (2). Rho activation leads to the assembly of contractile ►actomyosin filaments known as ►stress fibres, Rac stimulates the formation of ►lamellipodia, sheet-like membrane extensions containing an extensive branching network of ►actin filaments, and Cdc42 induces the assembly of ►filopodia, finger-like protrusions in which actin filaments are arranged in parallel.

Cell migration requires membrane extension at the front of the cell, formation of new adhesions and cell body contraction (3). In all of these steps, cytoskeletal rearrangements caused by the coordinated activation of Rho GTPases are crucial. Actin polymerisation within Rac-induced lamellipodia provides the protrusive force for membrane extension in the direction of migration. In addition, Rac activation leads to the formation of small, integrin-containing ►focal complexes, which link lamellipodia to the ►extracellular matrix. Cell body contraction depends on Rho-mediated actomyosin contractility. To translate contraction into cell movement, the cell rear has to detach from the extracellular matrix through release of integrin-based attachments, and this is also induced by Rho.

Rho proteins are also emerging as key regulators of the microtubule network and in some cell types this is important for cell polarization and directed cell migration. Cdc42 can affect cell polarity by localizing the ►microtubule-organizing center (MTOC) and ►Golgi apparatus in front of the nucleus, oriented toward the leading edge, possibly facilitating microtubule growth into lamellae and providing vesicular transport into leading edge membrane extensions. Rac promotes extension of microtubules into the leading edge and both Cdc42 and Rac are involved in tethering microtubules to the plasma membrane (1).

Besides cell migration, Rho GTPases are involved in additional cellular functions that involve the actin cytoskeleton. For example, rearrangement of membrane-associated actin filaments leads to localized changes in the structure of the plasma membrane and in this way drives phagocytosis. Both Rac and Cdc42 are required for immunoglobulin-mediated (type I) phagocytosis, whereas complement-mediated (type II)

phagocytosis requires Rho. In addition, Rac and Cdc42 are required for the uptake of apoptotic cells.

Cell-Cell Adhesion

It is well established that Rho GTPases are required for the assembly of functional cell-cell contacts, as well as for their disassembly during motility. The activity of RhoA and Rac1 is required for establishment and maintenance of ►cadherin-dependent cell-cell adhesion (4, 5), although the underlying mechanisms are not well understood. Inhibition of Rac or Rho prevents the formation of cadherin-containing intercellular junctions between keratinocytes. Furthermore, inhibition of Rho leads to rapid removal of E-cadherin from mature junctions. Expression of activated Rac, on the other hand, increases the amount of E-cadherin accumulating at sites of cell-cell contact in epithelial cells and both Rac1 and Cdc42 are necessary to maintain E-cadherin-mediated cell-cell adhesion in these cells. Interestingly, Rac activity is also required during ►adherens junction disassembly, demonstrating that Rac1 is involved in positive as well as negative regulation of cadherin-mediated cell-cell adhesion. Rho proteins may regulate E-cadherin-mediated adhesion in ways that are more indirect; through regulating E-cadherin endocytosis, they may control the amount of E-cadherin able to engage in cell-cell adhesion at the plasma membrane.

Molecular Interactions

Rho proteins interact with a diverse range of downstream targets to induce cellular responses. The control of actomyosin-mediated contractility by Rho involves the activation of Rho-kinases (ROCKs) (6), which in turn increase the level of phosphorylated myosin light chain (MLC), the regulatory subunit of myosin II, both by inhibiting MLC phosphatase and by phosphorylating MLC (Fig. 1). Rho also regulates actin polymerization and microtubule organization through the Dia proteins. The ability of Rac to induce lamellipodia is believed to involve the activation of the ►Arp2/3 complex via ►Scar/Wave proteins (7, 8). The Arp2/3 complex then facilitates the formation of new actin filaments that branch off existing filaments. In addition, Rac is thought to stimulate actin polymerisation by promoting the uncapping of actin filaments. By activating ►phosphatidylinositol 4-phosphate 5-kinase (PIP 5-kinase), an enzyme which converts PtdIns(4)P (PIP) into PtdIns(4,5)P₂ (PIP₂), active Rac is able to increase the amount of PIP₂ at the plasma membrane. By binding to PIP₂, actin filament capping proteins, such as CapZ, are then recruiting away from the ends of actin filaments, allowing filament extension. Furthermore, Rac and Cdc42 may also be able to decrease the

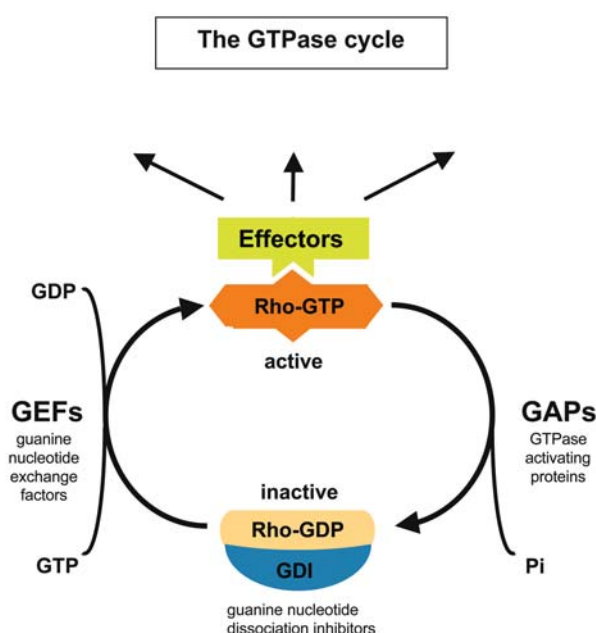

Rho, Rac, Cdc42. Figure 1 Rho regulates stress-fibre formation. GTP-bound Rho activates Rho-kinase (ROCK), which subsequently phosphorylates myosin light chain (MLC), leading to increased myosin II activity and stress-fibre formation and contractility. ROCK further increases myosin II activity by phosphorylating myosin light chain phosphatase (MLCK), thereby inhibiting MLC dephosphorylation. ROCK also phosphorylates LIM-kinase (LIMK), leading to actin-filament stabilization via inhibition of the actin-fibre depolymerizing protein cofilin.

rate of actin depolymerisation. *Via* their target p21-activated kinase (PAK), Rac and Cdc42 stimulate LIM-kinase, which in turn inactivates cofilin, a protein that can promote actin depolymerisation.

Rac and Cdc42 may modulate E-cadherin activity *via* IQGAP1, a scaffolding protein that negatively regulates E-cadherin-mediated adhesion. The RhoA targets ROCK and Dia act antagonistically to regulate cadherin-mediated cell-cell adhesion (4).

Regulatory Mechanisms

Generally, Rho proteins exist in an active, GTP-bound, or in an inactive, GDP-bound, state (Fig. 2). ▶**GTPase-activating proteins** (GAPs) stimulate the slow intrinsic GTPase activity of Rho proteins, thereby converting them from the GTP-bound form to the GDP-bound form and inactivating them. ▶**Guanine nucleotide exchange factors** (GEFs), on the other hand, promote the exchange of GDP for GTP and consequently activate Rho proteins (2). Upon activation Rho proteins usually translocate to the plasma membrane or other membrane compartments where they are able to interact with their different target proteins. The

Rho, Rac, Cdc42. Figure 2 Rho GTPases cycle between an inactive, GDP-bound and an active, GTP-bound state. Guanine nucleotide exchange factors (GEF) facilitate the exchange of GDP for GTP on Rho GTPases, thereby activating them, whereas GTPase activating proteins (GAPs) stimulate the intrinsic GTPase activity of Rho GTPases, reverting them into the inactive, GDP-bound state. In addition, Rho GTPases can associate with guanine nucleotide dissociation inhibitors (GDIs) to form an inactive complex. Effector proteins become activated upon binding specifically to the GTP-bound form of Rho GTPases.

membrane-association of Rho proteins is facilitated by prenylation at their C-terminus. In the absence of activating stimuli, Rho proteins are predominantly bound to ▶**guanine nucleotide dissociation inhibitors** (GDIs), which prevent them from binding membranes or interacting with their targets. The human genome contains over 60 GEFs and more than 70 GAPs for Rho proteins, indicating that Rho protein activities are subject to intricate regulatory pathways, to which additional mechanisms, such as the inhibition of RhoA activity by PKA-dependent phosphorylation or the regulation of Rho GTPase mRNA stability, add further complexity.

Rhodopsins/Rhodopsin

Definition

Rhodopsins are proteins found in all three kingdoms of life. They form a family of three subgroups. Visual rhodopsins from eukaryotes are coupled to G-protein regulatory networks. Rhodopsin is the light sensitive pigment of the retina formed from retinal linked through a Schiff's base to opsin. It is located in the disks of the outer segments of rods and cones. Upon illumination with light, rhodopsin achieves an activated state due to isomerisation of 11cis retinal into the all-trans form (► [retinoid cycle](#)). Rhodopsin in the activated state triggers the phototransduction process, by activating transducin and phosphodiesterase via hydrolyzing cyclic nucleotides, thereby closing a cation channel in the cytoplasmic membrane of the outer segment of photoreceptors. Microbial rhodopsins, detected in eukaryotes, eubacteria, and archaea are either ion translocating proteins or involved in the sensory response of microbes. The newly discovered Channelopsins are light activated, proton- or other cation channels.

Ribosomal RNA

Definition

Eukaryotic ribosomes are constructed from four types of ribosomal RNA. Three of these species (18S, 5.8S, and 28S) are derived from the processing of a single large precursor RNA, 45S rRNA, which is transcribed by RNA Polymerase I from tandem arrays of rDNA repeats. The remaining rRNA, 5S, is produced by RNA Polymerase III from a different gene cluster.

Definition

The amino acid sequence of proteins is encoded in the nucleotide sequence of the DNA. During gene expression, one strand of the DNA is transcribed into the complementary RNA copy (messenger RNA, ▶ [mRNA](#)) that is subsequently translated into protein by polymerizing amino acids in the sequence specified by the nucleotide sequence of the mRNA. The substrates of protein synthesis are aminoacylated ▶ [tRNAs](#) (Aa-tRNAs) that at their 3' ends carry specific amino acids in an energy-rich ester bond. Aa-tRNAs are produced by the action of aminoacyl-tRNA synthetases which each specifically recognize one amino acid and the tRNA that is specific for this amino acid as it has the anticodon triplet matching the respective codon triplet. Thus, the tRNA serves as an adaptor between the amino acid and the codon on the mRNA. Protein synthesis takes place on ribosomes that are large macromolecular assemblies consisting of several RNAs and numerous proteins. The ribosome presents the mRNA in such a way that Aa-tRNAs can bind to their respective codon and take part in peptide bond formation catalyzed by the ribosome. In their functions, ribosomes are assisted by a number of accessory translation factors.

Ribosome

Definition

The ribosome is the machinery that translates messenger RNAs into proteins, and it consists of a large and a

Characteristics

The Genetic Code

Three each of the four bases in RNA (guanine, G; adenine, A; cytosine, C; uracil, U) form one codon that specifies one particular amino acid. From the total of 64

(4³) code words, 61 stand for the 20 standard amino acids to be incorporated into proteins during translation (sense codons); the remaining three serve as termination signals that specify the end of the coding sequence (nonsense or stop codons). Because the number of codons is much larger than the number of amino acids to be coded for, most amino acids (except methionine and tryptophan) are encoded by two or more codons. One codon, AUG, stands for methionine; in a particular mRNA context, it specifies the start of the coding sequence, implying that the first amino acid of newly synthesized proteins is methionine. The codon triplets of the mRNA are decoded by the formation of three complementary base pairs with the anticodons of tRNAs. Internal codons are decoded by elongator tRNAs. Initiation codons are decoded by a particular methionine-specific tRNA, initiator tRNA, which differs from elongator tRNA^{Met} used for decoding internal methionine codons. The three termination codons, UAA, UAG, UGA, stand for “Stop”; these codons are recognized by proteins, the termination (or release) factors, rather than by tRNAs. The genetic code is the same in all organisms. Slight deviations, i.e. a few codons with different meanings, were found in mitochondria and ciliates.

The Translational Apparatus

Translation of mRNAs into protein requires a complex apparatus that consists of a large number of proteins and RNAs. Transfer RNA (tRNA) functions as adapter between the mRNA codon and the amino acid specified by the codon. tRNAs are aminoacylated by aminoacyl-tRNA synthetases. Decoding and peptide synthesis takes place on ribosomes, large ribonucleoprotein complexes consisting of three or four RNAs and 50 to 80 proteins, depending on organism and organelle. All phases of protein synthesis, i.e. initiation, elongation and termination, require the action of translation factors, which interact with the ribosome at defined stages of translation.

Transfer RNA

tRNAs are small RNAs (75–85 nucleotides) that have very similar secondary and tertiary structures; they contain a large number of modified nucleosides. The functional centers of the tRNA molecule are the anticodon and the 3'-terminal CCA sequence common to all tRNAs. The amino acid is attached to the 3'-terminal ribose by an energy-rich ester bond.

Decoding of mRNA codons on the ribosome entails the formation of base pairs between three bases of the codon and complementary bases of the anticodon. Most amino acids are specified by more than one codon, in some cases by up to six. In such cases, there are two or more tRNAs that are charged with the same

amino acid (isoacceptors) and have different sequences, including different anticodons. In the first and second codon position, base pairing with the anticodon strictly follows the Watson-Crick complementarity rules, i.e. G pairs with C and A with U. Base pairing at the third codon position is less restrictive, because “wobble” pairs (G:U, U:G, or I:U,C,A; I stands for inosine) are also “allowed”, i.e. energetically favorable. As a consequence, there are tRNAs that can pair with two or more codons differing in the third base, which reduces the total number of different tRNAs required to decode all 61 sense codons. Most organisms have 40–50 different tRNAs; a set of 22 tRNAs suffices for protein synthesis in mitochondria of mammalian cells.

The attachment of amino acids to the 3' end of tRNAs (aminoacylation) is catalyzed by aminoacyl-tRNA (Aa-tRNA) synthetases (amino acid:tRNA ligases). Aa-tRNA synthetases are specific for their respective amino acid and tRNA (or group of isoaccepting tRNAs). Generally, organisms contain 20 different Aa-tRNA synthetases, one for every amino acid incorporated. Aminoacylation takes place in two steps that are both catalyzed by the same Aa-tRNA synthetase:

1. Amino acid + ATP = Aa – AMP + PPi,
2. Aa – AMP + tRNA = Aa – tRNA + AMP.

The first step is the activation of the amino acid with ATP by formation of a mixed anhydride formed between the carboxyl group of the amino acid and the phosphoryl group of AMP. The second reaction is the transfer of the aminoacyl residue from Aa-AMP to tRNA to form an energy-rich ester bond with a hydroxyl group of the 3'-terminal ribose.

Aa-tRNA synthetases vary in size and subunit composition; there are monomeric enzymes with molecular masses around 50 kD, homo- and heterodimeric enzymes (100 kD) and homo- and heterotetramers with over 200 kD. Two classes of Aa-tRNA synthetases can be distinguished that differ in the structure of the catalytic center and transfer the amino acid to either the 2' or the 3' hydroxyl group of the terminal ribose of the tRNA. By spontaneous migration of the aminoacyl residue the 2' derivative isomerizes to the 3' Aa-tRNA that is the substrate for subsequent steps of translation.

The aminoacylation reaction is highly accurate, i.e. the frequency by which an incorrect amino acid is attached to a tRNA is low (about 10^{−4}). Most amino acids can be discriminated with sufficient accuracy in a single binding step on the basis of structure, size or chemical character. In the few cases where these criteria do not suffice for high-accuracy discrimination (isosteric or chemically similar amino acids, such as threonine and

isoleucine or isoleucine and valine, respectively), the required low error level is attained by hydrolytically discarding incorrectly formed products (editing). Editing synthetases have a second catalytic site where incorrectly formed Aa-AMP or Aa-tRNA is hydrolyzed. The recognition of the tRNA substrate is brought about by specific interactions between the Aa-tRNA synthetase and structural elements at various positions in the tRNA molecule (identity elements), frequently including residues in the acceptor arm and the anticodon. Isoaccepting tRNAs that are aminoacylated by the same synthetase possess the same pattern of identity elements.

Ribosomes

Ribosomes are large (diameter 20 nm; molecular weight several MD) ▶[ribonucleoprotein](#) particles (RNPs) that consist of two subunits of different size. They contain several molecules of ▶[ribosomal RNA](#) (rRNA) and many proteins that are mostly small (10–20 kD) and basic (Table 1). Ribosomes from bacteria and eukaryotes have similar architecture, although eukaryotic ribosomes are larger and have a higher molecular mass because they have larger rRNAs and more proteins. Mitochondrial ribosomes resemble bacterial ribosomes, but contain smaller rRNAs and many more proteins.

The structures of 30S and 50S ribosomal subunits are known at atomic resolution. In both subunits, the structure is determined by the tertiary structure of the

RNA to which the ribosomal proteins are attached. The three domains of 16S rRNA are represented in the body, the platform and the head domain of the 30S particle (Fig. 1a). The decoding center is built of parts of helices 44, 18 and 34 of 16S rRNA, and the only protein that reaches into the decoding center is S12. 16S rRNA forms contacts with the codon-anticodon complex that are essential for the accuracy of decoding. Monitoring the quality of codon-anticodon interaction is performed by helix 44 through A1493 and A1492 that contact base pairs at the 1st and 2nd positions respectively, in the minor groove of the codon-anticodon duplex (A-minor interactions); the 3rd position is monitored less stringently by a contact from G530 and other residues (Fig. 1b). The A-minor interactions formed by A1493/A1492 are sequence-independent, yet specific for Watson-Crick base pairs, providing the molecular basis for the induced-fit mechanism of decoding (see below).

Major landmarks of the 50S subunit (Fig. 2a) are the L1 region, the central protuberance that contains 5S rRNA and the stalk region where proteins L11, L10 and L7/12 (not seen in the structure) form an important site for elongation factor binding. The peptidyl transferase center, as localized by an analogue mimicking the tetrahedral intermediate of the peptidyl transferase reaction, is made up of RNA only, suggesting that the ribosome is a ▶[ribozyme](#). The exit tunnel for the growing peptide extends from the peptidyl transferase center through the body to the back of the subunit where the peptide emerges (Fig. 2b).

Ribosomes. Figure 1 Atomic structure of the 30S ribosomal subunit of ribosomes. (a) Overview of the 30S structure from *Thermus thermophilus* (ribbon representation). The three major domains of 16S rRNA are colored differently, and proteins are shown in various colors. (b) Recognition of codon-anticodon base pairs by ribosomal residues of the decoding center. Shown are the three anticodon bases (G34A35A36) bound to a codon triplet (U1U2U3) in the 30S crystal. Reprinted from Science 292 (2001) 897, with permission.

The structure of 70S ribosomes with three tRNA molecules bound in the binding sites for Aa-tRNA (A site), Pept-tRNA (P site) and the exit site for deacylated tRNA (E site) was determined by X-ray crystallography at 5.5 Å resolution (Fig. 3). The arrangement of the tRNAs in A and P sites with their anticodons and CCA ends respectively coming close together is clearly seen in the structure. There are a number of connections between the subunits, most of them made up of RNA. One prominent connection (bridge 2a) is formed of helix 69 of 23S rRNA and connects to the 30S decoding site (helix 44) and another (bridge 3) connects helix 44 (30S) and helix 71 (50S). Some bridges contact the A-site tRNA, e.g. helix 38 (bridge 1a, or “A-site finger”) from above and helix 69 from below, the latter also contacts the P-site tRNA. These interactions stabilize the tRNAs in their respective binding positions and presumably have to be released to allow tRNA movement during translocation. Structural and functional analyses suggest that rRNA is involved in the major functions of the ribosome, i.e. decoding, peptide bond formation and translocation, consistent with the high degree of conservation of the respective functional centers of rRNA in ribosomes from various organisms. Ribosomal proteins appear to

have important functional roles as well. Ribosomal proteins are required for rapid and accurate assembly of ribosomal particles *in vivo* and are probably essential for stabilizing certain structural elements of rRNA. For several ribosomal proteins a direct involvement in ribosome function has been demonstrated. ▶ **Mutations** in proteins S4, S5, S12 and others have strong effects on the fidelity of Aa-tRNA selection, suggesting an involvement of those proteins in decoding. In fact, all these proteins are located close to the decoding center. Proteins L7/12 that form the stalk of the 50S subunit of the bacterial ribosome and the corresponding P1/P2 proteins of eukaryotic ribosomes have an important role in the function of translation factors on the ribosome, including an involvement in the stimulation of the GTPase activity of those factors.

Translation Factors

All phases of ribosomal protein synthesis, except peptide bond formation itself, require that protein factors interact with the ribosome in order to proceed at physiologically relevant rates. There are factors for initiation, elongation and termination (Table 2). Several translation factors are GTPases that hydrolyze GTP at one point during their functional cycles. Atomic

Ribosomes. Figure 3 Crystal structure of 70S ribosomes from *Thermus thermophilus* with tRNAs bound to A, P, and E sites. Shown are the interface sides of 50S (left panel) and 30S (right panel) subunits. 23S and 16S rRNAs are shown in gray, 5S rRNA in blue at the top of the 50S subunit; proteins are in blue. tRNAs are in gold (A site), orange (P site), and red (E site). Connections between subunits are indicated in purple (RNA-RNA bridges) or yellow (RNA-protein bridges). Reprinted from Science 292 (2001) 883, with permission.

tRNA (N-formylmethionyl-tRNA^{fMet}, or fMet-tRNA^{fMet}) and the mRNA to the 30S ribosomal subunit. Usually the initiation site is found by base pairing between a short sequence in 16S rRNA and a partially or fully complementary sequence of the mRNA that is located about ten nucleotides upstream of the initiation codon (Shine-Dalgarno sequence). The initiation codon is recognized by the anticodon of the initiator tRNA bound to the 30S P site. 30S initiation complex formation in bacteria requires the function of three initiation factors, IF1, IF2 and IF3. IF3 promotes the dissociation of 70S ribosomes into subunits by binding to the 30S subunit and stimulates the binding of both initiator tRNA and mRNA. IF1 stimulates the function of the other two factors; it is bound to the 30S A site where it may help in directing initiator tRNA to the P site. IF2, a GTPase, is essential for the binding of initiator tRNA.

In the second phase of initiation, the 30S initiation complex is joined by the 50S ribosomal subunit. Subunit association triggers GTP hydrolysis by IF2 and subsequently all three initiation factors dissociate from the ribosome. The resulting 70S initiation complex contains initiator tRNA bound to the AUG start codon of the mRNA in the P site, and the following codon is presented in the A site. Binding of the respective Aa-tRNA to the 70S initiation complex initiates the first round of elongation.

The Elongation Cycle

The elongation of the peptide chain takes place in three main steps (Fig. 5). In the first step, bacterial EF-Tu (or eukaryotic eEF1 α) catalyzes the binding of Aa-tRNA to the A site of the ribosome. These factors are

Ribosomes. Table 2 Protein Factors in Translation

	Prokaryotes	Eukaryotes
Initiation	IF1	~12 eIFs
	IF2	
	IF3	
Elongation	EF-Tu	EF1 α
	EF-Ts	EF1 β,γ,δ
	EF-G	EF2
Termination		EF3 (fungi)
	RF1	eRF1
	RF2	-
	RF3	eRF3
Ribosome Recycling	RRF	

► **GTPases** that in their GTP-bound conformation form a high-affinity ternary complex with Aa-tRNA, which, in turn, binds to the ribosome and, after GTP hydrolysis, releases Aa-tRNA to enter the peptidyl transferase center. Peptide bond formation between Aa-tRNA in the A site and Pept-tRNA in the P site is catalyzed by the ribosome. The final step is translocation, which is catalyzed by EF-G (eEF2 in eukaryotes), another GTPase.

Aa-tRNA Binding

EF-Tu-dependent A-site binding of Aa-tRNA comprises a number of steps, as revealed by biochemical

Ribosomes. Figure 4 Initiation of translation in prokaryotes. Step 1: Subunit dissociation induced by IF3; step 2: Binding of fMet-tRNA, IF2-GTP, IF1, mRNA; step 3: 50S subunit joining, GTP hydrolysis, dissociation of Ifs.

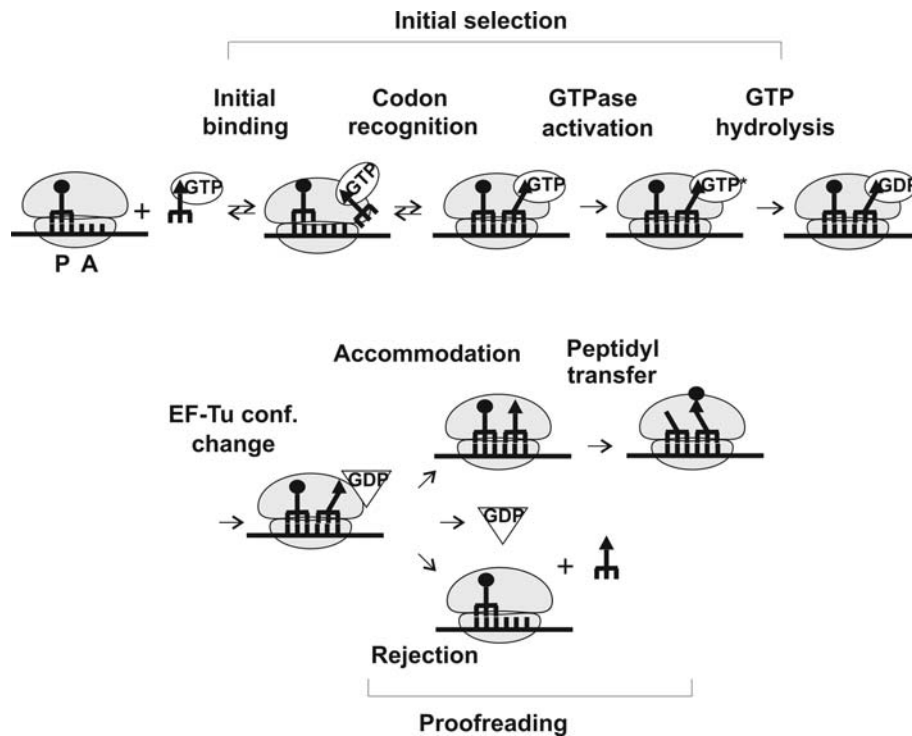

and rapid kinetic analysis (Fig. 6). The first step is the codon-independent formation of an unstable initial binding complex. During initial complex formation, EF-Tu-GTP-Aa-tRNA complexes interact with the ribosome in a stochastic fashion until one with the anticodon matching the A-site codon binds to form the codon-recognition complex. Codon recognition has two important consequences. One is stabilization of the complex by formation of base pairs between codon and anticodon as well as by ribosome interactions. The other is stimulation of the GTPase activity of EF-Tu by more than five orders of magnitude (GTPase activation). GTP hydrolysis leads to an extensive structural change in EF-Tu from the GTP- to the GDP-bound form, by which it loses the affinity for Aa-tRNA. The aminoacyl end of Aa-tRNA set free from EF-Tu-GDP moves into the peptidyl transferase center (accommodation) and takes part in peptide bond formation. EF-Tu-GDP dissociates from the ribosome and is reactivated by EF-Ts that acts as a guanine nucleotide exchange factor (GEF) and catalyzes the exchange of GDP for GTP. The functional cycle of eukaryotic eEF1 α is similar, with eEF1 β,γ acting as exchange factor. Because of the high concentrations of EF-Tu or eEF1 α present in the cell, practically all Aa-tRNA is

Ribosomes. Figure 5 Schematic of the elongation cycle.

bound in the ternary complex and immediately available for entering the ribosome.

The ribosome discriminates between correct and incorrect Aa-tRNAs or their complexes with EF-Tu-GTP with high accuracy. The average frequency of amino acid misincorporation *in vivo* is about 10^{-3} . This low level of missense errors is difficult to reconcile with the difference in the free energy of binding between codon-anticodon pairs that are correct, i.e. fully complementary, called cognates, and those that are nearly correct, having one mismatch, called near-cognates. These differences can be quite small (≤ 10 kJ/mol), predicting error frequencies of up to one out of 100 amino acids incorporated. Moreover, even this discrimination potential is unlikely to be used in full, because the high rates of the step(s) following codon recognition preclude the codon reading step reaching equilibrium. Thus, in order to reconcile an error frequency of at least 10^{-2} predicted for a single-step selection mechanism and the much lower error frequencies actually observed *in vivo*, the ribosome must either augment the precision of a single recognition step or use the same discriminatory interactions more than once in consecutive rejection steps that are separated by an irreversible, energy-dissipating

Ribosomes. Figure 6 Mechanism of Aa-tRNA binding to the ribosome.

Ribosomes. Figure 7 Schematic of the peptidyl transferase reaction between P site-bound Pept-tRNA and A site-bound Aa-tRNA.

Ribosomes. Figure 8 Mechanism of translocation.

step, i.e. GTP hydrolysis. Both mechanisms operate on the ribosome in that there are two steps of selection (Fig. 6), i.e. initial selection of ternary complexes prior to GTP hydrolysis and proofreading selection of Aa-tRNA after GTP hydrolysis. In essence, Aa-tRNA selection is controlled kinetically rather than by the thermodynamics of codon-anticodon interaction. The mechanism involves induced fit. Correct codon recognition induces a conformational change in the decoding site that is driven by the formation of interactions between ribosomal residues and base pairs of the codon-anticodon duplex (Fig. 1B). The conformational change in the decoding site, in turn,

accelerates the rates of the chemical steps of A-site binding, i.e. GTP hydrolysis by EF-Tu and peptide bond formation.

Peptide Bond Formation

Catalysis of peptide bond formation is the enzymatic activity of the ribosome. The rate of the uncatalyzed reaction is extremely low and catalysis by the ribosome accelerates the reaction by seven orders of magnitude. The reaction proceeds *via* nucleophilic attack by the α -amino group of Aa-tRNA (A site) on the carbonyl carbon of the ester bond of Pept-tRNA (P site) and leads to a tetrahedral intermediate which subsequently

Ribosomes. Figure 9 Termination of prokaryotic translation. Step 1: RF1 binding and stop codon recognition; step 2: Peptidyl-tRNA hydrolysis, RF3 binding and GDP-GTP exchange; step 3: GTP hydrolysis, dissociation of RFs; step 4: tRNA-mRNA dissociation promoted by RRF-EF-G.

breaks down to form deacylated tRNA (P site) and a new, one amino acid longer, Pept-tRNA (A site) (Fig. 7). The peptidyl transferase (PT) center is located on the 50S subunit of the ribosome. 50S subunits largely depleted of protein retained some PT activity, suggesting that the activity might reside in 23S rRNA, although attempts to obtain protein-free 23S rRNA that was active in the PT reaction were unsuccessful. Atomic structures of the large ribosomal subunits show that the PT center is composed of RNA exclusively (Fig. 2), implying that the reaction is in fact catalyzed by RNA. Thus, the ribosome is a ribozyme, actually the largest known and the only natural one with polymerase activity.

Ribosomes. Table 3 Antibiotics acting on prokaryotic translation

Antibiotic	Action
Tetracycline	Inhibits Aa-tRNA binding
Neomycin	Induces misreading
Streptomycin	Induces misreading
Chloramphenicol	Inhibits peptidyl transferase
Fusidic acid	Inhibits translocation
Thiostrepton	Inhibits translocation
Erythromycin	Inhibits peptide elongation
Puromycin	Peptide release

The catalytic mechanism of peptide bond formation is not known in full detail. Positioning of the 3' CCA ends of both Pept-tRNA and Aa-tRNA by forming base pairs with 23S rRNA in the PT center has an important role, as shown by mutational and kinetic analysis. Several base pairs between CCA sequences of substrate analogues and bases in the P and A loops of 23S rRNA in the PT center were revealed by the crystal structures. Ribosomal residues may also contribute to chemical catalysis, e.g. general acid-base catalysis, although the evidence is not clear.

Translocation

The elongation cycle is completed by translocation, that is the synchronous movement of the two tRNAs and the mRNA on the ribosome by exactly one codon triplet. Following the movement, deacylated tRNA spontaneously dissociates from the E site, so that the ribosome in the posttranslocation state has Pept-tRNA in the P site and an empty A site presenting the codon to be decoded in the next round of elongation.

Translocation is catalyzed by elongation factor G in bacteria (eEF2 in eukaryotes) that hydrolyzes one molecule of GTP during the reaction. Rapid kinetic analysis has revealed the following reaction sequence (Fig. 8). Binding of EF-G-GTP to the pretranslocation complex triggers rapid GTP hydrolysis (unbound EF-G has no GTPase activity). Ribosomal residues involved in GTPase activation include proteins L7/L12 and possibly also elements of 23S rRNA, such as the sarcin loop. GTP hydrolysis induces a conformational change in the factor that is coupled to a rearrangement of the ribosome that leads to rapid tRNA movement and the release of Pi from ribosome-bound EF-G-GDP-Pi. The sequence is completed by further conformational changes and, finally, dissociation of EF-G-GDP and deacylated tRNA. When GTP is replaced with

non-hydrolysable GTP analogues, translocation is much slower. This suggests a mechanochemical function of EF-G, coupling the energy of GTP hydrolysis to conformational work on the ribosome.

Termination

The elongation cycle is repeated until a termination codon appears in the decoding site. This is the signal for termination, during which the completed protein is hydrolytically released from Pept-tRNA (Fig. 9). Termination is catalyzed by termination or release factors (RF). In bacteria, RF1 recognizes the termination codons UAG and UAA, while RF2 is specific for UGA and UAA (in eukaryotes, one factor, eRF1, recognizes all three termination codons). The specificity of the release factors in distinguishing termination codons from sense codons is extremely high, hence the very low frequency of premature termination on sense codons. Binding of RF1/2 to a termination codon in the A site leads to hydrolysis of Pept-tRNA. Apparently, the factor binds to the termination codon in the decoding site and, at the same time, contacts the peptidyl transferase center and induces the hydrolytic activity, possibly by taking part in the activation and/or positioning of the hydrolytic water molecule. After release of the peptide, another release factor, RF3, a GTPase, promotes the dissociation of RF1/2 from the ribosome in a process that requires GTP hydrolysis. The posttermination complex releases the deacylated tRNA from the P site and dissociates into subunits, assisted by initiation factor IF3 that binds to the small subunit and stabilizes it in the unbound form. In bacteria, ribosome recycling requires another factor, ribosome-recycling factor (RRF), that together with EF-G promotes the dissociation of the posttermination complex and the formation of free ribosomal subunits.

Clinical Relevance

The translation apparatus of bacteria is the target for many natural antibiotics that affect certain steps of ribosomal protein synthesis; examples are listed in Table 3. Most of these antibiotics inhibit ribosome function by binding to ribosomal RNA. For instance, certain aminoglycosides (neomycin, paromomycin, gentamicin) bind to 16S rRNA in the decoding site and impair the accuracy of decoding, thereby increasing amino acid misincorporation. Streptomycin, from another group of aminoglycosides, binds to another site in 16S rRNA, but has the same effect. Tetracycline also binds in this region and interferes with productive binding of Aa-tRNA. There are many inhibitors of the peptidyl transferase reaction (e.g. chloramphenicol) that bind to the peptidyl transferase center of 23S rRNA. The binding site of erythromycin is located in the peptide exit tunnel of the 50S subunit and binding of the antibiotic precludes peptide elongation.

Thiostrepton binds to a single site in 23S rRNA and inhibits translocation by blocking conformational transitions of the ribosome that are important for the reaction.

The therapeutic use of many antibiotics is restricted at present, because resistant pathogens have evolved. Much effort is therefore spent to develop new antibiotics that act on translation or other targets.

Ribozyme

Definition

The word “ribozyme” is derived from the words ribonucleic acid (RNA) and enzyme, and it denotes an RNA molecule with catalytic properties. Naturally occurring catalytic RNAs catalyze phosphoryl transfer reactions, which require the activation of a 2′-OH group (self-splicing introns; hammerhead ribozyme; hepatitis delta ribozyme; hairpin ribozyme) or a water molecule (RNase P) for nucleophilic attack of a neighboring phosphodiester bond. The ribosome constitutes the first example of a natural ribozyme with (amino acid) polymerase activity. Synthetic ribozymes catalyzing a variety of chemical reactions have been obtained by *in-vitro* selection from random-sequence RNA.

Rickets

Definition

Rickets is a childhood disorder that disturbs normal bone formation (ossification). Rickets is characterized

by deficient mineralization of osteoid tissue with associated skeletal deformities. Rickets is primarily caused by a lack of vitamin D and calcium. A familial form of rickets is characterized by low blood phosphate level, defective intestinal absorption of phosphate, and unresponsiveness to vitamin D.

RING Finger Domain

Definition

RING finger domain is defined structurally by two interleaved metalcoordinating sites. The consensus sequence for the RING finger is: CX₂CX(9–39)CX(1–3)HX(2–3)C/HX₂CX(4–48)CX₂C. The cysteines and histidines represent two metal-binding sites. The first, second, fifth and sixth of these bind one zinc ion and the third, fourth, seventh and eighth bind the second zinc ion. This zinc-finger containing structure is characteristic for ubiquitin-ligases. Relatives of this structural motif are the U-box and the PHD domain.

RNA

Definition

RNA stands for ribonucleic acid. It mostly occurs as a single stranded molecule, and is an intermediate between DNA (genes) and proteins, or functional as such. It is instable compared to DNA due to its biochemical specificities.

RNA Dominance

Definition

RNA dominance refers to a model explaining how a 3'-UTR expansion mutation results in a dominant neuromuscular disorder; transcripts containing long tri- or tetranucleotide repeats exert toxic effects on RNA metabolism (e.g. splicing and transport) such as observed in myotonic dystrophy (DM1) and DM2.

RNA transport: nucleo-cytoplasmic trafficking

Definition

In eukaryotic cells, RNA synthesis and processing occur in the nucleus, whereas translation of RNA into protein occurs in the cytoplasm. The nucleus and cytoplasm are separated by the ▶nuclear envelope, which is comprised of two membrane lipid bilayers. ▶Nuclear pore complexes (NPC) are large protein assemblies that form channels across the nuclear envelope (1). Bidirectional transport of macromolecules occurs through the NPC and is mediated by soluble transport receptors (1, 2). In metazoans, the NPC is composed of about 30 or more different proteins that are termed ▶nucleoporins, which often contain clusters of hydrophobic phenylalanine-glycine (FG) dipeptide repeats (1). The FG repeats interact with nuclear transport receptors, which in turn are bound either directly or indirectly through adapter proteins to the RNA that is being transported and which is referred to as ▶cargo. The receptor-cargo complex binds to different nucleoporins as it is translocated across the channel of the NPC into the cytoplasm (1, 2, 3) (Fig. 1).

Characteristics

There are two major classes of RNAs, noncoding and coding. The noncoding RNAs include ▶ribosomal RNA (rRNA) and tRNA, which are involved in translation and small nuclear RNAs (snRNAs), which are involved in splicing. Coding RNA is also called messenger RNA or mRNA. Noncoding RNAs and mRNAs use different export pathways that are mediated by different ▶export receptors.

Export of Noncoding RNA

Noncoding RNAs have been found to depend on members of the karyopherin or importin/exportin family of transport receptors for their export (2). A characteristic of this group of export factors is their dependence on the small GTPase Ran. A gradient of ▶Ran-GTP is required to promote the directionality of export (2). In the nucleus, ▶karyopherins bind the cargo in the presence of the GTP-bound form of Ran, Ran-GTP. The Ran specific guanine nucleotide exchange factor, RanGEF is localized in the nucleus thus keeping levels of Ran-GTP high. The Ran-specific GTPase-activating protein, RanGAP is localized in the cytoplasm so that Ran exists there predominantly as inactive Ran-GDP. Conversion of Ran-GTP to Ran-GDP in the cytoplasm by RanGAP results in the release of the bound cargo and the karyopherin is recycled to the nucleus to bind and export more cargo RNA (2). Pre-rRNA is synthesized by RNA polymerase I after which pre-rRNA undergoes processing to generate the mature 18S, 5.8S and 28S rRNAs. The fourth rRNA is transcribed by RNA polymerase III. In a highly ordered process, the 28S, 5.8S and 5S rRNAs are assembled in

RNA Export. Figure 1 A cross section of the nuclear pore complex (NPC) is depicted, which shows the inner and outer membranes of the nuclear envelope. The nuclear basket and cytoplasmic fibrils are lined with nucleoporins. In higher eukaryotes, there are more than 30 different nucleoporins, many of which are present in multiple copies. Nucleoporin complexes are shown in the central core of the NPC.

a complex along with 50 ribosomal proteins. This complex is the 60S pre-ribosomal subunit. The 18S rRNA is assembled with 33 ribosomal proteins to yield the 40S pre-ribosomal subunit. The 60S and 40S subunits are exported separately to the cytoplasm where they form the translating ribosome. Export of both subunits is dependent on the karyopherin termed CRM1 or exportin 1 (2). CRM1 does not bind to the RNA cargo directly but instead interacts with export factors that bind to the RNA cargo and to CRM1 simultaneously. The interaction with CRM1 occurs through **nuclear export signals** (NES) on the export factors, which are comprised of short hydrophobic stretches of amino acids that are rich in leucine residues. TFIIIA, which contains an NES, has been shown to bind 5S rRNA to bridge it to CRM1. In yeast, a factor termed Nmd3 has been found to bring the 60S pre-ribosomal subunit to CRM1 but the human homologue of Nmd3 has not been identified. Further, while the 40S subunit also depends on CRM1 for its export, the factor responsible for bridging it to CRM1 has not yet been identified. CRM1 bound to Ran-GTP

has been shown to bind to a number of nucleoporins to translocate the pre-ribosomal subunits through the NPC to the cytoplasm. Upon Ran-GTP hydrolysis to Ran-GDP, the cargo is released and CRM1 shuttles back to the nucleus (2) (Fig. 2).

Pre-tRNA is transcribed by RNA polymerase III, after which a number of post-transcriptional modifications occur to generate mature tRNA. Export of tRNA is mediated by another karyopherin family member termed exportin-t (Exp-t) (2). Additional export factors are not required for tRNA export because Exp-t binds directly to highly structured, mature tRNAs but only in the presence of Ran-GTP. Like other karyopherins, Exp-t can bind to specific nucleoporins and can shuttle between the nucleus and cytoplasm (2) (Fig. 2).

Small nuclear ribonucleoprotein particles (snRNPs) are RNA-protein complexes that play critical roles in pre-mRNA splicing. The small nuclear RNA (snRNA) components of snRNPs are U-rich and thus are termed, U1, U2, U4, U5 and U6 snRNAs. All but U6 are transcribed by RNA polymerase II; U6 is transcribed by RNA polymerase III. Although snRNAs function in

RNA Export. Figure 2 Karyopherin/exportin family members mediate export of non-coding RNAs. The general scheme for export of non-coding RNAs is depicted on the left. The RNA molecule is bound by RNA adapter protein (s), labeled as factor X, which brings the RNA cargo to a member of the karyopherin/exportin family. The karyopherin/exportin must bind to Ran-GTP to bind the cargo. Upon entry to the cytoplasm, Ran GAP converts Ran-GTP to Ran-GDP and the cargo is released. The karyopherin/exportin is re-imported to the nucleus. For tRNA, the export receptor is exportin-t or Exp-t, which binds directly to the tRNA and does not require adapter proteins. In contrast, snRNAs are bound at the 5' cap by cap binding complex (CBC), a heterodimer that is comprised of 80 kD and 20 kD subunits. CBC in turn binds to phosphorylated adapter of RNA export (PHAX), which binds to CRM1, a karyopherin family member. Ribosomal RNAs (rRNA) transcribed by RNA polymerase I undergo processing to form the 18S, 5.8S and 28S rRNAs. A set of ribosomal proteins assembles on the 18S rRNA forming the 40S pre-ribosomal complex, which interacts with CRM1-Ran-GTP through an adapter that has not been identified. The 5.8S, 28S and 5S rRNAs form the 60S pre-ribosomal complex upon binding by 50 ribosomal proteins. In yeast, the adapter is Nmd3, but the human counterpart is not known. Some of the 5S rRNA binds to TFIIA, which bridges it to CRM1 for export.

pre-mRNA splicing in the nucleus, they must be exported to the cytoplasm to acquire the protein components of snRNPs. The assembled snRNPs are subsequently imported into the nucleus where they function in spliceosome assembly. Export of snRNAs to the cytoplasm also requires the karyopherin CRM1 (2). A factor termed PHAX, which stands for phosphorylated adapter for RNA export, was found to bind snRNAs and the Ran-GTP bound form of CRM1. It was further shown that a heterodimer that binds to the 7-methylguanosine cap that is added co-transcriptionally to all RNA polymerase II transcripts, binds to PHAX-CRM1-Ran-GTP. The heterodimer, termed cap-binding complex (CBC) is composed of a 20 kD protein (CBP20) and an 80 kD protein (CBP80). It has been demonstrated that CBC bound to the cap of snRNAs is required for their export, along with PHAX and CRM1 (2) (Fig. 2).

Export of Coding RNA

Export of cellular mRNA is independent of Ran and karyopherins. Instead, mRNA export is mediated by a conserved heterodimeric receptor that is structurally unrelated to the karyopherin family and notably, which

does not depend on Ran-GTP to bind cargo (3, 4). A preponderance of evidence has shown that the mRNA export receptor is a protein initially termed TAP and later termed NXF1 for nuclear export factor 1 (3, 4). The homologue of [TAP/NXF1](#) in yeast is called Mex67p. TAP/NXF1 interacts with p15, which is also called NXT1. The yeast orthologue is termed Mtr2p. Mutational analysis of Mex67p in yeast and knock-down of expression of TAP/NXF1 by RNA interference in metazoans have demonstrated that these are the receptors that are required for mRNA export. TAP/NXF1 interacts with nucleoporins in the NPC through a C-terminal domain and binding of TAP/NXF1 to its heterodimeric partner p15 appears to increase the interaction of TAP/NXF1 with the NPC. Further, TAP/NXF1-p15 does not bind directly to the mRNA cargo but instead requires RNA adapter proteins to bridge the interaction. Moreover, recent studies have revealed a functional coupling between mRNA export and upstream events in RNA biogenesis (4). Eukaryotic mRNAs are transcribed by RNA polymerase II. The pre-mRNAs are processed after synthesis in the nucleus by capping at the 5' end, cleavage and polyadenylation to form the 3' end and splicing to

remove intervening sequences. These events appear to occur co-transcriptionally and proteins required for each processing event interact with the highly conserved C-terminal domain (CTD) of RNA polymerase II. The CTD serves as a platform for RNA processing factors so that these factors can travel with the elongating polymerase until they reach the appropriate sequences on the nascent transcript where their action is required. A theme that has been emerging is that mRNA export is coupled to other aspects of mRNA biogenesis, probably to insure that only properly processed, mature mRNA exits the nucleus (4). This is because export of an incompletely processed pre-mRNA would have profound effects on the protein that was translated. In fact, unspliced mRNAs are retained in the nucleus. Nuclear retention is caused by interactions of splicing factors with splice site consensus sequences in partially processed transcripts and serves to ensure that translation occurs only on mature mRNAs. In metazoans, nuclear export of mature mRNAs has also been linked to pre-mRNA splicing (4, 5). Early reports showed that certain mRNAs transcribed from cDNAs failed to exit the nucleus and, therefore, did not express protein, whereas the same mRNAs expressed from intron-containing constructs could enter the cytoplasm and be efficiently translated. Further, spliced RNAs were more efficiently exported from *Xenopus* oocyte nuclei than identical RNAs transcribed from cDNAs (5). The basis of this

connection was uncovered with the discovery of a protein complex, which is deposited on pre-mRNAs undergoing splicing, at a specific position about 20 nucleotides upstream of exon-**▶exon junctions**. This exon junction complex or EJC consists of at least six proteins, which have been shown to function in pre-mRNA splicing, nuclear mRNA export, RNA localization and mRNA surveillance (5). One of these proteins, initially termed Aly and then subsequently called REF for RNA export factor, interacts directly with TAP/NXF1. **▶Aly/REF** is recruited to pre-mRNA sites near exon junctions by a helicase termed **▶UAP56**, which functions in spliceosome assembly and also appears to have role in mRNA export beyond the recruitment of Aly/REF (4, 5, 6). A role for Aly/REF in the export of mRNAs is supported by observations that Aly/REF remains tightly bound to the spliced mRNA, antibodies to Aly/REF that prevent its interaction with RNA reduced export of mRNA in *Xenopus* oocytes and excess Aly/REF increased the efficiency of mRNA export in mammalian cultured cells. However, knock-down of Aly/REF expression in *Drosophila* cells by RNA interference showed that Aly/REF was not absolutely required for the export of mRNAs, suggesting that there are additional **▶export adapters** with redundant functions. In contrast, knock-down of TAP/NXF1 showed that it was absolutely required for mRNA export (4, 5, 6) (Fig. 3).

RNA Export. Figure 3 Cellular mRNA export is mediated by the heterodimeric export receptor TAP/NXF1-p15. TAP/NXF1 is structurally unrelated to karyopherins and does not require Ran-GTP. Export of mRNA is linked to earlier steps in RNA biogenesis. Most metazoan mRNAs contain introns. Splicing occurs co-transcriptionally and this is depicted on a pre-mRNA that is being transcribed by RNA polymerase II (RNAP II). Processing factors interact with RNAP II C-terminal domain and travel with the elongating complex to sites where they are needed. An assembled spliceosome is shown and UAP56, a splicing protein recruits the export adapter Aly/REF to a position just upstream of the exon 1-exon 2 junction. Aly/REF is part of the exon junction complex (EJC). The mature mRNA, which is capped at the 5' end, polyadenylated at the 3' end and decorated with EJCs at each exon junction, is exported via TAP/NXF1-p15, which interacts with the NPC. Some cellular mRNAs that are intronless have been shown to be exported by Aly/REF. Others have been found to use SR proteins as adapters. Other export adapters probably also exist.

It should be noted that although splicing can enhance RNA export from intron-containing genes, it is not an unconditional requirement because export factors can interact with RNA independently of splicing. For example, naturally intronless transcripts, such as those encoding histones, contain specific sequences that recruit export factors independently of splicing. Interestingly, two members of a highly conserved family of serine-arginine-rich splicing factors, termed **SR proteins**, have been shown to interact with TAP/NXF1 and to be involved in the export of intronless mRNAs. SRp20 and 9G8, two SR proteins that play essential roles in splicing also appear to have roles in mRNA export (5) (Fig. 3). There may be other adapter proteins that bring mature mRNAs to TAP/NXF1. In contrast to metazoans, in yeast, where fewer than 5% of genes encode introns, recruitment of export proteins has been shown to occur co-transcriptionally. Mex67p, the homologue of TAP/NXF1 is the export receptor and Yra1, the homologue of Aly/REF is the export adapter that is required for yeast mRNA export (4).

Clinical Relevance

Because export of RNA to the cytoplasm is essential for the cell to make protein, there are no known human diseases that result from defects in RNA export. In fact, a general strategy for the replication of animal viruses is to disrupt the export of cellular RNA and to hijack components of export pathways to favor viral gene expression and replication. Thus, part of the pathogenesis of viral infection results from the shut off of host gene expression. Viruses with a DNA genome, such as herpesviruses, or which go through a DNA intermediate, such as lentiviruses and retroviruses, replicate in the nucleus and these viruses have evolved strategies that give an export advantage to viral RNAs over cellular RNAs. Human immunodeficiency virus (HIV), a lentivirus, and retroviruses encode essential viral proteins within introns of viral pre-mRNAs, which are transcribed by the cellular RNA polymerase II. Thus, unspliced and partially spliced transcripts must be exported to the cytoplasm. To circumvent retention in the nucleus, HIV encodes a protein termed Rev, which binds to a highly structured region within an intron in HIV pre-mRNA, termed the Rev response element or RRE. Rev contains an NES and is able to bind to CRM1 (2, 6). Thus, Rev facilitates the export of unspliced HIV transcripts through the CRM1 pathway rather than the TAP/NXF1 pathway used by cellular mRNA. In contrast, unspliced pre-mRNA in retroviruses is exported *via* the TAP/NXF1 pathway. A part of the intronic RNA forms a stem loop structure, termed the constitutive transport element or CTE and TAP/NXF1 binds directly to the CTE without the need

of an adapter protein (2, 5, 6). In fact, expression of excess CTE-containing RNA can interfere with export of cellular mRNA by saturating TAP/NXF1 (5). Herpes simplex virus type 1 (HSV-1) presents a different situation. Most of its mRNAs are intronless and thus do not undergo splicing and therefore do not acquire EJC. HSV-1 encodes a protein termed ICP27, which interacts with splicing complexes resulting in the inhibition of host splicing (6). Thus, host transcripts are retained in the nucleus. ICP27 then recruits Aly/REF to sites of viral transcription providing intronless viral mRNAs access to the TAP/NXF1 pathway (6). Although influenza virus has a RNA genome rather than a DNA genome, it replicates in the nucleus of infected cells. Influenza also interferes with cellular mRNA export through a viral protein called NS1. Inhibition of transport by NS1 appears to be due to its ability to impair 3' end formation of cellular mRNAs through interaction with two cellular factors that are required for polyadenylation (2). Finally, RNA viruses that replicate in the cytoplasm have also been shown to disrupt cellular nucleocytoplasmic trafficking. Poliovirus appears to target two nucleoporins in the NPC causing their degradation during infection. As a result receptor: cargo complexes do not dock at the NPC of poliovirus-infected cells (7). In this case, cellular proteins that are normally nuclear but which enhance poliovirus replication are trapped in the cytoplasm. In sum, RNA export to the cytoplasm is essential for gene expression. Complex and separate pathways that involve different soluble receptors and redundant export adapters have evolved to ensure that all types of cellular RNAs are efficiently exported to the cytoplasm.

RNA Expression Profiling

Definition

RNA expression profiling comprises the determination of the pattern of genes expressed i.e. transcribed, under specific circumstances or in a specific cell by quantitative analysis of their RNA expression level.

► [Protein Microarrays as a Tool for Protein Profiling and Functional Proteomics](#)

RNA Interference

Synonym

RNAi

Definition

RNA interference (RNAi) (also called “double-stranded RNA mediated interference”) refers to the mechanism by which double-stranded RNA (dsRNA) specifically suppresses the expression of a gene bearing its complementary sequence. The dsRNA is processed into small interfering RNAs (siRNAs), assembled in endoribonuclease-containing complexes known as RNA-induced silencing complexes (RISCs) that consequently cleave, thereby destroy the transcript of the silenced gene, namely the cognate RNA. The term “RNA interference” was first used by researchers studying the worm *Caenorhabditis Elegans*.

Synonyms

Double-stranded RNA-mediated gene silencing; Small interfering RNA-mediated gene silencing; Sequence-specific post-transcriptional gene silencing by double-stranded RNA

Definition

► [RNA interference](#) (RNAi) describes a mechanism of gene silencing in which double-stranded RNA (dsRNA) with identical sequence to a target mRNA mediates the destruction of the target. Target mRNA degradation is catalyzed by the multi-protein complex ► [RISC](#) (RNA-induced silencing complex), which recognizes dsRNA and cognate mRNA. This results in a reduction of the encoded protein and in the suppression of gene function (for review see (1, 2)).

Characteristics

RNAi was first detected in the nematode ► [Caenorhabditis elegans](#) and in plants and serves as a defence mechanism for the protection of cells against parasitic nucleic acids such as viral genomes. Despite its original recognition as a biological oddity, RNAi was very rapidly applied as a powerful genetic tool and genome-wide RNAi screens of gene functions were performed in *C. elegans*. For example, the factors regulating fat metabolism were analyzed systematically by RNAi (3). RNAi has gained particular attention among geneticists, molecular biologists and scientists in the field of experimental therapy for two reasons. Firstly, after sequencing of the human, mouse and rat genomes, simple experimental approaches are required that permit functional analysis of the vast number of annotated genes and of yet ill-defined potential genes. Secondly, genome-wide screenings for genes specifically expressed in normal development and physiology and in disease based on ► [microarray technology](#) and on alternative approaches such as ► [serial analysis of gene expression](#) (SAGE) or differential expression cloning have yielded large numbers of disease-associated candidate genes as well as ► [gene clusters](#) that need to be tested for functional involvement.

RNA interference became particularly prominent in the field of molecular medicine following reports from Tuschl's group in Germany and from Morgan's group in the USA who showed that mammalian genes can be effectively silenced by virtue of incorporation of short 19–21 nucleotide dsRNAs into somatic cells. Earlier reports had already suggested that sequence-specific gene silencing occurred following injection of 500 nucleotide long dsRNA into mouse embryos and embryonal cell lines (for review see (1)). Unlike in invertebrates and plants however, dsRNA of >30 nucleotides in length provoked antiviral/interferon

responses in somatic mammalian cells and induced a generalized translational repression and cell death. This non-specific response occurred even in cells devoid of effector proteins of the interferon pathway such as ▶PKR (dsRNA-dependent protein kinase) and IRF1 (▶interferon-regulatory factor 1). dsRNA <30 nucleotides in length, transiently administered to somatic mammalian cells using commonly available transfection procedures, did not induce non-specific responses. Rather, small interfering RNAs (▶siRNAs) mediated efficient silencing of the cognate mRNA. The siRNAs were synthesized chemically as 19 nucleotide fragments with two 3'-overhangs on each strand. An alternative to the costly chemical synthesis is *in vitro* transcription from DNA oligonucleotides using T7 polymerase followed by annealing of the two RNA strands. Chemically or enzymatically synthesized siRNAs are transiently transfected into mammalian cells using lipofection or electroporation or a combination of both methods. Directly transfected siRNAs exhibit efficient silencing at concentrations ranging from 0.05 to 20 nM. A typical transient siRNA-mediated silencing effect may last for 2–7 days, depending on the abundance of the cognate mRNA and protein, their stability and the efficacy of *de novo* transcription. The silencing effect is also diluted by cell division in the manipulated cells. The transient gene knockdown suffices for analyzing phenotypic effects, provided that rapid and robust cellular readouts for gene function are available. The currently accepted mechanism of RNA interference in mammalian cells is depicted in Fig. 1.

An example for siRNA-mediated knockdown of three closely related mRNAs encoding Raf-kinase isoforms is shown in Fig. 2. Many growth factor-receptor-mediated signals converge on Raf effector proteins. Raf-kinases may be activated by mutation in cancer and are being exploited as targets for therapeutic intervention. The isoform-specific knockdown demonstrates the high specificity of RNAi-mediated gene silencing and emphasizes its power for functionally dissecting complex signal transduction pathways as well as its potential for experimental therapy.

As an alternative to the incorporation of exogenous dsRNAs by common transfection procedures, siRNAs can be synthesized directly in cells through the expression of short hairpin RNAs (shRNAs). Such endogenously expressed shRNAs were initially detected in *C. elegans*. shRNAs fold back on themselves, creating a region of dsRNA and a loop structure. The mature siRNAs are produced by enzymatic removal of the loop. To overcome the disadvantages of transient siRNA expression, various retroviral expression systems have been developed. Most expression systems employ polymerase III promoters to drive the interfering RNA expression. It is noteworthy, however, that

RNA Interference in Mammalian Cells. Figure 1 A model for RNA interference in mammalian cells (ref.1). This model is deduced from dsRNA-induced silencing mechanisms which were commonly detected in plants, fungi and metazoans. The silencing mechanism begins with the processing of dsRNA silencing triggers into siRNAs by Dicer, a nuclease belonging to the family of RNase III proteins. The triggers are expressed from RNA polymerase III promoters. siRNAs bind to a multiprotein nuclease complex called RISC (RNA-induced silencing complex). RISC targets the cognate mRNA resulting in cleavage and degradation. Small interfering RNAs synthesised chemically or enzymatically by *in vitro* transcription using T7 polymerase from DNA templates can be incorporated directly into RISC, obviating Dicer activity. In contrast to the silencing mechanism in *C. elegans*, RNAi is not a self-propagating effect in mammalian cells. In nematodes, siRNAs can prime RNA-dependent RNA polymerases (RdRPs) along the targeted mRNA sequence to produce dsRNA homologous to upstream sequences of the initially targeted sequence. This results in an amplification of the RNAi effect throughout the nematode.

transient gene silencing may reveal the immediate effects of functional gene loss, while stable suppression of gene activity may allow adaptation processes in variant cell lines to occur.

Algorithms for designing siRNAs are available on-line from various public and commercial web sites. The initially established rules for siRNA selection had

RNA Interference in Mammalian Cells. Figure 2 Transient siRNA-mediated silencing of Raf-kinase isoforms in transformed mouse NIH/3T3 cells. Optimal silencing effects were detectable at 48h (**A-Raf**), 24 (**B-Raf**) and 48-72h (**c-Raf-1**) post-transfection. mRNA levels related to non-targeted isoforms remained unaffected at the indicated time intervals. **GAPDH**, RT-PCR control. siRNA duplexes were transfected twice in 24 h intervals using Oligofectamine. RNA was prepared from transfected cells 24-72 hr post-transfection and analysed by RT-PCR.

suggested not to target regions of the cognate mRNA that might bind to regulatory proteins, i. e. sequences close to the start site and to 5' and 3' untranslated regions (UTR). Twenty-three nucleotides conforming to the consensus sequence 5'-AA[N19]UU-3' (where N is any nucleotide) are selected from the mRNA. The selected sequence is subjected to [BLAST](#) analysis in order to exclude targeting of closely related mRNA sequences. The optimal GC-content of siRNA is between 30–70%. The siRNA is then constructed by designing sense and anti-sense N19 sequences, each with two 3' 2-deoxythymidine residues at the end. For choosing shRNA-targeting sequences, similar rules were initially applied (1). A targeting sequence of 5'-(N18-28)C-3' (where N is any nucleotide) is selected from the target mRNA. More recently, several authors have systematically investigated the sequence requirements for efficient RNAi by comparing multiple siRNAs targeting the same exogenous or endogenous genes. Additional rules were established including the positioning of A/U at the 5' end of the antisense strand, G/C at the 5' end of the sense strand, allowing at least

five A/U residues in the 5' terminal one-third of the antisense strand and avoiding any GC stretch of more than nine nucleotides in length (4). Others reported that duplexes targeting the middle of the coding sequence exhibited a poorer silencing effect, while targeting the 3' UTR was as efficient as targeting the coding sequence. Pooling of four or five duplexes per target gene was particularly efficient and efficient duplexes showed nucleotide preferences at positions 11 and 19 of the siRNA duplex (5). Yet another publication lists several characteristics for good siRNA functionality including low G/C content, lack of inverted repeats and sense strand base preferences affecting positions 3, 10, 13 and 19 (6).

RNA Interference – the Issue of Specificity

While efforts to optimize the efficacy of RNAi toward the target mRNA have quickly produced a substantial list of successfully silenced genes, “collateral effects” of siRNAs were initially neglected. The properties of siRNA-mediated gene silencing were analyzed on a genomic scale using the [enhanced green fluorescent](#)

protein (EGFP) of *Aequoria victoria* as a targeted transgene, because it has no known physiological role in the recipient cells (7). Neither the presence of EGFP nor its silencing was likely to perturb the transcriptome. To prove or disprove this assumption, cells retrovirally transduced with the EGFP-construct were transfected with siRNA targeting EGFP, with siRNAs representing scrambled EGFP sequences and mock transfected. 36K cDNA microarrays were interrogated with target RNAs prepared from transfected cells and the expression patterns were compared. No obvious changes in mRNA levels were observed indicating that “off-target” gene expression perturbation was not associated with siRNA-mediated gene silencing. In addition, Chi et al. did not find any evidence for “transitive” RNAi effects as has been shown in *C. elegans* (see Fig. 1). In contrast to this, other authors have reported off-target gene regulation by RNAi (8). siRNA directed against an exogenous luciferase gene regulated the expression of several endogenous genes despite the lack of a homologous target in the human genome. In experiments aimed at silencing mitogen-activated protein kinase 1 (p38 α), a signaling pathway effector kinase, the authors demonstrated that nine genes were silenced with similar kinetics, although none of them served a known functional role in the corresponding signaling pathway. In further kinetic experiments with siRNA molecules exhibiting various nucleotide exchanges deviating from the perfect targeting sequences, Jackson et al. found that “collateral” or off-target silencing may occur when as few as 11 contiguous nucleotides

matched the target mRNA. In conclusion, gene knockdown can occur as a result of degradation of mRNA targets with partial identity to the siRNA sequence in conjunction with the robust silencing of the desired target. Yet another important caveat has to be taken into account when the phenotypic effects of siRNA-mediated gene targeting are assessed. Although initial reports indicated that short interfering RNA duplexes do not elicit non-specific interferon-dependent cellular responses, a recent publication reports that efficient siRNA-mediated silencing of GAPDH, a housekeeping gene, induced activation of the Jak-STAT pathway and a global up-regulation of interferon-stimulated genes (9). This effect was not sequence-specific, since the silencing of five additional target genes had the same effect. In addition, the authors provided evidence that the off-target effect is mediated by the dsRNA-dependent protein kinase PKR. In conclusion, peer reviewers will ask future authors of publications based on RNA interference in mammalian cell cultures and mice, what kind of controls have been considered to exclude off-target silencing effects.

Genome-Wide Functional Screens in Mammalian Cells

Two very recent publications reveal the full power of RNAi application in mammalian cells. Two groups have generated retrovirus-based libraries comprising at least three shRNAs targeting about one third of human genes for suppression. One library was used to search for genes that modulate the function of the tumor

RNA Interference in Mammalian Cells. Table 1 Applications of RNAi in disease models

Model	Targeted gene	Phenotype
Hepatitis	<i>Fas</i> receptor	Prevention of infection and death
Acute liver failure	Caspase 8	Prevention of Fas-mediated cell death
HIV infection	HIV-encoded <i>Tat</i> and <i>Rev</i>	Inhibition of HIV-1 replication in cultured cells
Influenza infection	Influenza virus encoded nucleocapsid and reverse transcriptase	Prevention of virion RNA accumulation in cell lines and chicken eggs
Chronic myeloid leukemia	Bcr/abl	Decrease of bcr/abl expression and kinase activity
Drug resistance	<i>MDR1</i>	Decrease of drug resistance in several carcinoma cell lines
Oncogene-mediated tumorigenesis	<i>KRAS</i>	Loss of anchorage independence and tumorigenicity
Familial cylindromatosis	<i>CYLD</i> (among 50 de-ubiquitination genes)	Detection of gene in a cancer-related pathway Enhancement of NF κ B activation and prevention of cell death
Amyotrophic lateral sclerosis	Cu, Zn superoxide dismutase (<i>SOD1</i>) mutant	Protection of cultured neuroblastoma cells against cyclosporine A-induced cell death

suppressor p53 in a cell system indicative for bypassing p53-dependent growth inhibition. Screening of approx. 8,000 human genes identified 6 genes, including 53 itself, whose knockdown confers resistance to growth arrest (10). The second library comprising shRNAs targeting approx. 10,000 human genes was screened to identify components of the proteasome, which is responsible for regulated protein degradation in the cell. As a read-out for suppressed proteasome function mediated by shRNA, the authors used a reporter assay based on mouse ornithine decarboxylase coupled to a fluorescent protein. When the shRNA library was co-transfected with the reporter, transfectants exhibiting reporter protein accumulation were recovered, indicating that proteasomal function was impaired. Fifteen genes encoding known proteasome subunits were identified in this way (11). Thus, systematic [reverse genetics](#), a powerful approach for dissecting gene function in *C. elegans*, is no longer a desirable option for mammalian cells, but has become a reality. RNAi may indeed revolutionize reverse genetic approaches provided that the collateral or off-target effects can be controlled properly.

Clinical Relevance

Very quickly after the reports on successful RNAi in cultured mammalian cells, sequence-specific silencing of transgenes was demonstrated in mice. Transgene expression was suppressed following hydrodynamic transfection of synthetic siRNAs into the liver (12) or by injection into the tail vein (13). Several reports describe the use of sequence-selective siRNAs in various *in vitro* and *in vivo* models for cancer, viral infection and genetic disorders. Some selected examples of siRNA application in model systems are shown in Table 1 (for review see (14)).

RNA Maturation

Definition

The primary transcript of a gene (called heterogeneous nuclear RNA; hnRNA) is processed in the nucleus to produce the mature mRNA, e.g. the 3' end is modified by adding a stretch of adenosine nucleotides, and the non-coding introns are excised in a process called splicing.

- Full Length cDNA Sequencing
- Heteronuclear RNP Proteins

RNA Polymerase

Definition

The enzyme RNA Polymerase I is responsible for the synthesis of RNA from a DNA template ([► transcription](#)). Prokaryotic gene expression involves one type of RNA polymerase. In eukaryotes, three different types of RNA polymerase exist that each transcribe specific sets of genes.

1. RNA Polymerase I is located in the nucleolus and synthesizes only a single type of product, the

ribosomal RNA (rRNA), RNA Polymerase I accounts for the majority of RNA synthesis within the cell, transcribing all genes coding for rRNA.

2. RNA Polymerase II (POL II) is located in the nucleoplasm and synthesizes the messenger RNA (mRNA) precursor, heterogeneous nuclear RNA (hnRNA). All protein coding genes of the cell, whether they are constitutively expressed, developmentally regulated or restricted to certain types of tissues, are transcribed by RNA Polymerase II.
3. RNA Polymerase III (POL III) synthesizes transfer RNA (rRNA) and other small RNAs which are involved in the genetic translation of mRNA into the amino acid sequences of protein molecular (amino acyl tRNA). Some viral genes, such as some adenovirus and ▶Epstein-Barr virus genes, are also transcribed by RNA Polymerase III. RNA Polymerase III transcripts are generally very short (less than 300 nucleotides), and never encode any proteins.

RNA Polymerase I, II and III can be distinguished by their α -amanitin sensitivity, which is not sensitive, sensitive and species-specific, respectively.

Synonyms

DNA-dependent RNA polymerase I (Pol I or RNAP I); in *S. cerevisiae* also referred to as RNA polymerase A (Pol A). For the purpose of this overview, we will primarily discuss mammalian RNA polymerase I transcription.

Definition

DNA-dependent ▶RNA polymerases catalyse the sequential incorporation of ribonucleotides complementary to a DNA template in a 5' to 3' direction to produce a primary RNA molecule or ▶transcript, a process referred to as ▶transcription. Eukaryotes have three nuclear RNA polymerases that are multi-subunit complexes with core subunits evolutionarily conserved with those of the DNA-dependent RNA polymerases from *Archaea* and prokaryotes. The RNA polymerase I (Pol I) enzyme complex in most eukaryotes is solely responsible for transcription of the ▶ribosomal DNA genes, which are found in multiple copies in eukaryotic cells. Transcription of rDNA by Pol I occurs in a distinct subcompartment of the nucleus, the ▶nucleolus, and yields a primary ribosomal RNA transcript, which is processed into the mature 18S, 5.8S and 28S rRNAs (1). Following RNA modification, the rRNAs are assembled together with ribosomal proteins into pre-ribosomal subunits. These then exit the nucleolus and are exported from the nucleus to sites in the cytoplasm or endoplasmic reticulum where, with the help of tRNAs, the ▶ribosomes translate mRNAs into proteins. The rRNAs produced by Pol I are not simply a structural component of the ribosome but in fact catalyse peptide bond formation during protein synthesis on the ribosome (2).

Characteristics

RNA Polymerase I Transcription of rRNA Genes and Ribosome Biogenesis

On average a eukaryotic cell contains between 2 and 10 million ribosomes, the protein synthesis machinery. While these RNA-protein complexes are relatively stable, cell growth and subsequent division requires a doubling of the number of ribosomes. Transcription of the rDNA genes by RNA Pol I drives this production of ribosomes. In an actively growing eukaryotic cell, a large proportion of nascent RNA synthesis (more than 50%) is accounted for by the activity of Pol I, which constitutes a considerable energy expenditure to the cell. Therefore, several mechanisms have evolved to control transcription tightly and to balance the production of ribosomes with demand during cell growth and division (3, 4, 5, 6). Moreover, control of Pol I transcription is coordinated with the activities of the other two nuclear RNA polymerases, whose products contribute to ribosome biogenesis directly (i.e. the 5S ribosomal RNA synthesized by Pol III and the messenger RNAs synthesized by Pol II encoding the many ribosomal proteins) or to protein synthesis in general (i.e. the transfer RNAs synthesized by Pol III and the mRNAs synthesized by Pol II).

Structural and Spatial Organisation of Genes Encoding Ribosomal RNAs

There are at least 100 copies of the rDNA gene in a eukaryotic genome (in the human genome there are an estimated 400 copies). Presumably these levels are necessary to meet the demands of ribosome production in actively growing and dividing cells, though interestingly only about 50% of the genes are actively transcribed at any one time. There is an inverse correlation between densely packed nucleosomes and the transcriptional activity of the rDNA genes, as inferred from electron microscopy and psoralen photo-cross-linking experiments. Concerted changes in DNA methylation and histone modification mark the switch between active and non-active gene status (7).

The multiple copies of the rDNA genes are organised as tandem head-to-tail repeat units and in humans these rDNA clusters are located on the short arms of the five **▶acrocentric chromosomes** 13, 14, 15, 21 and 22. These chromosomal rDNA loci are referred to as the **▶nucleolar organising regions** (NORs) around which the nucleolus is formed. Each unit (in humans ~43 kb) contains an intergenic spacer (IGS)(~30 kb) and sequences transcribed by Pol I that encode the pre-rRNA (~13 kb). The repetitive nature of the rDNA is discernable in electron micrographs of nuclear **▶chromatin** spreads (Fig. 1). Non-transcribed DNA strands are interspersed with regions of densely packed polymerases engaged in transcription of the rDNA giving a 'Christmas tree' pattern as the primary transcripts emanating from Pol I complexes (the branches) grow with the distance the polymerases have travelled along the rDNA (the trunk) from the start site of transcription. In yeast, each repeat also contains a copy of the 5S rRNA gene in the IGS, transcribed by Pol III in the opposite direction to rDNA transcription by Pol I. The transcribed regions of the repeats encoding the major rRNAs are highly conserved and the alignment of encoded rRNAs in a pre-rRNA gene is always in the same order, 18S, 5.8S and 28S, and dictates the order of pre-rRNA processing and assembly of pre-ribosomal subunits. The non-transcribed spacer regions vary considerably between species. These contain the regulatory elements such as the **▶promoter** DNA region, which directs initiation of transcription, **▶enhancer** sequences that stimulate transcription initiation at the promoter and **▶terminator** elements 3' of the rRNA gene cluster that direct termination of transcription. The spacers also contain various other sequence elements including an origin of DNA replication, a DNA replication fork barrier and many repetitive sequence elements of unknown function.

Active transcription by Pol I of the rRNA genes is essential for the formation of nucleoli. The nucleolus

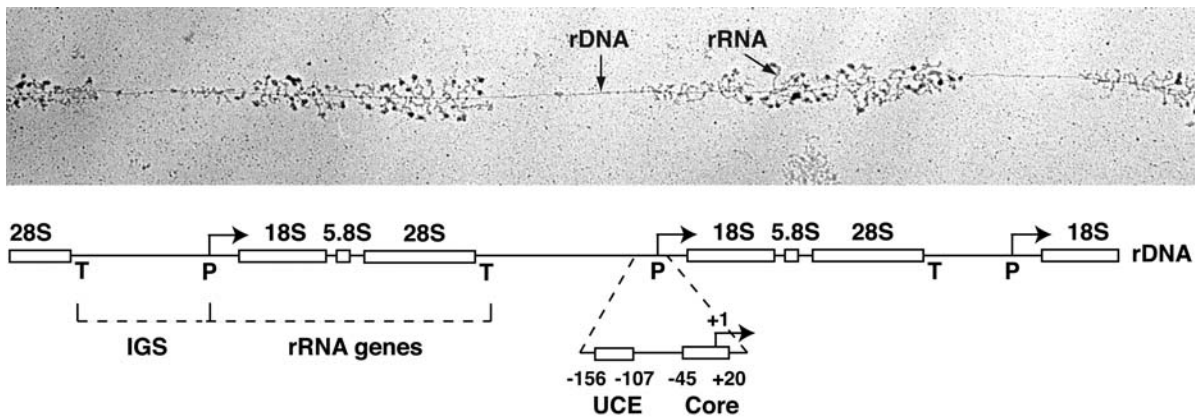

displays distinct structural features that may be linked to different functions. The fibrillar centres (FC) contain Pol I and the transcription factors important for transcription of the rDNA repeats. Transcription of the rDNA is thought to occur at the boundary of the FC and the surrounding dense fibrillar component (DFC). The DFC is where the pre-rRNAs are thought to be processed (endonucleolytic cleavages and exonucleolytic trimming) and modified (pseudo-uridylation and 2'-O-methylation), guided by a large number of small nucleolar ribonucleoprotein particles (snoRNPs) and, in part, this may occur co-transcriptionally. Surrounding these domains is the granular component where the assembled pre-ribosomal particles are found (8).

Pol I transcription is subject to cell-cycle control. Pol I transcription ceases when cells enter mitosis, concomitant with nucleolar disassembly. Some of the components of the Pol I transcription machinery stay attached to the rDNA in the condensed chromosomes throughout mitosis, whereas the Pol I enzyme itself appears to be transiently released. Upon completion of cell division and chromosome decondensation, transcription resumes and the nucleoli reform around transcriptionally active NORs. The emerging small multiple nucleoli grow and then fuse to form larger nucleoli, the size and number of which is in part dependent on the total level of Pol I activity in the cell.

RNA Polymerase I Transcription Machinery: Pol I and Transcription Factors

The core Pol I enzyme contains 14 subunits in *S. cerevisiae*, which have been cloned, and, with one exception, homologues for all of these have been identified in mammals. Seven of the subunits are unique to Pol I, two are shared between Pol I and Pol III and five are common to all three nuclear polymerases. It has been speculated that the shared subunits allow the organism to exert coordinate control over transcription by the three nuclear RNA polymerases, whereas the unique subunits bestow the core polymerase with the specificity required for control of the expression of specific subsets of genes. The two largest subunits of Pol I form the catalytic core of the enzyme and, while distinct for this polymerase, these subunits share considerable homology with the largest subunits of all other eukaryotic RNA polymerases.

Pol I itself, as with all eukaryotic nuclear RNA polymerases, is unable to recognise promoter sequences. **▶Transcription factors** with promoter sequence-specific DNA binding activity recruit Pol I to the start site of transcription, which is defined by the promoter DNA elements. A eukaryotic rRNA gene promoter consists of two elements (Fig. 1), the core element (in humans from -45 to +20, relative to the transcription start site at +1), which is essential and

RNA Polymerase I Transcription. Figure 1 Ribosomal DNA repeat organization. The electron micrograph (kindly provided by Dr Ann Beyer, University of Virginia, USA) shows two complete rDNA repeats in a chromatin spread from yeast cells. Transcription in these rDNA repeats proceeds from left to right, and the rRNA emanating from the RNA polymerase I molecules (themselves not clearly visible) is indicated. The dense particles associated with the rRNA are rRNA processing complexes. Underneath is a schematic representation of the two rDNA repeats. The rRNA genes encode the 18S, 5.8S and 28S rRNAs, which are produced by Pol I as a single transcript. The transcription start site (arrow) lies within the promoter (P). Transcription stops at the terminator (T). The non-coding and generally non-transcribed regulatory region of the repeat is referred to as the intergenic spacer (IGS). The human rDNA promoter region, with the upstream control element (UCE from -156 to -107) and the core (from -45 to +20, relative to the transcription start site at +1), is shown enlarged beneath one of the rDNA repeats.

directs specific initiation of transcription and the upstream control element (UCE, from -156 to -107). The exact spacing between these elements is important for the UCE to fulfil its role in stimulating transcription from the core. While the primary sequences are not conserved from human to yeast, the overall organisation of the two promoter elements does appear to be conserved.

The transcription factors required to achieve efficient promoter-specific initiation of Pol I transcription include ►SL1 (selectivity factor 1) (or murine TIF-IB) and ►UBF (upstream binding factor) in mammals and core factor (CF), TBP (TATA-binding protein), Hmo1 and upstream activation factor (UAF) in yeast (9, 10).

UBF is involved in the activation of Pol I transcription. Mammalian UBF, a 97 kD protein, contains several ►HMG (high mobility group) boxes, which are structural motifs of non-histone chromosomal HMG proteins, involved in binding the minor groove of the DNA and in DNA bending. UBF contains an amino terminal dimerisation domain important for activation of transcription. A dimer of UBF can organise approximately 140 bp of DNA into a single 360° loop and it has been suggested that UBF functions as an architectural protein at the promoter, binding the UCE and core elements and leading to a stereo-specific alignment of these elements. Due to the relaxed sequence specificity of binding by UBF, UBF distribution in the rDNA repeats is not restricted to these

regulatory elements however, suggesting it may have a more global role in influencing DNA topology throughout rDNA repeats. UBF can displace a linker histone H1 from a DNA-nucleosome assembly, suggesting a possible role in chromatin remodelling and antirepression. UBF also activates Pol I transcription by increasing productive transcription initiation events. Direct interactions of UBF with SL1 and Pol I subunits may be important for this. In one model, this activation was suggested to occur as a result of increased ►preinitiation complex formation, but evidence is emerging that UBF may have a role in stimulating events occurring subsequent to the formation of preinitiation complexes. In yeast, a single HMG-box containing protein, Hmo1, stimulates Pol I transcription, perhaps functioning similarly to UBF in vertebrates.

SL1 is capable of the independent recognition and binding of the mammalian rRNA gene core promoter. SL1 is a multimeric peptide complex of ~300 kD comprised of TBP (►TATA box binding protein) and at least three TAFs (►TBP-associated factors) specific to the Pol I transcription machinery, including TAF_{110/95}, TAF_{63/68} and TAF₄₈. TBP has a role in the initiation of transcription by all three nuclear polymerases in complex with subsets of TAFs that define its polymerase specificity. The TAFs of the SL1 complex confer upon SL1 the ability to position itself precisely at the core element of the rRNA gene promoter. Unlike the polymerase and UBF components of the Pol I

transcription machinery, SL1 is not interchangeable between species and indeed was named for its selective role in directing species-specific transcription. The promoter sequences of the rRNA genes are divergent between species and the TAFs in SL1, which have only limited sequence similarity between species, are responsible for sequence-specific promoter recognition. In *S. cerevisiae*, CF (core factor) appears to function like SL1, binding the core promoter element. Although, unlike SL1, CF is not stably associated with TBP, it does contain three subunits, Rrn6p, 7p and 11p, two of which have limited homology to the TAFs of SL1. TBP in yeast is found associated with upstream activating factor (UAF), a multiprotein complex consisting of Rrn5p, 9p, 10p, Uaf30p and histones H3 and H4. UAF stably interacts with the upstream DNA element in the yeast rDNA promoter. In mammals, UBF and SL1 remain stably associated with the promoter following transcription initiation by Pol I, potentially providing a re-initiation scaffold, whereas in yeast, UAF remains promoter-bound and CF dissociates from the promoter. At present no UAF-like complex has been identified in mammalian cells. The RNA polymerase II basal factor TFIID has also been shown to play a role in transcription by Pol I, although its precise function in this process remains unknown.

Different forms of the Pol I complex have been isolated in which the core enzyme (~600 kD) is associated with different subsets of polypeptides to form complexes of >1 MD. The majority of these Pol I complexes (Pol I α) are incapable of directing the initiation of transcription specifically from the rRNA gene promoter. Initiation competent Pol I complexes comprise only about 10% of the Pol I complexes of the cell (Pol I β) and are distinguished by the presence of the polypeptide hRRN3 (or murine TIF-IA), which is functionally conserved from human to yeast. SL1, or CF in yeast, recruits the initiation competent Pol I to the promoter *via* the interaction of its subunits with RRN3 in the Pol I complex. Following transcription initiation, the inactivated hRRN3/TIF-IA dissociates from Pol I, with conversion of the polymerase from the initiating to the elongating form. Other polypeptides associated with the Pol I core enzyme include kinases, components of the DNA repair and DNA replication machineries and proteins involved in chromatin remodelling. Their precise roles in Pol I have yet to be defined.

The Mammalian Pol I Transcription Cycle

Pre-initiation complex formation is an important and highly regulated step in Pol I transcription, involving the recruitment by SL1 of initiation competent Pol I containing the hRRN3/TIF-IA protein to the promoter (Fig. 2). SL1 also interacts with UBF, resulting in cooperativity in promoter DNA binding by these

RNA Polymerase I Transcription. Figure 2 RNA polymerase I and transcription factors SL1 and UBF in the formation of a transcription preinitiation complex at the human rDNA promoter. Selectivity factor SL1, a TBP-TAF complex, binds the rDNA core promoter element. SL1 interacts with hRRN3 associated with Pol I and consequently recruits and positions the initiation-competent form of Pol I (Pol I β). Transcription activator upstream binding factor (UBF) binds the rDNA promoter cooperatively with SL1, bending the promoter region substantially. Transcription initiation follows preinitiation complex formation.

factors. After promoter opening and conformational changes in the pre-initiation complex, Pol I incorporates the first few nucleotides and escapes the promoter. This rate-limiting step may be stimulated by the transcriptional activator UBF. The transition from the initiating to elongating form of the polymerase involves conformational as well as compositional changes of the Pol I enzyme complex. Elongation might require nucleosome displacement or rearrangement and the chromatin remodelling activities associated with the polymerase. Elongation may also be facilitated by TIF-IC, a factor associated with murine Pol I, as well as TFIIS, a known Pol II elongation factor. DNA topoisomerase activity may be required for relief of

the torsional strain accumulated during transcription. Transcription terminates at a T-rich sequence followed by an array of terminator sequences, to which TTF-1 (transcription termination factor-1) protein is bound. Dissociation of the transcripts from the terminated Pol I complex is mediated by PTRF (polymerase I and transcript-release factor). TTF-1 has also been implicated in the recruitment of chromatin remodelling activities to a terminator site just upstream of the UCE of the rDNA promoter, which thereby modulate chromatin structure and accessibility of the promoter.

Regulation of rDNA Transcription

Cell growth and division is dependent on the capacity of the cell to synthesize proteins, and this is related to the number of ribosomes. Under conditions of active growth and division, for example during early embryonic development, a cell can augment the efficiency of rDNA transcription, which drives ribosome biogenesis. There are two ways for cells to modulate the level of rDNA transcription, to change the frequency of loading of Pol I molecules onto already active genes and/or to engage more of the rDNA genes in transcription. Signal transduction pathways activated by growth factors, such as those including phosphatidylinositol 3-kinase (PI3K) and mitogen-activated protein kinase (MAPK), or influenced by nutrient availability of the cell, such as the mammalian target of rapamycin (mTOR) pathway, have been demonstrated to regulate Pol I transcription. For example, EGF or serum-induced activation of the MAPK pathway and nutrient regulated activation of the mTOR pathway lead to phosphorylation and modulation of the activities of UBF and Pol I-associated TIF-IA (RRN3). Phosphorylation of yRrn3 influences Pol I recruitment to the rDNA promoter. Growth factor stimulation of cells has also been demonstrated to increase the occupancy of the rDNA promoter by SL1. These same signalling pathways are known to regulate the activity of chromatin remodelling activities, which may be relevant for the activation of previously silent rRNA genes. The level of ribosome biogenesis appropriate to the external and internal cellular conditions can therefore be achieved through the control of rRNA synthesis *via* a multitude of signalling pathways and mechanisms.

Shutdown of Pol I transcription during mitosis and its reactivation upon entry into interphase is also regulated by the phosphorylation and dephosphorylation of components of the transcription machinery. SL1 and UBF, for instance, are phosphorylated by Cdk/cyclin complexes. Additionally, Pol I transcription can be directly modulated by casein kinase II (CK2) and cell-cycle regulators including the tumour suppressor proteins p53 and retinoblastoma (RB).

Clinical Relevance

Normal cell growth and proliferation require tight regulation of protein synthesis at the global level of the protein synthesis capacity of the cell as well as at the level of expression of individual protein-coding genes. The net result of up-regulated protein synthesis is the ability of cells to support runaway growth and proliferation. In most, if not all tumour cells, Pol I transcription and ribosome production appear elevated and there are also examples of tumour cells with increased levels of the proteins involved in Pol I transcription, such as UBF. The size and number of nucleoli, detectable following silver staining of tissue samples, reflects Pol I transcription levels and has been used for many years by tumour pathologists as a prognostic marker for the proliferative capacity of cells. Many proto-oncogenes and tumour suppressor proteins can regulate rRNA synthesis and so it is possible that deregulated Pol I transcription can be a predisposition for cancer susceptibility (11). Pol I synthesis of the rRNAs permits cell growth and division through ribosome biogenesis, but it is also likely that Pol I transcription itself regulates cell growth under certain circumstances. It is therefore crucial to understand the mechanisms and signalling pathways that control Pol I transcription of the rRNA genes. This may lead to the development of procedures to regulate Pol I transcription in different disease states.

The link between up-regulation of Pol I transcription and cancer and the lack of mutations associated with human diseases in components of the Pol I machinery both reflect the requirement for stringent control of Pol I transcription to achieve normal cellular growth.

bensaude@wotan.ens.fr

Definition

DNA-dependent RNA polymerases (RNAP) catalyze the synthesis of an RNA copy (transcript) of a DNA template. The α -phosphate of an incoming nucleotide triphosphate is ligated to the ribose 3'-OH of the last nucleotide incorporated in the elongating chain and a pyrophosphate molecule is released. Eukaryotic cells use three distinct but related enzymes, each specialized in transcription of a distinct subset of genes, RNAP I, RNAP II and RNAP III. RNAP II transcribes into pre-messenger RNAs (pre-mRNA) all genes that code proteins as well as many genes that specify small non-coding RNAs (snRNA). It is usual to distinguish three major steps in the synthesis of transcripts, initiation, elongation and termination. Following their synthesis, the transcripts undergo several modifications (processing or maturation). The 5' end of messenger RNAs (**►mRNAs**) is protected by addition of 7-methyl guanosine on the protruding triphosphate (capping). Intervening sequences or introns are excised and exons religated (splicing). The primary transcript is cleaved at a specific site (cleavage) followed by the addition of a polyadenylic tail extending over hundreds nucleotides (**►polyadenylation**). The coupling between transcription and processing of the primary transcript is an important characteristic of class II gene transcription. Processing and transcription occur within discrete nuclear structures, the transcription factories.

Characteristics

Structure of RNA Polymerase II

The yeast and mammalian RNA polymerases comprise 12 protein subunits ranging from 10 to 210 kD in

molecular weight thus forming complexes of 500 kD. Most subunits are specific for each polymerase but some are common to RNAP I, RNAP II and RNAP III. Five subunits are orthologues of the prokaryotic RNA polymerase subunits. Rpb1, the largest RNAP II subunit, possesses a unique carboxyl-terminal domain (CTD) made of multiple repeats of a seven amino-acid motif (Tyr₁-Ser₂-Pro₃-Thr₄-Ser₅-Pro₆-Ser₇) that has been conserved throughout evolution.

The yeast RNAP II has been crystallized and the resolution of its structure at 2.8 Å has been a *tour de force*. The transcribed double-stranded DNA tunnels through the enzyme and, in the vicinity of catalytic site, the complementary base pairs are disrupted forming a transcription “bubble” (Fig. 1). RNA is synthesized complementary to one DNA strand in the bubble. The CTD is localized next to the RNA exit site and plays a critical role in controlling the initiation and the elongation steps as well as in coordinating the maturation events.

Sequential Steps in the Transcription Cycle

Preinitiation and Initiation Steps

RNAP II is recruited on promoters through interactions with regulatory transcription factors, general transcription factors and coactivators. The regulatory transcription factors recognize characteristic DNA sequences and determine the pattern of gene expression as a function of cell type and extracellular signals. The general transcription factors (TFIIA, B, D, E, F, H) assist the assembly and the precise positioning of RNAP II within a “pre-initiation complex” (PIC) of transcription. The coactivators such as the mediator and/or chromatin modifying complexes relay the regulatory factor signaling to the general transcription factors. The core RNAP II may bind coactivators such as the mediator complex and form a holoenzyme prior to interacting with the promoter region. The double-stranded DNA opens within the PIC to generate a transcription bubble (Fig. 1). As transcription initiates, the polymerase dissociates from the preinitiation complex to proceed (promoter clearance). Formation of the transcription bubble and promoter clearance require the ATP-dependent DNA helicase and kinase activities of the general transcription initiation factor **►TFIIH**.

Protein Phosphorylation Governs the Entry into the Elongation Step

The CTD is not phosphorylated in pre-initiation complexes and its phosphorylation contributes to the disruption of the interactions with the mediator complex and with the general transcription factor TFIID. The CTD is phosphorylated first on the serines at position 5 in the repeated motif by CDK7, the kinase subunit of TFIH. Elongation of transcription beyond

RNA Polymerase II Transcription. Figure 1 The yeast RNAP II elongation complex. (a) Schematic presentation of the arrangement of nucleic acids during RNA chain elongation. The DNA template and non-template strands are in blue and green, respectively, and the RNA is in red. The active site metal ion A is indicated by a pink sphere. Protein elements that are proposed to be involved in the maintenance of the arrangement of nucleic acids are indicated. (b) Cutaway view of the RNAP elongation complex. Cut surfaces are lightly shaded. During transcription, DNA enters the enzyme from the right (the polymerase moves to the right). Structural features that appear to be important for function are labelled. Colouring of nucleic acids is as in (a). Exiting RNA and DNA strands are not revealed in the electron density map, but their anticipated locations are indicated by dashed lines. In this view, the clamp swings over the active center from back to front. Only one of the jaws (the lower jaw) is visible in the cutaway view. Taken from CRAMER P. (2002) Multisubunit RNA polymerases. *Curr. Opin. in Struct. Biol.* 12:89–97.

circa a hundred nucleotides is blocked by the negative elongation factor (NELF) and by the DRB sensitivity-inducing factor (DSIF). Phosphorylation of the CTD on the serines at position 2 and of the largest subunit of the DSIF by the CDK9 subunit of P-TEFb, the positive transcription elongation factor, is generally critical in relieving this block and allowing a productive transcription.

Factors that Favor Processive Elongation Through Chromatin Templates

Along the DNA matrix, RNAP II encounters numerous obstacles that slow down its progression and may provoke pausing or premature termination. Elongation factors such as TFIIS assist the paused RNAP II molecules in resuming transcription. Other factors enhance the catalytic rate of elongation by affecting the K_m and/or V_{max} of RNAP II and include TFIIF, the elongins, and the ELL family of proteins. Furthermore, the transcription process generates supercoils that slow down the enzyme progression and are removed by topoisomerases. Chromatin remains a major obstacle, which is overcome by chromatin remodeling factors that displace the nucleosomal components or by enzymes that covalently modify histones such as acetylases, methylases, ubiquitin ligases and kinases.

Recycling RNA Polymerase

Transcription terminates when cis-elements at the 3' end of the pre-mRNA sequence trigger cleavage/polyadenylation of the primary transcript by the cleavage/polyadenylation factors (CPSF/CstF) and signal the polymerase to fall off its DNA template. To reinitiate a transcription cycle, RNAP II must be dephosphorylated by FCP1, a highly specific TFIIF-dependent CTD phosphatase.

Integration of Pre-mRNA Processing with Transcription

Transcription and pre-mRNA processing are not separated in time and space. Capping occurs first on nascent transcripts roughly 20 nucleotides in length, while NELF and DSIF prevent elongation of the transcript. Splicing occurs next on the nascent transcript. Finally, termination of transcription is determined by cleavage and polyadenylation of the transcript.

The CTD Acts as a Platform for RNA Processing

The phosphorylated CTD binds to the capping enzyme, the spliceosome components and the cleavage/polyadenylation factors and stimulates their catalytic activities. Sequential phosphorylation of the serines at position 5 and of those at position 2 in the CTD

RNA Polymerase II Transcription. Figure 2 CTD phosphorylation and the transcription cycle. (I) Recycling. The “free” RNAP II core enzyme is not phosphorylated on the CTD. It may assemble with coactivators such as the mediator complex (Med) thus forming a holoenzyme. (II) Preinitiation. The unphosphorylated RNAP II core or holoenzyme assemble onto the promoter sequences with general transcription factors such as TFIID, TFIIA, TFIIB, TFIIE, TFIIH and TFIIH thus forming a preinitiation complex of transcription. The CTD is phosphorylated on serines at position 5 (5P) by the CDK7 subunit of TFIIH. (III) Initiation. Transcription begins. The phosphorylated CTD recruits the capping enzymes and the nascent transcript is capped at its 5' end. (IV) Elongation. Phosphorylation of the CTD on serines at position 2 (2P) by the CDK9 subunit of the positive transcription elongation factor (P-TEFb) is required to remove to block due to the DSIF/NELF factors and elongate transcription. (V) RNA Processing and transcription termination. The phosphorylated CTD recruits the splicing machinery (Spl) to remove introns and, finally recruits the cleavage and polyadenylation factors (CPSF and CstF) that cleave the transcript and add a polyadenylic tail at its 3' end. This step signals transcription to terminate and RNAP II falls off its DNA template. The resulting mRNA is then exported to the cytoplasm. (VI) To be recycled for another transcription round, RNAP II is dephosphorylated by the FCP1 CTD phosphatase.

repeated motifs contributes to the timed recruitment of the RNA processing machinery. The capping enzymes are recruited onto the CTD that have been phosphorylated by CDK7 and remain localized at the 5' ends of the genes. The triphosphatase component of the capping enzymes delays reinitiation by a novel RNAP II molecule and contributes to the recruitment of the P-TEFb that neutralizes the block imposed by NELF and DSIF. This transcriptional checkpoint may allow only capped mRNA to undergo processive elongation. Unexpectedly, RNA processing factors such as CPSF already interact with the preinitiation complex on the promoter. They are loaded later on RNAP II through the phosphorylated CTD.

Transcription, Splicing and mRNA Export Cross-talk

On the one hand, transcription and splicing factors share common components: U1 snRNA stimulates the

TFIIH initiation factor and the Tat-SF1 elongation factor binds to U2 snRNA. In some cases, the presence of splice sites enhances transcription levels. On the other hand, promoter and transcription elongation rate may determine the balance between the alternatively spliced variants. Indeed, a slow elongation rate favors the use of weak splicing donor and acceptor sites. Transcription and splicing are also connected to mature mRNA export into the cytoplasm through the nuclear pore. Indeed, proteins involved in RNA packaging and export from the nucleus are loaded on the nascent transcript through physical interactions with the RNAP II transcription elongation complex.

Integration of mRNA Quality Control with Transcription

Cotranscriptional mRNA quality control is a fascinating concept that has recently gained support in

eukaryotes a long time after being established in bacteria. The quality control is exerted at various steps from the incorporation of nucleotides into the nascent transcript to a test of proper translatability into protein.

RNAP II Proofreading

Misincorporation of a nucleotide arrests RNAP II, as base-pairing mismatch of this nucleotide prevents the progression of the transcription bubble. The incorrect nucleotide is then removed by the intrinsic 3'-exonuclease activity of the stalled RNAP II. This activity is stimulated by TFIIIS.

Non-sense Codon Mediated Quality Control

Premature stop codons or absence of stop codons may have detrimental consequences due to the synthesis of short truncated or carboxy-terminal extended abnormal proteins, respectively. Premature stop codons or the absence of stop codons are consequences of mutations or natural processes such as the DNA sequence shuffling responsible for immunoglobulin and T-cell receptor gene diversity. A non-sense mediated quality control eliminates the deficient mRNAs. In many cases, this phenomenon occurs in the nucleus through exosome-mediated degradation, alternative [▶splicing](#) or aggregation near the site of transcription. Non-sense stop codons are detected as premature if they precede the junction between two exons (exon splice junction). This detection involves the progression of a ribosome translating the mRNA into protein to remove the so-called exon-junction complex that remains left over after the splicing process.

Clinical Relevance

Diversion of Transcription Factors by Viral Proteins

The Tat protein of the human immunodeficiency virus directly recruits P-TEFb to phosphorylate RNAP II and activate viral transcription. The HDAG protein of hepatitis δ virus mimics the NELF largest subunit but, unlike its cellular counterpart, it activates RNAP II-mediated viral transcription.

Inhibition of RNAP II Transcription by Natural and Pharmacological Compounds

α -Amanitin from the fungus *Amanita phalloides* is a highly specific and potent inhibitor of RNAP II. It binds irreversibly to Rpb1, the largest subunit and blocks elongation of the transcript. Numerous anti-tumor drugs are DNA intercalators that also inhibit transcription.

Human Genetic Diseases Associated with Defects in RNAP II Transcription

Cockayne syndrome and trichothiodystrophy are cancer-free multisystem disorders associated with

deficiencies in the helicase activities of the TFIIH transcription initiation factor. The Von Hippel Lindau syndrome is associated with mutations in the Von Hippel-Lindau (VHL) tumor suppressor gene. Binding of the mutated VHL gene product to elongins B and C is reduced. Consequently, the VHL defect causes misregulation in the expression of a number of genes involved in oncogenesis. The human ELL gene can undergo translocation with the MLL gene, generating a MLL-ELL fusion protein in patients affected by acute myeloid leukemia. Congenital cataracts facial dysmorphism neuropathy (CCFDN) syndrome (OMIM 604168) is associated with a partial deficiency in the CTD phosphatase FCP1.

RNA Polymerase III

SARAH J. GOODFELLOW, ROBERT J. WHITE

Institute of Biomedical and Life Sciences, University of Glasgow, Glasgow, UK
rwhite@udcf.gla.ac.uk

Synonyms

Synonyms used for RNA polymerase III and some of its associated [▶transcription factors](#) are listed in Table 1.

Definition

RNA polymerase III is one of three highly related [▶RNA polymerases](#) found within the nuclei of eukaryotic cells. RNA polymerases are large, complex enzymes that synthesise RNA using specific DNA templates in a process known as gene [▶transcription](#)

RNA Polymerase III. Table 1 Synonyms used for the basal RNA Polymerase III transcriptional apparatus

Name used in essay	Synonyms
RNA Polymerase (pol) III	RNA Polymerase C, RNAP III
BDP1	B", TFIIIB90 (yeast), TFIIIB150 (human), TAF3B1, TFNR
BRF1	TFIIIB70 (yeast), hTFIIIB90 (human), hBRF (human), TAF3C, GTF3B, TAF3B2
SNAPc	PBP, PTF

(1). Each of the three eukaryotic nuclear RNA polymerases is dedicated to the transcription of a different set of genes. RNA polymerase III is responsible for approximately 10% of all nuclear transcription and synthesises a variety of small, untranslated RNAs, many of which have roles in cellular metabolism (1, 2). ▶**RNA polymerase I** transcribes genes encoding the large ▶**ribosomal** (rRNAs), which account for around 70–80% of cellular RNA synthesis (1), and ▶**RNA polymerase II** produces messenger RNAs that code for cellular proteins (1). The templates transcribed by RNA polymerases I, II and III, often referred to as class I, II and III genes respectively, are distinguished by distinct ▶**promoter** sequences. The polymerases themselves cannot recognise these promoters and so rely on accessory proteins known as transcription factors. Each of the RNA polymerases employs a distinct set of transcription factors, which bind to specific DNA elements within promoter regions and then recruit the appropriate RNA polymerase. Once the polymerase has been recruited, transcription can ensue. Features of the RNA polymerase (pol) III transcriptional apparatus and the genes transcribed by this enzyme are discussed below.

Characteristics

RNA Polymerase III

Pol III is a huge 600–700 kD complex composed of 17 subunits in yeast and humans, making it the largest of the three eukaryotic nuclear ▶**RNA polymerases** (2, 3, 4). Genetic studies in yeast have indicated that at least 16 of these 17 subunits are essential for pol III function and yeast viability (2, 3, 4). Five of the 17 subunits are shared by all three RNA polymerases, a further two are common to both pols I and III and ten subunits are unique to the pol III complex (2, 3, 4). All three polymerases perform the same fundamental function; they catalyse the covalent attachment of ribonucleotides to form an RNA chain that is complementary to the gene template being transcribed. Therefore, it is not

RNA Polymerase III. Table 2 Summary of pol III gene products and their functions

Pol III Product	Known Functions
tRNA	Involved in protein synthesis as a translational adaptor
5S rRNA	Involved in protein synthesis as a component of ribosomes
U6 snRNA	Involved in mRNA splicing
H1 RNA	Involved in tRNA processing (RNase P component)
MRP RNA	Involved in rRNA splicing
7SL RNA	Involved in intracellular protein transport (component of signal recognition particle)
7SK RNA	Involved in controlling transcriptional elongation by pol II
SINE transcripts	Unknown
VA RNA	Involved in adenovirus translational control
EBER RNA	Thought to be involved in Epstein-Barr virus translational control

surprising that these enzymes share some common subunits. However, the polymerases transcribe distinct genes with different characteristics and so they also have several unique properties. The subunits unique to pol III are presumed to contribute to pol III-specific properties, such as its distinct nuclear localisation, its interaction with specific transcription initiation factors and its ability to perform elongation and termination of transcription independently of accessory factors.

Genes Transcribed by RNA Polymerase III

Pol III transcribes genes that encode a variety of small (usually less than 300 bp), stable RNAs that do not get translated. As summarised in Table 2, many of these RNAs, including 5S ▶**rRNA** and transfer (t)RNAs, have essential functions in cellular metabolism, being involved in protein synthesis and transport and RNA processing (1, 2).

Promoters of Genes Transcribed by RNA Polymerase III

Gene promoters contain specific sequence elements, which direct the recruitment of the appropriate transcription factors and RNA polymerase through multiple protein-DNA and protein-protein interactions. One of the most notable features of the majority of class III gene promoters is that the crucial sequence elements are found downstream of the transcription start site,

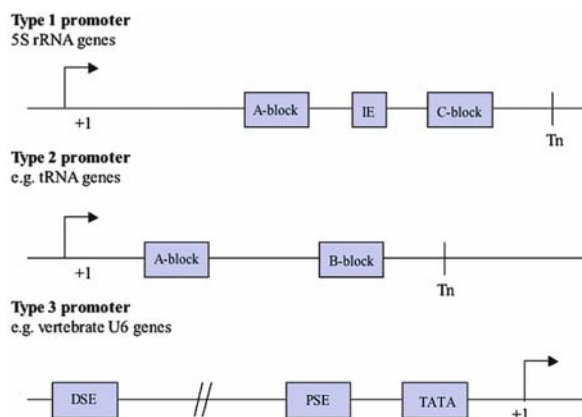

within the transcribed region (as shown in Fig. 1), rather than upstream as with class I and II genes. Promoters with such a structure are referred to as type 1 or 2. Type 1 promoters are unique to 5S rRNA genes and require three internal promoter elements for efficient transcription, an A-block, an intermediate element (IE) and a C-block (1, 2, 3, 4). The spacing between these elements is relatively restricted.

The majority of pol III transcribed genes, including those for **tRNAs** and adenovirus VA RNAs, have type 2 promoters. These consist of two essential, highly conserved sequence elements, an A-block (homologous to the type 1 promoter A-block) and a B-block. The spacing between the A- and B-blocks is not as restricted as the spacing between type 1 promoter sequence elements and in fact the position of the B-block is highly variable (1, 2, 3, 4).

A minority of pol III-transcribed genes in vertebrates have a type 3 promoter. Genes with type 3 promoters lack any requirement for internal promoter regions, with important sequence elements being found upstream of the transcription start site. For example, efficient transcription of the vertebrate U6 genes requires three extragenic promoter elements, a TATA box, a proximal sequence element (PSE) and a distal sequence element (DSE) (1, 2, 3, 4). The three types of promoter used by pol III are illustrated in Fig. 1.

Transcription by RNA Polymerase III

The transcription of a class III gene can be divided into three main stages, initiation, elongation and

RNA Polymerase III. Figure 1 Promoter structures utilised by pol III. The transcription start site on each promoter is indicated by '+1' and 'Tn' indicates the termination site. The important sequence elements of each promoter type are represented by coloured boxes. These are the A-, B-, and C-blocks, the intermediate element (IE), the TATA box (TATA), the proximal sequence element (PSE) and the distal sequence element (DSE).

termination. Initiation of transcription begins with the assembly of a transcription initiation complex at the promoter. Regardless of the promoter type, pol III itself has little affinity for promoter sequence elements and so relies on the specific transcription factors which form this transcription initiation complex for its accurate recruitment. Figure 2a shows a simplified illustration of the formation of a transcription initiation complex on the most commonly used pol III promoter type (type 2). This process requires two pol III-specific, basal transcription factors, the DNA-binding factor TFIIC and the polymerase recruitment factor TFIIB. TFIIC is one of the most complex transcription factors ever studied, having six subunits in yeast with an aggregate mass of 520 kD. Human TFIIC is even larger and more complex than the yeast factor and, in fact, there is little homology between the TFIIC subunits from these two species (2, 3, 4). Nonetheless, regardless of the species, TFIIC binds the A- and B-blocks of type 2 promoter DNA directly and then serves to recruit TFIIB. TFIIB is essential for the recruitment of pol III to all class III genes and consists of at least three proteins, TATA binding protein (TBP) and two TBP-associated factors, known as BRF1 and BDP1. Both BRF1 and BDP1 have been shown to make direct contacts with TFIIC, thus allowing TFIIB recruitment to the promoter (3). Each of the TFIIB components is essential for subsequent polymerase recruitment; however, only BRF1 has been shown to make direct contacts with the polymerase itself.

Figures 2b and c show transcription initiation complexes on type 1 and 3 promoters (4). As with type 2 promoters, TFIIB is directly involved in the recruitment of pol III. However, these promoter types rely on additional, gene-specific factors for efficient TFIIB recruitment. For example, the gene-specific transcription factor TFIIA is required for the productive recruitment of TFIIC, and hence TFIIB, to 5S rRNA (type 1) promoters (1, 2, 3, 4). Binding of TFIIB to type 3 promoters in vertebrates does not rely on TFIIC, but on an alternative factor known as SNAPc (1, 2, 3, 4). SNAPc binds to the PSE of type 3 promoters and facilitates the recruitment of TFIIB to the TATA box. The DSE of type 3 promoters binds an additional transcription factor known as Oct1, which further enhances SNAPc/TFIIB binding to promoter DNA. A form of TFIIB unique to vertebrates is required for pol III transcription from type 3 promoters (4). Thus, although the route to TFIIB binding differs for each promoter type, the outcome is the same; TFIIB brings pol III into the vicinity of the transcription start site, thereby facilitating transcription initiation. Table 3 summarises the basal transcription factors utilised by pol III and outlines their functions.

a *Assembly of a *pol III* transcription initiation complex on a type 2 promoter.*

b *Pol III transcription initiation complex on a type 1 promoter.*

c *Pol III transcription initiation complex on a type 3 promoter in the vicinity of the transcription start site.*

RNA Polymerase III. Figure 2 Transcription initiation complexes utilised by class III genes. The transcription start site on each promoter is indicated by '+1'. The important sequence elements of each promoter type are represented by boxes. These are the A-, B-, and C-blocks, the intermediate element (IE), the TATA box (TATA), the proximal sequence element (PSE) and the distal sequence element (DSE). *Pol III* and its associated transcription factors (TFIIB, TFIIC, TFIIIA and SNAPc) are shown as coloured shapes. On type 2 promoters (a), TFIIC recognises and binds the A- and B-blocks directly. Once bound to the DNA, TFIIC then recruits TFIIB via protein-protein interactions. TFIIB can then recruit *pol III* and transcription is initiated. Recruitment of TFIIC, and hence TFIIB and *pol III*, to type 1 promoters requires TFIIIA (b). TFIIB recruitment to type 3 promoters requires SNAPc (c).

RNA Polymerase III. Table 3 Summary of basal pol III transcription factors and their functions

Basal Pol III Transcription Initiation Factor	Known Functions
TFIIIB	Essential for the initiation of transcription of all class III genes. Recruits pol III directly.
TFIIIC	Binds directly to type 2 promoters, and to TFIIIA-bound type 1 promoters. Recruits TFIIIB.
TFIIIA	Binds specifically to type 1 promoters and recruits TFIIIC.
SNAPc	Binds PSE of type 3 promoters in vertebrates. Involved in the recruitment of TFIIIB to type 3 promoters.
Oct-1	Binds DSE of type 3 promoters in vertebrates. Necessary for the productive recruitment of SNAPc to the type 3 promoter PSE.

Following pol III recruitment, the two strands of DNA around the transcription start site are separated to form a transcription bubble (2, 3). This melting of the DNA helix allows the polymerase to access the template strand, and is required before transcription can proceed. DNA melting is performed by the polymerase, although the BRF1 and BDP1 components of TFIIIB also play an active role. Thus, TFIIIB serves not only to recruit pol III, but also participates in the formation of an open promoter complex (2, 3, 4).

Once the DNA strands have been separated, RNA synthesis can be initiated and the polymerase progresses into the gene and dissociates from promoter-bound TFIIIB (2). The transcription bubble moves downstream with the elongating polymerase. Although TFIIIC assembles within the transcribed regions of the majority of class III genes, this large factor is not dissociated from promoters during elongation (2). It is unclear at present how the polymerase passes DNA-bound TFIIIC during transcription. However, unlike pols I and II, pol III does not require any accessory factors for efficient chain elongation (2, 3, 4). Furthermore, termination by pol III also occurs independently of other factors; four or more T residues within the template strand of a class III gene are sufficient to signal the accurate and efficient termination of transcription (2, 3, 4).

Following the synthesis of the first transcript, pol III is known to be recycled on the same DNA template for several further rounds of transcription. As a

consequence, the slow initial step of polymerase recruitment is avoided, making the production of subsequent RNAs by pol III more efficient (1, 2).

Regulation of Transcription by RNA Polymerase III

As detailed in Table 2, many pol III products are known to be involved in protein synthesis, and hence are essential determinants of the biosynthetic capacity of cells. As a consequence, pol III transcription is tightly regulated, allowing cells to control the rate of protein synthesis in response to changing metabolic needs. Numerous studies in eukaryotic systems have demonstrated that pol III transcription is regulated under a variety of cellular and environmental conditions (2). For example, pol III transcription is low when nutrients or mitogens are limiting, but up-regulated when the availability of these growth stimuli increases. Pol III transcription is also regulated in response to a range of cellular stresses and during many fundamental cellular processes, such as during metazoan development and [cell differentiation](#), and during the [cell cycle](#) (2). This stringent control of pol III transcription is achieved by several regulatory proteins, which can interact with or modify components of the basal pol III transcriptional machinery and either activate or repress transcription. Some of these regulators are also responsible for coordinating the activities of all three nuclear RNA polymerases. Examples of pol III regulators and their physiological relevance are discussed below. However, several other molecules, not discussed here, have also been shown to regulate pol III transcription in various organisms. For a more complete review of these regulators see (2).

Negative Regulators of Pol III Transcription

Proteins known to act as negative regulators of pol III transcription include Dr1, Maf1 the [retinoblastoma protein](#) ([pRB](#)), and [p53](#) (1, 2, 3, 4, 5). Dr1 is a small nuclear protein, highly conserved in all eukaryotes. It represses pol III transcription by disrupting the interaction between TBP and BRF1, thereby inactivating TFIIIB, and preventing pol III recruitment to class III genes. Dr1 is also known to inhibit pol II transcription and can therefore coregulate the activities of both pols II and III (1, 2).

Maf1 was recently identified in yeast and shown to be a negative effector of pol III transcription in response to a variety of cellular stresses such as nutrient limitation and DNA damage (4). Although homologues of Maf1 have been identified in higher eukaryotes, a role for Maf1 in the regulation of pol III transcription has thus far only been demonstrated in yeast.

Unlike Dr1 and Maf1, RB and p53 are restricted to metazoan systems. RB is an important regulator of the mammalian cell-cycle, ensuring cells only progress through the cycle and proliferate in response to

appropriate external stimuli. Loss of RB function results in aberrant cellular proliferation and tumour formation. RB is therefore known as a ►**tumour suppressor** protein. In resting cells, RB binds and inactivates TFIIB, thereby restraining the unnecessary production of tRNAs, 5S rRNA and other pol III products (5). However, in response to growth stimuli, RB becomes inactivated by hyperphosphorylation. This leads to the release of TFIIB and the activation of pol III transcription, thus permitting an increase in protein synthesis and growth. This is a prerequisite for cell division, as cells must duplicate their contents prior to dividing in order to maintain a constant size. RB also regulates the transcription by pol II of certain genes whose products are involved in DNA synthesis, and transcription by pol I, which synthesises the large rRNAs. Therefore, this common regulatory mechanism allows components of the DNA and protein synthetic machinery to be produced in a highly coordinated manner during the cell-cycle.

p53 is also an important cell-cycle regulatory protein, mediating cell-cycle arrest or cell death in response to a variety of stresses including radiation, hypoxia and oncogenic stimuli. As with RB, p53 is a tumour suppressor protein whose function is thought to be compromised in all human tumours. Although unrelated to RB, p53 also represses pol III transcription by binding and inactivating TFIIB (5).

Positive Regulators of Pol III Transcription

Mitogenic stimulation of eukaryotic cells results in the activation of several intracellular signalling cascades, which promote growth and proliferation. Some of these cascades have been shown to lead to the activation of pol III transcription. In many instances, stimulation of pol III transcription results from an activation of TFIIB. As already discussed, derepression of TFIIB by RB in response to growth stimuli is an important mechanism for pol III activation in mammalian cells. However, several other mechanisms for the up-regulation of pol III transcription also exist. For example, ►**CK2**, a highly conserved eukaryotic protein kinase activated in response to growth stimulation, has recently been shown to phosphorylate and activate TFIIB, thus increasing pol III transcription in yeast and mammalian cells (4). Furthermore, the mitogen-activated protein kinase ►**ERK**, which is activated *via* the ►**ras** signalling pathway in mammalian cells, can also induce pol III transcription through phosphorylation and activation of TFIIB. In addition to these kinases, the ►**proto-oncogene** product ►**c-Myc** is a crucial regulator of cell growth in metazoans. c-Myc specifically activates pol III transcription again by targeting TFIIB, leading to an increase in tRNA and 5S rRNA production (5). Thus, it is clear that the pol III transcriptional machinery is a common target for

numerous growth-promoting pathways within eukaryotes.

Stimulation of pol III transcription in mammalian cells also occurs in response to viral infection (2, 5). For example, adenovirus, simian virus 40, polyomavirus, herpes simplex virus, hepatitis B virus (HBV), human T-cell leukaemia virus type 1, human papilloma virus (HPV), and pseudorabies virus have all been associated with pol III activation (2, 5). The resulting increase in the cellular biosynthetic capacity may be a general requirement for efficient viral propagation. In some cases, expression of certain viral genes also requires the host pol III transcriptional machinery directly. Multiple mechanisms, which target both TFIIB and TFIIC (2, 5), are thought to contribute to this increase in pol III transcription.

Clinical Relevance

The regulation of pol III transcription is clearly a crucial feature in normal cellular growth and proliferation. In mammals, pol III transcription can be restrained by two key tumour suppressors, p53 and RB and activated by known proto-oncogene products including CK2, ras and c-Myc (5). Inactivation of p53 and RB and abnormal activation of proto-oncogenes are common features of most human cancers, causing uncontrolled cell growth and division. High levels of pol III transcription are likely to contribute to the rapid growth that is characteristic of tumour cells. Indeed, it is well established that pol III transcripts are elevated in many tumour types, including ovarian and breast carcinomas (2, 5). Furthermore, viruses associated with human cancers are known to stimulate pol III transcription. For example, HPV, the causative agent in cervical carcinoma, and HBV, which can cause hepatocellular carcinoma, both activate TFIIB and hence pol III transcription (2, 5). Deregulation of TFIIB activity through viral infection, loss of tumour suppressors and/or activation of oncogenes is likely to play a role in the stimulation of pol III transcription in tumour cells. Abnormally elevated expression of TFIIC may also contribute to increased pol III transcription in tumours, as TFIIC subunits are consistently over-expressed in certain tumour types and virally transformed cell lines (5). Understanding the mechanistic basis and functional significance of the aberrant activation of pol III transcription in cancers may lead to the development of novel prognostic tools and therapies.

RNA Profiling

Definition

RNA profiling refers to the determination of the change in RNA expression (on, off, strong, weak, etc) of all or a majority of genes due to an experimental manipulation (genetic, surgical, environmental, etc.). Typically done with high-density DNA microarrays.

Rods

Definition

Rods are elongated photoreceptors of high light sensitivity, which contain the photopigment rhodopsin in a stack of disks that forms their outer segment. They transform light via the phototransduction process into

an electrical signal that modulates the release of transmitter (glutamate) in the inner segment. In the human retina, rods – in contrast to ►cones – contain only a single photopigment with a spectral peak at 500 nm.

►Retinitis Pigmentosa

ROI

►Region of Interest

Rolling Circle Mechanism

Definition

The rolling circle mechanism of DNA replication starts from circular DNA and is used in the replication of the DNA of some bacteriophages, and in the amplification of DNA coding for ribosomal RNA in amphibia. The circle is copied many times (as if it were rolling), giving rise to a long DNA strand that consists of many linked copies of the circular DNA.

►DNA Amplification

ROR Response Element

Definition

ROR response element refers to DNA recognition sequences for members of the ►REV-ERB and ROR orphan nuclear receptor families. The consensus sequence is WAWNTRGGTCA (where W = A or T and R = A or G). ROR stands for “retinoic acid receptor-related orphan receptor”

►Circadian Clocks

ROS

►Reactive Oxygen Species

Rosetta Stone Proteins

Definition

Some interacting proteins such as acetate CoA transferase in *E. coli* are fused into a single chain in other organisms. The homologous protein in human consists of two subunits, succinyl-CoA transferase a and b. The fused protein is called a Rosetta stone protein after the historical Rosetta stone of ancient Egypt, which contained the same text in three languages. The presence of Rosetta stone protein implies that the two independent proteins may be functionally linked with each other.

RRF

Definition

Ragged red fibers (RRF) are muscle fiber segments with large accumulations of mitochondria. The mitochondrial accumulations are unevenly distributed and can be stained red with particular tissue stains (Gomori trichrome stain), hence the name, ragged red fibers. RRF are considered a hallmark of mitochondrial myopathy.

►Mitochondrial Myopathies

rRNA

Definition

- Ribosomal RNA
- RNA Polymerase III

rRNA Processing Events

Definition

The 45S ribosomal RNA (rRNA) primary transcript undergoes extensive modification prior to its cleavage to generate rRNAs. These modifications include approximately 100 nucleotide methylations, and 100 isomerisations of uridine to pseudouridine. Small nucleolar RNAs (snoRNAs) are important in rRNA processing, with each snoRNA acting as “guide molecule” directing a specific modification.

RTK/RTK1

Definition

Receptor tyrosine kinases (RTK) comprise of a large family of cell surface receptors for polypeptide growth factors. RTKs are membrane spanning proteins with an extracellular, ligand-binding domain and an intracellular kinase domain. There are many subfamilies of RTKs; each subfamily has characteristic ligand-binding and kinase domains and is activated by distinct ligands, for example PDGFs, FGFs or ephrins. Upon ligand binding, the extracellular ligand binding domain phosphorylates certain tyrosine residues in other cytosolic proteins or adjacent RTK molecules (substrates) autocatalytically.

SCF Ubiquitin Ligase

Definition

The SCF (Skp -Cullin -F-box) ubiquitin-ligases are a group of highly diverse multi-subunit ubiquitin ligases. SCF triggers the degradation of various proteins including CDK inhibitors and cyclin E. The core subunits of the complex are always Skp1 and a Cullin, while the variable adaptor – the F-box protein – provides the variability to recognize a specific target molecule. The target molecule is then fixated in close proximity to the E2-enzyme which catalyses the transfer of ubiquitin onto the substrate.

Schizophrenia, Genetics

NADINE NORTON, MICHAEL J OWEN

Department of Psychological Medicine, Wales School of Medicine, Cardiff University, Cardiff, UK

nortonn@cardiff.ac.uk

owenmj@cardiff.ac.uk

Synonyms

Dementia praecox

Definition

Schizophrenia is a severe and disabling psychiatric disorder often with symptoms of hallucinations, delusions and thought disorder. Symptoms usually begin in late adolescence or early adulthood and are heterogeneous. Some psychiatric disorders have a specific identifiable pathology. However, it has not been possible to identify changes in the brain or other tissues that are “diagnostic” of schizophrenia. Thus diagnosis is purely clinical and is specified in the fourth revision of the Diagnostic and Statistical Manual of Mental disorders (DSM IV).

Characteristics

The prevalence of the disorder in the general population is 0.5–1% with compelling evidence from family, twin and adoption studies for genetic factors in its aetiology.

1. Family studies compare the prevalence of the disorder in relatives of affected individuals with the general population. The lifetime risk of 1% in the general population contrasts with the average risk to siblings (9%) and offspring of affected individuals (13%). The offspring of dual matings (between two affected parents) have a risk for the disorder of 46%.
2. Twin studies compare the concordance of the disorder in ►dizygotic (sharing on average 50% genes) and ►monozygotic (sharing 100% genes) twins. A dizygotic twin with an affected co-twin has a risk for the disorder of 17% and a monozygotic twin with an affected co-twin has a risk of 48%.
3. Adoption studies using three designs (►adoptive studies, ►cross-fostering studies, and ►adoptive family studies) have demonstrated a greater risk of schizophrenia in biological relatives of cases (where genes are shared but not family environment and experiences) than in control groups, further corroborating evidence of a genetic contribution.

Mode of Inheritance

Despite there being a clear genetic contribution to schizophrenia, ►discordance between monozygotic twins indicates that what is inherited is not the certainty of disease accompanying a particular ►genotype but rather a predisposition to developing the disorder, and certainly that other factors (such as environment) are involved. Furthermore, studies on different classes of relatives show that the recurrence risk decreases too rapidly with decreasing relatedness to an affected individual for schizophrenia to be a single-gene disorder or a collection of single-gene disorders. The

most likely mode of transmission is ►oligogenic or ►polygenic, also observed in other common disorders such as diabetes and asthma. This means that schizophrenia susceptibility is most likely the combined effect of the inheritance of a combination, or combinations, of different susceptibility and protective ►alleles in a number of (possibly many) genes. Until such genes have been identified, it is not possible to determine the number of susceptibility loci, the disease risk conferred by each locus or the degree of interaction among loci.

Cellular and Molecular Regulation

There are four main approaches to identifying disease genes in human populations.

Chromosomal Abnormalities

Identification of chromosomal abnormalities that co-segregate with schizophrenia may provide valuable clues to the location of susceptibility genes. The first example of this phenomenon came from a large Scottish family with 47% prevalence of mental illnesses including schizophrenia. A balanced reciprocal ►translocation between chromosomes 1 and 11 co-segregated with illness. Subsequent mapping of the translocation breakpoint has identified three disrupted genes of unknown function on chromosome 1. Unfortunately, such abnormalities have not been identified in other families and the mechanism by which the translocation confers disease susceptibility is so far unknown.

A second example of cytogenetic abnormality in schizophrenia is the association with chromosome 22q11 deletion syndrome (also known as DiGeorge syndrome and velocardiofacial syndrome [VCFS]). 22q11 deletion syndrome occurs in 1/4000 live births and results in a complex ►phenotype with multiple congenital abnormalities, characteristic dysmorphism, cleft palate, cardiac defects, learning disabilities and high rates of psychiatric disorder. Rate of schizophrenia in adults carrying the deletion is as high as 24%. Deletion of 22q11 has been detected in 1–2% of individuals with schizophrenia and only accounts for a small proportion of the risk of developing schizophrenia in the general population. However, mutations and ►polymorphisms in genes within the deleted region may make a more general widespread contribution to schizophrenia susceptibility and there is some evidence for genetic linkage and association to this region.

Genetic Linkage

Linkage studies aim to identify chromosomal regions that are co-transmitted with the disease in families with two or more affected individuals. Replicated positive linkages to several chromosomal regions are now

accumulating with evidence for linkage on chromosomes 1q21-q22, 5q21-q31, 6p24-p22, 6q, 8p22-p21, 10p15-p11, 13q14.1-q32 and 22q11-q22. With the advent of the human genome sequence, it is probably only a matter of time before susceptibility genes are identified by association studies focusing on genes within these regions.

Association Studies

Association studies aim to detect variations in genes (alleles) that are more (or less) common in cases than in the control population. Such studies are widely used on genes that are hypothesized to play a role in schizophrenia on the basis of their function. Such genes are termed “candidate genes”. To date, genes involved in dopaminergic and serotonergic ►[neurotransmission](#) have received a great deal of attention based on neurochemical evidence that antipsychotic drugs bind to dopamine and serotonin receptors. Two positive associations with schizophrenia are polymorphisms causing an amino acid variation (Ser9Gly) in ►[exon 1](#) of the dopamine D₃ receptor ►[gene](#) and a thymine/cytosine polymorphism at nucleotide 102 of the 5HT_{2A} gene but there are conflicting data for both findings. The catechol-O-methyltransferase (COMT) gene located on chromosome 22q11 is both a strong positional and functional candidate for schizophrenia. The gene encoding *COMT* is located within the VCFS deleted region and the protein metabolizes both dopamine and serotonin. An amino acid variation (Val/Met) in *COMT* has been associated with variation in enzyme activity. A recent study has identified a significant association with several variants (including the Val/Met polymorphism) that make up a ►[haplotype](#) for disease susceptibility. The Icelandic deCODE Genetics group showed association of the neuregulin (*NRG1*) gene (located on chromosome 8p22-p21) to schizophrenia identifying a significant core haplotype for disease susceptibility (relative risk 2.1). This finding has since been replicated in a Scottish population. A second positive association has come from the dysbindin (*DTNBP1*) gene on chromosome 6p. Initial association was with a rare haplotype in Irish families and replication has since been achieved in a German population.

Recent association findings in the *COMT*, *NRG1* and *DTNBP1* genes are potentially very important but should be viewed with caution. For each gene, it is the combination of several variants that show association to schizophrenia, and it has not been possible to identify a particular genetic variant that is responsible for increased susceptibility.

Microarray Studies

Microarrays are a new tool in molecular genetics for gene expression analysis. A recent study identified the

expression of several ►[myelination](#) related genes to be down-regulated in schizophrenic patients. Association studies of the genes identified by such analyses will undoubtedly follow.

Clinical Relevance

Schizophrenia is a severe and disabling psychiatric disorder. Once symptoms occur they persist for the entire lifetime of the patient. Not all patients respond well to current medications and unpleasant side effects often result. Genetic studies aim to identify susceptibility genes for schizophrenia so that we can better understand disease mechanisms, design more effective drugs with fewer side effects and provide earlier diagnosis and improved treatment.

Second Site Suppression

Definition

Sometimes two proteins coded by distinct genes are required for an activity. If two proteins interact with one another, then any mutations in one of the proteins which alter amino-acids involved in the interaction will destroy the activity. However, a second mutation in the other protein can sometimes allow the interaction to take place and restore activity. Second site suppression defines a mutation in a second gene that restores the wild-type phenotype of an already mutant individual.

Secreted Frizzled Related Proteins

Definition

Secreted Frizzled Related Proteins (FzB) are secreted proteins which bind Wnt and have similarity to the CRD of Frizzled.

► [Wnt/Beta-Catenin Signaling Pathway](#)

Secretion

Definition

Secretion is the process by which material is synthesised and then transported to the outside of a cell.

- Endocytosis
- Vesicular Traffic

Secretory Pathway

Definition

The secretory pathway comprises of a series of membrane-bounded compartments, including the endoplasmic reticulum (ER), vesicular-tubular clusters (VTCs), and the Golgi complex, through which a large number of newly synthesized proteins pass en route to the extracellular space or to other final, intracellular destinations.

- Vesicular Traffic

Secretory Vesicle

Definition

Secretory vesicle is a membrane bounded compartment in which secretory products accumulate.

- Cell Polarity
- Endocytosis
- Vesicular Traffic

Sedimentation Coefficient

Definition

Sedimentation coefficient denotes the ratio of the speed of molecular migration (► [sedimentation velocity](#)) in the centrifugal field, to the magnitude of the centrifugal field. This is a molecular constant dependent on the size and shape of the molecule, measured in units of Svedbergs ($1\text{ S} = 10^{-13}\text{ sec}$).

- Analytical Ultracentrifugation

Sedimentation Equilibrium

Definition

Sedimentation equilibrium describes the steady-state between sedimentation, diffusion, and chemical

reactions attained after sedimentation in the limit of long times.

- Analytical Ultracentrifugation

Sedimentation Velocity

Definition

Usually refers to the experiments on the hydrodynamic process of macromolecular sedimentation, by observing the evolution of the concentration distributions with time.

- Analytical Ultracentrifugation

Segment Duplication

- Gene Duplications

Segmentation

Definition

In the context of image processing, segmentation refers to an image processing method that is used to isolate a feature of interest from its context. It can be based on absolute differences in data signal and/or data gradient information.

- Electron Tomography

Segregation Analysis

Definition

Segregation analysis refers to a statistical method of inferring the genetic model underlying a particular phenotype (i.e. number of genes involved, allele frequencies, mode of inheritance, mutation rate etc.).

Selection, Selective Advantage

Definition

Selective advantage selection refers to a process that favours the survival of a given genotype in a population. Selection can be subdivided into natural selection, which operates in a natural ecosystem, and artificial selection, such as may occur in a laboratory or livestock breeding programme.

► Gene Duplications

Selection/Selectable Marker

Definition

Selection marker defines a fragment of DNA that can be built into a cloning vector or other construct, which

allows only those host cells carrying it to survive in a given medium. For example, selection markers are essential components of ES-cell based genome manipulation. Integration of foreign DNA into the ES-cell genome by homologous recombination normally occurs at very low frequencies. Therefore, those cells in which correct integration has occurred (positive selection), or in which DNA has integrated in an undesired non-homologous manner (negative selection), must be identified and selected for. Positive selectable markers, widely used for ES-cell based genome engineering and for bacterial hosts, are neomycin phosphotransferase neo, puromycin resistance gene puro and hygromycin resistance gene hygro. Negative selectable markers frequently used are herpes simplex, virus-1 thymidine kinase gene HSV-tk, and diphtheria toxin A dtA. For yeast, selection markers are mostly amino acid biosynthetic genes, which are selectable in auxotrophic hosts on defined media.

► Mouse Genomics

► Recombinant Protein Expression in Yeast

Selectivity

Definition

The selectivity of chemical analysis describes the degree to which chemical detection can distinguish between different metabolites, which are present within the same sample.

► Metabolomics

Selenocysteine

Definition

Selenocysteine is formed from serine by enzymatic transformation of a particular ►tRNA charged with serine to form Sec-tRNA^{Sec} (Sec, selenocysteine). An important example of codon redefinition is the incorporation of selenocysteine at UGA codons, which normally function as termination codons. With the help of a specialized translation factor (SelB in bacteria), Sec-tRNA^{Sec} binds to the ribosome and recognizes UGA when a particular structural element of the mRNA, the selenocysteine insertion sequence (SECIS), which recruits SelB is present, either within the coding

sequence downstream of the UGA (bacteria) or further away in the 3′-untranslated region (3′-UTR) of the mRNA (eukaryotes).

Selenoenzymes

Definition

Selenoproteins are defined as selenocysteine-containing proteins into which ► [selenocysteine](#) is incorporated by means of a specific genetic code. Most of the selenoproteins are redox-active enzymes, with the selenocysteine responsible for their catalytic functions.

Characteristics

Biological Significance of Selenocysteine

Selenocysteine is an amino acid analogous to cysteine with selenium in place of sulfur. The trace element selenium is also found in proteins in the form of selenomethionine that is incorporated non-specifically into methionine-containing proteins by accidental replacement of methionine.

Most of the chemical and physical properties of the analogous compounds of selenium and sulfur are similar. A difference that is significant for the importance of selenium in biological systems is, however, the fact that the selenohydryl groups of selenocysteine-containing proteins are anionic at physiological pH, while the sulfhydryl groups in cysteine-containing proteins are mainly protonated under these conditions. The experimental replacement of selenocysteine in the active center of a selenoenzyme with

cysteine therefore results in a drastic decrease in its catalytic activity.

Formation of the Selenoproteins

With the concentration of sulfur in living matter exceeding that of selenium by several orders of magnitude and with the similarity in the properties of the two elements, highly selective mechanisms are necessary to prevent substitution of selenocysteine by cysteine during protein formation. One of the unique features in the incorporation of selenocysteine is the use of the UGA codon that normally acts as a termination codon. Another is the biosynthesis of selenocysteine, which takes place on its ► [tRNA](#).

Selenocysteine insertion by means of the UGA codon requires a specific mRNA stem loop structure as well as four unique gene products, SelA, SelB, SelC and SelD. The UGA codon is recognized by the anticodon of a specific tRNA^{(Ser)Sec} (SelC) which is first loaded with serine. Selenocysteine synthase (SelA) then catalyzes the replacement of the side-chain oxygen of serine by selenium and thus the conversion of seryl- tRNA^{(Ser)Sec} into selenocysteyl-tRNA^{(Ser)Sec}. The selenium donor molecule for this reaction is selenophosphate, which is produced from selenide by means of selenophosphate synthetase (SelD). Selenocysteyl-tRNA^{(Ser)Sec} and a unique elongation factor SelB, homologous to the elongation factor EF-Tu for all other amino acid-tRNAs, form a complex which binds to the stem loop structure of the selenoprotein mRNA and mediates the incorporation of selenocysteine into the protein at the ribosome.

Eukaryotes differ from bacteria with regard to the position of the mRNA stem loop structure, named SECIS (selenocysteine insertion sequence) element, which is not situated immediately downstream of the UGA codon as in bacteria but in the 3′ untranslated region.

Hierarchy in Selenoprotein Expression

Another unique characteristic is the hierarchy in the selenium distribution among the selenoproteins in periods of insufficient selenium intake. With the formation of the selenoproteins depending on an adequate supply of the element, their concentrations are diminished in dietary selenium deficiency, but they do not decrease to the same degree in the different body compartments. During selenium depletion, regulation mechanisms strive to maintain the selenium levels in certain tissues, such as the central nervous system, the endocrine and the reproductive organs, and within these tissues the levels of certain selenoproteins. The liver, the skeletal muscle, the red blood cells and the blood plasma are at the bottom of this ranking order and show a relatively rapid loss, but here too, the concentrations of certain selenoproteins are more

affected than those of others. The hierarchy between the different tissues is achieved by the preferential supply of the element to the most important target organs. The intracellular hierarchy in the expression of selenoproteins may be regulated mainly by differences in the stability of their mRNAs in selenium deficiency. Due to these regulation mechanisms, it was virtually impossible to produce a severe decrease in the concentrations of the preferentially supplied selenoproteins in high priority organs such as the brain and the pituitary, even during extreme experimental depletion of laboratory animals.

The Individual Selenoproteins

Selenoprotein research is far from complete. Nearly 50 years after the discovery of the essentiality of selenium, we still do not know all the selenoproteins present in the human body, far less their biochemical functions and their biological roles. Earlier work on the identification of the individual selenoproteins was made difficult by the fact that, unlike many other protein families, their common characteristic is not found in their functions or their sites of action but in the selenocysteine residue and the genetic code responsible for its insertion. Accordingly, the first studies were carried out by means of protein purification and analysis of selenium and selenocysteine. The first selenoenzyme to be identified was glutathione peroxidase, in 1973. This was followed by the detection of a second enzymatic function in the form of the type I iodothyronine deiodinase in 1990. Several other selenoproteins have been identified in this way, including the thioredoxin reductases, another important enzyme family. By labeling rats with radioactive ^{75}Se and determining the tracer distribution in the proteins separated by gel electrophoretic methods, it was shown that selenium is present in more than thirty specific mammalian proteins or protein subunits. This finding was the basis for the detection of further selenocysteine-containing selenoproteins. The decoding of the mammalian genomes then offered the possibility of identifying the selenoprotein genes by computational screening methods and in this way 25 different human selenoprotein genes were identified. According to our current stage of knowledge, the selenoproteins can be divided into two groups, those with known biochemical functions and those with functions still unknown.

Selenoproteins with Known Functions

All the selenoproteins in this group are enzymes, with the selenocysteine residue responsible for their catalytic functions.

Glutathione Peroxidases

The glutathione peroxidases are either monomers with one selenocysteine residue or homotetramers of

selenocysteine containing subunits with molecular masses around 22 kD. They catalyze the reduction of hydrogen peroxide and various organic peroxides and thus protect cells from oxidative damage. Glutathione normally serves as the electron donor but there are cases where other thiols are oxidized in order to fulfill a specific biological role.

Cytosolic Glutathione Peroxidase (GPx1, cGPx)

is a tetramer, cytosolic and ubiquitous, with highest levels in liver and erythrocytes.

Gastrointestinal Glutathione Peroxidase (GPx2, GI-GPx)

is a tetramer, cytosolic and found only in the gastrointestinal tract and the liver.

Plasma Glutathione Peroxidase (GPx3, pGPx)

is a tetramer, extracellular glycoprotein, expressed in various tissues with the kidney as the main production site, which can also use glutaredoxin and thioredoxin as electron donors.

Human Glutathione Peroxidase 6 (GPx6)

is a tetramer, identified by computational screening of the human genome. GPx6 mRNA is only found in embryos and in the olfactory epithelium.

Phospholipid Hydroperoxide Glutathione Peroxidase (GPx4, PHGPx)

is a 20 kD monomer, present in tissues in both cytosolic and membrane-associated forms. The mitochondrial form is due to a precursor with a specific N-terminal leader sequence. The enzyme can reduce phospholipid and cholesterol hydroperoxides and may use other thiols as electron donors. It has a structural function as an inactive matrix component of the mitochondrial capsule of the sperm flagellum.

Sperm Nuclei Glutathione Peroxidase (snGPx)

is a 34 kD monomer, the only selenoprotein in sperm nuclei, which differs from GPx4 in its N-terminal sequence by having a nuclear localization signal encoded for by an alternative exon in the first intron of the gene. snGPx acts as a protamine thiol peroxidase responsible for disulfide cross-linking and stabilization of the condensed nuclei.

Iodothyronine Deiodinases

The iodothyronine deiodinases catalyze the monodeiodination of the iodothyronines at the 5'-position of the phenolic ring and/or at the 5-position of the tyrosyl ring. In this way they are responsible for the activation and inactivation of the thyroid hormones that regulate various metabolic processes and are indispensable for the normal development of the fetal brain.

Type 1 Deiodinase (D1)

is a membrane-associated homodimer of 27 kD subunits located mainly in the thyroid, liver, kidney and pituitary, which catalyzes 5'- and 5-monodeiodination. Its main functions are production of T_3 from T_4 and inactivation of T_4 to reverse T_3 and of T_3 to T_2 .

Type 2 Deiodinase (D2)

is a membrane-associated 31 kD monomer expressed mainly in the brain, brown adipose tissue, pituitary and placenta. It catalyzes 5'-monodeiodination, its main function being tissue-specific intracellular production of T_3 from plasma T_4 .

Type 3 Deiodinase (D3)

is a membrane-associated 32 kD monomer, predominantly found in the central nervous system, placenta and skin, which catalyzes 5-deiodination, regulates the supply of T_4 and T_3 from mother to fetus and protects the developing brain from excessive amounts of T_3 by inactivation of T_4 to reverse T_3 and of T_3 to T_2 .

Thioredoxin Reductases

Thioredoxin reductases, present in various tissues, were named for their ability to catalyze the reduction of oxidized thioredoxin. Reduced thioredoxin (Trx) is an electron donor for various redox-dependent systems (e.g. ribonucleotide reductase essential for DNA synthesis) and for the redox regulation of transcription factors and is involved in other cellular processes such as secretion, regulation of cell growth and protection against ►oxidative stress and ►apoptosis. Mammalian thioredoxin reductases are able to use other substrates including hydroperoxides and various enzymes and proteins. Three human thioredoxin reductase isoenzymes encoded for by different genes have been identified:

Thioredoxin Reductase 1 (TrxR1, TR1)

is a cytosolic homodimer of 56 kD subunits, which constitutes, together with Trx1, the cytosolic thioredoxin system.

Thioredoxin Reductase 2 (TrxR2, TR3)

is a homodimer of 56 kD subunits with an N-terminal mitochondrial leader sequence. Together with Trx2, it forms a mitochondrial thioredoxin system.

Thioredoxin-Glutathione Reductase (TGR, TR2)

is a microsomal homodimer of 65 kD subunits, mainly present in the testis. It differs from TrxR1 and TrxR2 by an additional N-terminal glutaredoxin domain and catalyzes the reduction of both oxidized thioredoxin and oxidized glutathione.

Further Thioredoxin Reductases

Multiple mRNA forms of TrxR1 and TrxR2 suggest the existence of further thioredoxin reductase species, which may differ with regard to their distribution among tissues and subcellular compartments and may have specific biological roles.

Other Selenoenzymes**Selenophosphate Synthetase 2 (SPS2)**

is a cytosolic 50 kD enzyme, present in various tissues, which catalyzes the production of selenophosphate and, as a selenoprotein involved in selenoprotein synthesis, is of special interest with regard to the regulation of selenium metabolism.

Methionine-R-sulfoxide Reductase (SelR, SelX, MsrB1)

is a cytosolic (and nuclear in some tissues) zinc-containing 12.6 kD enzyme that catalyzes the reduction of methionine-R-sulfoxide in a diastereomeric mixture of this sulfoxide and methionine-S-sulfoxide, present after oxidation of methionine by reactive oxygen species.

Selenoproteins with Functions Still Unknown**Selenoprotein P (SelP)**

is an extracellular heparin-binding 43 kD glycoprotein with 10 selenocysteine residues per molecule, produced in most tissues but with the liver as the main production site. It is secreted into plasma or interstitial fluids. Several studies suggest that it may act as a selenium transport protein but it may also have antioxidant properties.

Selenoprotein W (SelW)

is a cytosolic 10 kD protein found in various tissues but enriched in skeletal muscle, heart, brain, testis and spleen. Some studies suggest a redox function.

15 kD Selenoprotein (Sel15, Sep15)

is a selenocysteine-containing 15 kD subunit of a cytosolic 240 kD protein, found in various tissues but especially enriched in the prostatic epithelium. Some studies suggest anticarcinogenic properties.

18 kD Selenoprotein (Sel18)

is present in the mitochondrial membranes and is one of the selenoproteins most preferentially supplied with selenium.

Selenoproteins Identified in Silico

Computational screening of the human genome led to the detection of several selenoproteins with functions not yet known. They include (approximate molecular masses calculated from their cDNA sequences) SelH

(14 kD), SelI (48 kD), SelK (10.5 kD), SelM (16 kD), SelN (60 kD), SelO (73.5 kD), SelS (20.8 kD), SelT (20 kD) and SelV (38 kD). With the exception of SelV, which is expressed only in the testis, they are present in various tissues. SelK is a plasma protein, SelM a perinuclear protein and SelS a plasma membrane protein related to glucose metabolism. SelN is an endoplasmic reticulum glycoprotein that is expressed mainly in fetal tissues and developing cells and may be involved in early muscle formation.

⁷⁵Se-labeling studies in rats showed the existence of further forms of selenoproteins, which may be due to alternative splicing or posttranslational modification, but there is also the possibility that there may be further selenoprotein genes not yet detected by the computational screening methods.

Clinical Relevance

A vast number of publications deal with possible relationships between changes in selenium and selenoprotein status and diseases, but in many cases evidence for a cause-effect relationship has not yet been found. Unlike other proteins, selenoprotein expression depends not only on genetic factors but also on the dietary selenium supply and most of the information on the effects of diminished selenoprotein expression has so far been obtained in controlled selenium deficiency studies. Animal tissues affected in selenium depletion include cardiac muscle, erythrocytes, eye, kidney, liver, pancreas, skeletal muscle, skin, spermatozoa and testis. In humans selenium deficiency was found to be a pathogenic factor in cardiomyopathy, muscular disorders and thyroid hormone related diseases. Protective effects of selenium administration have been observed in carcinogenesis, several viral infections such as hepatitis and HIV and epileptic seizures.

Due to the hierarchy in selenium distribution, selenium depletion does not affect the most preferentially supplied tissues and selenoproteins to such a degree that lesions appear. Genetic changes, however, may affect any selenoprotein in any tissue.

Single nucleotide polymorphisms have been found in some selenoproteins. A variant allele for GPx1 was less responsive to the stimulation of its enzymatic activity by selenium supplementation and was associated with an increased risk of lung and breast cancer. Similarly two alleles of Sel15 were identified which responded differently to selenium supplementation and may be involved in cancer development or risk. Genetic alterations of GPx2 and SelP have been investigated in relation to colon cancer. Mutations of the SelN gene are involved in rigid spine muscular dystrophy, a neuromuscular disorder. It is very likely that numerous further variants will be found. With SelP, which is involved in selenium transport, genetic changes may lead to an insufficient supply to the high priority organs such as the central

nervous system. Alterations in GPx4 and snGPx may lead to infertile spermatozoa. As the selenoproteins have a wide spectrum of enzymatic and regulatory functions, polymorphisms may affect various metabolic processes and may thus play a role in a multitude of diseases.

Sequence Annotation in Evolution

STEFFEN HENNIG

RZPD - Deutsches Ressourcenzentrum für Genomforschung, Berlin, Germany
 hennig@rzpd.de

Definition

The history of life as far as we know at present spans the enormous time period of around 3.5 billion years. The ‘tree of life’ concept originally starting with Darwin's pioneering ideas was for more than a century mainly based on findings from the fossil record and morphological comparison of living species. With the availability of the DNA sequences of several complete genomes and the sequences of genes and their products (proteins), we now enter an era where the ‘tree of life’, which shows the main phyla as they arose from their respective ancestors, can be inspected directly by genome comparison between species.

Practical applications of sequence annotation in the context of evolution are, e.g. the development of the major histocompatibility complex (MHC) between primates (1) or over long time scales (2) or studies on the origin of vertebrates (3).

Characteristics

The main difference between ‘classical’ sequence annotation and annotation with an evolutionary focus is the proper definition of the genes and proteins related between species, i.e. the identification of ►[orthologs](#) and ►[paralogs](#) is essential. Evolutionary sequence annotation tries to find the root through the tree of species in order to gain insights either into the general ►[phylogeny](#) (e.g. how and when vertebrates arose from the invertebrate lineage) or focuses on specific gene families conserved between species. Finally it has to be noted that with the abundance of genome and protein data generated by the large-scale genome projects, we have, for the first time, the chance to investigate the mechanisms of evolution from first principles – by studying the dynamics of small changes in the genome and how they are transferred into functional genes and proteins.

A Survey of the Available Data

Table 1 lists the milestones in the public sequencing efforts carried out by the large sequencing centres and by various smaller groups. In 1995 the genome sequence of the bacterium *Haemophilus influenzae* comprising about 1.8 Mb was the first example of a completely sequenced genome. Since then the world-wide sequencing effort has scaled up a lot, the most spectacular results being the almost completed genomes of *Homo sapiens*, *Mus musculus* and several invertebrates (*D. melanogaster*, *C. elegans*, *S. cerevisiae*) and plants (*A. thaliana*). Besides the genomic sequencing projects, several groups have focused on the generation of full-length mRNA sequences, which allow determination of the corresponding protein sequences. For instance in SwissProt (by beginning of 2006) around 200000 protein sequences from over 9500 species are stored and functionally characterized.

Sequence Annotation in Evolution. Table 1 History of genome sequencing starting with the first completely sequenced genome of *H.influenzae*. Data are rounded and mainly reflect the correct order of magnitude. The number of genes and proteins is taken as equal for simplicity. SwissProt is one of the largest public collections of protein data for all species

organism	size [Mb]	year	no genes/ proteins
<i>Haemophilus influenzae</i>	1.8	1995	1700
<i>Escherichia coli</i>	4.6	1997	4400
<i>Saccharomyces cerevisiae</i>	12	1997	6200
<i>Caenorhabditis elegans</i>	102	1998	20000
<i>Arabidopsis thaliana</i>	114	2000	5300
<i>Drosophila melanogaster</i>	180	2000	13500
<i>Homo sapiens</i>	2860	2001	33000
<i>Mus musculus</i>	3000	2002	33000

Protein data: SwissProt (200000 proteins from 9500 species)

Proteins are the main subject of evolutionary studies based on sequence analysis, since even over distances of hundreds of million years, related proteins in different species can be identified by sequence comparison, while the corresponding mRNA sequences will have diverged too much for proper analysis. On the other hand, for species close in evolution (e.g. primates or rodents) analysis on the DNA level provides direct insights into the molecular mechanisms of evolution.

Methods of Analysis I: Evolution at the DNA Level

It is a widely accepted hypothesis that all living species have one common ancestor, who emerged around 3.8 billion years ago, although it is still unclear if LUCA (the last universal common ancestor) belonged to archaea or bacteria or represented another yet unknown phylum. The main argument for the existence of LUCA is the surprising number of proteins conserved from ancient bacteria up to higher vertebrates and the universal genetic code. Many details of the tree of life (Table 2) can be deciphered by comparative analysis of genome and protein sequences, which also gives important insights into the dynamics of evolution on the molecular level.

There are several processes which cause changes in the genome and therefore might be responsible for evolutionary changes: a) single base substitutions or

insertions/deletions, b) chromosomal rearrangements or duplications and c) horizontal gene transfer. The latter is known to happen frequently in microorganisms, where transfer of genes from one species to another has been reported in many publications. There are strong indications that especially in the early stages of life, horizontal gene transfer was an essential mechanism for the creation of new species, although the underlying principles are not yet understood. a) and b) are fundamental processes probably acting in all higher eukaryotes and are regarded by many scientists as the main driving forces of evolution.

The genetic code is not unique. There are 61 triplets of nucleotides (codons) coding for altogether not more than 20 amino acids. As a consequence there are base substitutions, which do not affect the resulting amino acid (▶**silent substitution**), mostly changes at the third codon position, while changes at the first or second position in almost all cases change the resulting amino acid (▶**non-silent substitution**). Figure 1 gives an example of a codon where a single base is substituted, which in one case doesn't change the resulting amino acid (glutamic acid) while in the other case it does (valine). In fact, the non-silent mutation shown in Fig. 1 is a classical example, since the same kind of single-base mutation affecting the β -globin chain of hemoglobin causes sickle-cell anemia.

The number of silent (S) or non-silent (N) substitutions observed between a pair of genes in two different species, or in one species if we consider duplicated genes, is an indicator of their relative age and also

Sequence Annotation in Evolution. Figure 1 Schematic presentation of single base substitution types in codons resulting in an unchanged or changed amino acid.

provides information about their evolutionary status. If we define $\omega = dN/dS$ as a cumulative ratio of non-silent/silent substitution rates per codon site, then $\omega > 1$ means that the corresponding protein is under strong evolutionary pressure (i.e. high rate of functional relevant amino acid changes), $\omega < 1$ indicates strong evolutionary constraints for amino acid changes (▶**purifying selection**) and $\omega \approx 1$ means a fully relaxed

status where both kinds of substitutions occur at the same frequency. Conery and Lynch (4) have studied the temporal behavior of ω for 9 different species with almost completely sequenced genomes. They identified duplicated genes within each species by sequence comparison of all available open reading frames, which resulted in a very rich set of duplicate pairs. The numbers of silent and non-silent substitutions per duplicate were counted. From this exhaustive study, they deduced that duplicated genes undergo different phases of selective pressure. For young duplicates, where the absolute number of silent substitutions per site is small ($S < 0.05$), they found in all species ω in the range of relaxed or strong evolutionary pressure ($\omega \geq 1$), while for older duplicates, non-silent substitutions are generally reduced ($\omega < 1$), indicating strong selective constraints.

On the assumption of the inherently stochastic nature of molecular evolution, the rates of silent and non-silent base substitutions also allow estimates of the relative age of the respective gene pairs. One of the most general mathematical models up to now has been developed by Yang and Nielsen (5). Their algorithm, which is implemented in the publicly available PAML package (Table 2), takes into account that for gene pairs in species separated by long evolutionary times, multiple steps of substitution at the same site might have occurred and therefore a proper model has to weight all possible paths of substitution steps leading from codon A to codon B. The different rates between non-silent substitutions changing the amino acids either from purine to purine (►transition) or from purine to pyrimidine (►transversion) are also explicitly included in Yang and Nielsen's algorithm. It takes as input two properly aligned nucleotide sequences and gives as output the estimated values for rates dS, dN, ω and the relative time distance t .

Methods of Analysis II: Evolution at the Protein Level

Typically, for species separated by hundreds of millions of years of evolution the divergence of DNA sequences is high. Analysis of mutations based on the methods described above is very difficult and has to deal with saturation effects. Protein sequences show a much higher degree of conservation during evolution, so that evolutionary studies of very distant species are normally performed by protein comparison. At this point it is helpful to introduce the concepts of orthology and paralogy. If two proteins from different species arose from one common ancestor protein they are described as orthologs, if a protein was the result of gene duplication within a single species it is described as a paralog. In all sequence based studies of evolution between species, it is very important to focus on the orthologous proteins, since we know e.g. from the results of Conery and Lynch (4) that the mutation rates

of duplicated genes within a species (paralogs) might be different from those of orthologs. An easy way to find the orthologous proteins for different species was proposed by Tatusov et al. (6). Given the complete protein sets for two species, the orthologs are found by an all-against-all sequence comparison, i.e. all proteins of species A are compared against all of species B and *vice versa*, followed by a ranking procedure, which finds those pairs of proteins in A and B with highest scoring hits with each other. The resulting best-hit pairs are the most likely orthologs between species A and B. Since extension of the algorithm to multiple species comparison is straightforward it has been widely used for the construction of groups of orthologous proteins for various species (3), e.g. in the COG database (Table 2). It should be noted that this algorithm is valid only under the condition that the compared protein sets are completely known, which is nearly fulfilled for many bacterial genomes and might also be a good assumption for the completely sequenced higher eukaryotes like yeast, *C.elegans*, *Drosophila*, *A.thaliana*, mouse and *H.sapiens*. For species with only few known proteins the method of Tatusov is not applicable.

When studying families of proteins with more than two members, the first step in building the corresponding phylogenetic tree, which is the representation of their relationship, is usually a multiple sequence alignment (MSA). There are various methods and tools available to construct an MSA, the most famous one may be the CLUSTAL program, which is freely distributed by the authors (Table 2). A comprehensive introduction to the field can be found in Durbin et al. (7), where all important concepts and algorithms for phylogenetic calculations are also treated in detail. The MSA is the input for the algorithm that builds the phylogenetic tree. CLUSTAL, for example, has an integrated neighbor-joining algorithm, which performs the tree construction directly from the MSA.

There are numerous methods to calculate phylogenetic trees, e.g. ►neighbor-joining (NJ) and ►parsimony. For a comprehensive overview the book of Durbin et al. (7) and the web page of J. Felsenstein (Table 2) are highly recommended. Figure 2 gives an example of a tree constructed by NJ for the α -catenin family of proteins, which are found in invertebrates and vertebrates. It was drawn with the additional constraint that the sea urchin protein (Q25430) should be the outgroup, since sea urchin is known (from the fossil record) to be the oldest species in the set. The tree nicely separates the two subgroups $\alpha 1$ and $\alpha 2$ of catenins in mammals (human, mouse), while in invertebrates (sea urchin, *Drosophila*) only one group is found. $\alpha 1$ catenin in humans is located on chromosome 5 (q31.2) and is important for cell adhesion. Mutations in $\alpha 1$ catenin are involved in the process of cancer invasion and metastasis. The human

Sequence Annotation in Evolution. Figure 2 Phylogenetic tree of the α -catenin class of proteins. CTN1/2 represent the α 1/ α 2 subgroups of the protein family in human and mouse. The tree was constructed by the Neighbour-Joining algorithm. The sea urchin protein was manually selected as the most likely outgroup.

α 2 *catenin* is found at a different locus (chrom.2p12) and probably has similar function.

A standard method for testing the quality of the tree is **▶bootstrapping**: In the final MSA single columns of the alignment are randomly shuffled and the tree-building algorithm is started again. This is repeated many times (1000 \times) and the most likely solution is just the tree that was found in most of the cases. Bootstrapping therefore gives a statistical measure for the resulting tree (score), which is very useful for automated quality tests.

The length of the edges, i.e. the lines connecting the nodes in the tree with the end-nodes representing the proteins, can be regarded as evolutionary distance on an abstract time scale. In the **▶molecular clock** hypothesis one assumes that amino acid substitution on an average happened at a constant rate over all branches of the tree. If the molecular clock is valid, knowledge about the true time distance t between two nodes in the tree is sufficient to convert all distances to the respective numbers of years. Molecular clock approximations have been used extensively in the last few years for estimates about the age of specific members of the human MHC family of genes (2) or for dating of the invertebrate-vertebrate split (3).

A Large Scale Study on Ancient Genome Duplications

The 2R hypothesis originally proposed by Ohno in 1970 postulates two rounds of whole genome duplications at

the origin of vertebrates to explain the increased complexity of vertebrates with respect to their invertebrate relatives. Ohno's work was mainly ignored for more than 20 years by the scientific community, but since the availability of several complete invertebrate and mammalian genomes has gained more and more attention. Several publications based on selected small gene families addressed the 2R hypothesis, but the final results gave no consistent picture. Recently, in an elaborate study I was involved in, several thousand protein families (3) from 4 invertebrate species (yeast, *C. elegans*, *Drosophila*, *Amphioxus*) were compared against the complete human protein set. The analysis steps can be summarized as follows:

- Clusters of proteins orthologous between all invertebrate species were constructed by the method of Tatusov and Koonin (see above). Only those proteins were taken which existed in not more than one copy in each invertebrate species.
- The resulting ≈ 3000 orthologs were compared against all human and mouse proteins, which were attached to the orthologous sets and classified into orthologs or paralogs. In total around 10,000 human proteins could be clearly attached to the invertebrate sets. Extra copies of human proteins (paralogs) were counted per group and the final statistics showed a tremendous increase of extra copies in mammals. Compared to the invertebrate orthologs (1 copy per definition), there are 3–4 copies in human.

- c) For all proteins in the respective groups, phylogenetic trees were constructed and the time distance between the human duplicates measured using the molecular clock model.
- d) The human gene sequences corresponding to the duplicated proteins were analyzed by the method of Yang (see above) for occurrence of silent and non-silent substitutions, which gave an additional measure of the time point of duplication.

In Fig. 3 the results of two different methods for time measurement are shown. As mentioned above the data contributing to the plotted bars were human duplicated proteins (genes), which were proven to be orthologs of invertebrate proteins existing only in one copy. The correspondence of both methods is remarkable. Both gave a time distribution around 500–550 million years ago (mya), which coincides quite well with estimates about the split between vertebrates and invertebrates. Moreover, by analyzing the positions of the human duplicates along the chromosomes, it could be shown that duplicated genes are found with high significance

Sequence Annotation in Evolution.

Figure 3 Distribution of duplication times for human genes, which have a known orthology to 3 invertebrate species. The methods used were molecular clock (blue boxes) and Yang and Nielsen's (YN) method (red boxes) as described in the text. Both methods give a relatively sharp maximum around 500–550 million years (myr), where a genome duplication might have happened. The second peak around 50 myr can be attributed to recent duplications.

in specific chromosomal segments, which can be interpreted as traces of an ancient genome wide duplication event.

Thus, by a combined approach using all the techniques and models described above, it was possible to identify an ancient duplication event centered around 550 mya, which might explain the increased genome complexity in higher vertebrates. In parts the hypothesis of genome duplication seems to be justified, with the restriction that only evidence for one round of genome duplication could be found.

Clinical Relevance

While the example above demonstrates mainly the potential of evolutionary sequence analysis for answering fundamental questions about the tree of life, there are various applications of the same methods with direct medical relevance. Evolutionary analysis of specific gene families like the MHC class contributed significantly to a deeper understanding of the basic mechanisms of the immune system. Comparative analysis of e.g. the MHC class II region in human, rhesus macaque and rodents showed that several genes in that region are primate specific (1) and seem to be under purifying selection as indicated by analysis of substitution rates at silent and non-silent codon sites. Furthermore, a deep phylogenetic analysis of MHC class I genes in vertebrates and their orthologs in invertebrates supports the hypothesis that many of the primate MHC genes are very young and subject to frequent changes in a birth-and-death like process, where single genes are duplicated, modified and frequently deleted again (2).

Sequence Comparison

MARTIN VINGRON

Max Planck Institute of Molecular Genetics, Berlin,
Germany
vingron@molgen.mpg.de

Definition

DNA and proteins are usually denoted as strings of letters representing the nucleotides or amino acids, respectively. Due to the common evolutionary origin of sets of genes these strings may display a marked similarity. Sequence comparison methods are employed for the detection of this similarity and for the identification of similar sequences in large [sequence databases](#).

Description

Sequence Alignment and Dot-Plots

Similarity among two or more sequences is displayed in the form of an alignment, which is an arrangement of the sequences on top of each other such that matching or conserved residues are aligned with each other, forming a column. This usually requires the introduction of gap characters to make up for insertions or deletions in the sequences. Figure 1 shows the alignment of the amino acid sequences of human alpha and beta chains of hemoglobin. An alignment of two sequences is called a pairwise alignment; an alignment of several sequences is called a multiple alignment. Generally it is assumed that a certain level of similarity among sequences is an indicator of homology, i.e. of a common evolutionary origin.

For two sequences, the exact definition of sequence similarity, its quantification and the algorithm for computing an alignment are tightly linked (1). The general goal is to find an alignment that introduces just enough gaps to pinpoint the conserved residues among the sequences. To this end, weights are assigned to the matching of letters and to the gaps. A reasonable scheme for nucleotide matching would e.g. assign +1 for pairing up two identical residues, -0.7 for pairing up two unequal residues. While good matches lead to a positive score, any gap that is needed gets penalized, say with the subtraction of 2 score points per gap

character. Frequently, a series of contiguous gap characters is assigned a score that is composed of a “gap-open” penalty plus a “gap-extension” penalty that is multiplied by the length of the contiguous gapped stretch. A dynamic programming algorithm is used to compute an alignment optimizing this score and at the same time the score itself. The most widely used variant of sequence alignment algorithm is the Smith-Waterman algorithm (2), which identifies those regions from the two sequences that match up best.

Graphically the similarity between two sequences becomes apparent when depicting stretches of matching residues in a rectangle spanned by the two sequences. Figure 2 shows an example of such a dot-plot. There, the coding DNA sequences of the alpha chain of human hemoglobin are compared to those of the beta chain of human hemoglobin. Sequence windows of length 31 were inspected. Within these windows a score is calculated where +5 was assigned for pairing up equal residues and -4 for unequal residues. The grey values of the dots scale with the similarity of the two windows. One can clearly discern a sequence of diagonal stretches along the length of the two sequences. Note that linking these diagonal stretches requires the introduction of jumps. These jumps correspond to positions where in an optimal alignment a gap would be introduced.

The alignment of proteins is usually based on more sophisticated scoring schemes for pairs of amino acids. Each possible amino acid pair is assigned a value that is derived from an analysis of observed exchange frequencies among amino acids in homologous proteins. Among the widely used examples of such amino acid exchange matrices are the PAM120, PAM250 (3), the BLOSUM62 (4) and the VT160 (5) matrices. The numbers in those names stem from a framework wherein the matrix describes a particular evolutionary distance. For example, in the PAM and VT series of matrices the evolutionary distance is measured in multiples of the time during which on average 1 amino acid in 100 is mutated.

When a sequence contains one or several subsequences that resemble each other, one speaks of internal repeats. Sequence alignment may be a suboptimal tool for the delineation of repeats because one needs to inspect an unknown number of alternative alignments in order to spot all instances of a repeated region. This problem is better approached by inspecting a dot plot comparing

a sequence to itself. In the presence of internal repeats the dot plot will display a characteristic pattern of parallel diagonals stemming from the subsequences that match up.

Multiple Alignment

Multiple alignment compares several sequences simultaneously and constitutes a computationally very hard problem. Practical programs rely on iterative execution of pairwise sequence alignment or implement heuristics to search the large space of possible multiple alignments. Scoring schemes are usually composed of the pairwise similarity scores, either of all protein pairs or of those protein pairs that are adjacent to each other in a phylogenetic tree. Widely used programs for multiple alignment are CLUSTALW (6) and DIALIGN (7) with the latter being more geared toward the identification of similar subsequences from and among the given ones. It should be noted, though, that no sequence alignment output by a program should be accepted without visual inspection, possibly leading to subsequent manual improvement. Alignment editors like seaview (8) are helpful in this context.

Applications

The applications of sequence alignment programs are manifold and range from evolutionary studies to structure prediction. In particular, a multiple alignment constitutes the typical starting point for a phylogenetic study. However, a certain circularity must be noted

there, since frequently a preliminary phylogenetic tree based on pairwise comparisons is used for the computation of the multiple alignment. Another prominent application of sequence comparison lies in function prediction. In particular, common [protein domains](#) can be detected that then lead to the hypothesis that both proteins share the function mediated by the particular domain. Structure prediction, and here in particular [homology modeling](#), also relies on a sequence alignment.

Database Searching

Sequences are collected in sequence databases. Given a new sequence the first question is whether it is similar to anything that is known already. This is answered by comparing the new sequence, the query, to all sequences in a database using the program BLAST (9). In effect, BLAST performs a similar operation to that of the Smith-Waterman alignment on the query against each sequence in the database, although much faster. BLAST can compare DNA with DNA and protein with protein, but it also allows comparison of for example, a protein sequence against a nucleotide database by implicitly translating in all reading frames. A more sensitive search is effected by the program PSI-BLAST (9), which uses newly identified sequences to initiate a new round of searching. Generally one faces a trade-off between speed and sensitivity here; the faster the search program the more unlikely it is to pick up distantly related sequences.

Correct judgment of the findings of a database search requires a statistical assessment of the scores that were achieved. Today, the random distribution of the similarity score is well understood (1) allowing us to determine the statistical significance of the hits that were obtained. A typical database search program will, for each sequence, output a so-called E-value. The E-value is an estimator of the number of sequences one would find by chance scoring better than this particular sequence. This figure not only reflects the quality of the similarity but also the size of the database, which constitutes a major factor in the judgment of significance.

Given a multiple alignment for a protein family or a protein domain, one often wishes to identify additional related sequences. This is achieved by converting the given alignment into an HMM, a hidden Markov model. An HMM can be thought of as an automaton that can generate sequences that look like the ones with which it was fed. A special algorithm can also compute the probability that another sequence could be the product of this generation process. HMMs are used for database searching by computing this probability for each entry in the database. Today, this process is the basis for the most sensitive database searching procedures (10).

Protein Families, Orthology, and Paralogy

Two homologous genes from two different organisms are called orthologous when on the evolutionary path from their most recent common ancestor to the present day genes no gene duplication event has occurred (11). Otherwise they are called paralogous. This definition is sometimes sharpened by also considering genomic order. Database searching serves as a basis for the delineation of protein families. Using each sequence in a database as a query for an individual search, one can compute an all-versus-all comparison. From this information, clustering algorithms are applied to determine groups of proteins that are likely to fall into families of paralogous genes. Determination of orthologous genes is more involved because one rarely has knowledge of the complete evolutionary tree of the genes under study in order to check for the absence of duplication events. Alternatively, the availability of complete sets of genes for two organisms allows the determination of orthology based on two “reverse” database searches. Two genes are likely to be orthologous when either one identifies the other one as most similar in a search among the genes of its organism. Linking together pairs of genes that have been determined as orthologous by this scheme leads to clusters of orthologous genes (12).

Genomic Comparison

Sequence comparison is not only used to identify homologous genes but has also become a major tool in the processing of genomic sequences. For example, alignment between the coding sequence of a gene and its genomic region is applied for the delineation of gene structure. When no coding information is available, comparison of genomic regions from say man and mouse may, by way of the conservation pattern, indicate the location of exons or possible regulatory elements. Emphasis in genomic comparisons is often on identifying near identical sequences to the query, where possible differences are due to sequencing errors or allelic differences. Software for this purpose is optimized for speed rather than sensitivity. A typical example is the program BLAT (13), which is used to locate a piece of sequence of an organism in a database holding this organism's genomic sequence. For the comparison of long stretches of sequence, a classical sequence alignment is not a practical output. The program BLASTZ (14) visualizes a comparison between two genomic regions by focusing the display on one organism or region and plotting over it the level of similarity one finds between the two sequences.

Pattern Finding

Complete genomic sequences are, in particular, supplying us with non-coding sequence in which to search for

regulatory signals. This, too, is approached using sequence comparison methods, albeit with an emphasis on subtle, short similarities. Input to such an analysis could come from for example a set of co-expressed genes as determined in a [▶microarray](#) experiment. The upstream regions of these genes are then expected to harbor common sequence patterns reflecting possible binding sites of transcription factors mediating co-expression of genes. Identifying such short patterns poses both an algorithmic and a statistical problem. Since the search space of all those subtle patterns is huge, not only deterministic algorithms but also stochastic algorithms have been developed for this purpose. A typical program to identify common motifs is MEME (16). The statistical issue stems from the simple observation that regulatory signals may be too short to be distinguishable from random patterns. A program can therefore only enumerate subtle patterns while the biological significance still needs to be established separately.

Sequence Databases

Definition

There is an ever-increasing amount of sequence data being generated from high-throughput methods such as large-scale genome sequencing projects.

Sequence databases contain DNA sequences, transcriptomics data (ESTs, ORESTES, full-length cDNAs) and/or proteomics data (protein sequence data, mutation databases and databases of regulatory regions and elements). Most of them provide additional annotated information such as gene expression, cellular role, protein family and taxonomic data for microbes, plants and humans. Each sequence can be identified by an Accession number.

Search and retrieval entry points are for example the ENTREZ portal (www.ncbi.nlm.nih.gov/entrez <<http://www.ncbi.nlm.nih.gov/entrez>>) and the sequence retrieval system (SRS) at the EMBL-IBI (<http://srs.ebi.ac.uk>). Classified protein family databases such as Prosite (www.expasy.org/prosite <<http://www.expasy.org/prosite>>) are helpful in grouping genes into protein families, and offer a valuable resource for integrating information on cellular and molecular function.

Serial Analysis of Gene Expression

Definition

Serial Analysis of Gene Expression (SAGE) is based on the massive sequential analysis of short cDNA sequence tags. Each tag is derived from a defined position within a transcript. Its size (14 bp) is sufficient to identify the corresponding gene, and the number of times each tag is observed provides an accurate measurement of its expression level. Since tag populations can be widely amplified without altering their relative proportions, SAGE may be performed with minute amounts of biological extract. The most attractive feature of SAGE is its ability to evaluate the expression pattern of thousands of genes in a quantitative manner without prior sequence information.

Shotgun Libraries

MATTHEW C. JONES, KIRSTEN E. MCLAY

The Wellcome Trust Sanger Institute, Wellcome Trust
Genome Campus, Hinxton, Cambridgeshire, UK

mcj@sanger.ac.uk

kem@sanger.ac.uk

Definition

Shotgun libraries are generated to allow the sequence determination of specific ►[DNA](#) molecules. This strategy involves the random breakage of a particular DNA molecule into small pieces. Many copies of the DNA are broken, creating multiple starting points for DNA sequencing distributed throughout the DNA molecule. A series of overlapping DNA sequences can be used to reconstruct the entire sequence of the original DNA molecule. The scattered and random distribution of the DNA fragments bears some resemblance to the random distribution of pellets from a shotgun, hence the name shotgun libraries.

Characteristics

Introduction

The information that defines the nature of an organism (through the medium of polypeptides) is passed from generation to generation in the form of the sequence of four nucleotide bases in the molecule deoxyribose nucleic acid (DNA). It is possible to infer this sequence by the process of DNA sequencing. The majority of DNA sequencing utilises the Sanger method of incorporating chain terminating dideoxy ribonucleotides, whilst synthesising a copy of template DNA. This involves annealing a primer oligonucleotide to the template DNA, and allowing cycles of DNA synthesis (mediated by a thermostable DNA polymerase) to take place. The DNA polymerase generates a complementary strand of DNA to the template, but if it incorporates a dideoxynucleotide (instead of the deoxynucleotide), the complementary strand cannot be extended further. By manipulating the levels of deoxynucleotides and dideoxynucleotides available to the DNA polymerase, strands of a vast range of lengths will be produced. All strands of a specific length will terminate with the specific dideoxynucleotide that is

complementary to the template nucleotide base that distance from the oligonucleotide primer. If the DNA polymerase also incorporates some type of label (most often in the form of fluorescent dye conjugated dideoxy nucleotides) then electrophoresis of the sequencing reaction with a suitable detection system for the label will allow inference of the DNA sequence of the template DNA.

A number of factors influence the length of sequence that can be determined in a sequencing reaction (also called a read, hence the term ►[read length](#)). Current technology limits read length to the range of up to one thousand bases. This is orders of magnitude less than many molecules that are the subject of DNA sequencing projects. In order to determine the DNA sequence of molecules longer than the read-length obtained by current technology, a strategy for generating related smaller DNA sequences has to be employed. Shotgun libraries represent one such strategy, which has enormous potential for using high levels of automation to generate very large quantities of DNA sequence information.

In shotgun libraries, the DNA molecule that is to have its sequence determined is broken, randomly, into small pieces. Because many copies of the DNA molecule are broken and the breakage is random, the location of starting points for sequencing is distributed throughout the DNA molecule. Each randomly generated fragment of the DNA molecule (or a subset of the fragments separated by size) is ligated into a specific point of another DNA molecule (the sequencing vector). This generates a collection (or library) of new DNA molecules, part of each consisting of the same DNA (the vector) and the remainder consisting of different parts of the original DNA molecule. Each of these new molecules is a ►[subclone](#) of the original molecule. Once the sequence of many of these subclones has been determined, that data can be assembled to begin to reflect the DNA sequence of the original molecule. ►[Assembly](#) consists of comparing the DNA sequence of subclones, one with another, and considering those with identical parts of sequence to overlap. Sequence assembly requires a considerable amount of computing power for all but the smallest sequencing projects. Because the subclones are distributed randomly, the DNA sequence derived from them is scattered through the final assembly. This scattered and random distribution bears some resemblance to the random distribution of pellets from a shotgun, hence the name shotgun libraries.

The generation of shotgun libraries involves a number of techniques. The best technique to use at each stage will depend upon a number of factors. The first consideration is the starting DNA. For many large scale projects this will itself be a subclone (into a ►[cloning vector](#), for instance a bacterial artificial

chromosome or ►BAC) derived from genomic DNA. DNA preparations of such primary subclones are relatively easy to produce. Alternatively, the starting DNA may itself be genomic DNA (the whole genome shotgun approach), which may be hard to produce in large quantities, depending upon the organism. If the starting DNA is hard to produce in quantity, optimisation of the following steps should be done with other DNA.

Shearing

There are several techniques for the random (or near random) subdivision of DNA molecules. DNase I in the presence of manganese ions introduces double strand breaks in DNA (1), but this process can be difficult to optimise. Several physical breakage methods involve the passage of DNA solutions through tubing at high pressure; for instance needle shearing (using a 30 G hypodermic needle), ►HPLC tubing (also used in the Hydroshear device) and clinical nebulisers. A very popular method is to use cavitation produced by a sonicator. The sonicator methodology uses a cup-horn sonicator probe, which is functionally similar to an ultrasonic bath. Tubes containing the DNA to be disrupted are suspended in the bath during sonication. Because there is no direct contact between the sonicator and the DNA sample, there is no opportunity for sample-to-sample contamination.

End Repair

Once the DNA has been disrupted, it is necessary to ensure that all the newly generated ends of DNA molecules are in the same form. One technique is to make all the ends of the molecules blunt. This is to ensure that there are neither 3' nor 5' single strand extensions. Provided that starting DNA is not limiting, the easiest way to do this is to use the single strand specific nuclease, mung bean nuclease (EC 3.1.30.1) to digest any single stranded extensions. Where starting DNA is limiting, the use of a mixture of T4 DNA polymerase and ►polynucleotide kinase in the presence of dNTPs will fill-in single stranded ends (rather than nibbling back) and may give a higher yield of subclones per unit amount of starting material.

Ligation

The kinetics of the reaction in which end-repaired DNA fragments are ligated into sequencing vector are such that smaller inserts are favoured over longer inserts. As the costs of each sequencing reaction are about the same, regardless of length of the insert, smaller subclones may not provide a cost-effective amount of sequence. Some methods of disrupting DNA are reputed to produce a smaller range of fragment sizes than other methods. Alternatively, it is relatively easy to

remove small fragments by using preparative electrophoresis in agarose gels. Some staining and visualising methods for DNA electrophoresis can have a deleterious affect on subsequent cloning, but there are strategies to overcome this. One method is to cut off marker tracks, stain and view against a ruler, and then use this measurement to recover agarose slices containing DNA of the desired size, which will not have been exposed to any deleterious influences. The DNA fragments will need to be recovered from the agarose slices. A number of proprietary methods are available for this. It is possible to lose significant amounts of valuable DNA fragments during this part of the process; this should be taken into consideration when dealing with limiting amounts of starting DNA.

Sequencing Vector

A large number of plasmids exist which would be suitable sequencing vectors for shotgun libraries. All feature a selection method (usually antibiotic resistance) to allow the maintenance of the plasmid (and recombinant plasmids derived from it) in bacterial hosts grown in selective conditions. It is necessary to have a single site for the action of a restriction endonuclease, which will leave the resulting ends in a suitable state to accept the fragments of the DNA to be sequenced. In order to encourage the formation of recombinant plasmids (those that contain an insert) rather than re-circularising the plasmid, the linearized vector plasmid can be treated with a phosphatase enzyme such as calf intestinal alkaline phosphatase or shrimp alkaline phosphatase. These enzymes remove the 5'-phosphate group of the linearized vector molecule, preventing T4 DNA ligase from recircularising the plasmid. As the mung bean nuclease treated insert-DNAs maintain 5' phosphate groups, these are a substrate for T4 DNA ligase to create recombinant molecules with the linearized vector plasmid. It is possible to create inserts made up of two or more independent pieces of starting DNA, but this will be minimised by size selection of DNA fragments by preparative agarose gel electrophoresis. Although dephosphorylation of vector should inhibit the generation of recircularised (insert-less) molecules, some will still be produced. Most sequencing vectors in common use have some way of distinguishing between molecules with and without insert DNA. Many systems employ alpha-complementing fragments of the gene for the enzyme β -galactosidase. In suitable bacterial hosts, and plated on media containing IPTG (isopropyl- β -D-thiogalactopyranoside) and Xgal (5-bromo-4-chloro-3-indolyl- β -D-galactoside) bacterial colonies containing vectors without inserts are blue, whilst those with inserts have no colour and appear white or cream.

Template Preparation

Once a library of fragments has been created, the nucleotide sequence of the shotgun fragments can be determined by shotgun sequencing.

An effective template purification method is required to ensure good quality template for use in the sequencing reaction. An individual bacterial colony containing the insert DNA can be selected and placed into a suitable growth media, such as Luria Bertani (LB) broth. To ensure retention of the plasmid, the growth media should be supplemented with an appropriate antibiotic, such as ampicillin. The yield and quality of the plasmid is dependent on the conditions in which the bacterial culture is grown, so it is important to regulate the incubation time and temperature to the optimum.

Plasmid DNA can be prepared by a variety of modifications of the original alkaline lysis method of Birnboim and Doly (2). The alkaline lysis procedure essentially relies on bacterial lysis by sodium dodecyl sulphate and sodium hydroxide. Subsequent neutralization with potassium acetate results in selective precipitation of the bacterial chromosomal DNA along with other cell components of high molecular weight, leaving the desired DNA in suspension. The plasmid DNA suspension can easily be aspirated off and precipitated using isopropanol. The aim of this preparation method is to obtain plasmid DNA that is uncontaminated with bacterial chromosomal DNA. This is a relatively cheap and effective way of obtaining template of good sequencing quality, with many commercial kits now available for DNA purification based on this original method. For high throughput template preparation, microtitre plates and robotic workstations are regularly used where large numbers of subclones will be involved.

It would be prudent at this stage to assay the yield of plasmid DNA by agarose gel electrophoresis prior to sequencing. It is essential to have high quality, quantified DNA to ensure that the sequence data is also of high quality. Running a standard marker alongside the purified DNA ensures that the DNA is of adequate concentration and insert size to proceed with sequencing.

Sequencing

The two main methods of DNA sequencing described in 1977 are the dideoxy chain termination method (Sanger) (6) and the chemical degradation method (Maxam and Gilbert) (5).

Although both techniques are still used today, in large-scale genome sequencing the Sanger method is most commonly used. The Sanger method involves the synthesis of a DNA strand from a single-stranded template by a **DNA polymerase**. By using the correct ratio of the four conventional deoxynucleotides (dNTPs) and one of four dideoxynucleotides (ddNTPs)

in a reaction with DNA polymerase, polynucleotide chains of varying lengths are produced. The ddNTPs are incorporated into the growing strand in the same way as the conventional dNTPs. Due to ddNTPs lacking the 3'-hydroxyl group necessary for chain elongation, when a ddNTP is incorporated into the new strand, the chain elongation will terminate at this position.

By using the four different ddNTPs in four separate reactions the complete sequence information can be obtained. One of the dNTPs is usually radioactively labelled which allows visualization on an autoradiograph following the electrophoresis of the four samples on a polyacrylamide gel. There have been many improvements to this original method, with terminator sequencing now using fluorescent forms of each ddNTP. These can now be added together into a single reaction because each of the ddNTPs has an individual high sensitivity dye attached to it.

One of the major advances in sequencing technology has been the introduction of cycle sequencing which allows the series of events in the dideoxy sequencing method to occur many times under the control of a thermal cycler. Cycle sequencing improves the efficiency and reliability of sequencing double-stranded DNA and results in longer DNA sequences with improved resolution. Another major advance has been the introduction of automated DNA sequencing instruments. These instruments enable the fluorescence emitted from the ddNTPs to be detected and the nucleotide sequence generated.

Data Assembly

Once the DNA sequence has been obtained, the individual reads can then be re-assembled with the use of a computer-based assembly program. Two main assembly packages GAP4 (3) and Consed (4) are widely used to aid the re-construction of the original DNA. Sequencing from both ends of the subclone dramatically improves the efficiency of the final sequence assembly. In contrast to single sequence, (sequencing from only one end of the shotgun subclones), the pairs of sequence reads have known orientation and spacing, aiding the accurate re-assembly of the original DNA molecule.

The majority of large-scale sequencing projects have adopted the shotgun sequencing approach, due to both efficiency and the possibility of automating most of the DNA template preparation and sequencing protocols.

Clinical Relevance

Many clinical disorders have a genetic component. This could range from single gene disorders (such as **cystic fibrosis**) in which sufferers are homozygous for a defective recessive allele at a single locus, to complex

multifactorial conditions, which are influenced by alleles at many loci and by environmental conditions. The studies of these diseases and the discovery of model conditions in experimental organisms have been affected by the large amount of data generated by the human genome project and genome projects for model organisms. All of these projects are dependent on shotgun libraries during their sequencing phase.

Sialic Acid

Definition

Sialic acid (neuramic acid) represents the parent acid of a family of amino sugars containing 9 or more carbon atoms. It may be regarded as the aldol condensation product of pyruvic acid and N-acetyl-D-mannosamine. Sialic acid has not been isolated and characterized as such, but several N- and O-substituted derivatives are widely distributed in nature.

Sialidase

Definition

Sialidase (Neuraminidase) hydrolyses the terminal (alpha)-2 → 3, 2 → 6 and 2 → 8-linkages which bind N-acetylneuraminic acid to N-acetylhexosamines and N- or O-ac(et)ylated neuraminyl residues in oligosaccharides, glycolipids and glycoproteins.

Signal Recognition Particle

Definition

Signal recognition particle (SRP) refers to a nucleoprotein complex that consists of a 7S RNA and 6 proteins. It prevents the release of secreted and transmembrane proteins into the cytosol. SRP binds the N-terminus of a nascent polypeptide chain emerging from a ribosome, transiently arrests translation, and targets the mRNA-ribosome-nascent polypeptide complex for endoplasmic reticulum where the translation is finished.

- [Repetitive DNA Transposons](#)

Signal Transduction (Pathway)

Definition

Signal transduction describes the sequential process initiated by the binding of an extracellular signal to a receptor converting an extracellular signal into a cellular response. Signal transduction pathway describes an intracellular response pathway of proteins that activate each other upon an extracellular stimulus (usually receptor activation), and which generally results in the modulation of the gene expression of target genes.

Definition

Cell adhesion to the ► [extracellular matrix](#) (ECM) is a biologically important event, providing structural and signaling information for biological processes such as

cell proliferation, differentiation migration and apoptosis, but also for tumorigenesis and metastasis. These adhesive interactions are basically mediated by integrins, a large family of heterodimeric transmembrane cell surface receptors. Besides connecting the ECM with the ►cytoskeleton, ►integrins are also capable of specifically inducing various signaling pathways upon ligand binding. These include the activation of mitogen-activated protein kinases, small ►GTPases and protein kinase C, as well as the modulation of phosphoinositide levels, leading to cell- cycle control and cytoskeletal re-organization (outside-in signaling). Furthermore, signals from inside the cell can modulate the integrin affinity for its ligands, followed by changes in cell adhesion and migration (inside-out signaling). Engagement of integrins results in integrin clustering and the binding of signaling and cytoskeletal proteins to the integrin cytoplasmic domains, leading to the formation of multiprotein complexes called focal adhesions. ►Focal adhesions are heavily enriched in structural and signaling molecules, anchor actin fila-

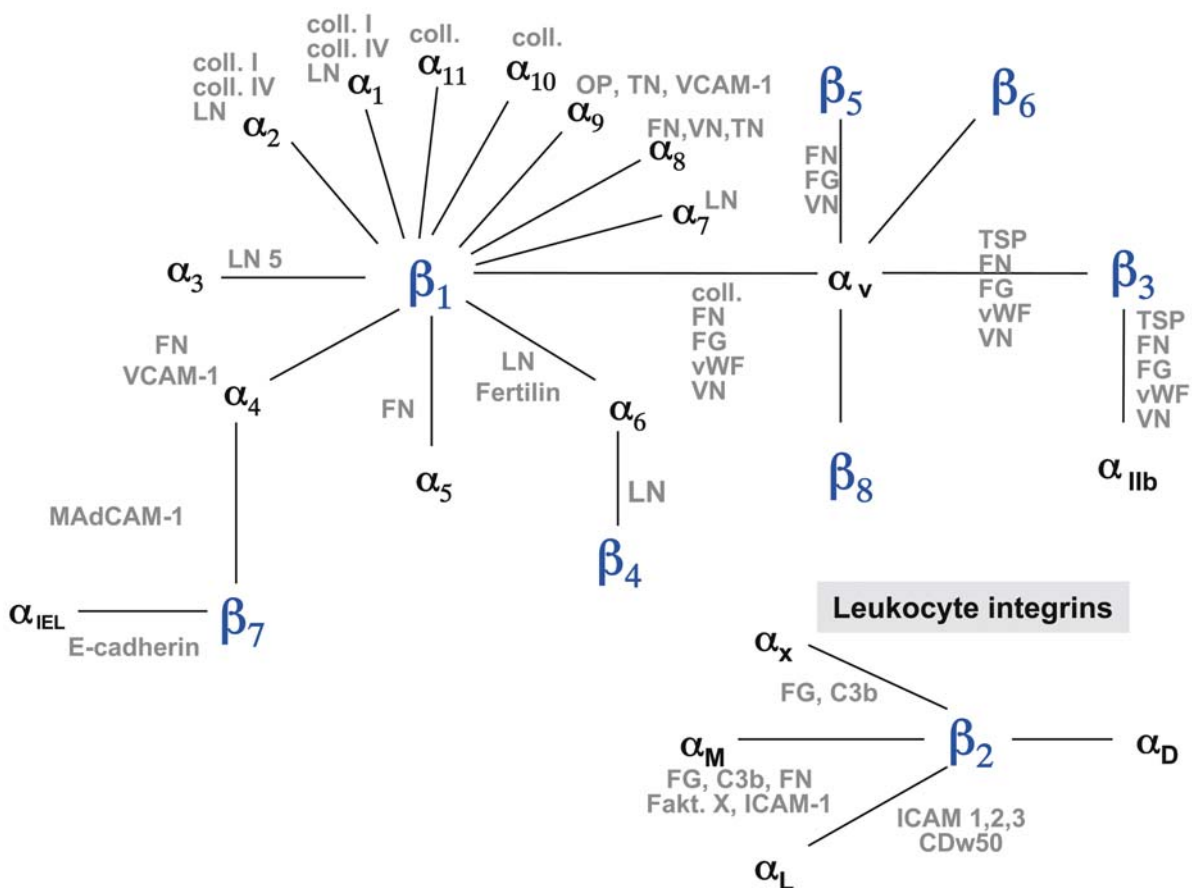

ments and are the starting points of integrin-dependent signaling processes.

The cytoplasmic domains of integrin subunits are essential for recruiting integrins to focal adhesions and for initiating integrin signaling cascades.

Characteristics

Integrins are a diverse family of glycoproteins that form heterodimeric receptors consisting of α and β subunits. These receptors possess a large extracellular domain responsible for ligand binding, a single transmembrane domain and a cytoplasmic domain that in most cases consists of 15–70 amino acid residues. The integrin receptor family in vertebrates includes at least 18 distinct α subunits and 8 β subunits, which can associate to form more than 20 distinct integrins.

The pairing of the two subunits determines ligand specificity. Integrin ligands are extracellular matrix proteins, counter-receptors on other cells such as ►ICAMs, soluble plasma proteins (e.g. fibrinogen, von-Willebrand factor; Fig. 1) or microorganisms.

Signal Transduction: Integrin-Mediated Pathways. Figure 1 Schematic overview of all known integrin receptors and their ligands. C3: complement component 3; Coll: collagen; FG: fibrinogen; FN: fibronectin; LN: laminin; OP: osteopontin; TSP: thrombospondin; VN: vitronectin; vWF: von-Willebrand factor.

Many of the integrins recognize the RGD (Arg-Gly-Asp) sequence within their ligands. Nevertheless, they are capable of distinguishing between different RGD-containing proteins, so that some bind primarily to fibronectin and others to vitronectin.

The strength of ligand binding is modulated by divalent cations, by receptor clustering and by the association of integrins with accessory molecules. Depending on the β subunit, integrins can be divided into subfamilies, the $\beta 1$ integrins being the largest subfamily. The $\beta 2$ integrins are exclusively expressed on leukocytes and are therefore also referred to as leukocyte integrins.

The name integrin was originally coined to denote the function of these proteins in linking the extracellular matrix (ECM) and the cytoskeleton. However, these receptors can regulate many aspects of cell behavior. Signaling enzymes, adaptor and cytoskeletal proteins regulated by integrin engagement control physiological processes through interactions with the cytoskeleton and with other receptors. The cytoplasmic domains of the integrin subunits are key nexuses of interaction between the extracellular environment and intracellular structures and signaling cascades. Upon activation by ligand binding, integrins cluster and recruit cytoplasmic proteins that form so-called focal adhesions. Focal adhesions can be considered as integrin-specific signal transduction entities that are starting points for F-Actin stress fibers and signaling cascades.

Both the α and the β subunit cytoplasmic sequences make important contributions to various aspects of overall integrin function including cytoskeletal reorganization, cell motility, signal transduction and modulation of integrin affinity for the respective ligand. Therefore a large number of cytoskeletal, adaptor and signaling proteins can interact with integrin cytoplasmic domains.

Regulatory Mechanisms

Protein-Interactions with the Cytoplasmic Domains

The cytoplasmic tails of integrins are generally short and always devoid of any enzymatic activity. Hence, integrins transduce signals by associating with adaptor proteins that connect the integrin to the cytoskeleton, cytoplasmic kinases and transmembrane growth factor receptors. Integrin signaling and assembly of the cytoskeleton are intimately linked. As integrins bind to ECM, they become clustered in the plane of the cell membrane and associate with a cytoskeletal and signaling complex that promotes the assembly of actin filaments. The reorganization of actin filaments into larger stress fibers, in turn causes more integrin clustering, thus enhancing the matrix binding and organization by integrins in a positive feedback system. For regulating these processes, the β cytoplasmic tails are required for correct subcellular localization of integrins, for activation of signaling pathways and for regulation of the affinity of integrins for their ligands.

The mechanisms by which integrin β tails function in both outside-in and inside-out signaling remain to be fully resolved. Nonetheless, these processes are probably mediated mainly through direct associations between integrin β tails and signaling and structural proteins. At least 21 proteins are known to bind to one or more integrin β tails. This diverse list of proteins includes actin-binding proteins, enzymes, adaptor proteins, a transcriptional co-activator and additional proteins of unknown function (1).

α -Integrin cytoplasmic tails are less well investigated for their role in signaling. The cytoplasmic tails and in particular the membrane proximal GFFKR motif, conserved among all α integrin subunits, might be critical for the regulation of the affinity states of the receptor.

A few proteins have been identified so far that interact with sequences of the cytoplasmic tails of α subunits (2). One protein that binds to the highly conserved GFFKR motif is **calreticulin**, which seems to be a modulator both of integrin adhesive functions and integrin-initiated signaling. But adaptor proteins, like paxillin, and signaling molecules, like phospholipase $C\gamma$, can also bind to these short sequences.

Transmembrane Associations and Signaling

The association of integrins with other transmembrane proteins provides additional coordinate signals to cells that are also specific for individual integrins. **IAP**, an immunoglobulin superfamily transmembrane protein, cooperates with $\beta 3$ integrins in binding thrombospondin to cells and it also activates an inhibitory trimeric guanine nucleotide-binding protein. The $\alpha 3\beta 1$ and $\alpha 6\beta 1$ integrins associate with tetraspan (four transmembrane domain) proteins, which may link these integrins to phosphatidylinositol signaling pathways. When stimulated, some α subunits are able to recruit the adaptor protein **Shc**, via the membrane protein **caveolin-1** (Fig. 2).

Cooperations with Growth Factor Receptors and Other Membrane Proteins

Integrins not only signal on their own but are also necessary for optimal activation of growth factor receptors. The receptors for insulin, platelet-derived growth factor (PDGF), epidermal growth factor (EGF) and vascular endothelial growth factor (VEGF) are optimally activated by their ligands only under appropriate cell attachment conditions. Although a systematic analysis has not been conducted, certain integrins appear to be preferentially associated with specific growth factor receptors. Thus the $\alpha \nu \beta 3$ integrin can be immunoprecipitated in complexes with the insulin, PDGF and VEGF receptors, whereas some $\beta 1$ integrins associate with the EGF receptor. Integrin clustering and association with the cytoskeleton appear to give rise to integrin/growth factor receptor

Signal Transduction: Integrin-Mediated Pathways. Figure 2 Schematic overview of integrin-mediated signaling pathways. For details see the text. Cell proliferation and cell survival are primarily regulated by FAK and Shc, and cytoskeletal structures by the activities of Rho family GTPases.

complexes. Aggregation of the growth factor receptors results in their partial activation, possibly bringing growth factor signaling closer to a threshold of manifest activity and enabling cross talk between integrins and growth factor receptors.

Integrin-mediated Signal Transduction Network Outside-in-Signaling

Integrins regulate physiological processes like migration, not only because they directly mediate adhesion but also because they induce intracellular signaling pathways that control cytoskeletal organization, force generation and survival (3). Depending on the ligand(s), integrins activate one or more signaling pathways. These typically involve phosphorylation of focal adhesion kinase (▶FAK), recruitment of adaptor proteins, activation of small GTPases and subsequent activation of downstream effector molecules (Fig. 2). These signals, in concert with signals derived from growth factors, regulate cell behavior in a complex tissue microenvironment.

FAK-Pathway

Subsequent to integrin activation, the cytoplasmic protein kinase FAK is activated. Activated FAK binds to several signaling molecules, mediating integrin-induced activation of the ▶Ras▶Erk pathway, which promotes cell proliferation. Phosphorylated FAK can activate Erk by recruiting adaptor proteins such as ▶Grb2 and Cas, as well as by activating protein kinases such as the ▶Src-family kinases.

FAK activation has also been shown to promote cell survival and cell migration. *Fak*-null mice die before

birth and cells isolated from these embryos have migration defects.

FAK and Src both phosphorylate ▶Cas at multiple tyrosine residues, causing Cas to associate with another adaptor protein, ▶Crk. The Cas-Crk complex is a component of the molecular migration machinery, inducing cell motility by activating the protein ▶DOCK-180, leading to the activation of the small GTP binding protein Rac.

Shc-Pathway

Upon integrin activation Shc is recruited by the ▶Fyn/caveolin complex into focal adhesions in response to ligation of integrins α1β1, α6β4, α5β1 or αvβ3. Formation of this complex leads to Shc-dependent cell-cycle progression, migration, anti-apoptotic signals and Erk-activation.

In migration Shc is the “random motility component”, whereas FAK and Cas support migration in a persistent direction.

Small G Proteins

Highly motile cells display dramatic alterations in their cytoskeletal organization that facilitate their migratory behavior. The ▶Rho family of small GTPases, including Rho, Cdc42 and Rac, can regulate these changes (4).

Rac is activated by ligation of integrins and promotes membrane ruffling and migration, whereas Rho activation is dependent on integrins, as well as ▶syndecan-4 and additional cell surface receptors like the LPA receptor and leads to the formation of stress fibers and the assembly of focal adhesions.

Rho can activate a ser/thr protein kinase known as Rho kinase. This kinase phosphorylates the myosin light chain (►MLC) phosphatase, thereby suppressing the activity of the enzyme. This increases the myosin binding to actin filaments and subsequently increases actomyosin contractility and the formation of focal adhesions and stress fibers.

Furthermore, integrins can stimulate the production of the membrane compound phosphatidylinositol biphosphate (►PIP2) in a Rho-dependent manner. Rho is able to activate the phosphatidylinositol-4-phosphate-5-kinase (PIP4-5-K) that produces phosphatidylinositol-(4,5)-biphosphate. Phosphatidylinositol-(4,5)-biphosphate modulates the activity of several cytoskeletal proteins like ►vinculin, which in turn connect the focal adhesion complex to the F-actin cytoskeleton.

Rac activation also potentiates Erk signaling and increases cellular sensitivity to growth factors. Another mechanism of Erk activation is provided by the Rac-dependent activation of p21-activated kinase, ►PAK. This ser/thr kinase regulates the actin cytoskeleton as well as the ►JNK/SAP kinase pathway.

PI3-Kinase Pathway

►PI 3-kinase is an important lipid kinase, which has recently been demonstrated to play a role in integrin signal transduction. Some of its lipid products can act as second messengers in the regulation of protein kinase C (►PKC) family members as well of as the protein kinase B/Akt. Association of FAK with PI 3-kinase in response to integrin activation has been demonstrated in both platelets and fibroblasts, thereby regulating cell proliferation, apoptosis and migration.

In addition, FAK/PI 3-kinase association in fibroblasts is stimulated by cell treatment with platelet-derived growth factor (PDGF), suggesting a mechanism of cross-talk between integrin and the PDGF receptor signaling pathway.

PKC Pathway

The protein kinase C family is also important for regulating integrin function and signaling. PKC is required for focal adhesion formation, cell spreading, Shc-dependent Erk phosphorylation and migration. PKC interacts with $\beta 1$ integrins using tetraspanin-family proteins as bridging molecules. Furthermore, PKC regulates $\beta 1$ transport within the cell.

Inside-Out Signaling

Integrins not only send signals to the cell in response to the extracellular environment, but they also respond to intracellular cues and alter the way in which they interact with the extracellular environment. This process – termed “inside-out-signaling” – regulates integrin adhesiveness by modulating the affinity and avidity of integrins for their ligands, thereby regulating integrin-dependent processes like migration.

The signaling mechanisms that regulate integrin affinity and avidity are likely to vary for different integrin heterodimers, but small GTP-binding proteins like Rho, Rac, Cdc42 and Ras as well as the protein kinase C are known to be involved (5).

Therapeutic Applications

Investigation of integrin receptors and integrin-mediated signaling has also led to a number of therapeutic applications and targets for tumor therapy. An anti- $\beta 3$ -integrin antibody is used as an integrin-directed drug for prevention of arterial restenosis.

Several other integrin-based drugs, such as peptides containing the integrin-binding RGD sequence and mimics of such peptides that specifically block individual integrins and their functions are also under development. These drugs target thrombosis ($\alpha \text{IIb}\beta 3$ in platelets), osteoporosis ($\alpha \text{v}\beta 3$ in osteoclasts) and tumor-induced angiogenesis ($\alpha \text{v}\beta 3$ in neovascular endothelial cells).

Single Nucleotide Mismatch

Definition

Single nucleotide mismatch describes the pairing of a nucleotide with a non-complementary nucleotide (e.g. pairing of G with T instead of C nucleotide).

► [Hereditary Nonpolyposis Colorectal Cancer](#)

Single Nucleotide Polymorphisms

Definition

Single-nucleotide polymorphisms (SNPs) are the most common type of human DNA genetic sequence variation, occurring on average 1 per 1000 base pairs. They occur when a single nucleotide (A, T, C or G) in the genome sequence is altered. SNPs are mostly bi-allelic, hence less informative than ►microsatellites. Yet they are more frequent and more stable than microsatellites, as well as more amenable to automation and DNA-chip technology. SNPs have drawn attention as potential markers of variation because they are both common (occurring relatively frequently compared with other markers) and plentiful (there may be as many as 30 million in the human genome).

Single-Cell Gene Expression Profiling: Cell-Level Biology by Multiplexed Expression Fluorescence *in Situ* Hybridization

JEFFREY M. LEVSKY, ROBERT H. SINGER
Anatomy & Structural Biology, Albert Einstein College of Medicine, Bronx, New York, NY, USA
rhsinger@acom.yu.edu

Definition

Single-cell expression profiling is a means to take a 'snapshot' of the gene activity of a specimen at the individual cell level. The active sites of ►transcription are detected for many genes in their native cellular context using ►*in situ* hybridization. This technique preserves each cell's characteristic repertoire of expressed alleles and the location of expressed alleles in the sub-cellular and tissue-level organization. The reaction is performed *in situ*, at the proper location of the gene activation events, to yield a visual analysis of complex expression patterns. Hybridization detection of transcription sites measures new transcription specifically, without considering total cell levels of transcripts, ►translation to protein and all the other

levels of post-transcriptional expression regulation. This allows detection of small incremental changes in transcript levels and direct analysis of causes and effects upstream of transcription. To date, the assay has been used to analyze fixed cell samples from *in vitro* cultures, allowing high temporal and spatial resolution of expression (1). Many hypothetical uses exist for this approach, from experiments to improve the basic understanding of single cell biology and finely demarcated expression patterns to future clinical application in diagnostics.

Characteristics

Cell Level Biology

Undisturbed single-cell biology is largely inaccessible to most popular molecular assays because samples used are invariably derived by summation of many single cell responses or by artificial amplification steps such as ►[polymerase chain reaction](#) (PCR). These procedures are necessary in order to reach a detectable threshold of biomolecules due to the sensitivity constraints of the techniques. Summation obscures individual cell biology and amplification can be uneven, distorting the perceived composition of the cellular contents (2). Using *in situ* hybridization, DNA and RNA can be detected in their natural location, while preserving cell-to-cell heterogeneity (3). Summation of multiple cell contributions is not required as a single cell's signal is visualizable due to the intensely fluorescent probes and highly sensitive microscopy methods used. Amplification is also not necessary as hybridization is performed on the native targets only. Using probes of determined fluorescence intensity, signals can be quantified to measure absolute numbers of transcripts. The sensitivity of ►[fluorescence in situ hybridization](#) has been demonstrated to be sufficient for the detection of single nucleic acid molecules and parts thereof, allowing considerable freedom to measure low levels of transcripts (4). This is a potentially important feature as most messenger RNAs are present in very small amounts – less than ten copies per cell.

Multiplexed Detection

Applying fluorescence microscopy to the detection of several genes' transcription simultaneously yields a profile of gene activity for individual cells, or 'single-cell gene expression profiling' (1). Multiplexing, or concurrent assay of many different targets, is necessary to study certain aspects of cell physiology. For example, the observation of co-expression events at the single cell level and determination of relative locations of functioning genes are only possible by simultaneous assay of several different mRNAs. In general, the larger the number of genes accessible to analysis the greater is the depth of profile and

information content in the dataset. The number of detectable entities depends on the encoding scheme used to represent specific genes. Using fluorescent dyes, color combinations and color ratios have been employed to assay tens of specific nucleic acids at one time *in situ* (3), although there is potential to detect far more species of interest by more complete usage of the spectrum of dyes and digital processing and interpretation of the signals.

Data Analysis

Fluorescence images are interpreted by computer in order to objectively assign specific signals to gene identities based on the color-coding scheme. Then, signals are segmented, or separated, by nucleus in order to yield a dataset of individual cells. The simplest resultant datasets from single cell profiling consist of a catalogue of specific nuclei and the activated alleles they possess. From this information, the percentage of cells expressing a specific gene can be determined, as a measure of tissue-wide activation. Cells can be sorted on the basis of particular expressed gene combinations in order to highlight cell type-specific correlated activations. Using basic statistics, one can determine the likelihood with which a nucleus found to express one gene would express another. Spatial characteristics are incorporated to derive structural data from single cell expression sets. This can involve the precise measurement of distances between different sites of transcription and between sites and other nuclear features. Functional organization of the nucleus is thereby determined for several genes at once. When structural information is added to observations of expression, significant amounts of data can be derived for the classification of individual cells.

Clinical Relevance

Although there are no current clinical trials using single cell expression study as a diagnostic, the technique provides many avenues for pre-clinical investigation.

Expression Modulation

Many changes in physiology are known to be associated with modulation of gene activity. This is particularly important in the dysregulation of oncogenes and tumor suppressor genes during cancerous transformation. Presence or absence of expression can be assayed by single cell monitoring, to theoretically yield prognostic information regarding development of cancer. Expression levels can be changed in more complex ways than mere activation and deactivation. For example, many transcripts possess alternative splicing products, which can be selectively processed under specific conditions. These and

other co-transcriptional mechanisms can be measured using fluorescence color coding and single cell monitoring (5).

Small Populations of Cells

In many cases, diagnosis and prognosis can depend on a very small number of cells that have certain pathophysiological expression characteristics. Assays that do not preserve cellular heterogeneity naturally average many cellular responses and may obscure the few affected cells that have clinical importance. For example, the presence of HIV RNA levels in lymphocytes or activity of genes involved in cancer progression to metastasis in a small cell population within a tumor could be used as diagnostic information. Monitoring changes on this small level is an advantage of the single cell approach (2).

Interactions

Cell-to-cell interactions at the micro level are thought to influence many biological processes, including development and cancer. Often the population of cells involved in such signaling is quite small and difficult to micro-dissect from surrounding tissue types. Visualization of single-cell profiles is one solution to exploring this biology because it obviates the need to separate cells physically for analysis. As cells are measured with preserved organization, computer-based analysis can be used to measure the distances between aberrantly expressing cells and a tissue marker. This would allow the study of expression as influenced by proximity to a heterologous tissue type, as occurs in epithelial-mesenchymal signaling in physiology and disease.

Therapeutic Consequences

Therapy based on conclusions drawn from single cell expression information is yet hypothetical, as the technique has not yet been applied to clinical materials. Single cell expression data provided by this technique has not been determined to correlate with any particular physiological results. However, a closer understanding of single cell behavior has tremendous promise in therapeutics. Above all, cell-level analysis will allow a firmer factual basis for cell behavior upon which models of physiology and pathophysiology can be tested. The technique serves to further our understanding of any process of disease that depends on particular cellular expression events.

Singlet State

Definition

Singlet state defines – in a multi-electron system like a molecule or an atom – a state of having a total electron spin quantum number equal to 0.

►FRET

Single-Wavelength Anomalous Diffraction

Definition

Single-wavelength anomalous diffraction (SAD) describes a method to determine the diffraction phases in protein crystallography, from a dataset measured at a wavelength for which the X-ray fluorescence, and the anomalous part f' of the scattering factor of a natural or artificially incorporated anomalous scatterer, is at or near a maximum. A tunable radiation source (synchrotron) is required for recording a high anomalous signal from the scatterer. By increasing the quality of the data measurement and the redundancy of the diffraction data set, even weak anomalous signals can be used for phase determination, e.g. when the diffraction experiment is performed at a wavelength far from the absorption edge of a scatterer (e.g. phasing based on anomalous scattering from sulfur with $\text{CuK}\alpha$ radiation from conventional rotating-anode X-ray generators).

Sister Chromatid Exchange

Definition

Sister chromatid exchange (SCE) refers to an observation through the light microscope of an exchange between the two sister chromatids in metaphase chromosomes. The basis is a differential staining of the sister chromatids; one chromatid is stained lightly and one is stained densely after they have completed two rounds of replication in the presence of the thymine analogue 5-bromo-deoxy-uridine (BrdU). Due to the semiconservative replication of DNA, one chromatid still has an original strand of DNA in the double helix opposite to a DNA strand that has incorporated BrdU. In the other chromatid both strands are substituted with BrdU. The latter stains less intensely than the former.

Skewed X-Inactivation

Definition

In females, one of two X chromosomes is deactivated well before birth, in the early stages of embryonic development. This means that either the paternal X chromosome is active, or the maternal X chromosome is active. In the female population, one expects a 1:1 distribution of such cells; i.e. about 50% of cells show activation of the paternal X chromosome and 50% show activation of the maternal X chromosome. A distribution which differs from the normal 1:1 is called a skewed X inactivation.

Skin and Hair

JOERG HUELSKEN

Epithelial Stem Cell Biology, ISREC, Epalinges, Switzerland

joerg.huelsken@isrec.unil.ch

Definition

The skin covers the outer surface of the body and forms the interface with the environment. Human skin has

a surface area of about 1.5–2.0 m² and accounts for 15–20% of our body weight. The skin serves a variety of functions: (1) protection: it builds a physical barrier to mechanical impact or penetration by microorganisms such as bacteria, viruses and fungi, it protects against ultraviolet light damage and prevents dehydration; (2) thermoregulation: it insulates the body *via* hair and adipose tissue and allows heat dissipation by sweat production and blood circulation; (3) sensation: it is the largest sensory organ which detects pressure, vibration, heat, cold, pain and itching; (4) metabolism: it stores energy in the adipose tissue and synthesizes vitamin D.

Characteristics

The skin consists of three layers, the epidermis, which is the most superficial layer, the dermis and the hypodermis or subcutis. The epidermis forms the external surface of the skin and is mainly composed of keratinocytes, which differentiate to form four layers, the ►stratum basale, ►stratum spinosum, ►stratum granulosum and ►stratum corneum (1). Keratinocytes are specialized epithelial cells responsible for epidermal cohesion and barrier function and are firmly interconnected with each other by desmosomes and ►keratin intermediate filaments (tonofibrils). Epidermal keratinocytes are generated in the stratum basale, migrate upwards while they differentiate terminally and are shed at the surface as cornified scales. This self-renewal process normally takes approximately four weeks. Interspersed in the stratified epithelium of the epidermis are other cell types such as melanocytes (UV protection), Merkel's cells (mechanosensory function) and Langerhans' cells and T-lymphocytes (immune defense). A complex basement membrane separates the epidermis from the underlying dermis, the connective tissue responsible for the mechanical resistance of the skin. This function is provided by dermal fibroblasts that synthesize fibers composed of collagens, reticulin and elastin interspersed glycosaminoglycans. The dermis contains sense organs for touch, pressure, pain and temperature (e.g. tactile corpuscles of Meissner, Pacinian corpuscles and free nerve endings) and a dense vascular network that supplies the avascular epidermis. A variety of cells of the immune system are found in the dermis such as perivascular macrophages, dendritic cells and mast cells. The subcutaneous layer below the dermis consists of loose connective tissue and many adipocytes that help to insulate the body.

The dermis also harbors epidermal appendages such as the pilosebaceous unit (hair follicle, sebaceous glands, arrector pili muscle) and sweat glands that extend deep into the dermis (2). Epidermal appendages, the epithelial parts of which are in continuity with the epidermis, develop during embryonic life through

complex epithelial-mesenchymal interactions by epithelial invagination. The hair follicle differentiates into three enclosed epithelial cylinders: the central most cylinder forms the hair shaft, the outer root sheath (ORS) represents the outermost cylinder that separates the whole structure from the dermis, and the middle cylinder, the inner root sheath (IRS), forms and guides the shaft in its passage outward. The shaft and the IRS move outward together. All mature follicles undergo a growth cycle consisting of phases of growth (anagen, 85–90% of hair cycle), regression and involution by ►apoptosis (catagen, 2–3% of cycle), rest (telogen, 10–15% of hair cycle) and shedding (exogen). A complete cycle lasts 2–6 years for human scalp hair during which it grows 0.4 mm/day. In addition to the cycling part, the follicle consists of an upper permanent, non-cycling portion. The lower end of this portion is defined by the hair bulge.

Molecular Interactions

Skin Neoplasms

Several benign and malignant neoplasms arise in the skin (3). These tumors often reflect the differentiation program of certain keratinocyte lineages, e.g. ►basal cell carcinomas (BCCs) mimic the relatively undifferentiated phenotype of the hair follicle outer root sheath, ►squamous cell carcinomas (SCCs) exhibit elements of interfollicular epidermal differentiation and ►pilomatricomas and trichofolliculomas contain cells undergoing differentiation along hair lineages.

BCC of the skin is the most common type of cancer in humans. Two ►tumor suppressor genes, *p53* and *ptch*, are major targets of mutation in sporadic BCC. P53 is important for the induction of cell-cycle arrest in response to cellular insults or DNA damage and can initiate cell death by apoptosis. Germline mutations of *ptch1* have been identified in Gorlin's syndrome, which is characterized, by multiple BCCs, keratocysts and skeletal defects. *Ptch* encodes a negative regulator of the ►Hedgehog signaling pathway. Hedgehog (Hh) signaling plays an important role in the patterning of many tissues and structures during embryogenesis. The response to the Hh signal is controlled by the tumor suppressor gene *ptch* and the proto-oncogene *smo* which both encode transmembrane proteins. In the absence of Hh, the activity of Smoothened (Smo) is suppressed by Patched (Ptc). Smo can signal to a cytoplasmic complex that includes the serine/threonine protein kinase Fused, Suppressor of Fused, and the transcription factor Cubitus interruptus (three genes in humans: *gli1*, *gli2* and *gli3*). Upon Hh stimulation, phosphorylation and subsequent processing of the transcription factor is blocked, and it is translocated to the nucleus as a full-length transcriptional activator. One of the general target genes is *ptch*, resulting in

feedback inhibition. In addition to *ptch1*, mutations in *ptch2* and activating mutations in *smoh* have been identified in sporadic BCC.

SCCs arise in areas of sun-exposed skin and typically involve ►UV signature mutations or ►LOH in key tumor suppressor genes involved in cell-cycle control, *p53*, *cdkn2a* and *rb*. Inactivating mutations in *p53* are an early event in carcinogenesis and have been found in precancerous lesions (actinic keratosis and SCC *in situ*). Through alternative splicing the *cdkn2a* locus encodes two proteins, INK4A and ARF, which positively regulates p53. INK4a is a cyclin-dependent kinase inhibitor that specifically blocks the activity of cyclin-dependent kinase 4 (CDK4) and CDK6 by preventing their interaction with D-type cyclins. These proteins act together to govern the phosphorylation status of the retinoblastoma protein (Rb). Hypophosphorylated Rb binds and inactivates E2F transcription factors responsible for cell-cycle progression. In addition, amplification of the proto-oncogene *ccnd1*, which encodes cyclin D1, has been identified in SCC. Activating mutations in the *ras* proto-oncogene occur in some spontaneous SCCs, and over-expression of *ras* can induce SCC in mouse models. However, expression of active Ras alone induces growth arrest in human epidermal cells by suppressing the cyclin-dependent kinase CDK4. This arrest can be overcome by inhibition of NFκB signaling which induces CDK4 expression. Moreover, expression of the α6β4 integrin is markedly increased in SCC but not in BCC and was shown to be essential for invasive growth of SCCs. This integrin is located to hemidesmosomes in the stratum basale where it attaches to laminin 5 in the basement membrane and can promote migration and survival.

Trichofolliculomas and pilomatricomas are well-differentiated hair follicle derived tumors. Mutations in *ctnnb1* have been found in these tumors with high frequency (1). *Ctnnb1* encodes for β-catenin, the central signal transmitter in the canonical ►Wnt signaling pathway (5). This pathway is crucial for pattern formation during embryonic development and for cell fate determination in the adult, e.g. in the skin and intestine. Many components of the Wnt signaling system have been identified. Extracellular Wnt/wingless ligands activate Frizzled receptors and through Dishevelled induce an increase in cytoplasmic β-catenin by preventing its degradation in proteasomes. Axin/Conductin, in cooperation with the tumor suppressor gene product ►adenomatous polyposis coli (APC), promote β-catenin degradation, which involves serine-threonine phosphorylation of the N-terminus of β-catenin by casein kinases and GSK3β and subsequent ubiquitination. Upon Wnt signaling, β-catenin

accumulates in the cytoplasm and is transported to the nucleus, where it interacts with members of the LEF/TCF family of transcription factors and activates gene expression. Mutations in a variety of human tumors have been identified in *apc* or in the N-terminal phosphorylation sites of β-catenin. These mutations result in accumulation of β-catenin, constitutive signaling and gene activation and are causally involved in human tumorigenesis. For example, germline mutations in *apc* have been linked to Gardner syndrome, which is characterized by early onset adenomatous polyps of the colon but also displays pilomatricomas and epidermoid cysts in the skin.

Human Keratin Diseases

A variety of epithelial fragility disorders was linked to mutations in epithelial *krt* genes. Most of these mutations are inherited as autosomal dominant traits and result in expression of a defective keratin protein, which tends to act in a dominant-negative fashion. For example, mutations in *krt14* and *krt5* have been identified in the skin blistering disorder epidermolysis bullosa simplex. These keratins are expressed in the stratum basale of the skin, and so patients suffer from blisters in response to mild mechanical trauma. Mutations in *krt1* and *krt10*, which are expressed in the stratum spinosum of the epidermis, lead to the skin thickening disorder bullous congenital ichthyosiform erythroderma. In this disorder, breakdown of suprabasal keratinocytes under mechanical stress leads to release of inflammatory cytokines. This stimulates uncontrolled proliferation of basal cells and induces hyperkeratosis.

Ectodermal Dysplasia

Ectodermal dysplasia (ED) represents a complex group of diseases characterized by impaired morphogenesis of epidermal appendages. Primary defects affect ectodermal structures including hair, skin, nails, teeth and sweat glands. EDs are rare diseases with an estimated incidence of 700 patients per million. Several genes that are involved in cell/cell communication and signaling have been identified in ED. The most frequent form of ED, X-linked anhidrotic ED, is caused by mutation in the *ed1* gene (*eda* in mice). The *ed1* gene encodes a transmembrane protein called ectodysplasin, which contains an essential tumor necrosis factor (TNF) domain. Ectodysplasin binds to receptors called XEDAR and EDAR (the human homologue of the mouse *downless* gene). Receptor activation is transmitted by the adapter protein EDARADD and signals via the NFκB and the JNK pathway. These pathways mediate positive signals for cell survival, growth and differentiation. Other genes,

which encode members of the EDA pathway such as EDAR, XEDAR, EDARADD and NEMO, have also been found to be mutated in ED. The NEMO gene encodes IKK γ , which is required for the activation of the IKK complex in the NF κ B pathway.

Regulatory Mechanisms

Multipotent stem cells are fundamental for tissue repair and tissue homeostasis in the adult and have been described in a variety of tissues such as bone marrow, gut and skin (4). Stem cells have been defined as a population of undifferentiated cells that are capable of self-renewing by symmetric divisions, production of a large number of differentiated progeny by asymmetric divisions, homing to an appropriate growth environment and tissue regeneration after injury. Tissue and lineage specification of stem cells is believed to be controlled in a self-organizing, dynamically regulated process based on cell-cell and cell-environment interactions. Within their tissues, stem cells are often localized to specific stem cell niches. In the skin, multipotent epithelial stem cells have been localized to a portion of the outer root sheath of the hair follicle, termed the hair bulge (2). These bulge stem cells can give rise not only to epidermal keratinocytes, but also to hair follicular keratinocytes and cells of the sebaceous glands. Stem-cell progeny were shown to exit the bulge and migrate either upwards into the stratum basale or downwards to populate the [▶hair matrix](#) of the follicle. These two progeny tissues contain the transit-amplifying (TA) cells of the skin that undergo a limited number of divisions before they terminally differentiate. Hair follicles periodically undergo cycles of destruction and reconstruction and entry into the hair cycle is believed to be induced by signals from the [▶dermal papilla](#). The exact nature of this signal is unknown, but it has been shown that Wnt signaling is essentially involved in anagen induction and controls lineage commitment of skin stem cells (1, 5).

SLE Pathogenesis, Genetic Dissection

CHUN XIE, CHANDRA MOHAN

Simmons Arthritis Research Center and Department of Internal Medicine/Rheumatology, The University of Texas Southwestern Medical Center at Dallas, Dallas, TX, USA

chandra.mohan@utsouthwestern.edu

Synonyms

Systemic lupus erythematosus; lupus

Definition

Systemic lupus erythematosus (SLE) is a chronic, systemic autoimmune disease that involves multiple organ systems, hence manifesting a wide array of clinical symptoms. The etiology of SLE remains unclear. However, it is certain that both genetic and environmental factors contribute to the development of the disease.

Characteristics

SLE is a disease predominantly affecting women, with a female:male ratio of 9:1. The prevalence is higher in African American, Afro-Caribbeans and Asians than in Caucasians (6). The hallmark of SLE is the presence of a multitude of autoantibodies, especially anti-nuclear

autoantibodies (►ANA), which in turn cause the tissue damage seen in SLE. The pathogenesis of SLE is not fully understood. However, the past decade of research has greatly deepened our understanding of this disease.

Genetics

Genetic Studies in Human SLE

Epidemiological studies have established that genetic predisposition is an essential component in SLE susceptibility. Familial aggregation of SLE has been demonstrated in several investigations. Twin studies have shown approximately 10-fold higher concordance rates among monozygotic twins than among dizygotic twins, showing the strong genetic basis of SLE. Inheritance patterns of this disease indicate it to be a complex trait that does not follow classical Mendelian inheritance. Both association and linkage studies have been applied to the genetic analysis of human SLE. In association studies, several groups of genes have been identified as potential candidate genes, including ►major histocompatibility complex (MHC; in man: ►HLA) class II, complement, Fc receptor and the genes for different cytokines or their receptors. The *HLA-DRB1* types *DR2* and *DR3* have been shown to be consistently associated with SLE in Caucasians. The association of *DR* alleles with SLE in other ethnic groups has been less consistent. Interestingly, MHC class II alleles have been associated more strongly with particular autoantibody profiles than with the disease itself. Deficiencies in components of the early classical complement activation pathway have been noted to be associated with the development of SLE. The low affinity alleles of Fc receptor II and Fc receptor III (*FcRIIa*, *FcRIIIa*, *FcRIIIb*) have also been associated with susceptibility to lupus nephritis.

Genome-wide linkage analysis has been used in the genetic analysis of murine lupus, and more recently, in human SLE as well. The advent of microsatellite-based gene mapping techniques made it feasible to “scan” the entire genome for SLE susceptibility. More than six genome-wide screens of human SLE families have thus far been published, each identifying more than 10 susceptibility loci, as recently reviewed (7). Although some of these independently identified loci coincide or overlap, others are clearly peculiar to individual studies. Out of these, 6 genomic regions meet the criteria for ‘significant’ linkage (LOD score >3.3), with supporting evidence (LOD score ≥1.0) from at least one other independent study. These loci (and corresponding candidate genes) include *1q23* (bearing *FcRIIIa*), *1q41-42* (bearing *PARP*), *2q37* (bearing *INPP5D*), *4p15-16* (bearing *CD38*, *BST1*, *NZF36*), *6p11-12* (bearing *HLA class II genes*, *C4a*, *TNF*), and *16q12-13* (bearing *NOD2*). About a dozen additional loci have also been shown to be suggestively linked to SLE in at

least 2 independent studies. Thus, it is very clear that human SLE is richly polygenic. Current efforts in several laboratories are focused on trying to identify the culprit gene(s) within these loci of interest.

Genetic Studies in Murine SLE

Mouse models have been extremely useful in genetic dissection and analysis of lupus, because of the ready availability of large numbers of animals with homogeneous genetic backgrounds (and standardized environmental conditions), which allow further genetic manipulation and functional analyses. Indeed, we have learned a great deal about the genetic basis of lupus in murine models over the past decade, as recently reviewed (2, 7). These models can be broadly divided into two main groups: “►Forward Genetic” models (also referred to as “synthetic” or genetically-mutated models), and “►Reverse Genetic” models.

Forward Genetic Studies

In genetically mutated models, disruption of a variety of regulatory genes and over-expression of other genes have been found to promote the development of lupus-like disease, often unexpectedly. Genes identified by this approach can perhaps be classified into 4 functional categories. The first group of molecules includes the complement components *C1q*, *C3*, *C4*, serum amyloid P-component (*SAP*), *CRP*, *DNase I*, etc. It is believed that the deficiency of these molecules impedes the clearance of apoptotic debris, which then serves to breach immune tolerance. The second group of genes infringes lymphocyte apoptosis, potentially resulting in lymphoproliferation and other features of lupus. These genes include *Fas*, *FasL*, *Pten*, *FLIP*, etc. The third group includes a large array of molecules that augment or modulate T- and B-lymphocyte function. Thus, the aberrant expression of *CTLA4*, *PD-1*, *PI3 kinase*, and *p21* genes has been shown to facilitate heightened T-cell proliferation and lupus-like phenotypes. Similarly, the over-expression of *Bcl-2*, *Blys*, *CD19*, *CD21*, and deficiency of *CD22*, *Lyn*, *Fyn*, *Shp-1* and *Btk* genes lead to generalized B-cell hyperactivity and other features resembling lupus. The last group of genes directly impacts the onset and progression of end-organ disease. For example, molecules such as the FcγR, adhesion molecules (e.g., ICAM-1), and chemokines (e.g., MCP-1) may impact intrinsic susceptibility to renal damage following an immunological insult.

Reverse Genetic Studies

In spontaneous lupus-prone models, dozens of genome-wide scanning studies have been performed, resulting in the mapping of more than 40 chromosomal

intervals associated with lupus susceptibility, as summarized in Table 1, and reviewed elsewhere (2, 7). These data have originated from studies using the NZB/NZW and the related NZM2410 strains, as well as the MRL/*lpr*, BXSB, and SWR/NZB strains. These lupus susceptibility loci appear to be randomly

distributed over all 19 chromosomes, indicating that murine lupus is also richly polygenic. Although some of these susceptibility loci have been repeatedly mapped to certain “hotspots” on chromosomes 1, 4, 7, and 17, the majority of detected loci appear to be strain-specific. Whereas the majority of the susceptibility

loci have originated from lupus-prone strains, a few loci have arisen from “normal” (non-autoimmunity prone) genomes. These studies have also demonstrated a “many to many” relationship between the different component lupus phenotypes and the susceptibility loci. Thus, for instance, *Sle1* on chromosome 1 has been demonstrated to be associated with production of autoantibodies, development of GN, as well as splenomegaly; on the other hand, *Nba2* on chromosome 1, *Sle3* on chromosome 7 and *Swrl-2* on chromosome 14 are all associated with the development of GN (2). In addition to these disease ▶susceptibility loci, several lupus resistance (or “suppressor”) loci have also been identified, including *Sles1*, *Sles2*, *Sles3*, and *Sles4*, all of NZM2410/NZW origin (3). It thus appears that the eventual disease outcome in any given strain or individual is the consequence of the interplay between a suite of lupus-accelerating or lupus-attenuating genes, impacting the immune system in apparently opposite fashions.

One of the strengths of using mouse models of lupus is the ability to perform “▶congenic dissection”. Essentially, in this approach, the researchers genetically transfer one or more of the susceptibility loci detected in the original mapping onto “normal”, non-autoimmune mouse backgrounds, in order to transform the polygenic model system into a series of monogenic disease models. This strategy has allowed researchers to analyze the function of each individual susceptibility locus thoroughly by phenotyping the corresponding mono▶congenic strains, and to further narrow the genetic intervals (to an interval that is small enough to allow physical cloning of the culprit genes) through the breeding and analysis of congenic recombinants. Congenic dissection of murine lupus has been extensively used in the analysis of disease in the NZM2410 model (2, 7). Thus, the three major susceptibility loci, *Sle1*, *Sle2*, and *Sle3*, have been successfully bred onto the non-autoimmune C57BL/6 (B6) background, and the phenotypes of each congenic strain have been thoroughly analyzed. B6 mice congenic for *Sle1* exhibit autoantibodies to H2A/H2B/DNA subnucleosomes, with minimal renal disease (1, 2). B6 mice bearing *Sle2*, on the other hand, exhibit B-cell hyperactivity with polyreactive IgM antibodies and an expansion of B1 cells, but without renal involvement (2). In contrast, *Sle3* leads to T-cell hyperactivation, modest sero-reactivity to several nuclear antigens, decreased activation-induced cell death, and moderate nephritis (2). Recently, fine mapping of the *Sle1* interval using congenic recombinants has revealed that *Sle1* consists of a cluster of several distinct loci, including *Sle1a*, *Sle1b*, and *Sle1c*, that independently breach tolerance to chromatin and

SLE Pathogenesis, Genetic Dissection. Figure 1 A model of SLE pathogenesis demonstrating how the epistatic interaction of several different lupus susceptibility genes might orchestrate disease.

Sle1d that facilitates GN (4). It is also intriguing to note that some of the lupus susceptibility loci identified, such as the loci on mid-chromosome 3, telomeric chromosome 6, proximal chromosome 7, mid-chromosome 10, and the *H2* locus on chromosome 17, appear to co-cluster with susceptibility loci for other autoimmune diseases, including murine diabetes, experimental autoimmune encephalomyelitis and collagen-induced arthritis (2). Importantly, some of the identified murine loci appear to be syntenic with some of the human intervals linked to SLE (7). Thus, NZM2410-derived *Sle1a* and *Sle1b* are syntenic with *1q21-23*, and *Sle1d* with *1q41*, on human chromosome 1. ▶Epistasis of different disease susceptibility loci plays a very important role in the genesis of lupus. This has

been well illustrated in the B6.*Sle* congenic models. As mentioned above, none of the B6.*Sle* monocongenic strains develop severe pathology. In contrast, when both *Sle1* and *Sle3* were transferred onto the B6 background, the resulting bicongenic strain developed high titers of nephrophilic anti-dsDNA antibodies, severe GN, and splenomegaly (2). Likewise, the triple congenic B6.*Sle* strain bearing *Sle1*, *Sle2*, and *Sle3* also developed severe systemic autoimmunity and fully penetrant, fatal GN (5). Thus, the “fully developed” version of lupus may require the combinatorial participation of several different genes, each impacting a different pathogenic step. Figure 1 illustrates how different genes may impact several of the key steps leading to the development of SLE. In the first step, genes such as *Sle1*, *C1q*, *SAP* and *DNase I* may act to initiate autoimmunity by breaching tolerance to nuclear antigens, leading to the formation of non-pathogenic autoantibodies. *Sle2*, *Sle3* and yet other genes may then serve to amplify the ongoing autoimmune response, leading to generalized T- and B-cell hyperactivation and the production of pathogenic, nephrophilic autoantibodies. The final step may involve genes such as *Sle1d*, *FcR*, *ICAM-1* (and possibly other adhesion molecules), *MCP-1* (and possibly other chemokines), that facilitate immune-mediated end organ injury. Recent advances in the fields of gene expression microarrays and proteomics are likely to add further dimensions to our understanding of lupus in the coming decade.

Clinical Relevance

Currently, the diagnosis of SLE is mainly based on clinical manifestations of the disease and immunological evaluation. Molecular diagnostics (and gene/molecule-targeted therapy) will be possible in the future as we uncover the genetic and molecular footprints of lupus.

Sleep Apnea

Definition

Sleep apnea is a breathing disorder characterized by brief interruptions of breathing during sleep.

► [Prader Willi and Angelman Syndromes](#)

Sleep Paralysis

Definition

Sleep paralysis is a phenomenon occurring rarely in healthy individuals and frequently in narcoleptic patients. Sleep paralysis is characterized by an inability to move, which either occurs at the transition from waking to sleeping or (more frequently) at the transition from sleep to wakefulness. In this state consciousness is preserved and the inability to move is felt as extremely unpleasant. Episodes might last several minutes.

Smith-Lemli-Opitz Syndrome

Definition

Smith-Lemli-Opitz syndrome (SLOS) is an autosomal recessive disorder characterised by multiple congenital anomalies including mental retardation, facial and brain abnormalities, and limb, heart, renal, genital and skeletal defects. SLOS is due to mutations in the gene encoding 7-dehydrocholesterol reductase, the last enzyme of cholesterol biosynthesis.

- [Hedgehog Signaling](#)

Smith-Magenis Syndrome

Definition

Smith-Magenis syndrome (SMS) is a contiguous gene syndrome (1:25000 newborns) that is caused by hemizygous deletion at human chromosome 17p11.2–p12, and characterized by behavioural abnormalities such as inverse sleep pattern (long nocturnal wake periods creating profound intrafamilial problems, and short daytime naps), autoaggression and self-injurious behaviors (presumably due to decreased sensitivity to pain). Facial dysmorphism is mild and growth is normal.

- [Microdeletion Syndromes](#)

SMN-Complex

Definition

The Survival of Motor Neurons (SMN) protein, the product of the spinal muscular atrophy-determining gene, is part of a large macromolecular complex (SMN complex). The SMN complex plays a critical role in the assembly of spliceosomal small nuclear ribonucleoproteins (snRNPs) and possibly other RNPs, in pre-mRNA ► [splicing](#), and in the assembly of mRNA factories (transcriptosomes).

Smurf

Definition

Smurf is a ►**Smad** ubiquitinylation regulatory factor that functions as an E3 ligase, which contains a HECT domain that specifically interacts with Smads and mediates their ubiquitinylation and proteasomal degradation. Two isoforms, Smurf1 and Smurf2, have been identified, and in addition to Smads they ubiquitinylate the TGF- β receptor complex.

►**Receptor Serine/Threonine Kinases**

SNARE Proteins

Definition

SNARE (soluble *N*-ethylmaleimide-sensitive factor (NSF) attachment protein receptors) proteins constitute an evolutionarily conserved super-family of small, coiled-coil membrane proteins (21 members in yeast and over 35 in mammals) with compartment-specific distribution patterns. SNAREs assemble as cognate pairs into specific complexes that drive fusion between appropriate lipid bilayers and exocytosis of intracellular vesicles. SNAREs constitute the essential minimal membrane-fusion machinery in eukaryotic cells. Most of them are attached to the membrane via a single, carboxy terminal transmembrane domain or posttranslational modification. The amino terminal cytosolic domain contains a conserved SNARE motif, a stretch of 60–70 amino acids organized in eight heptad repeats, which form α -helices and engage in the formation of coiled-coil structures.

Definition

Single Nucleotide Polymorphisms

Single nucleotide ►**polymorphisms** (►**SNPs**) are single-base changes that occur at a specific position in a genome. Very often this definition also comprises single-base insertions and deletions (so called “indels”). SNPs are the most abundant polymorphisms in the human genome, accounting for more than 90% of all sequence variations. In ►**diploid** species, SNPs are usually ►**biallelic** polymorphisms but have the potential to be tri- or even tetra-allelic. If in a general population the abundance of the less frequent allele of a base-change is not lower than 1% it is defined to be an SNP. Otherwise it is termed ►**point mutation**.

SNPs feature low mutation rates and have been estimated to occur in the human genome at a frequency of one in every 300–1000 nucleotides. In contrast to other ►**DNA markers** such as ►**STRs** (short tandem repeats), SNPs are more stable over generations. Due to the binary nature of SNPs, they can be more easily analysed than complex STRs. In order to achieve a maximum of information from DNA markers such as SNPs, the ►**haplotype** of an individual – i.e. the phase of the ►**alleles** of several SNPs on a single chromosome – is considered to be important for genetic studies.

Most SNPs occur in non-coding regions of the human genome. The frequency of SNPs in these regions is about fourfold higher than in ►**coding regions**. About 3% of the human genome refers to coding DNA. Given the size of the haploid human genome with 3×10^9 base pairs and one SNP on average per 300 nucleotides, there are approximately ten million SNPs, of which ca. 333,333 are expected to occur in coding sequences. Only half of these SNPs result in an amino acid change, which possibly represents 166,666 amino acid variations between two individuals.

Over half of the SNPs occurring in coding regions are ►**synonymous codon changes**; thus they do not affect protein biosynthesis. In humans, the C \rightarrow T/G \rightarrow A transition is the most common variant, representing about two-thirds of all SNPs. This striking abundance reflects the well-known ►**deamination** of 5-methylcytosine to thymine.

SNP Discovery

About 1.4 million human SNPs stored in public databases have been discovered in the course of the human genome sequencing effort. In this project several individuals were sequenced in parallel. Due to natural diversity the respective sequences differ slightly from one individual to the other. As a result of possible experimental errors and due to frequency changes of DNA markers from one population to the other, SNPs have always to be validated in the population to be studied. Furthermore, it quite often happens that no SNPs are available in the genomic region of interest. In this case novel SNPs have to be identified. In general, screening for SNPs comprises experimental approaches and ►*in-silico* procedures. Usually, SNP discovery is performed experimentally by DNA sequencing using a number of DNA samples in different populations. Although considered to be the “gold standard” for sequence determination, the ►Sanger sequencing method is prone to error production (as was observed in sequencing projects). Therefore experimental results must be confirmed, which is commonly done by screening polymorphisms in genomic sequences from different individuals using software analysis. This includes likelihood estimation of a particular locus on a genome being polymorphic. In this way true polymorphisms and sequencing errors can be distinguished.

SNP ► Genotyping

Genotyping refers to the assignment of different variants in an otherwise conserved DNA region. Gene variants can be associated with phenotypes such as ►complex diseases. ►Association studies were proposed as a suitable approach in those cases, where traditional family-based ►linkage analyses fail presumably because of many contributing loci. In practice, many SNPs from selected populations of affected and non-affected (control) individuals are scored. This is called case-control study design. A significant frequency change of typed SNPs indicates an association between these SNPs and the complex trait under investigation.

Mass Spectrometry

In principle, ►mass spectrometry embodies a very attractive solution for the detection of nucleic acids as it provides direct and fast analysis. The main advantage of mass spectrometry over other DNA characterisation techniques is its signal accuracy. Signals obtained reflect the molecular weight, a physical and intrinsic property, of an analyte. Two main inventions have paved the way for mass spectrometry in life sciences, matrix-assisted laser ►desorption/►ionisation time-of-flight mass spectrometry (►MALDI-TOF-MS) and electrospray ionisation mass spectrometry (►ESI-MS).

By means of either technology femtomolar amounts of nucleic acids can be detected. Besides these two methodologies alternative mass spectrometric procedures have been applied for the detection of SNPs, such as atmospheric pressure chemical ionisation (►APCI).

Characteristics

Matrix-Assisted Laser Desorption/Ionisation Mass Spectrometry

Franz Hillenkamp and Michael Karas discovered that irradiation of crystals formed by suitable small, acidic organic molecules, termed “matrix”, with a pulsed laser at a wavelength close to a resonant absorption band of these molecules induces an energy transfer and desorption process, evaporating matrix ions into the gas-phase. By embedding biomolecules such as peptides, proteins or short nucleic acids into the crystalline structure of matrix molecules, the biomolecules are co-desorbed into the gas-phase by fast heating. Ionisation occurs upon irradiation with the laser. However, the ionisation process in MALDI remains to be elucidated. Predominantly either positively or negatively single charged molecules are detected by MALDI. These ions are produced by a proton-transfer reaction between matrix and analyte molecules in the gas-phase. Ions are accelerated in an electric field. Usually, MALDI-MS is performed with simple and fast time-of-flight separation (MALDI-TOF-MS). By means of ion optics, molecules with (more or less) the same kinetic energy are guided into a flight-tube where they are separated according to their mass to charge ratio (m/z) before they finally reach the detector. The velocity of molecules is inversely proportional to the square root of their m/z . Molecules with a higher m/z ratio reach the detector later than molecules with a lower m/z .

Initially, MALDI was predominantly applied in protein chemistry. More recently it has also been employed for nucleic acid research. For the analysis of nucleic acids the main problem is the negatively charged sugar-phosphate backbone. In solution phosphate residues constitute a site of negative charge. Each oligonucleotide carries as many negative charges as phosphate residues. The affinity of phosphate residues for counterions such as sodium and potassium is high, but unfortunately not high enough to result in complete saturation. Metal ions cause adduct formation with phosphate linkages thereby significantly reducing the signal quality of nucleic acids. As a consequence purification strategies have been included in sample preparation protocols. Most popular procedures, including reversed-phase column purification, magnetic bead technology and gel filtration, are expensive and cumbersome for automation.

The acid instability of DNA poses another problem for MALDI analysis. Efficient MALDI matrices are

usually acidic. However in the gas-phase, long DNA molecules readily fragment in the presence of such matrices.

Several DNA characteristics have been observed and exploited for improved MALDI detection. ▶**Depurination** has been found for larger DNA oligomers. Replacing natural purines by 7-deaza-analogues is an efficient approach to overcome DNA degradation. Furthermore, ribonucleotides containing 2'-OH groups are more stable than DNA in the gas-phase. A third approach using chemical modification to improve MALDI detection of nucleic acids is named ▶**charge tagging**. Charge-tagged DNA carries either a single positive or a single negative charge. In this way MALDI detection sensitivity is increased about 100-fold compared to unmodified DNA and the susceptibility to ion adduct formation is significantly decreased.

The optimisation of the MALDI process also includes the identification of the most suitable matrix and sample preparation method. Three different matrix preparation methods are generally applied in MALDI depending on the matrix used; thin-layer (using for example α -cyano-4-hydroxy-cinnamic acid or derivatives as matrix), dried droplet preparations (using for example 3-hydroxypicolinic acid (HPA) as matrix) and Sequenom's SpectroChips™ (▶www.sequenom.com). For thin-layer preparations, matrix is spread over the MALDI target plate in a volatile solvent such as acetone. The solvent evaporates immediately, leaving behind a thin layer of small matrix crystals. Subsequently sample is dispensed onto the thin-layer in a solvent that does not dissolve the matrix crystals. Analyte molecules co-crystallise into the surface of matrix. Hence during laser desorption analytes are desorbed approximately equally all over the spot. Due to the limited thickness of the matrix layer, a better mass accuracy can be achieved than by dried-droplet preparations. However, efficient matrices for DNA analysis such as HPA can only be used for dried-droplet preparation because of their crystallisation behaviour. For dried droplet preparations, matrix and analyte solution are mixed and spotted onto the MALDI target plate. The mass accuracy for dried droplet preparations tends to be less stable than that for thin-layer preparations because of the uneven height of the matrix layer. As MALDI analysis is based on the determination of the time-of-flight of an ion, a variation of matrix layer height results in a shift in the starting point of desorption. Furthermore, certain positions on a dried droplet preparation tend to give rise to better results than others (so-called "sweet spots"). The disadvantages of dried droplet preparation can be overcome by using SpectroChips. Nanoliter quantities of analyte are transferred onto tiny spots of dried matrix (usually 3-hydroxypicolinic acid) deposited on silicon chips. As the entire preparation is volatilised with a few laser shots,

spot-to-spot reproducibility increases significantly compared to classical dried droplet preparations.

Electrospray Ionisation Mass Spectrometry

Electrospray ionisation mass spectrometry (ESI-MS) was mainly developed by John Fenn. It has become an important method in life sciences. Like MALDI-MS it has been used successfully for the analysis of biomolecules. ▶**Chromatographic procedures** are a preferred option for sample purification. ESI-MS can be coupled with ▶**capillary electrophoresis** or ▶**HPLC**. ESI is currently one of the gentlest methods for ionising molecules used in mass spectrometry, even gentler than conventional MALDI. In the process of ESI, charged droplets are generated at atmospheric pressure by spraying sample solution into an electric field. Analyte molecules are ionised in these droplets leaving the ion source largely intact. In addition to the time-of-flight separation also commonly used for MALDI, for ESI, ▶**quadrupoles** and/or ▶**ion traps** are used to guide the analyte molecules to the detector efficiently. In combination with ▶**tandem mass spectrometry** (MS/MS), which is based on the gas-phase collision induced fragmentation of biomolecules, structural and sequence information can be obtained.

ESI-MS can be used to detect intact ▶**PCR** products of up to 120 bases. Particularly in this mass range, its accuracy is better than that of MALDI-MS because of the multiple charge states of the analyte molecules used to determine their molecular mass. A number of procedures for the analysis of SNPs have been described in the past few years but most of them have not (yet) become mature technologies. An inherent drawback of ESI is that due to analyte injection throughput is severely limited. With one ESI mass spectrometer, several hundreds of samples could be analysed per day as routine, which is far too few for efficient screening or genotyping of SNPs. Therefore at present it is inconceivable that ESI will replace MALDI for DNA analysis in SNP discovery or in SNP typing applications.

SNP Discovery

Standardized DNA re-sequencing that is based on the procedure developed by Sanger and co-workers is currently the most straightforward approach to detect novel polymorphisms. Mass spectrometry was proposed as an alternative to gel- or capillary-based analysis of large DNA sequencing products (500–1000 bp). Among the procedures for sequencing DNA by mass spectrometry, most combined Sanger sequencing with MALDI-MS. However, only short sequences of up to 50 bases could be routinely detected, which impedes applications such as genome sequencing and efficient SNP screening.

Alternative (re-)sequencing approaches were introduced making use of base-specific fragmentation

patterns of genomic sequences of interest. For example workers from Methexis Genomics and Sequenom invented a method in which single-stranded RNA transcripts are produced from both strands of a PCR product and the resulting two RNAs are fragmented by the use of ►**RNAases**, for instance by G-specific RNase T1. Fragments are analysed by MALDI and signals are compared to values calculated from *in silico* digestions of reference sequences. Differences in expected masses can be identified and used for the detection of unknown SNPs and unambiguous sequence assignment.

SNP Genotyping

With the increased popularity of using SNPs in genetic analysis, the possibility of employing mass spectrometry for SNP typing has been extensively explored. After an initial step of complexity reduction and amplification of the genomic DNA, most (mass spectrometric) methods for SNP genotyping apply primer extension for allele querying. Other methodologies for the generation of allele-specific products include oligonucleotide hybridisation, oligonucleotide ligation and allele-specific cleavage of oligonucleotides.

The primer extension reaction is the most widely applied molecular biological procedure for SNP analysis. Primer extension is robust and flexible. What is more important for mass spectrometric analysis, it generates fairly small products. In a primer extension reaction, a ►**DNA polymerase** extends a primer upstream of the SNP of interest with a set of ►**dNTPs** and/or ►**ddNTPs** on a PCR product, resulting in allele-specific products. The DNA polymerase extends the 3'-end of the primer by specifically incorporating nucleotides that are complementary to the DNA template. The extension reaction terminates at the first ►**nucleobase** in the template where a nucleotide occurs that is complementary to one of the ddNTPs in the reaction mix. Generally, a thermostable DNA polymerase is used in a temperature-cycled reaction resulting in a linear amplification. Products of the primer extension reaction are detected by mass spectrometry. The different masses of the DNA products detected represent the different alleles. Most methods use MALDI detection to allow high-throughput analysis. Prominent assays are the MassEXTEND assay (formerly called PROBE assay), the PinPoint assay, the VSET assay, the GenoSNIP assay and the GOOD assay.

Clinical Relevance

The use of SNPs has attracted most attention to two major applications. Firstly, SNPs can help geneticists to trace sequences associated with susceptibility to

complex diseases. Secondly, candidate gene association studies can be a powerful tool for the development of personalised medicine. This area is called ►**pharmacogenomics**. Very often, drugs interact with proteins such as metabolising enzymes or receptors, not taking into account sequence variations within populations. Patients can therefore respond to different extents to the same drug. In the future, based on the results of pharmacogenomic research, physicians could routinely screen for particular SNPs and thereby tailor drug treatments to each patient's individual genetic background. Mass spectrometry is a powerful method to detect SNPs for clinical studies.

Somite

Definition

Somites are transient organizational structures of the embryo located on both sides of the neural tube. The total number of somites is constant and specific to each species. In avian embryos, each somite pair individualizes every 90 minutes until a total of about 50 somite pairs have been formed; in mice the number of

segments attains 65. The somites are initially epithelial and then dissociate into sclerotome that gives rise to the vertebrae, and the dermomyotome which evolves into dorsal dermis and vertebral muscles.

Somitogenesis

Institute, Paris, France
margab@pasteur.fr

Definition

Somites are transient segments of ►paraxial mesoderm that are present in developing ►cephalochordates and vertebrates. In many vertebrate species, somites form as blocks of cells, which bud off in a highly coordinated fashion from the anterior end of the unsegmented ►presomitic mesoderm (PSM), following an anterior/posterior gradient. The strict temporal and spatial regulation of somitogenesis is of crucial developmental importance because segmental structures (peripheral spinal nerves, vertebrae, axial muscles and early blood vessels) develop according to the periodicity of somite segmentation. Until recently, the mechanisms that govern somitogenesis were largely unknown. However, the identification of ►cycling genes, the expression of which turns on and off, has provided evidence for an intrinsic oscillatory mechanism in PSM cells. The newly formed somite, as it separates from the PSM (initial segmentation) has an epithelial structure, which matures in such a way that an epithelial ►dermomyotome is retained dorsally, while ventrally mesenchymal cells form the ►sclerotome. Multipotent mesodermal cells in the immature somite acquire a differentiated cell fate in response to signals from surrounding tissues. Subsequently sclerotomal cells differentiate into the cartilage and bone of the vertebral column and ribs while the dermomyotome gives rise to skeletal muscle and dorsal dermis.

Characteristics

Two main features characterise somitogenesis:

1. the formation of the somite and the molecular events leading to successive segmentation. The precise spatiotemporal regulation of somite segmentation

requires the activity of a biochemical oscillator known as the somite-segmentation clock. The molecular identity of the clock itself is still unclear, but genetic and embryological data indicate how the periodicity of somite formation is generated and how the position of segment borders is determined.

2. the developmental regulation of somite derivatives. The specification of somite derivatives such as bone and muscle depends on patterning signals secreted from adjacent tissues that lead to the activation, in particular somitic compartments, of genes promoting ►cell lineage specification.

Molecular Interactions and Regulatory Mechanisms

The Making of the Somite

Key transcription factors and molecules of different ►signal transduction pathways are involved in vertebrate segmentation, and have now begun to be identified.

Cycling Genes – see Review (1) and Fig. 1

The first evidence for such genes was provided by the observation of regular pulses of expression in PSM cells of the mRNA coding for the basic helix-loop-helix (b-HLH) transcription factor *c-hairy 1*. *c-hairy* mRNA is expressed as a wave sweeping across the whole PSM once during the formation of each somite. The existence of such an oscillator or clock, whose role is to generate a temporal periodicity which can be translated spatially into the periodic boundaries of the somites, was proposed originally as the “clock and wavefront” model. It involves a set of genes involved in Notch signalling (2). Such genes encode transcription factors of the Hairy and Enhancer of Split (HES) family, acting downstream of Notch signalling, as well as the glycosyl transferase, Lunatic Fringe, and the Notch ligand, Delta C. Their cycling behaviour in the PSM is

Somitogenesis. Figure 1 Oscillation of *Lfng/c-hairy1* and *Axin2* during Somitogenesis. Comparison of the three phases of *Lfng/c-hairy1* (in light grey, left side of each schema) and *Axin2* (in black, right side) expression during each oscillation of the segmental clock. *Axin2* is out of phase with *Lfng/c-hairy1* (S0, next somite to form; S1, most recently formed somite; S2, somite formed prior to S1)

regulated at the transcriptional level. All these genes oscillate in synchrony in the PSM, suggesting that they are downstream of a common cycling activator. The mechanism driving the oscillations of the cycling genes has been extensively studied in zebrafish, chick and mouse. In all species examined thus far, Notch activation lies at the heart of the oscillator. Notch plays a critical role in the control of the oscillations by directly activating the cycling genes, thus accounting for their synchronous expression. Notch activation drives the expression of transcriptional repressors of the HES family, which in turn negatively regulate their own expression and that of the other genes. This model, based on a negative feed-back loop, requires that the HER (Hairy and Enhancer of Split-Related) proteins be highly unstable and that their repressive effect be dominant over Notch activation. A second group of cycling genes linked to the Wnt signalling pathway has recently been uncovered. One cycling gene in this class has been identified which encodes the inhibitor of Wnt signalling, *Axin2*. In the mouse, *Axin2* is expressed in a dynamic sequence similar to, but out of phase with, that of the Notch-related cycling genes. *Axin2* is directly regulated by Wnt signalling and may participate in the establishment of an autoregulatory negative feedback loop involved in its periodic expression. Results with mouse *Wnt* mutants indicate that Wnt signalling acts upstream of the Notch-regulated cycling genes. Therefore, in the mouse, the segmentation clock appears to be composed of a Wnt-based regulatory loop that generates a series of Notch-based loops.

The Determination Front and Segment Boundary Formation

The secreted growth factor FGF8 (fibroblast growth factor 8) is implicated in converting the clock pulsation into the periodic arrangement of segment boundaries. *Fgf8* mRNA is strongly expressed in PSM precursors in the ►primitive streak and tail bud as well as in the posteriormost PSM, and its expression progressively decreases in more anterior cells, establishing a gradient. *Fgf8* mRNA is progressively degraded in newly formed tissues and this is translated into a gradient of FGF8 protein. This mechanism provides a novel model for morphogen gradient formation (3). It is proposed that, because of the progressive decrease of *Fgf8* expression during maturation of the PSM, when cells become located in the anterior PSM, they reach a threshold of FGF signalling allowing them to activate the segmentation programme. This threshold level is termed the “determination front”. Wnt3a has also been proposed to assume a role similar to that of FGF8 by establishing a gradient controlling segmentation in the PSM (2). At the level of the determination front, a gene coding for the transcription factor *Mesp2/c-mesol* becomes periodically activated in a one-somite wide

domain (2). It is tempting to speculate that the periodic activation of the genes of the *Mesp* family is controlled by the segmentation clock. This would provide a link between the segmentation clock, the determination front and the boundary-formation process. How the segmentation clock itself is activated remains to be established.

Hox Genes

Positional information along the body axis, defining for example the particular shape of the vertebrae, is controlled by the *Hox* genes in the somites. The segmentation clock also controls aspects of spatiotemporal activation of Hox genes providing a co-ordination between the positioning of segment boundaries and the future positional identity of the somite derivatives (4).

Maturation of the Somite and its Tissue Derivatives

The somite buds off from the PSM as an epithelial structure. Epithelialisation depends on a number of genes and notably the b-HLH transcription factor Paraxis. In its absence, somite derivatives form, but are disorganised (5). Patterning of the somite is characterised morphologically by the retention of a dorsal epithelium, the dermomyotome, while the ventral somite acquires the loose mesenchymal aspect of the sclerotome (Fig. 2). At the molecular level the homeo/paired domain protein Pax3, present in the PSM, continues to be expressed in the dermomyotome while the sclerotomal cells now express Pax1 (and Pax9). *Pax* genes are regulators of the myogenic and cartilaginous progenitor cells derived from the dorsal and ventral somite compartments respectively (6).

Further patterning of the somite occurs on the medial/lateral axis, such that the medial lip of the dermomyotome gives rise to the early myogenic progenitor cells in which the myogenic determination gene, *Myf5*, is activated (7). These cells are the first to contribute to the skeletal muscle of the ►myotome, a third somite compartment located between the dermomyotome and the sclerotome. As cells continue to enter the myotome, an intercalated (dermo)myotome domain can be distinguished, characterized by *Engrailed 1* expression. Myogenic cells derived from the medial dermomyotome later contribute to epaxial musculature, notably the deep back muscles. Subsequently muscle progenitor cells, specified in the lateral dermomyotome will also contribute to the myotome (Fig. 2). Entry of these cells into the myogenic programme also depends on the activation of *Myf5* and/or *Mrf4* and, later, *MyoD*, encoding other members of this b-HLH family of myogenic regulatory factors. Hypaxial muscles, which constitute most of the trunk musculature, originate from the lateral dermomyotome, which initially extends into lateral mesoderm as an epithelial

Somitogenesis. Figure 2 Schematic representation of Somitogenesis.

structure, the somitic bud. At certain axial levels – at limb level for example – the somitic bud disintegrates to give rise to migratory muscle progenitor cells which will activate myogenic regulatory factors once they have arrived at the sites where limb and other muscles will form. Genes coding for the transcription factors *Pax3* and *Lbx1* and for *Met*, a tyrosine kinase receptor, are implicated in the migration of these cells from the somite. A number of genes encoding homeo-domain factors are also involved in the specification of somitic cell-type derivatives. *Meox1* and *Meox2* genes function together and upstream of several genetic hierarchies that are required for the development of somites. Double mutant animals lack an axial skeleton and skeletal muscles are severely deficient. The genes encoding the homeoproteins *Six 1.4* and *5* have been shown to be expressed in somites during development. The *Six* proteins, acting in collaboration with an *Eya* co-activator, can directly transactivate some skeletal muscle target genes. The central dermomyotome also gives rise to cells which will form the dorsal dermis in which the homeoprotein *Msx1* is expressed, as well as contributing muscle precursor cells to the older myotome as the epithelial structure of the dermomyotome disintegrates. It has been proposed that a subpopulation of endothelial cells is also derived from the dorsal somite. The sclerotomal cells of the ventral somite give rise to the axial skeleton, both the vertebral column and the ribs. The sclerotome is also patterned on the medio-lateral axis. *Pax1* is more rapidly down-regulated in the lateral domain where rib primordia will develop, in close proximity to the myogenic cells of the somitic bud. A further sclerotomal compartment (the ►syndetome), lying under the myotome, is characterized by the expression of the b-HLH transcription factor, scleraxis. Cells expressing this factor will

contribute to tendon formation, at the expense of skeletogenic *Pax1* expressing cells (8).

Signalling from Surrounding Tissues Regulates the Tissue Specification of Somitic Cells

The dorso-ventral and medio-lateral axes of the newly formed somite become patterned in response to signals from surrounding tissues (6, 7). These also play a role in activating the genes that determine the entry of cells into a differentiation programme. The notochord and floor plate of the neural tube are sources of Sonic hedgehog (Shh), which plays a key role in sclerotome formation. Shh, with other Hh homologues, are required for the activation of *Pax1*. In the dorso-medial sclerotome *Pax1* probably acts transiently to render cells competent to respond to ►BMP signalling which promotes chondrogenesis. *Bapx1/Nkx3.2*, a homeodomain transcriptional repressor, expressed initially in the same domain as *Pax1*, also lies downstream of Shh signalling and probably plays a role in repressing transcription factors that inhibit the chondrogenic-promoting activities of BMPs. The recently identified sub-compartment of the sclerotome, that contributes to tendon formation, is subject to FGF signalling from the adjacent myotome.

The dorsal somite is patterned by positive and negative signalling from axial structures, and from surface ectoderm and lateral mesoderm. Shh probably has a long-range effect on the medial dermomyotome, although its direct effect on *Myf5* activation in this domain is controversial. Wnt signalling from the dorsal neural tube and surface ectoderm is critical for *Myf5* and *MyoD* activation, and indeed *Pax3* expression also depends on Wnt signals from surface ectoderm. The early activation of *Myf5* in the medial dermomyotome depends on TCF/βcatenin mediated Wnt

signalling, whereas later activation of *MyoD* in the lateral domain is influenced by Wnt7a which acts through a non-canonical Wnt pathway. Negative regulators of Wnt signalling, such as the Frzbs show complex expression patterns in the somite, where they probably contribute to the fine modulation of dorsal somite maturation. BMPs from the surrounding tissues inhibit the onset of myogenesis. The negative influence of BMP signalling from the dorsal neural tube is counteracted by Noggin, produced in the medial dermomyotome and later in the lateral domain where it neutralises the effect of BMP4 signalling from lateral mesoderm. Other signalling systems, such as those mediated by IGF and PDGF, have also been implicated in the onset of myogenesis in the dorsal somite. FGF signalling within the somite is also involved in later phases of myotome development. FGF inhibitors, the Sproutys, show complex expression patterns as the somite matures. Notch signalling in the myotome is also a negative regulator of myogenesis, affecting *MyoD* expression. In conclusion the dorsal somite, which is the source of all skeletal muscle apart from that in the head, is subject to highly complex positive and negative signalling which regulates the spatiotemporal specification of myogenic cells (7). Tissue determination genes, such as *Myf5*, are controlled by a correspondingly complex series of regulatory elements (9) which integrate these incoming signals, leading to the activation of the gene and hence the entry of a particular sub-population of cells into the myogenic programme.

Southern Blot

Definition

Southern blot describes a method in molecular biology, pioneered by E. M. Southern, where DNA fragments are first separated according to molecular weight on a gel, then transferred to an absorbent sheet of material, such as Nylon membrane, and finally analyzed with a (non-) radioactive probe that only sticks to the DNA sequence(s) of interest. Southern blotting is very appropriate to detect the presence/absence or size changes of a certain stretch of DNA.

Sphingomyelinase

Definition

Sphingomyelin (SM), and in particular its metabolite, ceramide, is involved in a variety of cellular processes including differentiation, cellular senescence, apoptosis and proliferation. Ceramide is produced by hydrolysis of SM by acid or neutral sphingomyelinase, and can act as a second messenger. Some members of the TNF receptor family stimulate sphingomyelinases. Ceramide produced by neutral SMase activated by TNF-R1 seems to be involved in the regulation of MAP kinases and PLA2, whereas ceramide generated by acid SMase, which can be activated by Fas and TNF-R1, is involved in NF- κ B activation and apoptosis induction.

Synonyms

Autosomal recessive spinal muscular atrophy; proximal spinal muscular atrophy; infantile spinal muscular atrophy; spinal muscular atrophy, infantile acute form, Werdnig-Hoffmann disease; spinal muscular atrophy, infantile chronic form; juvenile spinal muscular atrophy; spinal muscular atrophy, childhood and adolescent form; Kugelberg-Welander disease

Definition

Spinal muscular atrophy (SMA) is characterized by symmetric proximal muscle weakness and is caused by degeneration of the ► [anterior horn cells](#) of the spinal cord. SMA is clinically subdivided into three types

based on age of onset and clinical severity. Type I SMA (Werdnig-Hoffmann disease; OMIM #253300) is characterized by the onset of severe muscle weakness and hypotonia in the first few months of life, and the inability to sit or walk. Fatal respiratory failure usually occurs before the age of 2 years. Type II SMA (intermediate type; OMIM #253550) is characterized by the onset of proximal muscle weakness before 18 months of age, the ability to sit but not to walk unaided, and survival beyond 4 years of age. Type III SMA (Kugelberg-Welander disease; OMIM #253400) is characterized by the onset of proximal muscle weakness after the age of 2 years, the ability to walk independently until the disease progresses and survival into adulthood.

Since the discovery of the disease gene, *SMN1* (OMIM #600354), there has been considerable progress in understanding of molecular genetics and pathogenesis of SMA. It is now understood that SMA is caused by deficiency of the SMN protein. There are diseases that present symptoms resembling those of SMN-deficient SMA, but are caused by mutations in genes other than *SMN1* (1).

Characteristics

SMN1, the SMA Disease Gene and *SMN2*

By gene deletion or ► [gene conversion](#), *SMN1* exon 7 is homozygously absent in 94% of patients with clinically typical SMA (2). *SMN1* and its centromeric homologue, *SMN2* (OMIM #601627), lie within the telomeric and centromeric halves, respectively, of a large inverted repeat in chromosome region 5q13 (Fig. 1). *SMN* consists of 9 exons (exons 1, 2a, 2b, 3 through 8), with the stop codon present near the end of exon 7. Although *SMN2* typically differs from *SMN1* in nucleotides in intron 6, exon 7, intron 7, and exon 8, the coding sequence of *SMN2* differs from that of *SMN1* only by a single nucleotide (c.840C > T) in exon 7 (Fig. 1). In contrast to *SMN1*, at least one copy of which is indispensable for the normal survival of motor neurons, *SMN2* is dispensable since approximately 5–10% of normal individuals lack both copies. The failure of *SMN2* to compensate fully for the loss of *SMN1* is due to the sequence difference (c.840C > T) in exon 7. Although translationally silent, the c.840C > T transition in *SMN2* decreases the activity of an ► [exonic splicing enhancer](#) so that less full-length transcript is generated, leading to deficiency of stable SMN protein (Fig. 2). The *SMN* gene duplication occurred more than five million years ago, before the separation of human and chimpanzee lineages, but the *SMN2* gene sequence *per se* appeared for the first time only in *Homo sapiens*.

SMN1 Deletion Mutations and Conversion Mutations

Approximately 94% of individuals with clinically typical SMA lack both copies of *SMN1* exon 7 (2).

Spinal Muscular Atrophy. Figure 1 Genomic Organization of the *SMN1* and *SMN2* genes. *SMN2* typically differs in nucleotides in intron 6, exon 7, intron 7 and exon 8 from *SMN1*.

Spinal Muscular Atrophy. Figure 2 Transcript and protein productions from the *SMN1* and *SMN2* genes. Most transcripts from *SMN2* are truncated forms, and produce unstable proteins.

Loss of *SMN1* can occur by deletion (typically a large deletion that includes the whole gene) or by gene conversion to *SMN2*. A large majority of genes converted from *SMN1* to *SMN2* had *SMN2* sequences in most of the polymorphic nucleotides except for the *SMN1* sequence in exon 8. Minor variants of hybrid *SMN* genes have been described. These include *SMN2* intron 6 and exon 7 juxtaposed to *SMN1* intron 7 and exon 8, *SMN2* exon 7 flanked by *SMN1* intron 6 and exon 8 and *SMN1* sequences in all of the polymorphic nucleotides except for the *SMN2* sequence in exon 8; the latter is not a disease allele. A number of hypotheses have been proposed for the generation of these hybrid genes, including unequal recombination, intrachromosomal deletion and gene conversion. The gene conversion hypothesis is generally accepted.

The absence of *SMN1* exon 7 sequence correlates with either a functional or a *de facto* absence of the *SMN1* gene. At least one of the factors underlying the variable phenotype of SMA is the *SMN2* copy number. Individuals with type III SMA have, on average, more

copies of *SMN2* than individuals with type II or type I SMA, and probably express more full-length transcript, and thus more stable SMN protein, from *SMN2*. *SMN2* copy number also correlates directly with length of survival of SMA patients.

SMN1 Small Intragenic Mutations and Polymorphisms

The SMA in many of the approximately 6% of SMA patients who do not lack both copies of *SMN1* is probably unrelated to *SMN1*. However, in a substantial number of the SMA patients who do not lack both copies of *SMN1*, small intragenic mutations (also referred to as “subtle” or “non-deletion” mutations) in *SMN1* have been identified (2). These intragenic mutations provide solid evidence that *SMN1* is indeed the SMA gene, since intragenic *SMN1* mutations are associated with the SMA phenotype regardless of the status of other candidate genes. Twenty-nine small intragenic mutations have been reported [Table 1, modified from (1)]. The most common locations for these mutations are exon 6 and exon 3. The two most frequently reported small intragenic mutations, both in exon 6, are the p.Y272C missense mutation (c.815A>G) and the c.770_780dup frameshift mutation.

SMN polymorphisms have been reviewed (2). Most polymorphisms are present in the promoter region and intron 6.

SMN1 ▶ De Novo Mutations

SMN1 has a high rate of *de novo* deletion mutations due to a high frequency of recombination and crossover events. The high rate of *de novo* mutations in *SMN1* probably underlies the high carrier frequency for SMA in the general population despite the high genetic lethality of the disease. Most reported *de novo* deletion mutations were paternal in origin, and 1.7% of affected individuals received *de novo* deletion mutations mostly from their fathers. The large inverted repeat at chromosome 5q13, as well as smaller repeat sequences around the *SMN1* and *SMN2* loci, probably predispose to unequal crossing over and other recombination events, and therefore probably underlie the high *de novo* mutation rate of *SMN1*. However, the reason why *de novo* mutations of paternal origin are much more frequent than those of maternal origin is unknown. The paternal *de novo* mutation rates have been calculated as 1.6×10^{-4} (1). However, this figure is based on very small numbers of patients who had *de novo* mutations. Further studies are necessary to calculate *de novo* mutation rates more precisely.

Cellular and Molecular Regulation

The SMN Protein and the SMN Complex

SMN is a ubiquitously expressed protein (38 kD) consisting of 294 amino acids. Most of the SMN

protein in a normal individual is derived from *SMN1*, whereas the scanty amount of the SMN protein in an affected individual with homozygous absence of *SMN1* is derived from *SMN2* (Fig. 2). SMA patients with homozygous absence of *SMN1* always have at least one copy of *SMN2*. Homozygous deletions of the mouse *SMN* cause embryonic lethality, and human *SMN2* can rescue mice from embryonic lethality, and alleviate symptoms resembling human SMA in a dose dependent manner (3). Thus, the SMN protein is essential and indispensable for cell survival. It still remains a question why relative deficiency of such a ubiquitous and essential protein, SMN, causes loss of neurons, but not other cell types. It is probably because requirements of the SMN protein may differ among various cell types.

SMN is involved with biogenesis of uridine-rich small nuclear [▶ribonucleoproteins](#) (UsnRNPs) and facilitates cytoplasmic assembly of UsnRNPs into the spliceosome, a large snRNA-protein complex that catalyzes pre-mRNA splicing (3, 4). In the nucleus, SMN appears to be directly involved in pre-mRNA splicing. SMN associates with multiple other proteins to form a complex (4, 5). Core SMN-interacting proteins in the complex include [▶Gemin2](#), Gemin3, Gemin4, Gemin5, Gemin6, and Gemin7. Substrates and substoichiometric components include Sm and Sm-like (LSm) proteins, uridine-rich snRNAs (UsnRNAs), fibrillarin, GAR1, coilin, profilin, ZPR1, OSF, nucleolin, B23, hsc70, RNA helicase A, RNA polymerase II, snurportin, importin β , galectin1/3, and heterogeneous nuclear RNP-Q and RNP-R (3, 4, 5). UsnRNP assembly is mediated by the SMN complex, which subsequently facilitates hypermethylation of the methyl-G caps of UsnRNAs (4). The hypermethylated cap (m_3 G-cap) structure is specifically bound by snurportin, which then interacts with the import receptor importin β and, together with a not-yet-known import receptor that recognizes the Sm core, mediates UsnRNA import into the nucleus (4). After each round of assembly, the SMN complex must be reloaded with fresh Sm proteins to regain its activity, and this loading reaction may be regulated by the PRMT5 complex, composed of methylosome [pICln, WD45, and PRMT5 (JBP1)] and Sm proteins (4, 5). Sm proteins B, D1 and D3 are methylated by methylosome before being loaded into the SMN complex (4).

Modifying Factors for SMA

SMN2 is a well-established disease-modifying gene for SMA, and has been shown to decrease severity of SMA in a dose-dependent manner. The copy number of *SMN2* also correlates with longer survival of individuals affected with type I SMA. The dosage effect of human *SMN2* has also been observed in animal model of SMA (3, 6). However, the *SMN2* copy numbers in

type I, type II, and type III SMA overlap. Therefore, there must be other modifying factors.

Other candidate modifier genes include *NAIP*, *H4F5* (*SERF1*), and *Htra2-1* [reviewed (1)]. It remains a possibility that SMA phenotypes are modified by genes responsible for other neuromuscular disorders, including *IGHMBP2*, *HEXA*, *SCO2*, and others [reviewed (1)]. It is also possible that some of the components of the SMN and PRMT5 complexes and other components of the spliceosome may be modifiers for SMA.

Clinical Relevance

SMN1 Normal and Disease Allele Frequencies

SMA is the second most common severe autosomal recessive disease, affecting 1/10,000 live births, with a disease allele frequency of 1/100 and a carrier frequency of 1/50 (1). Approximately 60% of SMA cases are type I, and the remaining 40% type II or III with more type II cases (1).

Various *SMN1* normal and disease allele frequencies for each SMA type as well as in the general population have been estimated (1). Most disease alleles in SMA are deletions (or conversions) of at least exon 7 of *SMN1*, or what is referred to as “0-copy” alleles (frequency, 9.8×10^{-3}). A normal chromosome 5 usually has one copy of *SMN1* (“1-copy” allele; frequency, 9.6×10^{-1}). However, two copies of *SMN1* are often present on the same chromosome 5, for which the term “2-copy allele” (frequency, 3.3×10^{-2}) is used. We refer to disease alleles with small intragenic mutations in *SMN1* as “1^D” (“1-copy-Disease”) alleles (frequency, 1.8×10^{-4}). The 1^D alleles are indistinguishable from normal, 1-copy alleles by standard molecular analysis.

Molecular Genetic Testing

Since the discovery of the disease gene *SMN1*, various methods of molecular genetic testing for SMA have been developed [reviewed in (1)], including linkage analysis, PCR-[▶restriction fragment length polymorphism](#) (RFLP), PCR-[▶denaturing high-performance liquid chromatography](#) (DHPLC), quantitative *SMN* [▶gene dosage analysis](#), *SMN1* small intragenic mutation analysis, and [▶haploid analysis](#). A reasonably sensitive PCR-RFLP assay is the most commonly used method to detect SMA patients who lack both copies of *SMN1* exon 7. *SMN* gene dosage analysis may utilize quantitative competitive PCR-RFLP or quantitative real-time PCR. *SMN* gene dosage analysis is performed to identify a carrier individual with only one copy of *SMN1*, or to identify an SMA patient who has a small intragenic mutation in the patient's only copy of *SMN1*. Such a patient cannot be detected by the standard PCR-RFLP assay. The haploid analysis technique can be used in combination with *SMN* gene dosage analysis to determine *SMN1* copy number in each chromosome 5. This method will be particularly

useful to detect a carrier individual who has two copies of *SMN1* on one chromosome 5 and a deletion/conversion mutation on the other chromosome 5. Such a carrier cannot be distinguished from a normal individual by *SMN* gene dosage analysis alone.

Genetic Counseling and Risk Assessment

Methods of SMA genetic risk assessment in various clinical settings have been described in great depth (1). Risk assessment is an integral part of genetic testing and counseling. The purpose of genetic risk assessment is to provide family members with risk estimates as accurately as possible for their decision-making. Risk assessment for SMA is particularly important, because of the complexity of SMA genetics. The disease allele frequency is relatively high, small intragenic mutations are undetectable by the standard assays including *SMN* gene dosage analysis, the paternal *de novo* mutation rate is high and the presence of two copies of *SMN1* on one chromosome 5 can mask a deletion/conversion mutation on the other chromosome 5 in *SMN* gene dosage analysis.

Potential Therapeutic Approach

Currently there is no therapy that cures SMA. However active investigations are underway, and new therapeutic approaches will probably emerge in the near future. Potential approaches include: 1) to increase full-length mRNA from *SMN2* by an *in vivo* alteration in the splicing pattern of *SMN2* exon 7 through activation of trans-acting factors or ►antisense oligonucleotides (7), 2) to increase the overall transcription level of *SMN* mRNA by activating the *SMN* promoter, 3) to stabilize the *SMN* protein, 4) to repair degenerated motor neurons, 5) to replace degenerated motor neurons by ►stem cell therapy and 6) to target modifying factors other than *SMN2* (6). A high throughput drug screening for the identification of compounds that up-regulate full length *SMN* protein is underway (6). Further understanding of the molecular genetics and pathogenesis of SMA will facilitate the development of new therapies that may cure SMA in the future.

Synonyms

Removal of introns and joining of exons in RNA

Definition

Most eukaryotic protein coding genes are discontinuous, with the ► **exons** (coding sequences) interrupted by stretches of the ► **introns** (non-coding sequences). Splicing is required for excision of the introns with

concurrent joining of the exons from the primary transcripts. Precise splicing of precursor mRNA (pre-mRNA) is necessary to place the coding sequences in frame for protein ► **translation** and thus is critical for genetic expression in eukaryotes. Through regulated splicing, a single gene is capable of generating multiple transcripts encoding proteins with different functions. Thus, splicing is a post-transcriptional mechanism by which the diversity of higher eukaryotic genomes can be greatly expanded.

Characteristics

Introns in Nuclear Pre-mRNA

Splicing of nuclear pre-mRNA is directed by sequences at the splice junctions of the intron and a region near the 3' splice site that includes the branch point. These elements are well conserved in yeast but much less so in higher eukaryotes (Fig. 1a). Nevertheless, intron sequences almost invariantly start with the dinucleotide GU and end with AG. In some higher organisms, a minor class of pre-mRNA introns exists, which exhibits highly conserved but not conventional consensus sequences at the splice sites. Indeed, the two types of pre-mRNA introns are spliced by distinct, but analogous, splicing apparatuses.

Mechanism of Nuclear Pre-mRNA Splicing

Pre-mRNA splicing occurs *via* a two-step ► **transesterification** pathway (Fig. 1b). In the first step, the branch point adenosine initiates nucleophilic attack by its 2' hydroxyl at the 5' splice junction, generating 5' exon and intron-3' exon RNA species as intermediates. The latter, referred to as the lariat intermediate, contains a characteristic 2'-5' ► **phosphodiester** linkage. The second step involves nucleophilic attack at the 3' splice junction by the 3' hydroxyl of the liberated 5' exon. This results in joining of the two exons and release of the intron in a lariat form.

Splicing of pre-mRNA is catalyzed by a dynamic complex of 3 MD, termed the ► **spliceosome**. The spliceosome is composed of four small nuclear ► **ribonucleoproteins** (U1, U2, U4/U6 and U5 snRNP), each of which contains one or two snRNA and a number of proteins. As illustrated in Fig. 2, *de novo* assembly of the spliceosome on each pre-mRNA is an ordered process with several distinct intermediates, namely E (early)/commitment (CC), A, B, and C complexes. These subcomplexes can be distinguished by their snRNP and protein factor composition. In complex E, the U1 snRNP recognizes the 5' splice site *via* a base-pairing interaction and protein factors SF1 and U2 snRNP auxiliary factor (U2AF) bind to the elements near the 3' splice site. Complex A is subsequently formed when the U2 snRNP binds *via* a base-pairing interaction with the branch site sequence.

Splicing. Figure 1 (a) Canonical splicing signals in yeast and metazoan pre-mRNA introns. Highly conserved residues are shown in large bold letters. (b) The chemical reaction of pre-mRNA splicing. Splicing proceeds via two consecutive transesterification steps (see text). The 2'-5' phosphodiester bonds are shadowed.

This complex is then joined by the preassembled U4/U6-U5 tri-snRNP to form complex B. Complex B promotes a major structural change and is poised to perform the first chemical reaction. This reorganization of the spliceosome results in dissociation of the U1 and U4 snRNPs, U6 base-pairing with both the U2 snRNA and the 5' end of the intron and formation of a U6 intramolecular stem-loop structure. Concurrently, a dramatic change of protein components occurs during spliceosome activation, including dissociation of several snRNP proteins and recruitment of some protein factors that are less stably associated with snRNPs. Subsequently, the activated spliceosome catalyzes the first transesterification reaction, leading to the formation of complex C. After the second catalytic step, the mRNA is released and the disassembled snRNPs are then recycled for new rounds of splicing. Although current dogma asserts that the spliceosome is built in a stepwise manner, recent identification of a splicing-competent penta-snRNP complex from *S. cerevisiae* suggests the possibility that *in vivo* intron removal is orchestrated by a pre-assembled spliceosome.

Splicing. Figure 2 The spliceosome assembly pathway. This diagram emphasizes snRNP binding and remodeling events in each intermediate complex. The current model holds that U1, U2 and U4/U6-U5 snRNPs bind sequentially to the pre-mRNA. A major conformational change in the spliceosome occurs to form complex B* and creates the catalytic site for the first step. The first transesterification takes place in complex C, whereby the 5' exon is released and the lariat intermediate is formed.

Splicing. Figure 3 Model of the spliceosomal catalytic core. The core comprises the U2-U6 and intramolecular U6 helices. U6 and U2 base pair with the 5' splice site and branch site sequences of the pre-mRNA, respectively. Conserved residues of intron and snRNAs are highlighted. The phosphate 5' (arrowhead) of the bulged U residue in the U6 stem may coordinate a Mg^{2+} ion for catalysis. The dashed line indicates a proposed long-range tertiary interaction. Open circles in the U6 stem are putative non-Watson-Crick interactions. The gray sphere represents a non-conserved residue.

There is compelling evidence that the chemical reaction of pre-mRNA splicing is catalyzed by an RNA structure that is provided by a network of RNA-RNA interactions in the spliceosome. The catalytic core structure is mainly contributed by a U2-U6 helix and an intramolecular U6 stem-loop (Fig. 3). The former juxtaposes the reactive sites for the first catalytic step by the combined interactions of U2 with the branch site and U6 with the 5' splice site. In the intramolecular stem of U6, an evolutionarily invariant U residue situated at the bulge region coordinates an Mg^{2+} ion that may stabilize the RNA tertiary structure or even participate directly in the catalysis of the phosphoryl-transfer steps. Accordingly, selected pieces of U2 and U6 snRNAs can form a high-order structure, analogous to that of the spliceosome core, in the presence of Mg^{2+} . This protein-free U2-U6 RNA complex is capable of catalyzing a reaction closely related to the first chemical reaction of splicing. Thus, the spliceosome acts as a metal-ion affiliated RNA enzyme. In addition to RNA components, protein factors also contribute to the catalytic steps of splicing. A number of splicing factors possess the DExD/H box, characteristic of RNA-dependent \blacktriangleright ATPases. These proteins are thought to participate in ATP-dependent structural transitions during splicing. Among these factors, U5-associated protein Brr2 promotes unwinding of the U4/U6 snRNA duplex, which is crucial for

spliceosome activation. After U4 dissociation, the Prp19 protein complex joins to stabilize the remaining snRNPs and promote a structural change in the U6 snRNP that leads to activation of the spliceosome. More directly, the U5-associated Prp8/p220 protein is in close proximity to the splice sites and the snRNAs in the active site and may act as a cofactor to stabilize tertiary interactions in the catalytic core or to facilitate its formation.

Ensuring the fidelity of splice site recognition is a challenging objective for splicing in higher eukaryotes because a majority of metazoan pre-mRNAs contain poorly conserved splice sites and multiple introns. Many splicing factors containing a domain rich in arginine-serine (RS) dipeptides (thus called \blacktriangleright SR proteins) can promote spliceosome assembly and pairing of the 5' and 3' splice sites across introns. It is noteworthy that vertebrate pre-mRNA exons are often short (<300 nucleotides) compared to introns that vary considerably in size (10^2 – 10^5 nucleotides), invoking the exon definition model. SR protein-mediated splice site recognition must also occur across exons and joining of neighboring exons is then achieved by interactions between the SR proteins bound to individual exons. In cells, pre-mRNA splicing occurs while \blacktriangleright transcription proceeds. \blacktriangleright RNA polymerase II transcription complexes specifically recruit mRNA processing activities to nascent transcripts. RNA Pol II can facilitate exon recognition and juxtaposition *via* its interaction with splicing factors during transcriptional elongation, integrating a role of transcription into exon definition. Moreover, the Pol II \blacktriangleright promoter content can predetermine differential splice site selection, further supporting an intimate relationship between transcription and pre-mRNA splicing *in vivo*.

Alternative Pre-mRNA Splicing

Another level of complexity in pre-mRNA splicing among higher eukaryotes comes from alternative splicing. \blacktriangleright Alternative splicing is a phenomenon by which the splicing machinery assembles various combinations of exons to produce different mRNA isoforms from a single pre-mRNA, potentially generating multiple proteins with distinct functions. Alternative splicing may occur in a tissue- or development-specific manner or in response to specific cellular signals. Nearly 60% of human genes are estimated to undergo alternative splicing, allowing a much higher diversity within the proteome.

Alternative splicing patterns basically result from alterations in splice site utilization, including the use of alternative 5' or 3' splice sites, inclusion or exclusion of exons and retention of introns. Determination of splice site selection is generally initiated by binding of a *trans*-acting RNA binding protein with sequence specificity to a corresponding *cis*-element on the

pre-mRNA. Upon binding to the ►exonic splicing enhancer (ESE), the *trans*-acting factors may stabilize snRNP association with the regulated intron through protein-protein interactions and thus enhance splice site utilization. Binding of a splicing stimulation factor can be excluded by antagonizing factors that recognize neighboring ►exonic splicing silencers (ESS), resulting in lower usage of the splice site. Splicing enhancers or silencers may reside within introns as intronic elements. Most *trans*-acting splicing regulators have a modular structure. They carry either an RNA recognition motif (RRM) or K-homology (KH) domain for RNA binding. In addition, they possess one or more domains that mediate protein-protein interactions or determine their subcellular localization. SR proteins constitute a large family of splicing regulatory factors and play crucial roles in alternative splicing. Notably, differential ►phosphorylation of RS domains is a mechanism that controls the activity, localization or stability of SR proteins. Developmental or ►signal transduction pathways may therefore modulate the functions of splicing regulators, providing a mechanism for a wide range of splicing regulation.

A well-characterized example of splicing regulation is the control of sex determination in *Drosophila* (Fig. 4a). Sex-lethal protein (Sxl) is an RRM-containing protein expressed from an early promoter during early development of female fruit flies. Sxl blocks access of U2AF to the 3' splice site preceding a default exon of its own mRNA and thereby represses exon inclusion. This allows stable expression of Sxl protein and initiates a positive autoregulatory feedback loop in females. By a similar mechanism, Sxl protein directs 3' splice site utilization of the *transformer* (*tra*) pre-mRNA, leading to production of functional Tra protein in females. Tra protein, a member of the SR protein family, functions as a positive splicing regulator. Tra binds cooperatively with constitutive proteins Tra2 and RBP1 to an exonic enhancer sequence of the *doublesex* (*dsx*) pre-mRNA, thereby promoting inclusion of the female-specific exon and leading to production of the sex-specific transcriptional regulator Dsx^F. Numerous studies have so far indicated that interplay between regulatory elements within pre-mRNAs and *trans*-acting factors (SR and ►heteronuclear RNP proteins) is key in regulation of alternative splicing.

Clinical Relevance

Genetic mutations in protein coding regions may generate functionally defective and sometimes harmful proteins that are detrimental to cell functions. However, accumulating evidence has indicated that some ►translationally silent mutations have a significant impact on the yield or quality of gene products. Conceivably, mutations that disturb the splice site sequences or splicing regulatory elements may

influence the efficiency or patterns of mRNA splicing, which can in turn cause diseases or vary ►penetrance of mutations on phenotypes.

Defects in Pre-mRNA Splicing Can Cause or Predispose Individuals to a Disease

The notion that exonic nucleotide changes cause altered splicing is clearly exemplified by the study of ►spinal muscular atrophy (SMA) (Fig. 4b). SMA is caused by mutations of the *survival of motor neuron 1* (*SMN1*) gene, which encodes a protein required for the biogenesis of splicing snRNPs. The duplicated gene *SMN2* is remarkably similar to *SMN1* with only a few nucleotide substitutions. Although expressed, *SMN2* cannot completely compensate for the loss of *SMN1* function in SMA. Compelling evidence indicates that a silent C to T ►transition in exon 7 of *SMN2* results in inefficient inclusion of exon 7 by either disruption of an ESE or activation of an ESS. The level of functional SMN protein is thus reduced in all tissues, but deficiency of SMN inflicts particularly severe damage on motor neurons, leading to SMA. It is also evident that aberrant splicing analogously results from ►missense or ►nonsense single-base substitutions that disrupt regulatory *cis*-elements prevalent within exons. Intronic mutations near the splice sites may perturb association of the spliceosome and subsequently result in aberrant splicing (Fig. 4b). ►Growth hormone deficiency type II is an inherited condition resulting in patients of short-stature. In some alleles, mutations in the *GH* gene disrupt a 5' splice site, leading to exon skipping. The truncated GH produced exerts a dominant-negative effect that causes the symptom. Similarly, individuals with ►Frasier syndrome (FS) acquire mutations that inactivate an alternative 5' splice site downstream from exon 9 of the *Wilms tumor suppressor* (*WT1*) gene. Notably, in the wild-type allele, two functionally distinct WT1 isoforms can be generated by the use of different 5' splice sites for exon 9. Thus, the 5' splice site mutations detected in FS may result in an imbalance between the two isoforms that leads to pathogenic effects. Nucleotide alterations near the 3' end of an intron may also have detrimental effects on splicing. An example is the *cystic fibrosis transmembrane conductance regulator* (►CFTR) gene, in which an abbreviated polypyrimidine tract near the 3' end of an intron is associated with an increased frequency of exon skipping and severity of ►cystic fibrosis phenotypes. Furthermore, *trans*-acting mutations that disturb the function of the basal splicing machinery or splicing regulatory factors can potentially affect splicing on a broad scale. Alterations in the abundance or activities of splicing regulators have been implicated in ►neoplasia and ►malignancy by inducing misregulated splicing of mRNAs associated with ►cell transformation and cell-cell and cell-matrix interactions. Finally, it is likely that more pathogenic splicing abnormalities

Splicing. Figure 4 (a) Alternative splicing events in the sex determination pathway of *Drosophila*. The binding of Sxl protein to its own and *tra* pre-mRNAs blocks access of U2AF, leading to exon skipping or the use of a downstream 3' splice site. In *dsx* pre-mRNA, Tra with other splicing regulators binds to the enhancer of exon 4, thereby promoting the use of the preceding 3' splice site. (b) Simplified schemes of the disease-causing mutations described in the text. In SMN, the C to T substitution in a putative splicing regulatory element (hatched box) leads to exon skipping. In three other cases, intronic mutations or deletions also cause exon skipping or a shift of splice site utilization.

have yet to be unveiled. Mapping the functional significance of ▶[single-nucleotide polymorphisms](#) (SNPs) has been a powerful tool to identify potential

disease-causing mutations. With completion of the human genome project, it is now possible to search for SNPs on a genomic scale and identify their potential effects on splicing.

Split-Hand-Foot

Definition

Split-hand-foot refers to a malformation of the hands/feet with an extremely variable phenotype, mainly characterized by missing central rays. Two main types are described; in the “lobster claw deformity” the hand or foot is divided by a cleft – the two parts can be opposed like lobster claws. Monodactyly is characterized by deficiency of the central and radial digits

Spo11

Definition

Spo11 is a Type IIB topoisomerase homolog present in eukaryotes. It is expressed during ▶[meiosis](#), where it

initiates meiotic recombination by essentially introducing double strand DNA breaks through mechanisms resembling DNA cleavage by Type II topoisomerases.

► [DNA Topoisomerases](#)

Sporadic (Cases of Disease)

Definition

Sporadic cases (of disease) are incidents of a disease with no discernable involvement of a genetic cause. Sporadic tumors, for instance, refers to tumors arising in individuals without an inherited mutation in cancer genes.

SR Proteins

Definition

SR proteins comprise of a highly conserved family of splicing factors in higher organisms, characteristic of a domain enriched in arginine/serine dipeptide repeats (known as RS domain). Some SR proteins shuttle between the nucleus and cytoplasm and appear to have a role in the export of some mRNAs.

► [RNA Export](#)

► [Splicing](#)

Src

Definition

v-Src (synonyms v-Src, c-Src) is a 60 kD protein encoded by the oncogenic retrovirus, rous sarcoma

virus. The protein derives its name from its ability to induce sarcomas in experimental animals and malignant transformed cells in tissue culture. c-Src, or cellular Src, is the normal cellular progenitor of v-Src. Both v-Src and c-Src belong to the family of Src kinases (other members are for example lck, lyn, fyn), which comprise cytoplasmic tyrosine kinases that transfer phosphate from ATP to tyrosine residues within specific protein substrates. The resulting phosphate acts as a docking site for other molecules that transmit growth signals to the nucleus on a chain of events involving multiple phosphorylation and binding reactions. c-Src contains a carboxy-terminal region that maintains the molecule in a mostly inactive state. In v-Src, this 12 amino acid region is deleted, rendering the molecule constitutively active. The Src kinase family consists of several members, which play important roles in numerous receptor signaling pathways.

SRY – Sex Reversal

STEPHEN S. WACHTEL
Reproductive Genetics, University of Tennessee,
Memphis, TN, USA
swachtel@utmem.edu

Synonyms

Sex-determining region Y; Sex-determining gene; Testis-determining gene; XX male syndrome; XY

gonadal dysgenesis; True hermaphroditism; Mixed gonadal dysgenesis

Definition

The *SRY* (*sex-determining region Y*) gene was discovered in 1990 by Andrew Sinclair and colleagues, working in the laboratory of Peter Goodfellow (3). *SRY* is the switch that determines the sex of the mammalian embryo. In the presence of a functioning *SRY* gene, the ► [indifferent embryonic gonad](#) becomes a testis; the testis secretes ► [testosterone](#) and ► [anti-müllerian hormone](#) (AMH) and the embryo becomes a male. In the absence of the *SRY* gene, the gonad becomes an ovary; testosterone and AMH are not secreted and the embryo becomes a female. Since *SRY* is on the Y chromosome, XY embryos become males and XX embryos become females – under normal circumstances. But errors in the expression and regulation of *SRY* may lead to development of testes in XX embryos and failure of testicular development in XY embryos. These errors of gonadal or primary sex determination constitute the various forms of ► [sex reversal](#) discussed here.

Characteristics

According to Alfred Jost (1), sex determination may be viewed as a series of orderly processes: (i) establishment of genetic sex at fertilization (XY or XX), (ii) translation of genetic sex into gonadal sex (testis or ovary) and (iii) translation of gonadal sex into body sex (male or female). Step (ii) is sometimes referred to as gonadal or primary sex determination and step (iii) as secondary sex differentiation. We are here concerned with errors occurring at step (ii) – i.e. gonadal sex reversal resulting from aberrant translation of the Y-chromosome-mediated sex-determining message. Examples of gonadal sex reversal in the human are XX male syndrome, XY gonadal dysgenesis, true hermaphroditism and mixed gonadal dysgenesis.

XX Male Syndrome

Crossover of X and Y chromosomes during male meiosis may result in ► [translocation](#) of the *SRY* gene from the Y to the X. When XX embryos carry the translocated *SRY* gene, they become “XX males.” Human XX males are outwardly unremarkable in appearance, with normal intelligence and standard psychosexual orientation. But their gonads are small and sterile, their body hair may exhibit female patterns of distribution and abundance and about a third develop female-like breasts. The *SRY* gene has not been detected in about 20% of cases of XX male syndrome. Absence of *SRY* in these cases is often associated with abnormal differentiation of the external male genitalia (► [hypospadias](#) etc.). Evidently, sex reversal in these cases is due to constitutive activation of the

testis-determining pathway – i.e. to the spontaneous ►[transcription](#) of sex-determining genes downstream from *SRY*. About 1/20,000 newborn human males has the XX sex chromosome constitution.

XY Gonadal Dysgenesis

When the *SRY* gene is lost or mutated in XY embryos, the indifferent gonad becomes an ovary. But in humans, ovaries lacking two X chromosomes are unstable. There is a progressive loss of germ cells and a breakdown of follicular integrity. Although ovarian ►[follicles](#) may occasionally persist into adulthood, the XY ovary is usually represented at or around the time of birth by a dysgenetic streak gonad devoid of endocrinological activity. The resulting syndrome, occurring in about 1/20,000 women, is characterized by amenorrhea, eunuchoid habitus, tall stature and elevated ►[gonadotropins](#). In general, the external genitalia are feminine, but breast development is minimal. Pubic and axillary hairs are sparse and uterus and tubes are most often hypoplastic, although successful pregnancy has been reported in rare cases after hormonal intervention and ►[embryo transfer](#). Some 25–30% of women with this condition develop gonadal tumors. Geneticists were surprised to learn that the *SRY* gene is intact in most women with XY gonadal dysgenesis. In these cases, testicular differentiation is blocked by the action of other genes, which negate or antagonize the function of *SRY*.

True Hermaphroditism

Simultaneous occurrence of testicular and ovarian tissue, in separate gonads, or in a single gonad called the “ovotestis,” can lead to profound ambiguity of the secondary sex traits. This condition, called “true hermaphroditism” has been recognized for thousands of years, but less than 500 cases have been reported in the medical literature. The clinical diagnosis requires presence of testicular tubules and ovarian follicles. In adults the most striking features are ambiguous genitalia and well-developed breasts, but there is a bewildering variety of whole body ►[phenotypes](#), ranging from nearly normal female to nearly normal male. After surgery, some human true hermaphrodites have borne children. About 60% of human true hermaphrodites have the XX chromosome constitution. Some 12% are XY, and some have mosaic chromosome constitutions such as XX/XY. The testicular tissue of XX true hermaphrodites resembles that in XX males; they produce no sperm. *SRY* is not detected in most XX true hermaphrodites, indicating that testicular differentiation in these cases is induced by constitutive activation of downstream genes, as in XX males who lack *SRY*.

Mixed Gonadal Dysgenesis

In this variant of true hermaphroditism, there is a degenerative ovary – a streak gonad – on one side of

the body and a testis on the other. Affected persons have an uterus and at least one fallopian tube. The external genitalia are ambiguous, and the body type may range from masculine to feminine. Common karyotypes are 46,XY and 45,X/46,XY. Cryptic mosaicism – i.e. hidden 45,X cell lines in the dysgenetic ovarian gonad – may be suspected in patients with the “46,XY” karyotype. *SRY* would be expected to be present in 46,XY cell lines and absent in 45,X cell lines. This would explain the asymmetrical development of gonads in this condition. Development of testis *versus* contralateral ovary could also be explained by mosaic expression in XY gonads of a mutant testis-determining gene.

Cellular and Molecular Regulation

SRY

Each of these sex-reversed conditions is due to aberrant expression or absence of *SRY* or other genes in the sex-determining cascade. The *SRY* gene is situated on the short arm of the human Y chromosome in band Yp11.3, near the ►[pseudoautosomal region](#). It consists of a single ►[exon](#), which contains a conservative motif common among the high mobility group (HMG) proteins. The conservative motif, called an “►[HMG box](#),” spans 79 amino acids (►[Amino Acids: Physicochemical Properties](#)) associated with DNA binding. The *SRY* protein binds to sequences AACAAAG and AACAAAT and can bind to DNA 4-way junctions regardless of sequence. *SRY* intercalates in the minor groove of the DNA double helix and can bend DNA as much as 85°, thereby facilitating contact between remote ►[nucleotide](#) sequences. This would support the presumptive role of *SRY* as a transcription factor. *SRY* protein is expressed in the nuclei of the primordial ►[Sertoli cells](#), which organize the seminiferous tubules of the differentiating testis.

The Y chromosome mutations that cause XY gonadal dysgenesis tend to cluster in the *SRY* HMG box. But in the 1990's, just after the discovery of *SRY*, some 80% of women with XY gonadal dysgenesis were found to have intact *SRY* genes. This underscored the existence of a testis-determining pathway and other downstream genes, perturbation of which could block the male determining dictate of the Y chromosome. Other genes that have been found to impact differentiation of the testis are *SOX9*, *WT1*, *SFI DAX1* and *WNT-4*. The *AMH* gene, which plays a significant role in secondary sex differentiation of the male, is a downstream target of *SOX9*.

SOX9

The *SRY* gene is one member of a family of genes that code for HMG proteins. Collectively, these are known as *SOX* (*SRY-like HMG box*) genes. In one, *SOX9*, located on chromosome 17q24.1-q25.1, mutations are associated with campomelic dysplasia, a skeletal

malformation syndrome notable for bowing of the long bones and other abnormalities. Affected children with the 46,XY karyotype often exhibit XY gonadal dysgenesis, indicating that *SOX9* is part of the testis-determining pathway. In addition, there is evidence that duplication of *SOX9* can cause XX sex reversal – i.e. can induce the formation of XX testes – in the absence of *SRY*. Since *SOX9* is the first marker to appear in newly differentiated Sertoli cells, the *SOX9* gene may be an early downstream target of *SRY*. In the mouse embryo, *Sox9* is expressed on day 10.5 in the indifferent gonads of presumptive male and female. But when *Sry* is expressed on day 11.5 (the time of differentiation of the mouse testis), transcription of *Sox9* is increased in the male and decreased in the female.

AMH

The antimüllerian hormone, encoded by the *AMH* gene on chromosome 19p13.3-p13.2, blocks formation of the uterus and fallopian tubes in male embryos. There are indications that transcription of *AMH* is activated by *SOX9* (reviewed in 2). For example, the *AMH* ▶promoter contains an HMG binding site reactive with *SOX9* *in vitro*, and some XY women with *SOX9* mutations may have persistent uterus and fallopian tubes. This would place *AMH* in the male sex-determining pathway, although AMH itself is not involved in the formation of the testis.

WT1

Wilms tumor of the kidney, accounting for 15% of childhood cancers, may be found in association with aniridia, urogenital malformations and mental retardation (“WAGR syndrome”). The tumor develops as a consequence of mutation or loss of the *WT1* tumor suppressor gene on chromosome 11p13. Affected XY children exhibit gonadal dysgenesis, implying a role for *WT1* in testicular differentiation. The gene contains 10 exons, which generate 24 isoforms – i.e. functionally similar proteins having minor differences in amino acid sequence. *In vitro*, certain WT1 isoforms activate the *SRY* promoter and the *DAX1* promoter (see below).

SF1

The *SF1* (*steroidogenic factor*) gene plays a critical role in development of the adrenal gland and the gonad in humans and in mammals generally. Thus mutation in *SF1* results in adrenal failure and XY gonadal dysgenesis. In mice with homozygous *Sf1* deletions, the gonads and adrenals fail to develop and the pups die shortly after birth. Since these organs begin but do not complete development, *SF1* probably participates in formation of the indifferent gonad, but not directly in testicular organogenesis. The human *SF1* gene is on human chromosome 9p33 and contains a conservative DNA binding motif consisting of two zinc fingers.

DAX1

Human XY embryos carrying duplications in Xp21 are sex reversed (2, 4). This indicates occurrence of an X-linked gene, duplication of which can block the function of *SRY*. The gene is called *DAX1* for *dosage sensitive sex reversal-adrenal hypoplasia congenita-critical region of the X chromosome, gene 1*. It is a member of the nuclear hormone receptor superfamily, and encodes a nuclear protein that binds DNA and regulates transcription mediated by the retinoic acid receptor. Mutations in *DAX1* cause adrenal hypoplasia congenita but do not affect sex determination in human males. In mice, XX embryos lacking both copies of the *Dax1* gene become females. In mouse embryos, *Dax1* is expressed in the somatic cells of the indifferent gonad regardless of karyotype, but it is down-regulated in the developing testis. These observations suggest that, in addition to its endocrinological function, *DAX1* acts as an antagonist to *SRY*.

WNT-4

The product of the *WNT-4* gene on human chromosome 1p35, is one of a family of locally acting cellular growth factors. In both sexes, *WNT-4* is expressed in the ▶mesonephros and in the adrenal gland. In females, *WNT-4* signaling is required for development of the müllerian ducts and differentiation of oocytes and interstitial cells. Although the gene is expressed in the gonads of both sexes, it is down-regulated in the developing testis. The following observations indicate a key role for Wnt-4 signaling in gonadal sex determination. In mice, deletion of *Wnt-4* causes XX sex reversal. In humans, duplication of the WNT-4 region on chromosome 1 causes XY sex reversal. Moreover, *Wnt-4* up-regulates *Dax1*, so duplication of *Wnt-4* would be expected to suppress expression of *Sry*.

Summary

On the basis of the preceeding observations, the mammalian sex-determining pathway can be perceived as a complicated network of genes on several different chromosomes (Fig. 1). Although the particular steps of the pathway remain to be clarified, several of the individual genes have been identified. The pathway is initiated by *SRY*, a transcriptional activator with downstream targets including *SOX9*. The mechanism by which *SRY* is activated is unknown.

For the present, the various etiologies of gonadal sex reversal can be characterized as follows. XX sex reversal (XX male syndrome), resulting generally from translocation of the *SRY* gene to the X chromosome during meiosis, may also result from deletion of the *WNT-4* gene or from duplication of *SOX9* – in the absence of *SRY*. Ambiguity of the external genitalia in *SRY*(–) XX males and *SRY*(–) XX true hermaphrodites

SRY – Sex Reversal. Figure 1 Hypothetical cascade for differentiation of the XY testis. *SF1* and *WT1* genes may play a role in the development of the indifferent embryonic gonad, and *WT1* may also bind the *SRY* and *DAX1* promoters. According to this scheme, *SRY*, turned on in the indifferent XY gonad, activates *SOX9* leading to differentiation of the testis. *DAX1* antagonizes *SRY*, and duplication (dup) of *DAX1* leads to XY gonadal dysgenesis. *WNT-4* up-regulates *DAX1*. Duplication of *WNT-4* also leads to XY gonadal dysgenesis.

can be attributed to failure of activation of other genes downstream of *SRY*. Differences of gonadal phenotype in XX male syndrome and XX true hermaphroditism could be attributed to ▶lyonization involving X-linked sex-determining genes as yet undiscovered. XY sex reversal (XY gonadal dysgenesis) may result from loss or mutation of the *SRY* gene. It may also result from mutation within *WT1* or *SF1* or from duplication in the *DAX1* or *WNT-4* genes. XY gonadal dysgenesis in association with campomelic dysplasia is due to mutation within the *SOX9* gene. Sex reversal in a single gonad in an XY true hermaphrodite could be attributed to mosaic expression of the mutated or duplicated gene. As noted above, this could also explain nonmosaic cases of XY mixed gonadal dysgenesis.

Clinical Relevance

The manner in which the embryonic gonad is induced to become testis or ovary is a prime question in developmental biology and may have special relevance to the practice of medicine – particularly in the areas of pediatrics and endocrinology. Elucidation of the sex-determining cascade and identification of the individual sex-determining genes will provide insights into the nature and development of the various sex reversed syndromes, with implications for diagnosis and therapy.

JÜRGEN HESCHELER¹, BERND K. FLEISCHMANN²

¹Institute of Neurophysiology, University of Cologne, Cologne, Germany

²Institute of Physiology I, University of Bonn, Bonn, Germany

j.hescheler@uni-koeln.de

Definition

In general, stem cells are defined by their capacity to keep (i) the potential to proliferate *in vitro* in an

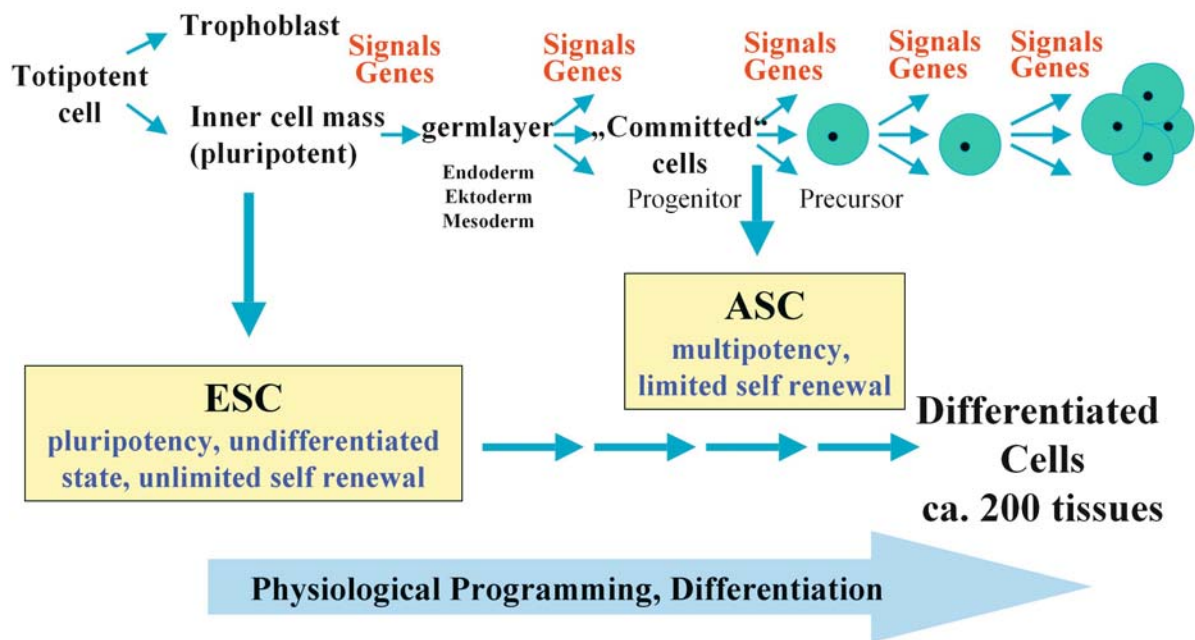

(ii) undifferentiated and (iii) ► [pluripotent](#) or ► [multipotent](#) state, thereby maintaining a normal and stable ► [karyotype](#) even with continual passaging (► [self-renewal](#)). The most prominent stem cells are of course the earliest formed during development, named ► [embryonic stem \(ES\) cells](#), which occur within the inner cell mass of blastocysts and are the origin of all the cells within our body. Obviously during their further development, mammalian organisms keep a pool of undifferentiated cells, which hold a certain regenerative potential for the organs. It is not yet unequivocally clarified what the properties of these ► [adult stem cells](#) are, but it is mostly assumed that they are in the genetic state of committed cells, i.e. progenitor cells which are already genetically determined to become a certain organotypic cell. It is still unproven whether adult stem cells have the potential to transdifferentiate, i.e. to cross boundaries and assume a different fate from that of the organ they are derived from (stem cell plasticity, see Fig. 1).

Characteristics

The term “blood stem cell” had already been used in the scientific literature as a key word in the 1960s. It appeared intermittently but gained attention when the first publication came out in the middle of the 1980s on the clinical use of blood stem cells to restore hematopoiesis in patients rendered aplastic as a consequence of extensive radiation and/or chemotherapy. Twenty years later, stem cells became even more interesting, since there was growing evidence that this population of undifferentiated cells was much more diverse. In the meantime stem cells (i.e. neural, ► [mesenchymal stem cells](#)) displaying the principal properties of self-renewal and differentiation were identified in various organs. Nowadays it is generally agreed that adult as well as embryonic stem cells provide one of the most promising tools to develop new therapeutic strategies in regenerative medicine, including the treatment of cardiac infarction and heart failure, diabetes type I, Parkinson's disease, spinal cord lesions and all other degenerative diseases. The concept of cell replacement therapy is based on the differentiation of stem cells, either *in vitro* or *in vivo*, and their implantation into the damaged tissue. Stem cells also provide an extraordinarily interesting tool for developmental biology as the consecutive expression of genes and proteins can be investigated during organotypic development under controlled conditions. Stem cells also open a new field of high turnover systems for screenings of new drugs or toxic agents under physiological conditions.

Adult Stem Cells

Stem cells are defined as clonogenic self-renewing progenitor cells that can generate one or more

Stem Cells: an Overview. Figure 1 Stem cell plasticity.

specialized cell types. Hence, the first group consists only of embryonic stem (ES) cells. These pluripotent stem cells are capable of generating all the differentiated cell types in the body. ES cells in turn generate the second group, which are called organ- or tissue-specific stem cells. Such multipotent stem cells generate cell types, comprising a particular tissue in embryos and in some cases in adults. The prototypic example of this second group is the hematopoietic or blood stem cell, which generates all the cell types of the blood and immune system. In addition, in tissues such as the intestine and skin, ongoing cellular turnover provides a rationale for the persistence of stem cells. In other organs such as the brain and heart, the presence of stem cells is proven by their isolation from these tissues and their subsequent growth in culture and differentiation, either *in vitro* or after transplantation *in vivo*. It is not clear however, whether these cells are actually used by the body to replace diseased or damaged cells. Adult stem cells can be autologous and are ethically less sensitive, but evidence for their multipotency, particularly cross-lineage is much weaker and it is not clear whether transplantation to damaged tissue is sufficient to induce differentiation to a functional cell *in vivo*, or whether *in vitro* differentiation protocols analogous to those being developed for embryonic stem cells would be a more effective approach. Mesenchymal stem cell populations retain the capacity to differentiate into the osteogenic lineage and produce cartilage or bone tissue when implanted within porous hydroxyapatite biomaterials in immunocompromised mice.

► Hematopoietic Stem Cells

The small population of multipotent hematopoietic stem cells (PHSCs) in the bone marrow is classified into short-term reconstituting cells (STRCs) and long-term reconstituting cells (LTRCs), based on how quickly the transplanted cells can produce progeny in an irradiated recipient. They can be purified using a combination of cell size, density, fluorescent dye uptake, resistance to cytotoxic chemicals and cell-surface markers including Thy1.1, Sca-1, c-kit, lineage markers, CD 38 and CD34. Experimental transplantation studies indicate that the best reconstitution occurs when both cell populations are present, the more mature cells activating the immature cells after myeloablation, whereas the mature cells provide negative control in normal animals. Functionally the type of assay that has been most widely used for the quantitation of mouse stem cells is the *in vivo* repopulating assay. Typically hematopoietic stem cells are derived from the bone marrow, which is collected from the femur and tibia of mice. Cells are suspended in PBS and incubated with rat anti-mouse monoclonal antibodies specific for the following hematopoietic lineages: CD4 and CD8 (T lymphocytes), B-220 (B lymphocytes), Mac-1 (macrophages), GR-1 (granulocytes) and TER-119 (erythrocytes). Cells are then rinsed in PBS and incubated for 30 min with magnetic beads coated with goat anti-rat immunoglobulin. Lineage-positive cells are removed by a biomagnet and the 10% remaining lineage-negative cells are then stained with ACK-4 biotin followed by streptavidin-conjugated phycoerythrin and sorted by FACS. The Lin-cells are

selected as c-kit-positive and c-kit-negative with a 1–2 log difference in staining intensity.

Mesenchymal Stem Cells

The term mesenchymal stem cells (MSC) refers to the adult mesenchymal progenitor cells with the potential to produce progeny that differentiate to produce a variety of mesenchymal cell types including fibroblasts, muscle, bone, tendon, ligament and adipose tissue. It is not known if these cells actually have the capacity to self-renew, which is a property of stem cells. MSC may be found in muscle, skin and adipose tissue as well as in bone marrow. MSC in bone marrow may be identified by colony-forming units that produce fibroblasts and make up a very small percentage of the total marrow population. MSCs or their progeny in the bone marrow provide a stromal microenvironment for hematopoiesis. During development, MSCs in the bone marrow may derive from the developing vessels or from circulating precursors.

MSCs may be isolated from bone marrow, peripheral blood, fat, skin, vasculature and muscle, where they are most probably responsible for normal tissue renewal as well as for response to injury. MSCs are negative for primitive hematopoietic cell markers but express antibody-defined markers, SH2, SH3 and SH4 and STRO-1. Systemic transplantation of MSCs has not always led to functional results in tissue. MSCs are obtained by the Caplan protocol, i.e. under sterile conditions the femur and tibia of 2-month-old female rats are excised and the cells are dispersed. The mesenchymal population is isolated on the basis of its ability to adhere to the culture plate.

►Neural Stem Cells

Fetal tissue has long been used as a source of multipotent neural progenitors. However, until recently, the adult CNS was considered incapable of self-renewal or repair. The discovery of stem cells within the adult CNS rendered this concept at least in part, obsolete. These cells are capable of self-renewal, and can give rise to highly differentiated progeny (neurons and glia) thus conforming to the standard definition of a stem cell. Adult neural precursors were initially obtained from the forebrain subventricular zone and have since also been isolated from the hippocampus, spinal cord, striatum, septum, cortex and optic nerve. Both the adult stem cells and those of fetal origin are isolated *via* dissection.

►Stem Cell Plasticity or Stem Cell Transdifferentiation

Orlic and coworkers (4) suggested pronounced transdifferentiation of hematopoietic precursors into cardiomyocytes. However this was questioned by three independent groups very recently. These studies appear to indicate that hematopoietic precursors do not

transdifferentiate into cardiomyocytes after injection into the injured mouse heart (3).

►Embryonic Stem Cells

Embryonic Stem (ES) cells originate from the inner cell mass of the pre-implantation embryo, the blastocyst. They are pluri-potent, completely undifferentiated and keep the potential for unlimited expansion, the unlimited self-renewal capacity. Stem cells with similar properties can be also obtained from embryonic carcinoma (teratocarcinomas) and embryonic germ cells. The latter are derived from primordial germ cells isolated primarily from the genital ridge. ES cells have the potential to proliferate infinitely *in vitro* in an undifferentiated and pluripotent state thereby maintaining a normal and stable karyotype even with continual passaging. Remarkably, *in vivo* they can be reincorporated into normal embryonic development by transfer into a host blastocyst or aggregation with blastomere stage embryos. They can contribute to all tissues in the resulting chimeras including gametes. When cultivated *in vitro*, ES cells differentiate under appropriate cell culture conditions, i.e. in the absence of leukemia inhibitory factor (LIF) into cell types of all three germ layers, endoderm, ectoderm and mesoderm. However, the differentiation process occurs only when ES cells are cultivated under culture conditions where they can form multicellular spheroidal tissues, termed embryoid bodies. In recent years a large number of different cell types have been described to differentiate within embryoid bodies. These include hematopoietic and endothelial cells, cartilage and neurons as well as smooth, skeletal and cardiac (6) muscle cells. The capacity of ES cells to differentiate into cell types of the mesodermal lineage has been extensively used by us and others to investigate the molecular and physiological events occurring during development into the cardiovascular system, i.e. cardiac and endothelial cells. We have observed cardiac development from mouse ES cells as early as 7 days after formation of the aggregates, which correlates well with the murine embryo, where the first beating is seen on day E8.5–E9.5 (i.e. 8.5–9.5 days post coitum). Cardiomyogenesis in embryoid bodies is paralleled by the development of vascular structures, which starts on day 5 of differentiation and results in the formation of hollow capillary-like tubules within 3–4 days. These improve the supply of nutrients and oxygen to the embryoid bodies as well as the export of catabolic end products (5). The close relationship of ES cells and primordial germ cells has recently been demonstrated by the group of Schöler who succeeded in differentiating premitotic oocytes from a pluripotent ES cell line (1). Furthermore, it could be shown that ES cells give rise to primordial germline cells and haploid male gametes.

Before clinical use of human ES cells for therapeutic trials, two major prerequisites must be fulfilled: (i) they must be safe, i.e. the development of tumors because of the high proliferative potential must not occur and (ii) the rejection of the transplanted cells must be prevented. For criterion (i) the technology of “lineage selection” has been developed in order to allow only the needed cell to differentiate from human ES cells, whilst survival of all other cells is prevented. This can be achieved by modifying the culture conditions and/or adding a combination of various growth factors and signaling molecules, which preferentially support the growth of a specific cell type, but prevent the development of the unwanted cell types. Up to now, the transgenic drug selection approach has proven to be the most specific and effective for reliable purification of ES cell-derived organotypic cells. Application of antibiotics will eliminate all other cells except those containing the resistance gene (purification of over 99.5%).

In respect of criterion (ii) several suggestions have been made. The simplest one is the establishment of a stem cell bank containing a large number of different human ES cell lines with various human leucocyte antigen (HLA) determinants. An alternative suggestion is to use “therapeutic cloning”, i.e. the exchange of the haploid nucleus of a donor oocyte by that of the patient. It has been demonstrated that the oocytes with the new nucleus develop to the blastocyst stage from which a new ES cell line can be generated, which is allogenic to the patient (2). In order to reduce the large number of donor oocytes, it may also be possible to differentiate oocytes by the method introduced by Schöler (1).

Definition

Two adrenal corticosteroids, the mineralocorticoid aldosterone and the glucocorticoid cortisol, exert profound influences on many physiological functions by virtue of their diverse roles in growth, development and maintenance of homeostasis. Their actions are mediated by intracellular receptor proteins, the **glucocorticoid (GR) and mineralocorticoid (MR) receptors**, which function as hormone-activated transcription factors that regulate the expression of, respectively, the glucocorticoid and mineralocorticoid target genes.

Characteristics

GR is ubiquitously expressed in almost all human tissues and organs. The presence of glucocorticoids is crucial for the integrity of CNS function and for maintenance of cardiovascular, metabolic and immune homeostasis. Increased glucocorticoid secretion during stress alters CNS function, assists with adjustments in energy expenditures and modulates the inflammatory/immune response. Since glucocorticoids possess a broad array of life-sustaining functions, only partial or incomplete glucocorticoid resistance has been reported so far, suggesting that complete inability of glucocorticoids to exert effects on their target tissues is incompatible with human life.

MR mediates the sodium-retaining effects of aldosterone in the kidney, salivary and sweat glands, as well as colon. In addition, the MR located in the central nervous system (CNS) – also called glucocorticoid receptor type I – appears to have a role in the regulation of stress response and feedback control in the hypothalamic-pituitary-adrenal (HPA) axis. MR has a high affinity for both aldosterone and cortisol. The circulating levels of cortisol are over 100× higher than those of aldosterone. The MR of the distal convoluted tubule and possibly other mineralocorticoid target tissues are protected from the actions of cortisol by expression of 11β-hydroxysteroid dehydrogenase type 2, which converts cortisol into the inactive cortisone.

Structure and Actions of the Glucocorticoid and Mineralocorticoid Receptors

GR and MR are members of the steroid/sterol/thyroid/retinoid/orphan receptor superfamily of nuclear transcription factors, with over 150 members currently cloned and characterized across species. The human GR cDNA was isolated by expression cloning in 1985. Located on chromosome 5, the gene of the GR is comprised of 9 exons (Fig. 1a). It encodes two 3' splicing variants, GRα and GRβ, as a result of alternatively using either terminal exon 9α or 9β. The GRα encodes a 777 amino acid protein and is the classic GR that mediates actions of glucocorticoids,

while the shorter GRβ cannot bind the ligand and its physiological and pathological roles are not well understood. The cDNA for human MR was isolated by low-stringency hybridization using human GR cDNA as a probe in 1987. The gene coding for MR also consists of 9 exons (Fig. 1b) and its locus is on human chromosome 4.

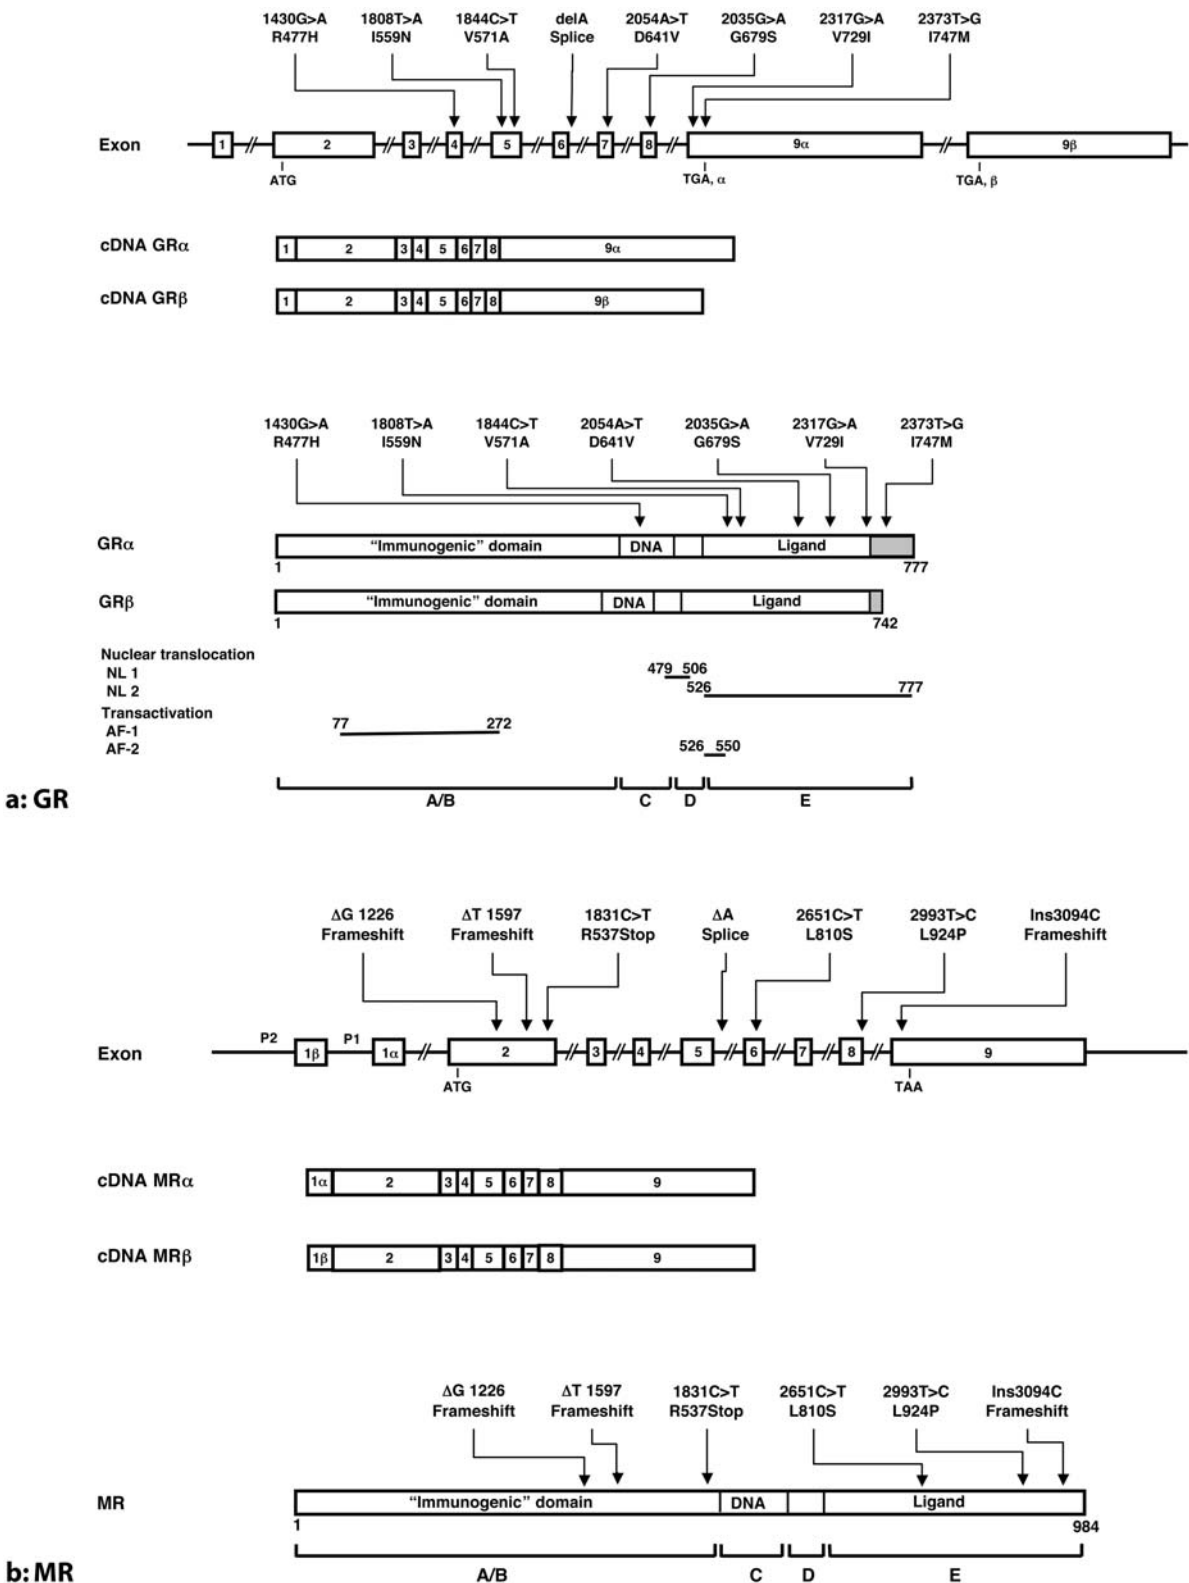

GR and MR in the unliganded state are located primarily in the cytoplasm, as part of hetero-oligomeric complexes including heat shock proteins 90, 70 and 50. After binding to their agonist ligand, they undergo conformational changes, dissociate from the heat shock proteins, homodimerize and translocate into the nucleus. There, the ligand-activated GR and MR directly interact with DNA sequences in the promoter regions of target genes.

The promoter-bound GR and MR then modulate the transcription rate of responsive genes by facilitating the formation of transcription initiation complexes including **RNA polymerase II** and its ancillary factors. In addition to these molecules, GR and MR, *via* their two transactivation domains, attract several proteins and protein complexes, namely co-activators, which help to transform the receptor signal to the transcription initiation complex as well as contain intrinsic histone acetyltransferase (HAT) and other enzymatic activities, through which they loosen the chromatin structure and facilitate access and/or binding of transcription machinery components to DNA. They include molecules known as acetyltransferase co-activators, such as the homologous p300 and cAMP-responsive element binding protein (CREB)-binding protein (CBP), the p160 family of coactivators and p/CAF, as well as huge protein complexes including SWI/SNF and thyroid hormone receptor-associated protein (TRAP)/vitamin D receptor-interacting protein DRIP complexes.

Clinical Relevance

Glucocorticoid Receptor Mutations

Familial/sporadic **glucocorticoid resistance syndrome** was first described in 1976, as a disorder characterized by hypercorticism without Cushingoid features. Since then, over 10 kindreds and sporadic cases with abnormalities of the GR number, affinity for glucocorticoids, stability and translocation into the nucleus have been reported (1). However, the molecular defects have been elucidated in only 5 kindreds and three sporadic cases (Fig. 1A). The proband of the original kindred was homozygous for a single non-conservative point mutation, replacing aspartic acid with valine at amino acid 641 in the GR LBD. This mutation reduced binding affinity for dexamethasone three-fold and caused concomitant loss of transactivation activity (1). The proband of the second family had a 4-base deletion at the 3'-boundary of exon 6, removing a donor splice site (1). This

Steroid Hormone Receptor Defects, Molecular Basis. Figure 1 Genomic, complementary DNAs, protein structures and localization of known pathologic mutations of the human glucocorticoid (a) and mineralocorticoid (b) receptors. The human glucocorticoid or mineralocorticoid receptor genes consist of 10 exons. Exon 1 is not

mutation resulted in complete ablation of one of the GR alleles in affected members of the family. The proband of the third kindred had a single point mutation in a homozygous state at amino acid 729 (valine to isoleucine) in the LBD, which reduced both the affinity and transactivation activity of GR (1). There was also an interesting sporadic case of a heterozygous man carrying a *de novo* germ-line mutation at amino acid 559 (isoleucine to asparagine) also in the LBD close to the NL1 (1). This mutant GR bound no ligand but exerted dominant negative activity on the wild type receptor. This was caused by inhibition of the translocation of the wild type receptor into the nucleus (1).

Study of a fifth case/kindred with glucocorticoid resistance and a GR mutation in the LBD (amino acid 747, replacing isoleucine with methionine) in a heterozygous state revealed that the mutant receptor had mildly reduced affinity for dexamethasone and markedly decreased transactivation activity, interestingly associated with dominant negative activity on the wild type receptor. The mutation is located several amino acids more amino terminal to helix 12 of the GR LBD and causes defective formation of the activation function (AF) 2 surface that interacts with several co-activators. The sixth and seventh sporadic cases also had mutations in a heterozygous state, replacing arginine to histidine at amino acid 477 and glycine to serine at amino acid 679, respectively (2). The former is located in the second zinc finger in the DBD. This mutant receptor has no transactivation activity due to impaired binding to glucocorticoid-response elements (GREs). The latter mutation is in the LBD, outside the ligand-binding pocket. This mutation causes 50% reduction of ligand binding affinity with comparable reduction in transactivation activity.

The proband of the eighth familial case had a point mutation in a homozygous state replacing valine to alanine at amino acid 571 in the LBD (3). The mutant receptor had a 6-fold reduction in binding affinity to dexamethasone and 10–50 fold less transactivation activity than the wild type receptor. Interestingly, the proband also suffered from a 21-hydroxylase deficiency, suggesting that association of this congenital

disease exacerbated the hyperandrogenism and virilization potential of the glucocorticoid resistance syndrome.

A complex negative feedback system exists in the human CNS that regulates glucocorticoid homeostasis. Glucocorticoids exert negative feedback effects on several higher regulatory centers; thus, the negative loop is activated in patients with loss-of-function GR mutations, resulting in compensatory increases in ACTH and cortisol secretion (Fig. 2). Although adequate compensation is apparently achieved by elevated cortisol concentrations in the great majority of the patients described, excess ACTH secretion also results in increased production of adrenal steroids with mineralocorticoid activity and enhanced secretion of adrenal androgens. The former, together with cortisol, is responsible for causing symptoms and signs of mineralocorticoid excess, such as ▶hypertension and/or hypokalemic alkalosis, whereas the latter cause varying manifestations of hyperandrogenism, such as acne, hirsutism, male pattern baldness and menstrual irregularities and infertility in women. Precocious puberty has been seen in a child due to early and excessive prepubertal adrenal androgen secretion.

Patients are treated with high doses of mineralocorticoid-sparing synthetic glucocorticoids. The goal is to suppress the increased levels of ACTH, which cause overproduction of mineralocorticoids and androgens (Fig. 2) (1). As all cases described thus far have had partial inactivation of GR activity, the use of potent synthetic glucocorticoids with minimal intrinsic mineralocorticoid activity, such as dexamethasone, is a rational approach.

Mineralocorticoid Receptor Mutations

Inactivating Mutations of the Mineralocorticoid Receptor

The mechanism by which aldosterone stimulates sodium transport in its target tissues may involve the synthesis of a protein associated with the function of the amiloride-sensitive sodium channel (ASSC). The latter is located in the apical membrane of epithelial cells of the renal distal convoluted tubule and in the plasma membranes of cells in other tissues involved with salt conservation. The phenotype of patients with

translated, exon 2 codes for the immunogenic domain (A/B), exons 3 and 4 for the DNA-binding domain (C), exons 5–9 for the hinge region (D) and the ligand-binding domain (E). The glucocorticoid receptor gene contains either exon 9 α or 9 β alternatively spliced to produce the classic GR α or the nonligand-binding GR β . C-terminally gray colored domains in GR α and GR β compose specific portions. Functional domains of the glucocorticoid receptor are indicated. The mineralocorticoid receptor gene contains either exon 1 α or 1 β alternatively spliced to produce the MR α or MR β cDNAs, respectively, but produces a single MR protein. Locations of the known mutations in the glucocorticoid (A) or mineralocorticoid (B) receptor genes are indicated in their genomic and protein structures. GR, glucocorticoid receptor; MR, mineralocorticoid receptor; HR, hinge region; DBD, DNA-binding domain; LBD, ligand-binding domain; NL1 and 2, nuclear localization signal 1 and 2; AF-1 and -2, activation function-1 and -2.

Steroid Hormone Receptor Defects, Molecular Basis. Figure 2 The increased activity of the hypothalamic-pituitary-adrenal (HPA) axis in patients with glucocorticoid resistance results in hypersecretion of CRH, ACTH, cortisol, deoxycorticosterone (DOC), corticosterone (B) and adrenal androgens causing salt retentions and hyperandrogenism.

loss-of-function mutations of the MR mimics that of patients with defects in the subunits of the ASSC, who, however, represent the bulk of patients with ►**pseudo-hypoaldosteronism** type 1 (PHA1) or mineralocorticoid resistance.

In kindreds with PHA1, both autosomal dominantly and recessively transmitted forms have been observed. The autosomal recessive form was associated with severe disease, with manifestations persisting into adulthood and was found to be caused by loss-of-function mutations in genes encoding subunits of the ASSC. However, recently, Geller et al. identified heterozygotic MR gene loss-of-function mutations in one sporadic case and four autosomal dominant cases of PHA1 (Fig. 1b) (4). These included two frameshift mutations, each deleting a single base pair in exon 2; the resultant frame shifts led to a gene product lacking the entire DNA- and hormone-binding domains, as well as a dimerization motif. Two families had an identical mutation, introducing a premature termination codon in exon 2 at position 537. One case showed a single base-pair deletion in the intron-5 splice donor site. Subsequently, Tajima et al. reported a fifth family with a pathological mutation in the MR gene from patients with autosomal dominant PHA1 (5). The proband had a single point mutation on one chromosome at codon 924

(leucine to proline) in the LBD of MR. A sixth inactivating MR mutation was found in a sporadic case of PHA1, harboring a frame shift mutation with insertion of a cytosine at position 3094 of exon 9, which resulted in a nonsense protein with a first stop codon at position 1012 (6).

As indicated above, all reported MR mutations causing the PHA1 phenotype were in the heterozygous state affecting only one of two MR alleles, indicating that PHA1 can be caused by haploinsufficiency. Patients develop PHA1 at a very early stage of their life and their clinical condition remits with age, although plasma aldosterone concentrations and renin activity remain high. These findings suggest that the intact MR gene is required for the reabsorption of salt in infancy, while by some other as yet unknown mechanism, the defect of MR function may be overcome partially with age.

Treatment of PHA1 caused by MR mutations is by supplementation with sodium chloride. The amounts of salt may be different from patient to patient depending on their degree of salt waste. The salt administration may be lessened or become unnecessary later in their life.

Activating Mutation of the Mineralocorticoid Receptor

The first activating MR mutation was found as an early-onset hypertension markedly exacerbated in pregnancy (Fig. 1b) (7). The probanda had a point mutation replacing serine at amino acid 810 by leucine in a heterozygous state. The mutation is localized in helix 5 of the MR LBD; the leucine side chain projects into the ligand-binding pocket, potentially forming additional van der Waals interactions with alanine 773 of helix 3 and the C19 methyl group of steroid hormones. Therefore, the mutation changes the ligand specificity of the mutant receptor, conferring receptor binding to progestins in addition to mineralocorticoids and glucocorticoids. Thus, the patient developed hypertension particularly in pregnancy due to the activation of the mutant receptor by progestins secreted from the placenta.

Structural Databases

The earliest protein structures were solved in the 1970s by X-ray crystallography, and later by NMR-spectroscopy, and deposited in the Protein Databank (PDB). This resource, which is now based in the Research Collaboratory of Structural Biology (RCSB) Rutgers University, contains around 30,000 structures of macromolecules (these are mainly protein structures but also include some nucleic acid- and carbohydrate structures), comprising of more than 60,000 individual

protein domains (► www.rcsb.org/pdb). Since the early 1990s, there have been sufficient structures to cluster evolutionary relatives into protein families and super-families. This has given rise to comprehensive hierarchical databases of protein structures, such as CATH and SCOP (structural classification of proteins, ► <http://scop.mrc-lmb.cam.ac.uk/scop/>), which rely on a combination of manual expert classification and structural comparison methods.

► [Protein Databases](#)

Structural Genomics

Definition

Structural genomics refers to a large-scale project to determine the three-dimensional shapes of all proteins and other important biomolecules encoded by the genomes of key organisms, using both experimental and computational techniques. A rational, genome-driven target selection, high-throughput innovations, and international coordination are key elements of structural genomics. Structural genomics is sometimes also called ► [structural proteomics](#).

Structural Genomics: Structure-to-Function Approaches

UDO HEINEMANN

Max Delbrück Center for Molecular Medicine, Berlin, Germany

heinemann@mdc-berlin.de

Definition

According to international consensus, the term ► [structural genomics](#) (also sometimes referred to as ► [structural proteomics](#)) describes a large-scale project to determine the three-dimensional shapes of all proteins and other important biomolecules encoded by the genomes of key organisms. To reach this goal, structural genomics initiatives select protein targets for structure analysis following bioinformatics-driven

strategies based on known genome sequences. In order to complete a large number of structure analyses by X-ray crystallography or ► [NMR spectroscopy](#), high-throughput innovations in several preparative, analytical and computational aspects of protein structure determination are required and a degree of international coordination of the common effort is called for. Very often, little is known about the function of a protein after its three-dimensional structure has been elucidated. Although the structure often allows the formulation of hypotheses regarding the biochemical function of a protein molecule, additional computational and experimental analyses are usually required to derive function from structure.

Description

Structural genomics initiatives were formed in the late 1990s when it became clear that, after the completion of the sequence analysis of many genomes, the attention of researchers needed to focus on the gene products in order to gain an understanding of gene function. As a part of a broad research program in ► [functional genomics](#), the systematic, genome-driven and high-throughput crystal and NMR structure analysis of proteins was initiated. Gene products other than proteins have so far remained outside the focus of structural genomics. The new approach meant a paradigm shift for many structural biologists. Whereas, in the past, each laboratory invested much effort in the production and structural analysis of a few, biochemically well characterized protein molecules, now they were dealing with a multitude of different proteins, many with partially or completely unknown function. Herein lies a practical problem and intellectual challenge, which will be addressed in this paper. How may functional insight be derived from three-dimensional protein structure in the initial absence of relevant biochemical data? The concepts, scope and achievements of structural genomics will be briefly summarized before the main issue of deriving function from structure is addressed. With regard to this, alternative approaches, either relying on bioinformatics or based on experiment, will be discussed.

Structural Genomics

Structural genomics aspires “to determine the three-dimensional shapes of all proteins and other important biomolecules encoded by the genomes of key organisms” as stated at the Second International Structural Genomics Meeting held at Airlie House, VA, USA, in April 2001. This is an ambitious research agenda, indeed. It does not, however, imply that all these structures have to be determined experimentally. Accepting the assertion that a reasonably accurate protein structure can be modeled by a computer based on a template structure sharing at least 30% sequence

identity, one may conclude that approximately 16,000 carefully chosen new protein structures will be required to permit the ▶**homology modeling** of the large majority of all protein structures (1). For structure analysis by X-ray crystallography or NMR spectroscopy, these proteins must be selected by bioinformatics tools to represent sequence families of yet unknown three-dimensional structure. In addition to the protein structures already available in the ▶**Protein Data Bank**, these structures would represent the large majority of all ▶**domain folds** present in proteins.

In order to reach the goal of 16,000 or more new protein structures within a reasonable time, high-throughput innovations are needed to speed up the sample preparation and structure analysis steps. Laboratory automation, robotics and improved software have been developed over the past few years for expression cloning of protein-coding genes, for protein purification and biochemical and biophysical characterization, for X-ray diffraction experiments, for the acquisition of NMR spectra and the processing of the experimental data and for structure modeling and validation. These innovations permit the structure analysis of many proteins in parallel, but without loss of accuracy. Especially, but not exclusively for those structural genomics centers dealing with eukaryotic proteins, the yield of crystallizable soluble protein samples from recombinant sources has proven rate-limiting in the structure analysis. Most target selection schemes focus on the coverage of new sequence families and place little priority on prior knowledge of protein function. For example, schemes have been developed that select proteins for structure analysis in part by crystallizability. The structures of these proteins may hold very valuable functional clues which can give the analysis added scientific impact, but often the protein function will not be immediately revealed without further analysis.

In a similar way to genomic sequencing, structural genomics stands to benefit from international coordination. Under the guidance of the International Structural Genomics Organization (ISGO, ▶<http://www.isgo.org/>) modes of international cooperation in structural genomics have been established. The most visible aspect of this cooperation is the construction and maintenance of a ▶**Target Registration Data Base** (Target DB) at the Protein Data Bank. 20 structural genomics consortia from around the world enter their target proteins into the Target DB and allow the database to automatically monitor the progress of the structure analysis of these proteins (Table 1). The 20 projects contributing to the Target DB are the core of the worldwide structural genomics effort.

Through structural genomics, a renewed emphasis has been placed on methods developments in all aspects of protein structure analysis from which the structural

biology sector as a whole stands to benefit. For the US structural genomics pilot centers forming the Protein Structure Initiative (PSI), these innovations have allowed a significant increase in the output of new protein structures over recent years and a significant reduction in the cost per structure. As of August 10, 2004, world-wide 36,603 (32,531) protein-coding genes had been cloned, 7138 (5783) proteins had been purified, 924 (683) crystal and 343 (64) NMR structures had been determined and 940 (624) structure entries had been added to the Protein Data Bank according to the summary status report from the Target DB. The numbers in parentheses denote the contribution of the nine PSI pilot centers. Compared to the number of 25,348 structures (proteins, peptides, viruses, and protein-nucleic acid complexes) currently archived in the Protein Data Bank, the 940 structures contributed by structural genomics projects may still seem little. It must be pointed out, however, that the content of the Protein Data Bank is highly redundant with multiple copies of the same protein molecule or variants present, so that the contribution of structural genomics to the number of domain folds or sequence families covered is probably much higher. Unfortunately, reliable statistics regarding the source of protein structures representing new sequence families in the Protein Data Bank are not available.

In addition to assigning a three-dimensional fold to a sequence family, a structure determined in structural genomics projects, as any other protein structure, may provide a wealth of insight into the function of the molecule. In view of the accelerated rate at which these structures can now be determined and the typical scarcity of biochemical information accompanying the proteins, assigning function at a rate matching that of structure determination is now a major challenge. This is akin to moving “from words to literature in structural proteomics” (2). We are mainly interested in the type of functional insight that can be deduced from the three-dimensional structure, but not from the sequence.

In the following discussion of functional assignments from structure, function is always taken to mean “biochemical function”. How a protein molecule performs its enzymatic role, how it physically interacts with large and small ligands and how it cooperates to form larger cellular structures can often be illuminated by the three-dimensional structure. Conversely, crystal or NMR structures have very limited direct use for explaining biological function. They cannot tell us whether a protein arrests the cell-cycle, in which signaling pathway it is active or how it affects the phenotype of an organism.

Function from Structure: Bioinformatics

Bioinformatics lends itself to high throughput and may thus be employed for functional assignments based on

structure. The first check a crystallographer or NMR spectroscopist will perform once a new protein structure has been unveiled is to look for structural homologs already present in the Protein Data Bank, using standard bioinformatics tools such as DALI, VAST or DEJAVU (3, 4, 5). Even if his structure represents a new sequence family, more often than not will he find a similar fold in a protein of known function. From this, the hypothesis may be generated that the protein of interest shares a similar function, since it is known that the vast majority of known [protein folds](#) is associated with one type of function only. The hypothesis thus generated may subsequently be proven or disproven by experiment. Obviously, this approach will fail for some of the very common folds such as the TIM barrel, the P-loop NTP hydrolases or the Rossmann fold, which all support numerous biochemical functions, but it allows the formulation of reasonable hypotheses for many other proteins. Likewise, heterologous interactions of our protein of interest with other folds, which may be of biological relevance, may be predicted based on the structure, since, again, the majority of folds is associated with one or very few interacting folds.

In general, computer-based approaches have been of limited use in assigning functions to proteins adopting a fold not observed before. Enzymes may be an exception to this rule, since their active sites tend to be defined by strict spatial relationships between few amino acid side chains or backbone segments. If this precise arrangement of structural elements is present in a new protein structure, there is a good possibility that the enzymatic function is retained. At least this observation, which may be derived from checking the protein structure against an atlas of active-site geometries (6), will give rise to a highly detailed hypothesis (that the protein is an enzyme, which chemical reaction it catalyzes, which substrate it accepts) that can be

experimentally tested. Alternative approaches for identifying enzymes based on three-dimensional structure and not on sequence and for predicting their functions have recently been described. One uses a vector machine-learning algorithm based on protein secondary structure, amino acid propensities and surface properties to discriminate enzymes from non-enzymes (7). Another analyzes protein surface charges to locate potential active sites in proteins (8).

Function from Structure: Experimental Approaches

Even without sophisticated bioinformatics analysis it is often possible to find clues for function in a novel protein structure. A decade ago, we determined the crystal structure of the major cold shock protein, CspB, from *Bacillus subtilis* (9). At the time of the structure analysis, proteins of this family had been reported to be involved in gene regulation, but there were also ideas that they might act as antifreeze proteins. By revealing one basic face on the surface of an acidic protein with a number of unusually exposed aromatic side chains anchored in sequence motifs known to be involved in RNA binding, the crystal structure of CspB clearly had the looks of a single-strand nucleic acid-binding protein. This *ad hoc* hypothesis could be corroborated by demonstrating that CspB indeed bound preferentially to one strand of a 35-bp promoter fragment, but not to the double strand or to the complementary single strand (9). Only recently, however, have we been able to show by crystallographic analysis that indeed exactly those amino acids that had been predicted from the structure of the isolated CspB (Max et al., unpublished) are involved in binding of a 6-nt ssDNA fragment.

Another well-documented example of protein function deduced, *via* experiment, from structure concerns the tubby proteins. These are found in various multicellular eukaryotes and are associated with at least three human

disease phenotypes. As in the case of CspB, the molecular architecture, revealed by crystal structure analysis, was considered ideal for DNA binding (10). This finding, along with the location in the protein of disease-related point mutations, prompted experiments that proved the binding of tubby to double-stranded DNA, its nuclear localization and transcription activation by tubby.

In a structural genomics context, it is imperative that functional assays can follow the structure analysis swiftly in order to avoid undue delay in making the structural data available to the public. There are a number of examples on record to show that this is possible. The protein YrbI from *Haemophilus influenzae* (HI1679) was shown to adopt an α/β -hydrolase fold resembling haloacid dehalogenases. Based on this observation, enzymatic assays on a number of potential substrates were performed that showed YrbI to be a Mg^{2+} -dependent phosphatase. A new class of truncated thioredoxins was defined following the crystal structure analysis of the archaeal protein MTH895 and structure-prompted experiments proving the thioredoxin activity. Likewise, the archaeal protein TM1643 could be shown to be an L-aspartate dehydrogenase by structure analysis followed by enzymatic screening. A combination of crystal structure analysis, bioinformatics and biochemistry was employed to reveal the structure and function of the *E. coli* protein BioH, which was known to be involved in biotin biosynthesis but had no assigned biochemical function. Screening the protein structure against a library of enzyme active sites (6) led to the discovery of an enzyme active site harboring a Ser/His/Asp catalytic triad characteristic of hydrolases. A series of hydrolase assays then identified short-chain carboxylesters as preferred substrates and marked BioH as a carboxylesterase.

Metal centers in proteins often mark active sites and can guide a functional annotation, either directly from the structure or *via* experiment. The *Methanococcus jannaschii* protein MJ0936 has a three-dimensional structure reminiscent of nucleases, phosphatases or nucleotidases and possesses a binuclear metal cluster when crystallized from solutions containing either Ni^{2+} or Mn^{2+} . Enzymatic activity was found against indicator substances for phosphatases, clearly annotating this protein as a metal-dependent phosphatase. The human protein FLJ36880 of unknown function was shown by crystal structure analysis to be dimeric and to have one active site per subunit in which a Mg^{2+} ion is coordinated by three carboxylate groups. Structure and sequence comparisons indicated that this protein is a fumarylacetoacetate hydrolase family member with yet uncharacterized substrate specificity.

Occasionally, structure analysis can serve to correct misannotations in databases as in the case of the protein product of the open reading frame Rv3853 from

Mycobacterium tuberculosis, which had been annotated as an S-adenosylmethionine (SAM)-dependent methyltransferase and assumed to catalyze the final step in menaquinone biosynthesis (gene denoted *menG*). The crystal structure clearly showed this protein to have a structure completely unlike all known SAM-dependent methyltransferases and instead suggests a role as subunit of a larger assembly binding nucleic acids or proteins. A similar question mark is set by the crystal structure of the human oncoprotein gankyrin linked to hepatocellular carcinoma (11). Gankyrin has been described to interact with and modify the phosphorylation status of the retinoblastoma protein (Rb), and an LXCXE sequence motif present in gankyrin was implicated in this process. However, the crystal structure showed this sequence motif in gankyrin to adopt an α -helical conformation (Fig. 1), whereas in other Rb-binding peptides the LXCXE sequence is extended, thus casting doubt on the proposed gankyrin-Rb interaction.

Small molecules bound to proteins can be another source of functional clues from crystal and NMR structures. For example, the human protein hp14.5, a member of the large YjgF/YER057c/UK114 protein family was found to adopt a trimeric structure in crystals and to bind benzoate molecules picked up from the crystallization buffer at its inter-subunit clefts (Fig. 2). The clefts are lined by residues conserved in this protein family (12). Both hp14.5 and its rat homolog, L-PSP, have been described to act as translational inhibitors, the latter protein also being ascribed ribonuclease activity against single-stranded RNA. Therefore, it seems likely that the benzoate molecules mark a hydrolytic active site on the surface of hp14.5, even though the physiological substrates remain to be identified (12). This may be achieved by NMR-based ligand screening as shown for the hp14.5 homolog HI0719 from *Haemophilus influenzae*. By this technique, HI0719 was shown to bind several small α -keto acids or α - β -unsaturated acids, i.e. molecules with chemical similarity to benzoate. The same residues in the inter-subunits clefts were involved as in hp14.5, corroborating the assignment of this cleft as the site of enzymatic activity in YjgF/YER057c/UK114 proteins. NMR or co-crystallization screening for ligands using appropriate libraries is in principle automatable and could develop into a valuable technique for structure-based functional annotations of proteins.

Post-translational modifications of proteins can easily be detected in crystal and NMR structures of proteins. They also can be sources of functional information, since they are characteristic of the subcellular location of proteins in eukaryotic cells and indicative of the functional state of a protein. Unfortunately, proteins produced recombinantly in *E. coli* will only carry a subset of the post-translational modifications observed

Structural Genomics: Structure-to-Function Approaches. Figure 1 Crystal structure of the human oncoprotein gankyrin, the product of the first gene shown to be associated with hepatocellular carcinoma. The structure of gankyrin (11) is organized into five complete and two incomplete ankyrin repeats (left). An LXCXE sequence motif (¹⁷⁸LACDE¹⁸² in gankyrin) usually implicated in binding to the retinoblastoma (Rb) tumor suppressor protein adopts an α -helical conformation in gankyrin (right). LXCXE peptides have previously been found in an extended conformation when bound to the pocket domain of Rb (11). Figure taken and modified from (11).

Structural Genomics: Structure-to-Function Approaches. Figure 2 Crystal structure of the trimeric human protein hp14.5 (12). The inter-subunit clefts are lined with residues highly conserved in members of the large YjgF/YER057c/UK114 protein family spanning all kingdoms of life. Benzoate molecules picked up from the crystallization buffer bind to the clefts, probably marking them as active sites of hydrolytic activity. The identity of the substrates turned over by hp14.5 remains to be determined. Figure courtesy of B.A.Manjasetty.

in eukaryotic proteins. This is one reason why it might be desirable to invest work in developing high-throughput techniques for protein production in recombinant yeast, insect, mammalian or other eukaryotic cells.

In conclusion, it seems that structural genomics has much to gain from techniques allowing the assignment of function to initially uncharacterized proteins on the basis of their three-dimensional structure. There are examples demonstrating how it can be achieved, but the development of automatable methods for high-throughput enzymatic assays or ligand-binding screens is only just starting.

Structure-based Drug Design

GERHARD KLEBE

Institute of Pharmaceutical Chemistry, Philipps-University, Marburg, Germany
klebe@mail.uni-marburg.de

Definition

Structure-based design starts from the assumption that a drug molecule exerts its biological activity through specific binding to a macromolecular target receptor, usually a protein. In consequence, the biological function of this target protein is modulated and hopefully this process leads to the cure of the disease. Prerequisite for strong and selective target binding is a perfect structural and chemical complementarity of ligand and receptor. The strategy of “structure-based design” comprises a variety of methods to discover and optimize small molecule ligands that fit precisely into a depression at the surface of a protein where the actual function of the protein is usually carried out. Through perfect and high affinity binding the ligand modulates the function of the protein. The design process starts with the information that can be extracted from the shape and composition of the binding pocket, estimates the properties a putative ligand must exhibit to be accommodated and tries to translate these properties into molecular skeletons of possible drug molecules. After synthesis and biological testing, the structure of the designed ligand together with the protein is determined (Fig. 1). This complex is the starting point for a new design cycle (Fig. 1) that

hopefully results after several cycles in a prospective drug candidate for clinical trials.

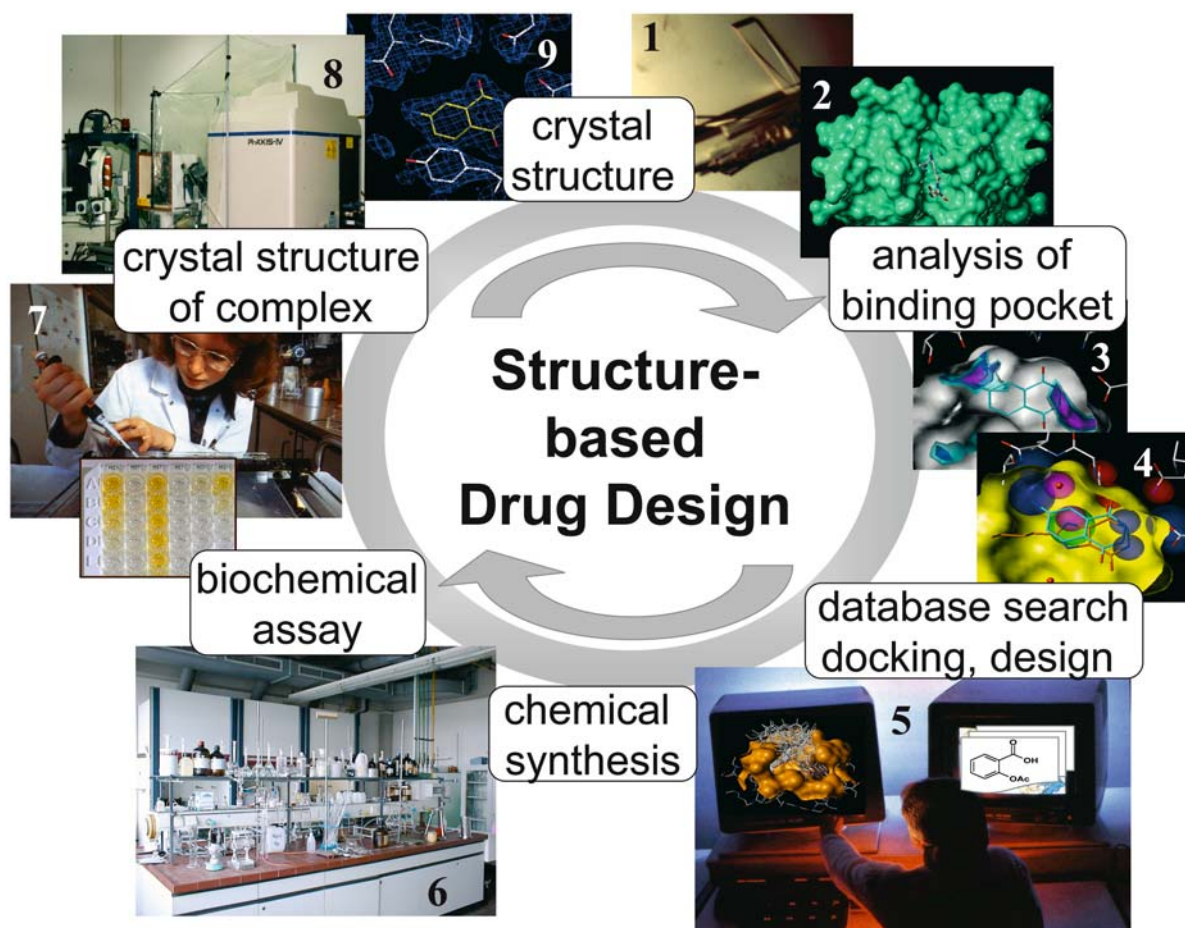

Characteristics

Structure-based Drug Design Needs Structures

The number of proteins of known 3D structure has increased exponentially over the last few years. Whereas in 1988 only 200 structures had been published, the number has now increased to nearly 30,000 examples. Of these, many are proteins with bound ligands. This dramatic growth is mainly due to technological and methodological improvements in gene technology, protein chemistry, protein purification and structure determination techniques. It is predominantly ► [protein crystallography](#) and multidimensional high-resolution ► [NMR spectroscopy](#) besides ► [cryo electron crystallography](#) that give us experimental access to the spatial arrangement of atoms in molecules. While many of the structures of globular water-soluble proteins have been determined, the number of structure determinations of membrane-bound proteins is steadily increasing. After the human genome project has been accomplished, advances in ► [proteomics](#) and ► [bioinformatics](#) have opened the floodgates to thousands of new proteins that might serve as putative targets for drug discovery. Worldwide efforts in ► [structural genomics](#) now aim to obtain a comprehensive view of the world of proteins. In addition, this impressive increase in experimentally resolved protein structures will be accompanied by an even larger number of protein models computed by ► [homology modelling](#). Thus, in the near future we will be increasingly faced with the situation that the 3D structure of a therapeutically relevant protein is available at an early stage of a drug development project. However, suitable ligands ready to interfere with the biological function are missing.

What is Required: The Complement of the Binding Site

Structure-based drug design starts from a detailed analysis of the binding pocket (Fig. 1). Usually such a binding pocket is the site in a protein where an endogenous ligand such as an ► [agonist](#), ► [antagonist](#), ► [effector](#) or ► [substrate](#) is recognized and in the case of enzymes chemically modified. This recognition of small molecule ligands or molecular portions of substrate molecules occurs in well characterized clefts or cavities located at the protein surface or accessible from the outside by some mechanism involving globular protein movement. Recognition between molecules is effected by the formation of noncovalent contacts among ligand and protein ► [functional groups](#). These groups and the overall shapes of ligand and binding pocket must be mutually complementary, similar to a lock and its key, to efficiently establish these interactions. Thus, analysing the recognition

Structure-based Drug Design. Figure 1 Structure-based drug design starts with the detailed analysis of the binding pocket of the target protein (1). Using different probes the binding pocket is analyzed in terms of “hot-spots” of binding (2, 3). The centers of such areas, indicated as beneficial for the occupation with particular ligand functional groups, are contoured and translated into a protein-based pharmacophore (4). The latter is then used to constrain a database screening on the computer (5). Docking is applied in the last step of a sequential filtering strategy and the generated solutions are ranked according to the predicted affinities. After synthesis (6) and biological testing (7) the discovered hits are soaked or co-crystallized with the protein to determine their binding modes (8). Their structures serve as a starting point for the following drug design cycle (9).

properties exposed by the protein in the binding pocket allows one to estimate what the prerequisites on the side of the ligand will be. The composite picture of all these properties required by a ligand is called “the pharmacophore”. If this ligand-defining [▶pharmacophore](#) is established using binding-site features, it is also called a “protein-based pharmacophore hypothesis”.

A Quantitative Picture: Mapping “Hot Spots” of Binding

To find quantifiable measures for such a hypothesis several tools have been developed that map the binding-site features fast and efficiently. The archetypal method in this area is Peter Goodford's GRID program. It is based on a [▶molecular mechanics force field](#). The

entire area of the binding pocket is analyzed and special, more local regions such as sub-pockets are contoured in terms of interaction energies that various types of functional groups experience at the intersections of a regularly spaced grid. Other methods use information about frequently observed contact geometries to identify the “hot spots” of binding in the binding pocket (Fig. 1).

As a subsequent step, this information about the hot spots of binding that define the type of functional groups required by the protein to be present in a putative ligand has to be translated into real molecules. This step is not trivial, since the information about the type of functional group is rather generic and only indicates the kind of interaction required, e.g. “a hydrogen-bond donor or acceptor” or “a bulky hydrophobic group”.

Docking: Fitting of Molecular Skeletons into the Binding Pocket

Most approaches in structure-based drug design try to place actual molecules into the binding pocket (Fig. 1). A force field together with molecular dynamics can be used to guide the placement of the ligand into the binding pocket. Much faster methods exist that exploit the results of the hot-spot analysis, classify the ligand in terms of its functional groups and test for complementarity in the placement or docking step. After such a first small molecule fragment (a "seed") has been placed, two strategies can be followed. In a *de novo* design approach, further fragments are retrieved from a library and subsequently attached to the initial seed to finally result in a molecule fitting as well as possible. The consecutive addition of new fragments should consider some rules about the synthesis of molecules so that the ligands finally suggested are easy to make. As an alternative, the complete molecules to be docked into the binding pocket can be taken from a library. *Via* computational simulation they are decomposed into fragments and, starting with the placement of a seed or anchor fragment, the entire molecule is constructed stepwise in an incremental build-up procedure. These docking methods have been accelerated so that nowadays libraries of up to several million compounds can be screened on the computer with respect to their putative protein binding. However, the different suggestions produced by docking have to be compared and ranked in terms of the expected **binding affinities**. The problem of predicting binding affinity based solely on the generated ligand binding geometry is a very difficult task and substantial effort is at present being given to this essential step in computer screening (also termed virtual screening). The libraries used for docking runs are either compiled from existing molecules that are in stock or from those that can be purchased after being identified as potential hits. Alternatively, libraries of virtual compounds can be screened and synthesis postponed to a later stage considering only the most likely hits. In recent years, much effort has been spent in the optimization of such screening libraries to focus the search on molecules that are predicted to possess satisfactory bioavailability properties.

Iterative Design: A Stepwise Optimization from Lead to Drug Candidate

As a next step, the hits detected by computer methods are confirmed experimentally in a functional assay and subjected to a structure determination together with the protein. This elucidates the actually adopted binding geometry of the first hits in the binding pocket. In a subsequent step, the information provided by their binding geometry is used to either improve the protein-based pharmacophore hypothesis for a further screening cycle or, through analysis of the observed binding mode of the first hits, a hypothesis can be established as to how

to improve the interactions of these ligands with the protein. Usually this newly designed compound is the starting point for a further design cycle involving docking, computer modelling, chemical synthesis, biological testing and structure determination (2, 3).

Today structure-based drug design is used as a routine tool in the development of new drugs. Many projects have been reported where this technique has significantly contributed to the discovery and development of clinical candidates and marketed drugs (4, 5, 6). However, the process of ligand-protein binding is very complex and at present only poorly understood. A particular complication arises from the fact that the conformations of the ligand and the protein mutually adapt to each other. It can be expected that ongoing research will contribute to a more profound understanding of the basic principles that determine selective and tight ligand-receptor recognition. This understanding will be a prerequisite for improving the concepts and strategies in structure-based drug design. In many systems protein function is triggered by the formation of protein-protein complexes. Evidence has been collected that the formation of such protein-protein complexes, resulting in large contact interfaces of several hundred square-angstroms, can also be modulated by small molecules. However, today it is not understood how this modulation is performed in structural and energetic terms. Nevertheless, it can be expected that, once the principles of such interference are known, a structure-based route to novel and innovative drugs will be opened.

3D Structure Determination by NMR

ZHEN-YU J. SUN, GERHARD WAGNER

Department of Biological Chemistry and Molecular Pharmacology, Harvard Medical School, Boston, MD, USA

zhen-yu_sun@hms.harvard.edu

gerhard_wagner@hms.harvard.edu

Definition

► **Nuclear magnetic resonance (NMR)** is a technique used for observing signals from isotopes with magnetic moments. For biological applications these are primarily ^1H , ^{13}C , ^{15}N , ^{19}F , ^{32}P and occasionally ^{113}Cd , which can sometimes be used to substitute for protein-bound metals, such as zinc or calcium. Between 0.2 and 0.5 ml of dissolved sample in concentrations of 0.2 mM or higher are needed for the experiments and placed in a glass tube in the center of a high-field magnet. Irradiation of the samples with trains of radio frequency pulses, termed ► **pulse sequences**, produces response signals that allow detection of ► **correlations** between different nuclei. This can reveal information about the three-dimensional structure and dynamic state of biological macromolecules, such as proteins or polynucleotides. Proteins can adopt well-defined 3D structures or form flexible chains, each exhibiting characteristic NMR signals. In the case of folded protein, the protein structure can be determined using a sequence of procedures that have evolved over the past two decades. The routines used for structure determination depend on whether proteins can be enriched with NMR-active ► **stable isotopes**. If this is not possible, one has to rely on spectroscopy with ^1H only, since this is the only NMR-active stable isotope found at high abundance in proteins. This limits structure determination to proteins of less than 15 kD. In order to study larger proteins and to facilitate structural analysis, most proteins studied today are labeled with ^{13}C , ^{15}N and occasionally ^2H , using bacterial expression systems. This enables structure determinations of proteins in the 40 kD range and beyond.

Description

Preparation of Protein Samples Suitable for NMR Structure Determination

The most important and time-consuming step is the production of a sample that is suitable for the process of protein solution structure determination. A typical NMR sample has a protein concentration of 0.2–1.0 mM in 0.2–0.5 ml buffer at a pH of less than 8 and should ideally be stable at room temperature for one week or longer. Often, the protein solubility and stability can be improved by increasing the salt concentration (up to 300 mM NaCl) and by variation of pH, temperature and buffer, as well as by adding small amounts of detergents. In some cases, new protein constructs are required in which a few surface-exposed non-essential hydrophobic residues are substituted with hydrophilic ones. Occasionally, a small ► **SET** (solubility enhancement tag) is attached, such as the highly soluble 6 kD B1 domain of streptococcal protein G (GB1), to make the total construct more soluble and inhibit irreversible precipitation. The procedures for isotopically enriching proteins for

NMR studies sometimes require serious efforts to optimize expression strategies and develop purification protocols. Although different expression systems for labeling have been developed, including insect cell, yeast, slime mold and mammalian cell lines, the expense of the stable isotopes limits the expression of most proteins to the old-fashioned *E. coli* as a host. Different protein expression vectors can result in varying amounts of total, soluble and insoluble (inclusion body) proteins being produced. To facilitate purification, soluble proteins are often expressed with a glutathione S transferase (GST), protein G B1 (GB1) or hexa-histidine tag that can be removed subsequently by enzymatic cleavage. Insoluble proteins are easy to purify but must be painstakingly refolded into their native conformations for structural studies. Impurities remaining in the NMR sample after purification are not of serious concern if they constitute less than 5% of the solute and do not include endogenous proteases.

Sequence Specific Assignments for Unlabeled Proteins

For short peptides and small proteins, it is possible to complete the ^1H resonance assignments without isotope labeling. The strategy used in this case relies only on two-dimensional experiments as shown in Fig. 1 (1). The first step is to assign the amino acid spin system of each residue by through-bond ^1H - ^1H correlations with ► **COSY**-type experiments. The experiments used can correlate through the scalar coupling spins that are separated by no more than three chemical bonds. The second step is to find sequential through-space connectivities between the backbone amide protons and protons of the preceding residue. This step uses the dipole-dipole interaction, which gives rise to cross peaks in two-dimensional ► **NOE** (nuclear Overhauser effect) spectroscopy (► **NOESY**). In the third and final step, the sequentially connected amino acid spin systems are matched to the protein sequence. At this point, the spin-system topologies are checked for consistency with those expected from the primary sequence.

Sequential Backbone Resonance Assignments for Labeled Proteins

Labeling of proteins with ^{13}C and ^{15}N dramatically facilitates structure determination. In this case, backbone and side-chain ^1H , ^{13}C and ^{15}N resonances can be assigned efficiently and unambiguously with a set of so-called triple-resonance ($^{15}\text{N}/^{13}\text{C}/^1\text{H}$) experiments (2, 3). This set typically includes three pairs of experiments termed HNCA and HN(CO)CA, HNCB and HN(CA)CO and HNCACB and HN(CO)CACB. The letters indicate the nuclei that are connected by the particular pulse sequence (Fig. 2). The experiments are recorded in pairs where the N-H group is correlated with either the CA, the CO or the CB signals of the

3D Structure Determination by NMR. Figure 1
Schematic illustration of the sequential assignment strategy for unlabeled proteins. The intra-residue spin systems identified from COSY-type experiments are shown as enclosed by dotted lines. The sequential NOE connectivities are shown by solid lines with arrows.

same or the preceding residue. The intra-residue correlations between the carbon and the backbone amide resonances are compared with the sequential inter-residue correlations and the matching pairs are linked to a thread of spin systems assigned to the protein amino acid sequence. This set of six triple-resonance experiments run for obtaining the complete backbone assignments typically takes a total of 6–12 days, depending on the protein concentration and molecular weight. By using ▶non-uniform sampling techniques and cryogenic probes (4), the total experimental time for recording the set of six triple resonance experiments can be shortened to one day. The spectral data can be analyzed with the aid of computer automation programs to establish sequential assignments within a few hours after the spectra have been recorded and processed.

Side-Chain Assignments for Labeled Proteins

Side-chain assignments for labeled proteins are typically pursued with the HCCH-TOCSY experiment, which connects all ^{13}C - ^1H resonances that belong to the same amino acid spin system (2). The aliphatic ^{13}C and ^1H resonances are then correlated with the backbone NH *via* the C(CO)NH and H(CCO)NH experiments. Incidentally, the correlations identified from the C(CO)NH experiment are also particularly

useful in assisting the sequential backbone assignments by providing the amino acid type information. Precise chemical shift assignments, crucial for unambiguous assignment of the NOE cross peaks, can be obtained with a recently developed method that combines simultaneously-evolved nuclei (SEN) HC(CO)NH experiments and non-uniform sampling techniques. In this way, two 3D experiments plus the C(CO)NH and H(CCO)NH experiments can yield the same information as a four-dimensional HC(CO)NH experiment, but at much higher resolution and in as little as three days. This method has the benefit of correlating all side-chain ^{13}C and ^1H resonances with the backbone amide groups in a single data set and the assignment procedure can be easily automated.

Collection of Structural Parameters Initial Fold Determination

The protein secondary structure topology can be first identified from the deviation of the backbone atoms and beta carbon chemical shifts relative to the random coil values for specific amino acids. Two-dimensional NOESY and three-dimensional heteronuclear ^{15}N - or ^{13}C -edited NOESY experimental data are acquired in order to extract the inter-nuclei distance information. With 3 to 4 NOE distance constraints assigned per residue on average, the initial protein 3D fold can be determined with software programs such as CYANA, XPLOR and CNS. The computation methods include distance geometrical algorithms that use NOE constraints and simulated annealing methods that minimize a target function derived from the violations of NOE constraints (inconsistencies between the input distance constraints and the distances obtained in the computed structural models). At this stage the distance constraints related to the backbone amide, side-chain aromatic and methyl groups are most important for defining the regular secondary structure elements and the hydrophobic core of the protein. Several software programs such as ARIA and CANDID have been developed to assign NOE peaks automatically and to calculate the initial protein fold.

Structure Refinement

Based on the initial protein model, more NOE peaks can be assigned and more distance constraints included in the structure refinement stage. During this iterative process, it is also critical to eliminate wrong NOE assignments that would cause distorted structures and prevent convergence of structure calculations. The erroneous NOE assignments leading to serious constraint violations can be tracked by calculating structures where NOE constraints are eliminated for a single residue, di-peptides, tri-peptides, etc. while sliding the window of “constraint-silencing” along the protein sequence. Disappearance of constraint

3D Structure Determination by NMR. Figure 2 Schematic illustration of the triple-resonance experiment strategy. HNCA and HN(CO)CA, HNCO and HN(CA)CO and HN(CA)CB and HN(COCA)CB for backbone sequential assignments of labeled proteins.

violations and improvement of the target function in one of these cases would reveal the presence of the incorrect NOE assignment within the “silenced” segment. On average, 10–20 constraints per residue are required for calculating good NMR structures. Hydrogen-bond constraints, backbone dihedral angle constraints, orientation constraints from residual dipolar couplings and stereo-specific assignments of methylene and methyl groups as well as side-chain rotamer libraries can significantly improve the convergence and precision of the NMR structure ensemble.

Structure Validation

The quality of the final ensemble of NMR structures is routinely checked with validation software, such as ▶[ProcheckNMR](#). Coordinates and restraint files are

usually submitted to the protein data bank (PDB), where the staff of the data bank perform additional validation procedures. As an example of an NMR-derived protein structure, Fig. 3a shows the backbone traces of several superimposed structures for the extra-cellular part of the CD3γ heterodimer, which is a crucial element of the invariant portion of the T-cell receptor complex. Some rules of thumb for assessing the quality of NMR structures include: (1) the average root mean square deviation of backbone atoms relative to the mean structure should be smaller than 1.0, (2) the number of residues with backbone phi-psi angles in the disallowed region in the Ramachandran plot (obtained from ProcheckNMR) should be less than 1%, (3) there should be no NOE distance violations greater than 0.5 and no dihedral angular constraint violations greater than 5°.

Clinical Applications

NMR structural studies of proteins are helpful for understanding the basic health-related cell functions and the underlying mechanisms of some diseases by studying protein complexes and protein conformational changes in solution that are at or close to physiological conditions. Examples include studies of the synergistic co-folding of many cancer-related transcriptional activator complexes and the conformational changes and folding intermediates of prion proteins.

Therapeutic Consequences

Protein structures determined by NMR can accelerate the drug development process. First, the structural studies of protein-protein and protein-ligand interactions can be used to identify the target sites for drug intervention and provide the basis for rational drug design (5). A model of the oncogene protein Bcl-xL with an inhibitor docked to its BH3-domain binding site is shown in Fig. 3b. Second, NMR resonance assignments acquired during structural determination can also be used in rapid drug screening by monitoring specific protein signal changes or signal transfer to interacting chemical compounds (6). ►**SAR (structure-activity-relationship) by NMR**, a good example of both applications, involves first identifying weak interacting compounds and then covalently linking two fragments with neighboring binding sites to form a tighter-binding drug target.

3D Structure Determination by X-Ray

RICHARD A. ENGH

Max Planck Institute of Biochemistry, Martinsried,
Germany
engh@biochem.mpg.de

Definition

3D structure determination using X-ray radiation refers to the calculation of the spatial distribution of electrons in a crystallized molecule – the crystal structure – based on the distribution of intensities of X-rays diffracted by the crystal. The macromolecules or molecular assemblies that are relevant to genomics and proteomics, here generally referred to as proteins, require data collection from single crystals. The degree of order of the crystal, dependent on the structural homogeneity (rigidity, purity) of the molecule and on the quality of the crystal, determines the spatial resolution to which the electron distribution may be estimated. Additional sources of information and assumptions about the properties of the electron density distribution simplify the structure solution and greatly enhance the accuracy of the final model, the crystal structure.

The process by which the three dimensional structures are determined depends on a variety of factors, including molecule size, the types of atoms in the molecule, knowledge of similar structures, quality of crystals, the available X-ray sources and the information desired from the 3D model. Structural genomics proteomics programs often aim to determine structures of a wide variety of structures in a highly automated, high throughput mode and generate thereby a reference database of 3D structures. Other programs may aim to characterize particular macromolecules more fully by solving their structures in a variety of crystallization environments; still others may focus on very high-resolution chemical phenomena.

Description

Purpose of Structural Models

The goal in solving a crystal structure determines how the problem is approached throughout the entire process. For ►**structural genomics** (see related articles), the goal may be to determine structures for the largest number of genomic or protein sequences, giving priority to new folds in order to enable at least homology modeling for most sequences. Large-scale automation may accelerate the search for suitable conditions for protein expression, purification and crystallization for a wide range of proteins. Studies of protein-protein interactions require the crystallization of the relevant protein complexes; the requirements for the crystal structure determination depend on the structural information available for the individual components. Structures of extremely large protein complexes have special requirements for experimental equipment as well as theoretical techniques. Studies of enzyme catalysis mechanisms may require very high resolution and careful structure determination to avoid the introduction of chemical bias into the model and its analysis. Similarly, structures provide the greatest value for drug design purposes when they have a ►**resolution**

that enables the analysis of solvent interactions and that shows details of chemical geometries.

Protein Preparation

Although many proteins have been purified from their natural sources for crystallization, recombinant methods are now standard as they typically provide the purest protein in the highest amounts. The structure determination of a protein for which no approximate three dimensional model is available will require the presence of heavy, electron rich atoms in one or more crystals of the protein in order to solve the ►phase problem. These can be introduced intrinsically into the protein by the incorporation of non-natural amino acids. Most common is the substitution of selenomethionine for methionine using auxotrophic organisms.

The protein sequence must also be chosen with respect to the expected crystallizability of the protein. Crystal formation requires ordering crystal contacts between ordered protein domains. Thus, crystallization chances are enhanced if the inherent flexibility of the protein is minimized and if surface properties of the protein may be varied in order to increase the variety of possible ordering crystal contacts. As a result, it may be critical to prepare a variety of constructs with varying lengths and varying point mutations at the surface to produce a “crystallizable” protein. These constructs need to be chosen with respect to the desired use of the structure and with an eye toward monitoring possible artifacts introduced by the variations.

Crystallizability is also enhanced by maximizing the structural homogeneity of the protein and by minimizing flexibility and also heterogeneous ►post-translational modifications, such as phosphorylation, deamidation, mixed disulfide bond formation and so on. Autocatalytic functions of a protein may require inactivation of the protein in order to prevent the presence of an equilibrium mixture of states. Finally, affinity tags appended to the protein may assist purification, but may also increase structural heterogeneity and inhibit crystal growth.

Crystallization (See ►X-Ray Crystallography – Basic Principles)

A protein may crystallize when it tends to form ordered interactions with identical molecules in an arrangement compatible with a three dimensional periodic lattice. The conditions under which this occurs are not predictable for a given protein, so that the crystallization strategy is generally to screen ►precipitant conditions and monitor for the appearance of crystals. The most common method for protein crystallization is to mix a protein solution with a precipitant solution in vapor phase contact with a larger reservoir of precipitant solution and allow volatile components to equalize their chemical potentials (or conceptually their concentrations) *via* vapor phase

diffusion. This typically increases the protein concentration (if water is the principal volatile constituent) or the precipitant concentration (for volatile precipitants such as alcohols) or both, in order to create a supersaturated state. Mixing protein with precipitant may already suffice to produce a suitable supersaturated state (batch crystallization). Diffusions through membranes, gels or channels are alternative mechanisms for mixing precipitant with protein. The initial crystallization conditions found may have produced crystals suitable for data collection, if not, many variables such as temperature, additives, protein buffers, pH and so on may be varied in order to optimize crystal quality.

Crystal Preparation for Data Collection

The crystals may need or benefit from additional modification prior to measurement. Soaking the crystal in a solution of ligands may be required for co-crystal structure determination. Soaking the crystal in a solution of heavy atom derivatives may be necessary if the structure is to be solved by MIR or MAD techniques (see below). The crystal quality may be improved by soaking in solutions that alter the solvent content of the crystal. An alternative to these soaking experiments may be found in controlled humidity gas phase experiments, where the addition of ligand or heavy metals may be performed *via* ink jet type devices. Crystals can be harvested into thin walled glass capillaries, adjacent to mother liquor solution to maintain crystal quality during data measurement. These crystals decay during measurement, usually due to the formation of chemically reactive free radicals that diffuse through the crystal. Freezing the crystals in liquid nitrogen greatly retards crystal decay. With the widespread availability of ►synchrotron radiation, freezing with liquid nitrogen has become virtually essential because of the high level of radiation damage and heat deposition due to high intensity synchrotron radiation.

Data Collection and Evaluation (See ►X-Ray Crystallography – Basic Principles)

Data is collected by illuminating the crystal with intense X-ray radiation and measuring the positions and intensities of the diffraction spots as a function of crystal rotation. The rotation range that provides a complete dataset depends on the symmetry of the crystal and on whether ►anomalous diffraction data may be measured. The strategy of data collection is also determined by the strategy of solving the “phase problem” (see related article). If the structure can be solved by molecular replacement, a single complete dataset without anomalous diffraction data is sufficient. If multiple isomorphous replacement (MIR) methods are used, multiple datasets of multiple crystals soaked with different heavy atoms must be measured. For multi-wavelength anomalous dispersion (MAD, see

related article) methods, a single crystal containing anomalous scatterers may be measured at multiple wavelengths. Because of the high intensities and tunable wavelengths of synchrotron X-ray radiation, data collection at synchrotron sources is preferred because of the shorter data collection times or is required because of tunable wavelengths. Advances in X-ray generation technologies do however make laboratory generators cost-effective for many applications.

Initial Phasing

“Phasing” is the critical step in solving the structure from the diffraction measurements, equivalent to solving the “phase problem” of crystallography (see related article). Without phases, the measured diffraction intensities can be converted into the ►[Patterson function](#), a three dimensional function of interatomic vectors (the electron density function is a three dimensional function of atomic positions). As listed above, molecular replacement, multiple isomorphous replacement and multiple anomalous dispersion are three methods used to estimate the phases of the diffraction intensities. (A fourth, direct method, can be used in special cases, see related article.) Molecular replacement relies on the availability of a closely related structure for phasing. Phases can be estimated from the model if its position and orientation in the unit cell are known. The problem in molecular replacement is thus to determine the six parameters that determine the position and orientation, usually by first fitting the three rotational parameters to the Patterson function or its equivalent, then the three positional parameters. The method can fail if the model is not sufficiently similar to the molecule in the crystal or if the model represents too small a subset of the contents of the asymmetric unit of the crystal.

Multiple isomorphous replacement (MIR) relies on the use of one or more strongly scattering atoms bound at different fixed positions in the crystal. Because of the strength of their scattering, their positions in the unit cell can be determined directly. This enables calculation of the phases and amplitudes of the X-rays scattered by the heavy atoms, which combine with the phases and amplitudes of the X-rays scattered by the native structure by ►[vector addition](#). Estimation of the phases of the X-rays scattered by the native crystal can then be estimated by analyzing the intensity shifts caused by the addition of the heavy atoms. This method can fail if addition of the heavy atom scatterers alters the crystal packing, so that the different crystals are no longer isomorphous.

Multi-wavelength anomalous dispersion (MAD) methods are in principle similar to MIR methods, except that multiple wavelengths are used instead of multiple crystals. The requirement is the presence of atoms that have significant ►[anomalous scattering](#). This type of scattering is wavelength dependent, because it is strongest at wavelengths near ►[electronic transition](#)

[energies](#). Measurement at multiple wavelengths and calculations of differences allows identification of the positions of the anomalous scatterers, their relative vector contributions to the total scattered radiation and, again by analysis of the vector addition properties, the phases of the total scattered waves.

Structure Refinement

Once the phases have been estimated well enough to provide an interpretable electron density, the structure may be built. For molecular replacement, the initial model needs revision; for the other methods, an initial model needs to be generated. This is a straightforward task for an easily interpretable electron density, either automatically or manually, using suitable computer graphics and model building programs. In either case, the test of the interpretability of the electron density is that the phases, re-estimated using the new model, should produce an electron density still clearer than the first and from which further corrections, if any, are also clearer.

This iterative procedure is a process of fitting the model parameters, in this case the spatial coordinates and parameters that model atomic motion (usually the ►[temperature factor](#) or B-factor), to best fit the measured data, the diffraction intensities. When the temperature factor is a single value per atom, the number of parameters to be fitted for an N-atom model is 4N. For an asymmetric unit consisting of one single domain protein, 4N can be 15,000 or higher; larger asymmetric units and/or multimeric proteins are much larger still. Therefore, the diffraction data require additional information in order to maintain a reasonable parameter to observation ratio. This additional information also allows considerable improvement in the accuracy of the model.

The most useful information derives from the requirement for a reasonable chemical geometry of the final structure. Average chemical bond lengths are known to accuracies of hundredths of ►[ångströms](#); average bond angles to within tenths of degrees. Bonds and angles in protein structures can deviate from these averages, but the deviations will be small and restraints can be included in the iterative model refinement procedure to improve model accuracy. Because however the restraints introduce bias into the model, restraints must be selected carefully if the structural information is to be used to analyze details of chemical geometries in the structure. This can be the case if, for example, the structure is to clarify mechanisms of enzyme catalysis. The final crystal structure is thus usually derived from experimental diffraction data supplemented by knowledge of chemical geometries in the macromolecule. Sources of errors in the final model include experimental noise, crystal defects, false assumptions regarding chemical identities in the protein, such as ►[protonation states](#) or post-translational modifications,

false identification of solvent molecules and oversimplification of motion models. Proper interpretation of the structure requires consideration of these effects, crystal packing and crystallization condition artifacts and that a single crystal structure fails to show a full range of protein flexibility. Multiple structure determinations in a variety of conditions and crystal packing arrangements are required to adequately assess these effects. Alternate methods such as NMR (See Related Article) can assist the interpretation of crystal structures by characterizing flexibilities in solution.

Sumoylation

GUILLAUME BOSSIS, FRAUKE MELCHIOR
University of Göttingen, Göttingen, Germany
f.melchior@medizin.uni-goettingen.de

Definition

The term SUMO, which stands for small ubiquitin related modifier, refers to a family of eukaryotic proteins that are structurally and functionally related to ubiquitin. Alternate names for SUMO proteins are sentrin or Smt3. Like ►ubiquitin, SUMO proteins can be covalently coupled to specific nuclear or cytoplasmic proteins in the cell. SUMO attachment, also called “sumoylation”, is achieved through an enzymatic cascade that involves E1, E2 and E3 enzymes and ATP. The resulting ►isopeptide bond between SUMO and its targets can be cleaved by the function of specific proteases (isopeptidases). Reversible sumoylation serves to regulate protein functions by, e.g., changing protein/protein or ►protein/DNA interactions, localization or stability.

Characteristics

SUMO Genes and Proteins

The number of SUMO proteins that are expressed within an organism varies significantly. *S. cerevisiae* contains a single SUMO gene, *Smt3*, which is essential for progression through the cell-cycle. Eight SUMO proteins are known to exist in *Arabidopsis*, but only one each in *C. elegans* and *D. melanogaster*. In mammals, the SUMO family comprises three members, SUMO-1, -2, and -3. Human SUMO-1 is a 101 amino acid protein with 18% sequence identity to ubiquitin. hSUMO-2 and its twin SUMO-3 are very similar (95% identical), but are each only approximately 50% identical to SUMO-1. Different SUMO proteins within one organism appear to serve distinct functions and/or are subject to distinct regulation. For example, under normal growth conditions SUMO-1 is mainly found in conjugates, while SUMO-2 and -3 exist predominantly in free form. Interestingly, SUMO-2/-3 become rapidly conjugated upon certain stress stimuli. The mechanisms underlying these differences are not currently understood.

SUMO Structure

Despite low sequence conservation between SUMO and ubiquitin, their three dimensional fold is very similar. It is characterized by the characteristic $\beta\beta\alpha\beta\beta\alpha\beta$ ubiquitin-folding motif. Nascent SUMO proteins contain a short stretch of C-terminal amino acids that needs to be removed before SUMO can be

conjugated to other proteins. Processing of the C-terminus, which is accomplished by SUMO proteases of the Ulp family (see below), exposes a glycine-glycine motif required for conjugation. A hallmark for SUMO family members that is absent from ubiquitin and other ubiquitin-related proteins is a flexible N-terminal extension that varies in length between 10 and 20 amino acids. The precise function of this N-terminus is currently unknown, but *in vitro* and *in vivo* evidence suggests that it can serve in SUMO-SUMO chain formation.

The Mechanism of Sumoylation

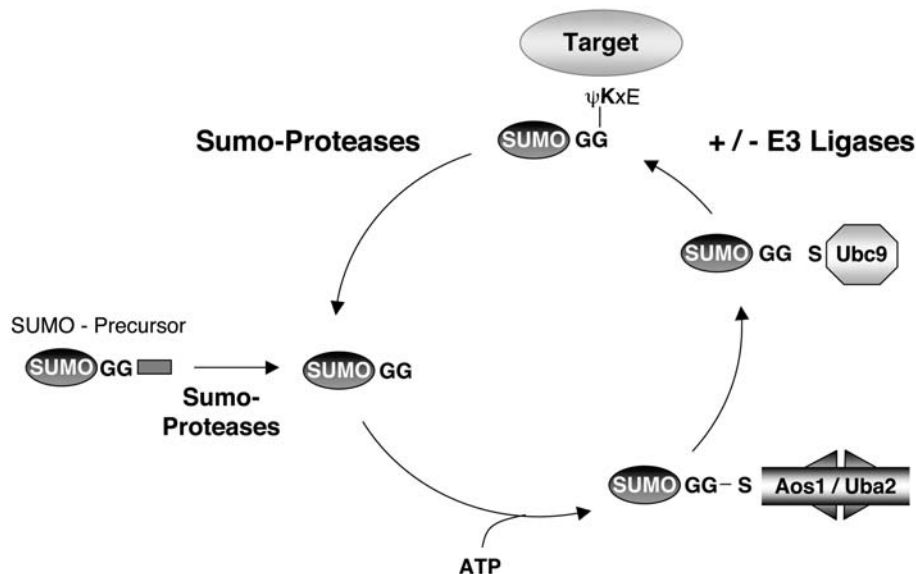

SUMO proteins serve as small protein tags that are covalently coupled to many distinct cellular proteins (targets). Coupling is accomplished by isopeptide bond formation between the carboxy terminal glycine in mature SUMO and an -amino group in a lysine side chain of the target. Considering the structural homology between SUMO and ubiquitin, it is not surprising that the conjugation mechanisms are related. Both processes require ATP and involve three distinct types of enzymes (E1 activating, E2 conjugating and E3 ligating enzymes). While ubiquitination often results in ►ubiquitin chain formation, sumoylation usually leads to attachment of one or several single SUMO entities. Evidence for chain formation exists as well, but whether SUMO chains are physiologically relevant is still an open question.

SUMO Activating Enzyme Aos1/Uba2

Activation of the C-terminal glycine of SUMO is the first step towards isopeptide bond formation. This is achieved *via* an ATP dependent mechanism that results in ►thioester bond formation between SUMO and the SUMO specific E1 enzyme. The SUMO activating enzyme consists of two subunits, Aos1/Uba2 (SAE1/SAE2), that resemble the N- and C-terminal halves of the single ubiquitin E1 enzyme, respectively. Aos1/Uba2 is strongly enriched in the nucleoplasm, but present also in the cytoplasm.

SUMO Conjugating Enzyme Ubc9

Once activated, SUMO is transferred to the single E2 conjugation enzyme Ubc9 (again, a thioester bond is formed). It is localized mainly in the nucleus, but is also present in the cytoplasm and at ►nuclear pore complexes. Ubc9 shares significant homology with the large number of ubiquitin conjugating enzymes (Ubc's), but is specific for SUMO proteins. An important difference between Ubc9 and Ubc's is Ubc9's ability to directly and specifically recognize SUMO targets *via* their SUMO attachment site motifs (see below). Consequently, the last step in forming an isopeptide bond – transfer of activated SUMO to an -amino group in lysines of the acceptor protein – can in principle be

Sumoylation. Figure 1 Sumoylation and desumoylation cycle. SUMO is synthesized as a precursor, whose C-terminal extremity is cleaved by SUMO specific proteases (C-terminal hydrolase activity). Mature SUMO is activated by the SUMO E1 activating enzyme (composed of the two sub-units Aos1 and Uba2) in an ATP dependant manner, before it is transferred to the E2 conjugating enzyme Ubc9. Isopeptide bond formation with a target protein is accomplished with (or in some cases without) the help of an E3 ligase. Three types of SUMO Ligases are known so far, the PIAS family, RanBP2 and PC2. SUMO is often conjugated to lysine residues that are located within the consensus motif ψ KxE (ψ is a bulky hydrophobic residue). SUMO can be removed from the target by SUMO proteases (isopeptidase activity). Of note, several known SUMO proteases contain C-terminal hydrolase as well as isopeptidase activity.

accomplished by Ubc9 alone. However, modification of most targets is extremely inefficient and slow in the absence of additional factors (E3 ligases).

SUMO E3 Ligases

Three types of factors have been identified that strongly accelerate sumoylation of specific targets *in vitro* and/or *in vivo*. These are referred to as SUMO E3 ligases or E3 ligase like factors. The first type is encoded by the protein inhibitor of activated STAT (PIAS) family. PIAS proteins were originally identified as co-regulators for **STAT** – and **nuclear hormone receptor** – mediated transcription. PIAS proteins are characterized by a predicted RING domain (the **SP-RING**), and are thought to function like ubiquitin RING finger E3 ligases as adaptors between the thioester charged E2 and specific targets. PIAS proteins reside predominantly within the nucleus, where they are enriched in diverse subnuclear domains, but are also found in the cytoplasm. Mammals express at least 5 different PIAS proteins, PIAS1, PIAS3, PIAS α , PIAS β and PIAS γ , all of which have been shown to function as SUMO E3 ligases. Two PIAS homologs, Siz1 and Siz2, exist in yeast. They appear to be responsible for sumoylating a

large number of proteins, as simultaneous disruption of both genes significantly reduces overall levels of sumoylation.

The second type of SUMO E3 ligases is currently represented by a single vertebrate specific member, the nuclear pore complex protein RanBP2/Nup358 (Ran binding protein/nucleoporin of 358 kD). Its SUMO ligase activity is restricted to a 30 kD domain, which shows no homology to PIAS proteins or ubiquitin ligases. RanBP2 is a major component of cytoplasmic filaments of nuclear pore complexes, where it serves as a docking site for complexes that travel into or out of the nucleus. This allows speculation that RanBP2 may sumoylate specific proteins on their way into or out of the nucleus.

The third SUMO E3 ligase type that has been described is the human Polycomb member Pc2. Polycomb group proteins form large protein complexes that are involved in gene silencing. Pc2 is unrelated in sequence to PIAS or RanBP2, and its mode of function awaits further investigation.

Comparison of different SUMO E3 ligases demonstrates that they have some target preferences *in vitro*. In combination with their distinct localizations *in vivo*,

this may contribute significantly to selective modification of target proteins within the cell. Whether additional SUMO E3 ligases exist, and how the distinct SUMO E3 ligases function on a molecular level to accelerate modification of specific targets is currently unknown.

Deconjugation

A key feature of posttranslational modification with SUMO is its reversible and at times highly dynamic nature. Cleavage of the isopeptide bond between SUMO and its targets is accomplished by SUMO-specific proteases (SUSP) of the Ulp1 family (also referred to as SENP for sentrin specific proteases). These ►cysteine proteases, which contain a C-terminal 200 amino acid catalytic core domain with similarity to adenovirus proteases, also serve in maturation of nascent SUMO.

Two members of the Ulp family exist in yeast (Ulp1 and Ulp2). The essential protein Ulp1 localizes to nuclear pore complexes, the non-essential Ulp2 is nucleoplasmic. Mammals express a much larger family of Ulp proteins, in part due to the presence of several distinct genes (7 in humans), in part due to extensive alternative splicing. The exact number of distinct SUMO-specific proteases in mammals is currently unknown. Analysis is complicated by the recent discovery that not all Ulp family members are specific for SUMO. At least one of the Ulp genes (*SENP8*) encodes a protease with specificity for the ubiquitin related protein Nedd8. Several full length and splice variants encoded by the genes *SENP1*, *SENP2* and *SENP6* have been characterized in some detail. All the proteins contain the catalytic core, but vary in the length and sequence of their N-terminal domains. The most prominent difference between these different proteases is their localization to different subcellular compartments (the nucleoplasm, nuclear bodies, the nuclear pore complex, the nucleolus and the cytoplasm). Differences in catalytic properties, e.g. preferences for one or the other SUMO protein, have also been described, but a systematic analysis is still lacking.

Molecular Interactions

With the exception of non-covalent SUMO – enzyme interactions, most proteins (targets) bind to SUMO covalently. These targets have no apparent affinity for SUMO proteins themselves. Instead, binding is accomplished through interaction with conjugating and ligating enzymes and subsequent isopeptide bond formation with SUMO. One determinant for covalent SUMO interaction is the presence of a SUMO attachment site in the target. In many proteins this motif consists of just four amino acids, ψ KxE/D (ψ stands

for a bulky hydrophobic residue, K is the lysine to which SUMO is attached). Interestingly, short peptides containing this minimal motif can be sumoylated *in vitro*. Obviously, the sequence ψ KxE/D exists in many non-sumoylated proteins, and additional features such as accessibility and secondary structure of the motif will be important for recognition by Ubc9. In the efficient SUMO target RanGAP1 this motif is part of an accessible loop structure. Alternative SUMO attachment sites are beginning to emerge, e.g. in PCNA, but it is not yet clear how they are recognized by Ubc9.

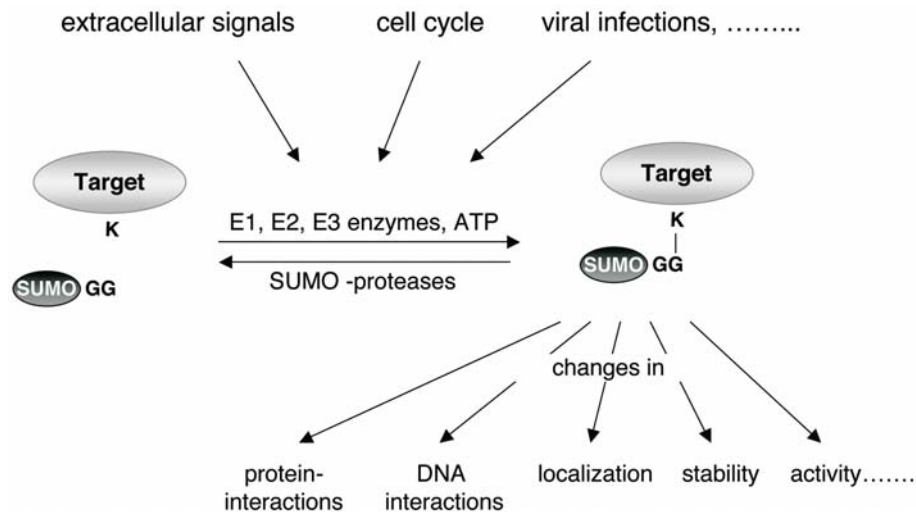

The number of known covalent interactors (SUMO targets) has reached more than 100 and is growing rapidly. Characterized SUMO targets fall into just a handful of protein groups, most of which have functions within the nucleus. These include transcription factors (e.g., p53, c-jun, ►HSF, Sp3, Lef1, Elk1, nuclear hormone receptors), regulators of transcription and/or chromatin remodeling (e.g., nuclear hormone receptor co-regulators, histones deacetylases, DNA methyl transferases) or proteins involved in replication and DNA repair (topoisomerases, PCNA, thymine-DNA glycosylase). Sumoylated proteins are however not restricted to the nucleus. Examples are yeast septins, which reside at the ►bud neck and are modified specifically in mitosis, *Dictyostelium* MAP kinase kinase MEK1, whose sumoylated form is found in the cytoplasm and at the cell cortex and the Ran GTPase activating protein RanGAP1, whose sumoylated form is found at cytoplasmic filaments of nuclear pore complexes.

Regulatory Mechanisms

Two aspects of regulation will be discussed here. First, reversible attachment of SUMO to specific targets can be constitutive or a highly regulated mechanism. Second, SUMO attachment serves to regulate proteins in their function or stability. Selected examples will be discussed to highlight both aspects.

SUMO Attachment Can Be Regulated

While some proteins appear to be modified constitutively, many proteins obtain SUMO only transiently, for example at a specific time of the cell-cycle, upon heat shock or DNA damage, or due to extracellular signals. The precise mechanisms underlying this dynamic modification are unknown for most targets. From the available data it is however clear that regulation can be accomplished by several distinct means. First, upstream events may result in phosphorylation or dephosphorylation of a specific target, which in turn allows or inhibits interactions of the target with the sumoylation machinery. For example, the heat shock factor HSF1 is sumoylated upon phosphorylation

Sumoylation. Figure 2 Regulation and function of sumoylation. SUMO conjugation is a reversible process that affects many different nuclear and cytoplasmic proteins (more than 100 targets are currently known). Modification of a specific target can be constitutive or regulated, e.g., by extracellular signals, position in the cell-cycle, viral infections, DNA damage. Consequences of modification are target specific, and include, amongst others, changes in protein-protein and protein-DNA interactions, localization, stability or activity.

in close proximity to its SUMO acceptor site. That this is due to better recognition by the modification machinery was demonstrated by the finding that a phosphomimetic mutant of HSF1 is more efficiently modified *in vitro* than its wild type counterpart. Down-regulation by target phosphorylation has for example been reported for the transcription factors c-Jun and Elk1. Second, upstream events can also act at the level of the modifying or demodifying enzymes. Cell-cycle dependent changes in localization have, e.g., been reported for the E3 ligase Siz1 in *S. cerevisiae*. Siz1 is predominantly intranuclear in interphase, but it partially relocates to the bud neck in mitosis. Concomitant with this, yeast septins, which localize to this site, are sumoylated. The fission yeast isopeptidase Ulp1 also undergoes cell-cycle dependent changes in localization (it moves from the nuclear periphery to the nucleoplasm during mitosis), but this has not yet been linked to changes in the sumoylation pattern of specific proteins.

SUMO Attachment Regulates Protein Function

Considering that addition of even a single phosphate can have dramatic effects on proteins, it is not surprising that attachment of the 11 kD SUMO protein may have significant consequences for its targets. Due to its size it may mask large binding interfaces, add new interaction sites or influence the folding of a protein. Consequently, a plethora of distinct target specific

functions have been reported for sumoylation. These include, but are not limited to, roles in nuclear import and export, enhancement or repression of transcription, changes in activity, increase or decrease in protein stability and inhibition of mono- or poly-ubiquitination. On a molecular level, the only common denominator that one can extract from available data is that SUMO alters target interactions. These may be with proteins or with DNA (RNA interactions have not yet been reported) and they may either be positively or negatively influenced by SUMO.

In conclusion, posttranslational modification with SUMO is an essential and widely used regulatory mechanism. Like phosphorylation, its effect on protein functions is not predictable, but has to be analyzed for each target individually.

Superantigens

Definition

Superantigens are usually bacterial antigens that possess potent immunostimulatory properties and the ability to crosslink MHC class II molecules with T-cell receptors. Thereby, they polyclonally activate large fractions (2–20%) of the T-cell population at picomolar concentrations. Studies have implicated superantigens in the pathogenetic aspect of such diseases as food poisoning, toxic shock syndrome, and autoimmune phenomena.

The best characterized superantigens are the microbial toxins from *Staphylococcus aureus* and *Streptococcus pyogenes*. Superantigens associated with *Streptococcus pyogenes* are also hypothesized in part to be responsible for psoriasis. Antigens associated with *Mycobacterium tuberculosis*, the rabies virus, and possibly HIV may also function as superantigens.

Superresolution

Definition

The light microscopic optical resolution is given by $d = 0.61 \lambda / NA$, where λ designates the wavelength of the employed light, and NA the numerical aperture of the utilized objective lens. Objects with sizes smaller than d are always imaged as diffraction-limited light spots (see also ► [Localization Precision](#)). The details of such objects cannot be recognized, and further magnification produces only an enlargement of the light spot, but does not reveal further detail. Usually one matches the half-width of the diffraction-limited spot to the size of a single picture element (pixel) of the detector. In contrast to this, superresolution imaging means that the diffraction-limited spot is mapped with a higher magnification onto the detector, such that a single spot extends over a greater number of pixels (at minimum 3 3, but up to 10 10).

Surface Plasmon Resonance

KARL-WILHELM KOCH

Division of Biochemistry, Institute of Biology and Environmental Sciences, Carl von Ossietzky University, Oldenburg, Germany
karl.w.koch@uni-oldenburg.de

Definition

► [Surface plasmon resonance](#) (SPR) is an optical phenomenon that is observed on ultrathin surfaces (50 nm) of specific metals like gold, silver and copper

(1, 2, 3). The metal layer is located at the interface between two media of different refractive indices (a prism and a compartment containing an aqueous buffer). When light is shone on to the prism under the angle of total internal reflection, the electric field of the photons extends about one quarter of the wavelength (► [evanescent electric field](#)) beyond the reflecting interface into the medium of lower refractive index (Fig. 1). A resonance phenomenon occurs when a thin metal film is present at the reflecting surface. Free electron clouds or certain electron densities of the metal interact with the evanescent electric field and the incident light energy is converted into electron density waves in the metal film under specific conditions. As a result the intensity of the reflected light beam on the side of the prism is extinguished. This reduction of reflected light intensity is maximal at a specific angle of the incident light beam called the resonance angle (Fig. 1). Changes in mass at the surface layer are related to changes in resonance angle. This allows the detection of binding events on the surface in real time and thereby the determination of rate and binding constants.

Description

Configuration of System

SPR technology is applied in optical biosensors to monitor interactions of biomolecules and is available in commercial systems like e.g. Biacore®. A typical

Surface Plasmon Resonance. Figure 1 Principle of surface plasmon resonance. A light source emits monochromatic light that traverses a prism at a certain angle θ and is totally internally reflected at the interface of two media. A thin metal layer is at the boundary between the prism and a medium of lower refractive index (e.g. aqueous buffer). Interaction of the evanescent electric field and the electron constellations of the metal causes a reduction in the reflected light intensity (RI). This is illustrated as a gray shadow in the reflected light beam and as a decrease of RI in the graph RI versus θ . Changes in the dielectric properties in the vicinity of the metal surface change the resonance conditions and lead to a shift of θ (I→II).

configuration consists of a light-emitting diode as light source (near infra red), an optical unit with a glass prism, an array of light-sensitive diodes as detector unit and a microfluidic cartridge system with channels and valves to allow delivery of solvents and samples into the system (1). Interaction of molecules occurs on the surface of special sensor chips that are introduced into the system. The sensor chips are docked to the microfluidic cartridge with their metal (gold) coated surface and are in contact with the glass prism on the other side. The only variable in this configuration is the refractive index of the medium on the side of the gold-coated sensor chip surface and the buffer flow. Thus, any binding event on the gold-coated surface or any transient change of buffer close to the surface is seen as a change in the resonance angle. Changes in resonance angle are directly correlated to changes in mass at the surface layer. Any given change of mass results in the same change of refractive index for all proteins and peptides. Thus, the detection principle is independent of the amino acid sequence of a given protein. A shift in the resonance angle of 10^{-4} is defined as 1 resonance unit (RU) and corresponds to an increase of surface mass of 1 pg protein/mm². The whole dynamic range of the system is 30 kRU. The use of the system is not restricted to proteins and peptides, but can also be applied to the study of glycoproteins, oligosaccharides, lipids and nucleic acids. The relation of mass changes to changes in the refractive index is the same as for proteins.

Immobilisation Strategies

In order to use SPR to study interactions of biomolecules in a protein-protein or protein-lipid system etc., it is necessary to immobilize one binding partner termed the ligand on the surface of a sensor chip. The other binding partner termed the analyte is supplied in the mobile phase and injected into the buffer stream flowing over the sensor chip surface. Several immobilization strategies employing a variety of chemical or biochemical procedures have been used so far (3). These can be summarized as in the following.

Immobilization on ► Carboxymethylated Dextran Surfaces

Sensor chips with a gold surface are coated with carboxymethylated dextran of approx. 100 nm thickness. Carboxy groups on this matrix can be modified to enable covalent coupling to primary amines (-NH₂), sulfhydryl groups (-SH), aldehyde (-CHO) or carboxyl (-COOH) groups. First, the dextran matrix is activated by derivatization with N-hydroxysuccinimide (NHS) to yield a reactive N-hydroxysuccinimide ester. The activated carboxy group then can react with substituents carrying an uncharged primary amino group. This allows direct covalent linkage of proteins and peptides (amine coupling) by lysine or free NH₂-termini.

Alternatively, activated carboxy groups are further derivatised by 2-(2-pyridinyldithio)ethaneamine hydrochloride (PDEA) yielding a modified surface with a reactive disulfide group. Proteins and peptides can be selectively coupled by cysteines *via* a disulfide exchange reaction (ligand thiol coupling). A second way to utilize thiol chemistry for coupling is to introduce a reactive disulfide group into the ligand before immobilization, which then allows direct binding to a thiol group on the surface (surface thiol coupling).

The aldehyde coupling procedure is a method to immobilize glycoproteins, glycoconjugates and polysaccharides. The dextran surface of the sensor chip is derivatised by NHS (see above) and can subsequently react with hydrazine to yield a hydrazide surface. Glycoconjugates with *cis*-diols are oxidized by periodate to an aldehyde function. Aldehydes then readily react with hydrazide on the sensor chip surface.

Immobilization by Antigen-Antibody Interaction

Antibody coated surfaces allow a monospecific immobilization of the ligand. The antibody can be directly coupled to activated carboxy groups *via* amine coupling or, in a less random process, bound to immobilized ►protein A or ►protein G on the sensor chip surface.

Immobilization of Tagged Proteins

Fusion proteins containing a glutathione-S-transferase or a maltose-binding protein can be coupled in a site directed way on a surface with the corresponding antibody. Specific sensor chips harbouring a preprepared NTA (nitriloacetic acid)-matrix can be loaded with Ni²⁺ and are designed for the immobilization of poly-histidine-tagged proteins. The high affinity interaction between biotin and ►streptavidin or ►avidin allows the immobilization of biotinylated proteins.

Immobilization of Lipids and Membrane Proteins

A special challenge of SPR applications is the immobilization of lipid bilayers on the sensor chip surface to study membrane proteins and membrane bound processes. Commercially available hydrophobic sensor chips contain hydrophobic groups within a dextran matrix, which capture ►liposomes from the mobile phase and anchor the lipids in the form of a bilayer on the surface. Liposomes with integrated membrane proteins can be immobilized in the same way. Alternative approaches to immobilizing membrane proteins are to utilize an immobilized antibody (within the dextran layer) directed against the membrane protein or to first immobilize a lectin that binds with high affinity to the glycosyl moiety present in most membrane proteins.

Blank gold surfaces of sensor chips without any additional coating also offer the possibility of using a

►self-assembled monolayer (SAM) as a basis for further immobilization steps. When ►alkane thiols are used to build up a SAM *via* a sulphur-gold contact, lipids can be fused to this layer and thereby form a heterobilayer. When alkane thiols are mixed with other thiols, e.g. biotin thiol or alkane thiols modified with COOH- or OH-groups, further derivatization is possible and allows building up of sandwich-like structures on the chip surface.

Data Acquisition

Interaction analysis by SPR is performed by injection of one binding partner into the buffer stream that is carried through the flow cell over the surface coated with the corresponding immobilized binding partner. Binding events on the surface of the chip are sensed and recorded as a change in resonance units resulting in a graph called a sensorgram. A typical sensorgram consist of an association phase and a dissociation phase (Fig. 2). Dissociation of a formed complex on the sensor surface is usually initiated by the end of analyte injection when only the running buffer is in the mobile phase. Association and dissociation rate constants can be obtained from a sensorgram by applying suitable curve fitting procedures, which in addition give equilibrium binding constants (see below) (4, 5). Further, SPR is a tool to investigate an interaction process by qualitative and semiquantitative analysis. These applications include, but are not restricted to

- screening for a possible interaction partner out of a heterogeneous mixture of biomolecules
- identification of an interaction site within a protein by screening of peptide libraries or testing of overlapping protein constructs
- investigation of mutations in proteins
- small molecule screening to facilitate drug design

Quantitative Analysis of Sensorgrams

A sensorgram is a change of resonance units RU with time and reflects the formation of a complex

The rate of formation of complex AB with time t is

$$d[AB]/dt = k_a[A]([B]_0 - [AB]) - k_d[AB] \quad (2)$$

or as a change of resonance units with time

$$dRU/dt = k_a C(RU_{\max} - RU_t) - k_d RU_t \quad (3)$$

dRU/dt is the rate at which a complex of two components A and B is formed. RU_{\max} represents the total binding capacity on the surface of the sensor chip and is equivalent to the number of immobilized binding sites B at $t = 0$ ($[B]_0$).

Surface Plasmon Resonance. Figure 2 Example of SPR Sensorgrams. Traces represent simulated SPR recordings showing an increase in resonance units (RU) when two binding partners associate and a decrease in resonance units when they dissociate. The two states I and II correspond to different angles θ under which surface plasmon resonance is maximal and therefore the reflected light intensity RI reaches a minimum (Fig. 1). The concentration of the binding partner in the mobile phase (analyte) was varied from bottom to top as follows: 0.1 μ M, 1 μ M, 10 μ M, and 100 μ M. Dissociation constant $K_D = 26.4 \mu$ M.

RU_t is the number of occupied binding sites at time t (equivalent to $[AB]$). $RU_{\max} - RU_t$ is the number of free binding sites on the chip surface at time t (or $[B]_0 - [AB]$); k_a and k_d are association and dissociation rate constants, respectively. C is the concentration of the binding partner in the mobile phase ($[A]$).

At equilibrium $dRU/dt = 0$, the equation

$$k_a C(RU_{\max} - RU_t) - k_d RU_t = 0 \quad (4)$$

can be arranged to

$$k_a C RU_{\max} - k_a C RU_t = k_d RU_t \quad (5)$$

$$C RU_{\max} - C RU_t = k_d / k_a RU_t \quad (6)$$

$$RU_t / C = K_A RU_{\max} - K_A RU_t \quad (7)$$

At equilibrium RU_t is expressed as R_{eq} . A Scatchard plot analysis (R_{eq}/C against R_{eq}) can be used to obtain K_A (or K_D) from the slope of the plot.

Integration of the rate equation (3) yields:

$$RU_t = \frac{C k_a RU_{\max}}{C k_a + k_d} (1 - e^{-[(C k_a + k_d)(t - t_0)]}) \quad (8)$$

The dissociation phase of a sensorgram can be described as

$$dRU/dt = -k_d RU \quad (9)$$

or in integrated form

$$RU_t = RU_0 e^{-k_d(t-t_0)} \quad (10)$$

Primary data from a sensorgram RU *versus* t during the association phase can be directly fitted to equations (8) and (10) assuming a 1:1 interaction model.

Common Problems in SPR Experiments

Recorded sensorgrams very often do not fit to a simple 1:1 binding model as outlined above. In most cases deviations from this bimolecular interaction model originate from experimental artefacts that can influence a correct analysis of sensorgrams (2, 3, 5). These include:

Non-Specific Binding

An analyte molecule could interact with the coating of the sensor chip surface or could interact with the immobilized ligand in a non-specific manner. The problem can be addressed by running the experiment in parallel on a control surface and subtracting the control signal.

Heterogeneity of Chip Surface

Immobilization of the ligand can occur at different sites on the molecule. For example a protein might have several exposed lysines that react with the activated dextran surface. The problem can be avoided by using a more specific site-directed immobilization, for example by selective coupling to an introduced cysteine. High immobilization densities of the ligand can also lead to a heterogeneous surface, where binding conditions within the dextran matrix are different from the conditions on the surface of the dextran layer. This problem can be avoided by using low surface densities on the chip surface (see also mass transfer limitations).

Mass Transfer Limitations

Several factors determine the transport of the analyte to the immobilized ligand on the sensor chip surface. It has to pass the unstirred layer on the boundary layer between chip surface and buffer flow, it has to partition into the matrix and diffuse through the dextran matrix to reach the immobilized ligand within the matrix. During dissociation, rebinding of the analyte can occur due to a hindered transport of the analyte away from the ligand-binding site. These diffusion processes can affect the observed chemical rate constants and lead to a misinterpretation of the kinetic evaluation of sensorgrams. The main ways to avoid problems arising from mass transfer limitation are the use of very low surface densities (only several fmol/mm²) and high buffer flow rates.

Other Problems

A variety of other problems can influence an SPR analysis, e.g. multivalent interactions, steric hindrance, crowding or matrix effects like swelling or shrinking of the dextran layer by changing the composition of the running buffer. Most problems can be avoided by using low surface densities, appropriate control injections and reversing the geometry of ligand immobilization, i.e. to immobilizing the other binding partner.

Clinical Applications

SPR is a tool of basic biomedical research and is applied in academia and industry. It is widely used for the characterization of antibodies and in particular for epitope mapping of antibodies. In combination with high-throughput screening in the area of drug discovery, it serves to characterize small molecules as well as antibodies. In addition it is a tool in the quality control of products in the biomedical industry.

Therapeutic Consequences

As a typical tool of basic research SPR has only indirect therapeutic consequences, which might originate from characterization of ligand-analyte interactions.

Tandem Mass Spectrometry

Definition

The term tandem mass spectrometry is also called ▶ **MS/MS** analysis. It utilizes two mass spectrometers in a series connected by a chamber known as a collision cell. The sample to be examined is essentially sorted and weighed in the first mass spectrometer, followed by collisional fragmentation induced by an inert gas, and fragment mass analysis in the second mass spectrometer. By using this method, compounds of a complex mixture can be identified. MS/MS can also be applied for identification of structures of organic molecules and for sequencing of proteins.

Definition

Familial HDL-deficiency syndromes such as Tangier disease (TD) are rare autosomal recessive disorders of lipid metabolism caused by mutations in the ▶ **ATP-binding cassette transporter ABCA1** (5). These syndromes are characterized by the almost complete absence of plasma ▶ **high-density lipoproteins** (HDL) and variable degrees of ▶ **hypertriglyceridemia**. TD was originally discovered in 1961 among inhabitants of Tangier Island in the Chesapeake Bay (USA), most of whom are descendants of the first settlers of 1686 (2). The clinical features of the classical TD phenotype of familial HDL-deficiency syndromes include very large, orange tonsils that have a characteristic gross and histological appearance and enlarged liver, spleen and lymph nodes, morphologic abnormalities which are the result of excessive accumulation of cholesteryl esters in these organs of the reticulo-endothelial system (RES). The principal cell types found in the spleen resemble monocyte-derived macrophages and platelets. Besides reduced HDL, ▶ **hypcholesterolemia** and abnormal ▶ **chylomicron** remnants are observed in the plasma. A second subset of patients with familial HDL-deficiency is characterized by premature atherosclerosis, which typically manifests with severe coronary artery disease (CAD). Some TD individuals present both with splenomegaly and CAD.

Characteristics

Defective ABCA1 Causes TD and Familial HDL-Deficiency Syndromes

Because of the well-established critical antiatherosclerotic properties of plasma HDL, considerable efforts were made throughout the past decades to identify the molecular defect underlying familial HDL-deficiency syndromes such as TD. The major breakthrough came in 1999, when it was discovered that mutations in the human ABCA1 gene cause these syndromes, thus identifying ABCA1 as a major regulator of HDL metabolism (5) (Fig. 1). In agreement with these observations, a recent study revealed that mice lacking functional ABCA1 exhibit plasma lipid alterations that are concordant with those found in TD (4).

Tangier Disease. Figure 1 Schematic structure of human ABCA1 and the association of known mutations with HDL-deficiency syndromes. Filled circles indicate mutations, open circles represent single nucleotide polymorphisms (numbered by their positions relative to the N-terminus). ABC, ATP-binding cassette; CAD, coronary artery disease; SM, splenomegaly.

Other findings in ABCA1 null mutant mice include vitamin K deficiency, hemorrhagic diathesis, reduced platelet counts and renal failure (4). Moreover, selective disruption of ABCA1 in circulating cells demonstrated that macrophage ABCA1 exerts substantial antiatherosclerotic activity in atherosclerosis. Importantly, this effect is independent of plasma HDL.

Originally, ABCA1 (formerly designated ABC1) was identified in the mouse in 1994. It is the defining member of the A subclass of ATP-binding cassette (ABC) transmembrane transporters which currently includes 12 members which share similar structural features. ABCA1 is expressed in a multitude of human organs with the highest expression levels in placenta, liver, lung, adrenal glands and fetal tissues. A characteristic feature of ABCA1 is that it is upregulated by cholesterol influx in macrophages and suppressed by HDL mediated cholesterol export. The human cDNA codes for a 2261 amino acid polypeptide with a molecular weight of 220 kD. Structurally, ABCA1 exhibits all the characteristics of a full-size transporter i.e. it consists of two tandemly oriented transmembrane domain-ABC subunits (Fig. 1). ABCA1 shows highest amino acid homology (54%) with the recently cloned leukocyte transporter ABCA7 and the retina-specific ABCA4 (52%). The human gene maps to chromosome 9q31.1 and is composed of 50 exons spanning a region of approximately 149 kb.

Association Between Mutation Topology and Clinical Phenotypes in Individuals with TD

More than 50 mutations within the coding region of the human ABCA1 gene have thus far been identified

(Fig. 1). When looking at the topological distribution of known mutations within the ABCA1 protein product, two findings deserve specific attention. First, mutations within the ABCA1 gene appear to occur in clusters. Major mutation clusters can be found in the C-terminal moiety of the first extracellular domain, the N-terminal ATP binding cassette and the C-terminus (Fig. 1). Secondly, mutations in the first extracellular domain and the C-terminus mutations are frequently associated with a cardiovascular phenotype. In contrast, amino acid exchanges in or in the proximity of the N-terminal ATP binding cassette appear to coincide with splenomegaly. These observations raise the possibility that amino acid substitutions within a few selected domains of the ABCA1 protein may, to a significant degree, determine the type of clinical presentation. Accordingly, one may postulate a critical function for the C-terminal moiety of the first extracellular domain and the C-terminus in the development of the cardiovascular phenotype.

ABCA1 appears to be localized in Golgi derived vesicles and on the plasma membrane (4). Surface expression of ABCA1 is up-regulated in macrophages by cholesterol loading. Recent evidence indicates that ABCA1 and *cdc42* are associated with a Lubrol-detergent resistant raft subfraction, whereas ABCA1 is not detectable in Triton-resistant rafts. In addition, the fact that ABCA1 is detectable in cytosolic vesicles and the Golgi compartment of unstimulated fibroblasts also raises the intriguing possibility that it is a mobile molecule that may shuttle between the plasma membrane and the Golgi as a constituent of a vesicular transport route. This is in line with the observation that

the trans-Golgi network in ABCA1 deficient cells is significantly dilated. Initial studies on the biological role of ABCA1 supported the view that this transporter, like MDR1 and MDR3, functions as a plasma membrane lipid pump. This was based on experiments showing an increase in cholesterol and phospholipid export under conditions of forced expression of ABCA1 in ABCA1 null mutant cells from patients with genetic HDL-deficiency which characteristically display the reverse scenario (4). However, recent work from our laboratories indicated that the ATP turnover of ABCA1 occurs at a very low rate whereas Mg^{2+} -dependent ATP binding induces conformational changes. Based on this information it is likely that ABCA1 acts rather as a regulator facilitating cholesterol/choline-phospholipid export within the cellular lipid export machinery than exerting a genuine translocator function. It will be exciting to elucidate the exact molecular mechanisms by which ABCA1 mediates the export of lipid compounds from the cell. In this context, a most critical aspect is the question as to which molecular partners interact with and thus potentially modulate ABCA1 function. Work from our laboratory has provided potential clues by demonstrating that ABCA1 interacts with a C-terminal PDZ binding domain in the [▶ \$\beta_2\$ -syntrophin/utrophin complex](#) that may couple ABCA1 to the [▶F-actin cytoskeleton](#). Moreover, evidence has recently been presented that ABCA1 function depends on binding to [▶Fas-associated death domain \(FADD\)](#) protein, an adaptor molecule involved in death receptor signal transduction (1).

Cellular and Molecular Regulation and Clinical Relevance

The TD Gene ABCA1 Controls Susceptibility to Atherosclerosis

Macrophages play a key role in the initiation and progression of atherosclerotic lesions. In the nascent lesion, they transform into foam cells through the excessive accumulation of cholesteryl esters. Dysfunctional lipid homeostasis in macrophages and foam cells ultimately results in the breakdown of membrane integrity and cell death. An interesting clue as to how ABCA1 may be implicated in the control of monocyte/macrophage targeting in TD comes from the observation that apoAI mediated lipid efflux in ABCA1 deficient cells is paralleled by the down-regulation of the protein cdc42 and filopodia formation. Cdc42, like rho and rac, is a member of the family of small GTP-binding proteins that controls formation of filopodia. [▶Rho proteins](#) induce the formation of stress fibers and focal adhesions and rac proteins regulate formation of lamellipodia and membrane ruffles. It is thus conceivable that ABCA1 modulates cellular mobility of monocytes/macrophages through this mechanism and

thus may affect recruitment of monocytes into the vessel wall. At the vascular wall level, this regulator function on filopodia formation may even extend to platelets, vascular smooth muscle cells and endothelial cells since these cells are also capable of expressing ABCA1.

The finding that ABCA1 is up-regulated in human macrophages during sustained uptake of cholesterol and that it facilitates cholesterol export from the cell render it a likely antagonistic player in foam cell development and the formation of the lesions of atherosclerosis. A number of transcriptional control elements have been identified in the ABCA1 promoter region. Among these, the [▶zinc finger protein ▶ZNF202](#) appears to function as a major repressor of ABCA1 transcription. Other factors that regulate the transcription of ABCA1 include [▶oncostatin M](#) and [▶geranylgeranyl pyrophosphate](#) (3). In addition, several [▶cis-acting elements](#) have been identified that control the expression of ABCA1. These include an E-box and consensus sequencing that are known to interact with the transcription factors Sp1/3, however, no [▶PPAR \$\alpha\$ - or \$\gamma\$ -consensus elements](#) are present in the ABCA1 promoter region.

Among patients with TD, one subgroup develops premature CAD, whereas another one presents predominantly with splenomegaly indicating differences in macrophage targeting to tissues in ABCA1 deficiency, which may be a reflection of the nature of the mutation in the ABCA1 gene. Based on this, it stands to reason that ABCA1 *per se* determines monocyte targeting into tissues. In recent experiments using chimeric [▶LDLR-/- mice](#) lacking ABCA1 in their blood cells, we tested the hypothesis that the selective disruption of ABCA1 in circulating cells, in particular macrophages, affects macrophage targeting into the vascular wall and lesion formation *in vivo*. Our results demonstrated that the absence of ABCA1 from leukocytes only is sufficient to induce aberrant monocyte recruitment into the spleen identifying ABCA1 as a critical leukocyte factor in the control of monocyte targeting. Moreover, it could be shown that LDLR-/- chimeras deficient in ABCA1 develop significantly larger and more advanced atherosclerotic lesions compared to chimeric LDLR-/- mice with functional ABCA1 (6). Of particular importance was the observation that targeted disruption of leukocyte ABCA1 function did not affect plasma HDL cholesterol levels. These results thus provided direct evidence that leukocyte ABCA1 exerts significant anti-atherosclerotic activity which is clearly independent of plasma HDL. Given the fact that macrophages are by far the predominant inflammatory cell type within lesions of atherosclerosis, these data strongly suggest that the observed increased susceptibility to atherosclerosis is largely attributable to the absence of

ABCA1 from lesional monocytes/macrophages. The view that macrophage ABCA1 functions as an important antiatherosclerotic factor has also been supported by more recent studies. For example targeted inactivation of ABCA1 in macrophages leads to increased lesion formation and foam cell accumulation in [▶apoE null mutant mice](#). Furthermore, in a reciprocal approach using ABCA1 over-expressing transgenic [▶apoE null mice](#), it has been shown that forced expression of human ABCA1 results in significantly smaller, less complex lesions in [▶apoE knockout mice](#). Interestingly, ABCA1 is highly expressed in differentiating megakaryocytes and circulating platelets indicating that monocytes/macrophages are not the only source of ABCA1 within the hematopoietic system (unpublished data). It is thus possible that altered platelet function due to the lack of ABCA1 may contribute to the observed anti-atherogenic effect.

Targeted Gene Disruption

Definition

Experimental replacement of an endogenous gene by a mutated (non-functional) version within the otherwise unchanged genome is called targeted gene disruption. Embryonic stem cells altered in this way allow the generation of mouse strains that stably carry the single gene mutation in the germ line, and therefore propagate it in a mendelian fashion to the offspring. Complete loss of the gene function in homozygously mutated mice often mimics deficiency states in humans.

william_hahn@dfci.harvard.edu

Synonyms

Telomerase Reverse Transcriptase; *TERT*

Definitions

► [Telomeres](#) consist of large arrays of short, G-rich sequences and specific binding proteins. These nucleoprotein structures compose the ends of linear eukaryotic chromosome and play important roles in chromosome replication, the maintenance of chromosomal stability and cell lifespan regulation. In mammals, the telomere sequence is TTAGGG. Telomeres are synthesized by a ► [ribonucleoprotein](#) ► [reverse transcriptase](#) called telomerase. Catalytically active telomerase is composed of two core components, an RNA subunit (telomerase RNA component: TERC) and a catalytic protein subunit (telomerase reverse transcriptase: TERT).

Characteristics

Biochemical Characteristics

Telomerase synthesizes telomeric repeats using a template provided by TERC. Recent evidence suggests that like many other reverse transcriptases, telomerase exists as a dimer (1). Several proteins associate with these two core components (TERC and TERT), but none of these proteins are necessary for telomerase activity *in vitro*.

Biological Characteristics

Telomeres shorten with successive rounds of cell division. Telomere attrition to critically short lengths leads to end-to-end chromosomal fusions and induces ► [apoptosis](#). Constitutive expression of telomerase stabilizes telomere length. Experimentally, constitutive expression of TERT directly immortalizes some types of human cells (2) and cooperates with specific combinations of oncogenes to transform human cells (3).

Clinical Relevance

Cancer

Telomerase activity is strongly associated with human cancer and most human cancer cell lines exhibit stable telomere lengths during propagation in culture. These observations suggest that telomere maintenance by

telomerase is an important factor in the development of cancer. However, recent work indicates that telomere biology plays a complex role in cancer development, serving both to suppress and facilitate malignant transformation.

Limitation of Replicative Lifespan and Suppression of Tumor Formation

Normal human cells exhibit a restricted replicative lifespan when propagated in culture. In primary human cells, telomeres shorten with successive cell division and this shortening correlates with their replicative capacity. Since most asynchronously proliferating normal human cells fail to maintain stable telomere lengths, these observations indicate that alterations in telomere state trigger ►replicative senescence, an irreversible proliferative arrest, and limit replicative capacity. This telomere-induced limit suppresses malignant transformation.

Telomere Shortening Promotes Genomic Instability and Tumor Initiation

Telomere shortening eventually leads to telomeres that are too short to protect chromosomes from fusion. Cells that harbor critically short telomeres exhibit increased genomic instability and most die by apoptosis at a period called ►crisis. However, rare cells survive crisis. Such survivors typically exhibit gross changes in karyotype called ►aneuploidy and are immortal. Despite exhibiting critical telomere shortening upon entering crisis, cells that survive crisis maintain stable telomere lengths by the activation of telomerase. Thus, critical telomere shortening induces chromosomal instability that promotes, among other events, the acquisition of mechanisms to maintain stable telomere lengths. This stabilization of telomere length permits immortalization and facilitates further malignant progression. In addition, the genomic instability induced by critical telomere shortening facilitates the further accumulation of other genetic alterations that contribute to malignant progression.

Telomerase Activation and Tumor Promotion

Although the expression of *hTERT* alone facilitates the acquisition of the immortal state, telomerase alone fails to transform human cells. However, telomerase expression cooperates with certain oncogenes to induce cell transformation. The observation that inhibition of telomerase in human cancer cells limits the proliferation of human cancer cell lines and induces cell death suggests that telomerase activation is a critical event during malignant transformation. Recent work suggests that telomerase activation contributes to transformation both by stabilizing telomere lengths and by affecting cell physiology in a manner independent of its effects on telomere length.

Telomerase as a Therapeutic Target

Since telomere maintenance plays an important role in cancer development, targeting telomeres and telomerase is a potential target for cancer therapeutics. Preclinical studies targeting telomerase by pharmacological or biological means show much promise but further efforts are necessary to develop useful clinical agents.

Dyskeratosis Congenita

Dyskeratosis congenita (DKC) is a rare inherited condition, characterized by bone marrow failure, abnormal skin pigmentation, abnormal nail growth, premature aging and an increased risk of malignancy, particularly of the skin and gastrointestinal tract. Most patients succumb to bone marrow failure and/or cancer. Epidemiological studies demonstrate two patterns of inheritance, X-linked and autosomal dominant. The major X-linked form of the disease is due to mutations in a nucleolar protein, dyskerin, which participates in the processing of ribosomal RNA (4). Dyskerin is also found in the telomerase complex, and cell lines derived from patients with the X-linked form of DKC are deficient in telomerase activity. Germline mutations in the RNA component of telomerase (*hTERT*) are found in the autosomal dominant form of DKC (5). Thus DKC is a disease of telomerase deficiency.

Telomerase Reverse Transcriptase

- Telomerase

Telomere

Definition

A telomere (also called telomeric repeats) is a region of highly repetitive DNA at the end of a eukaryotic chromosome. They are formed by tandem repeats of short DNA sequences and associated proteins. Telomeres facilitate complete DNA replication of the chromosome, and prevent the chromosomal ends from joining with other chromosomes. The shortening and possible disappearance of telomeres is believed to be the basis for cessation of cell division in many cells, which eventually leads to senescence. One reason why continuously proliferating cancer cells are immortal, is thought to be that their telomeres do not shorten with each round of cell division due to the action of telomerase.

Tetratricopeptide Repeat Motif

Definition

The tetratricopeptide repeat (TPR) motif is a protein-protein interaction module of 34 amino acids with the consensus sequence 4 (W/L/F), 7 (L/I/M), 8 (G/A/S), 11 (Y/L/F), 20 (A/S/E), 24 (F/Y/L), 27 (A/S/L), and 32 (P/K/E), which is often arranged in tandem arrays. It is found in multiple copies in a number of functionally different proteins having specific interactions with partner proteins.

- ▶Peptidyl Prolyl Cis/Trans Isomerases

TGF

Definition

TGF stands for transforming growth factor. It is a member of the family of growth factors originally identified by their ability to induce malignant transformation of cells in culture. They affect cell proliferation but also synthesis of extracellular matrix proteins in cells. TGF α belongs to the EGF family of ligands for receptor tyrosine kinases. TGF β is the prototype and the collective name for a superfamily of secreted disulfide-linked dimeric polypeptides, which are ligands for receptor serine/threonine kinases. TGF β 's exhibit potent morphogenetic roles during embryogenesis. They modulate growth, apoptosis and differentiation of most adult cell types.

TGF- β and related family members bind to receptor heterodimers that activate the ▶Smad proteins to bind to DNA.

Th-1 Biased T Cell Response

Definition

A Th-1 biased immune response specifically primes specific T cell responses associated with strong IFN γ production.

►DNA-based Vaccination

TH1/Th2 Cells

Definition

Th1/Th2 cells are subsets of T helper lymphocytes, they are defined by their capabilities for production of different sets of cytokines.

►Rheumatoid Arthritis

Thalassaemia

Definition

Thalassaemia is an inherited disorder characterized by defective haemoglobin synthesis (Haemoglobinopathies), which is caused by a mutation in the gene coding for the α or the β globin subunit. In β -thalassaemia, homozygous patients are affected by a most severe transfusion dependent anaemia (thalassaemia major), whereas carriers with one inherited gene are healthy (thalassaemia minor). α -thalassaemias are genetically more complex, because the α -globin gene locus contains two highly linked virtually identical genes. When only one or two of the four genes are deleted, carriers are healthy. When three genes are deleted, a haemolytic anaemia of varying severity develops (Hb H disease). A deletion of all four genes usually results in stillbirth (Hb Barts hydrops fetalis).

►Polyadenylation

Thanatophoric Dysplasia

Definition

Thanatophoric dysplasia refers to a dominant lethal form of chondrodysplasia characterized by very short

limbs and flat vertebral bodies. Activating mutations within fibroblast growth factor receptor 3 (FGFR3), a receptor tyrosine kinase, are responsible for the disease.

►Bone Disease and Skeletal Disorders, Genetics

Therapeutic Immunization

Definition

Therapeutic vaccines are administered to patients post-exposure to control chronic infection.

►DNA-based Vaccination

Thermodynamic Integration

Definition

Thermodynamic integration (TI) denotes a statistical thermodynamical method to calculate the free energy difference between two states A and B by gradually transforming the potential of state A into that of state B according to a defined path variable or coupling parameter. The free energy change is obtained by integrating over ensemble averages of the derivative of the potential with respect to the coupling parameter.

Definition

DNA, like other biopolymers, can assume a large number of different structures, a feature often referred to as structural polymorphism. Since structure generally dictates or modulates biological function, it is

important to know the relative stabilities of the different structural forms. Such assessments require thermodynamic data.

Today we know that DNA molecules are far more polymorphic than originally implied by the elegant Watson-Crick double helical structure. In addition to this fully paired duplex structure, DNA also can form imperfect duplexes with misaligned templates or hairpin loops, as well as duplexes with damaged/modified bases, mismatches or gaps. DNA can also form higher ordered structures, such as triplexes, tetraplexes and organized aggregates. The relative stabilities of these polymorphs depend on base composition, base sequence, strand length, solution conditions and the stability of interactions with effector molecules, including proteins.

Recent advances, perhaps most visible in the Human Genome Initiative, have presented new and compelling means and objectives to exploit the exquisite specificity of nucleic acid [hybridization](#). Precise knowledge of the temperature dependent stability of nucleic acid (and nucleic acid analog) complexes is necessary for the rational design and optimization of hybridization probes for use in high throughput screening, nucleic acid based diagnostics and therapeutics and numerous emerging biotechnology applications. While the subject of this article is DNA duplex thermodynamics, the principles described are general for nucleic acid complexes and, with appropriate modification, can be applied to nucleic acid-protein and nucleic acid drug interactions.

The set of thermodynamic parameters describing a DNA system can be used for 2 purposes, to understand the forces that stabilize the various forms of DNA and to develop predictive models of structure and interactions. Thermodynamic analysis is based on characterization of the macroscopic properties of the system containing the DNA, which under [equilibrium](#) conditions define a [thermodynamic state](#). The thermodynamic state is described by a set of [state functions](#). Because only changes in the state functions are measurable, thermodynamic analysis describes the differences between thermodynamic states. The measured thermodynamic parameters depend on the differences between the states and not on the path taken from one state to the other. Selection of an appropriate reference state is critical for the successful application of the thermodynamic model. To compare thermodynamic descriptions of different systems, one must be careful to establish a common [reference state](#). Typically the fully disordered, single stranded state observed at high temperature is used in DNA thermodynamic studies. It is reasonable to assume that sequence effects are irrelevant under these conditions. In principle, the state functions can be dissected into contributions from various forces, although rarely is

sufficient information available to do so with confidence. However, part of the power of the thermodynamic approach is that one need not invoke a microscopic model to make use of the information.

Thermodynamic Parameters

A variety of parameters are used to describe a thermodynamic system. The most important state function is the [free energy change \(\$\Delta G\$ \)](#), which represents the relative stability of two states. The free energy change can be dissected into contributions from the [enthalpy change \(\$\Delta H\$ \)](#) and the [entropy change \(\$\Delta S\$ \)](#). The enthalpy change is dominated by short-range interactions, including van der Waals contacts and base stacking interactions, with a small net contribution from hydrogen bonding between the paired bases. The enthalpy change describes the temperature dependence of the free energy change, i.e. the shape of the melting curve, and is the most readily measurable of the thermodynamic parameters. The entropy change (ΔS) represents changes in order associated with the two states. The entropy term includes contributions from conformational changes, although it may be dominated by rearrangements of associated solvent molecules and counterions. Empirical correlations between changes in the solvent accessible surface area of macromolecules and the [heat capacity change \(\$\Delta C_p\$ \)](#) at constant pressure have been reported. The heat capacity change is related to the temperature dependence of the enthalpy and entropy changes. Although it is not a true thermodynamic parameter, the [melting temperature \$T_m\$](#) is used frequently and erroneously to describe stability. Because it describes the midpoint of the thermally induced order disorder transition the T_m has some utility. The T_m value represents the thermal stability as opposed to the thermodynamic stability described by ΔG . Because it depends on concentration (for duplexes and higher order structures) and because it does not describe the shape of the melting transition, the T_m is not useful for predicting the relative stability of nucleic acid complexes at different temperatures. A complete thermodynamic description of the system is necessary to make accurate predictions of relative stabilities.

Characteristics

Nearest Neighbor Model

While one need not consider the structure of DNA to apply the thermodynamic approach, interpretation of the thermodynamic parameters in terms of a structural model is useful so long as one recognizes that the thermodynamic parameters do not depend on the model. The stability of a DNA duplex based on its structure can be predicted at several levels of detail. Duplexes tend toward greater stability as the GC base pair content increases. However, large stability

differences are observable between duplexes of like or similar base pair composition. Therefore sequence information must be included to provide accurate predictions of duplex stability. The [▶nearest neighbor model](#) has proved to be a very useful approach to including sequence effects on DNA thermodynamics. In the nearest neighbor model the thermodynamic parameters are assumed to be divisible into pairwise contributions from each set of neighboring base pairs. Of the 16 possible nearest neighbor base pairs only 10 are unique and need to be determined experimentally (2). Several sets of experimentally determined DNA nearest neighbor thermodynamic parameters have been published, including those from the Gotoh, Breslauer, Klump, Blake, Benight, Sugimoto and SantaLucia laboratories (4). While there is some variation for specific sequences, these data sets provide roughly equivalent predictions, as shown by Benight (4). For short oligonucleotides the thermodynamic parameters can be predicted by adding values from a table of nearest neighbor contributions (1) (including small corrections for certain conditions, such as self complementary oligonucleotides). Because the nearest neighbor model does not take explicit account of helix length it must be used with caution when applied to intermediate length oligonucleotides. Additivity of the nearest neighbor values fails for polymeric DNA as polymer length exceeds the length of the cooperative melting unit; however, the same data set of pairwise thermodynamic values can be used within a polymer model (6).

Limitations of the Nearest Neighbor Model

Excepting some scattered data, consideration of the important issues of template misalignment, i.e. mismatches and loops, and damaged or modified bases is not to date included in the nearest neighbor data sets. In addition, the nearest neighbor data sets are specific for particular solution conditions, with the concentration of monovalent cations being the primary variable. Use of the nearest neighbor values for the stability of duplexes under different solution conditions should be done with caution, although for most solution conditions the effects will scale roughly independent of sequence. Thermodynamics addresses only equilibrium states. While the path between states is not reflected in the thermodynamic parameters, it is important for describing some aspects of nucleic acid behavior and for determining the appropriate model to derive model-dependent thermodynamic data (5). There are two contributions to the formation of a duplex, [▶helix initiation](#) and [▶helix propagation](#). As the two strands come together a few base pairs form an [▶initiation complex](#); this is a [▶bimolecular process](#) and depends on DNA strand concentration. Subsequent to the helix initiation step base pairing propagates to form the

complete double helix; this process is pseudomonomolecular, because the strands have already found each other, and does not depend on strand concentration. Formation of short oligonucleotide duplexes is dominated by the initiation step and is strongly dependent on concentration. Formation of polymeric duplexes is dominated by helix propagation and is effectively independent of concentration. Both short oligonucleotide and polymer formation are well described by traditional models. The formation of intermediate length helices depends in a complex way on both helix initiation and propagation. Current models do not describe such molecules satisfactorily.

Measurement of Thermodynamic Parameters

The preferred method for measuring thermodynamic parameters for DNA is [▶differential scanning calorimetry](#), wherein the apparent heat capacity of the DNA-containing solution is measured directly as a function of temperature. A heat capacity anomaly is observed over the temperature range where the strands separate. The area under the DSC curve is proportional to the energy holding the duplex together. Thus integration of the DSC curve provides a direct measurement of the ΔH value associated with the disruption of the duplex (3). From the shape of the curve one can derive values for ΔS , ΔC_p and T_m . The value of ΔG at any temperature is readily determined from the familiar relation $\Delta G = \Delta H - T \Delta S$. Note that the calorimetric approach requires no assumptions about the mechanism of DNA strand separation; one need know only the DNA concentration to normalize the DSC [▶thermogram](#). The requirement for relatively large amounts of DNA and the requirement for expensive instrumentation have inhibited the widespread use of the calorimetric methodology.

By assuming that the duplexes under study dissociate in a [▶two-state process](#), one can apply the [▶van't Hoff equation](#) ($\Delta H = -R(\partial \ln K / \partial (1/T))$, where R is the gas constant and K is the equilibrium association constant) to extract thermodynamic parameters from experimental data that quantify the relative amounts of duplex and single stranded DNA as a function of temperature. Because the data are not sufficient to extract the additional parameter, when employing the van't Hoff model, it is generally assumed that $\Delta C_p = 0$. From DSC data it is known that ΔC_p is finite, but small. The most common application of the van't Hoff methodology is to optical absorbance *versus* temperature curves. The absorbance of ultraviolet light by duplex DNA is reduced relative to the corresponding single strands, thus providing a means of quantifying their relative populations. Several methods of analysis provide van't Hoff model-dependent thermodynamic parameters from UV melting curves (3). The primary advantage of this method relative to calorimetry is the availability

of suitable instrumentation. The data derived can be reliable if the design of the experiments explicitly considers the assumptions of the model.

Clinical Relevance

Biological Consequences

Thermodynamic driving forces provide one avenue by which one can attempt to understand and ultimately perhaps manipulate nucleic acids *in vivo*. Although solution conditions in most *in vitro* studies differ significantly from *in vivo* conditions (water activity, high protein and nucleic acid concentrations, disproportionately high concentrations of numerous small effector molecules (ions, metabolites), increased viscosity etc.) some correlation between the thermodynamic properties of nucleic acids *in vitro* and *in vivo* exist. The incorporation of incorrect bases during DNA replication resulting in mispairing, be it opposite normal bases or opposite chemically damaged bases, is at least partially determined by the thermodynamic stability of such base mismatches within the polymerase active site. Recognition of DNA damage and subsequent repair by the cellular repair machinery may, in part, depend on the impact of the defect on thermodynamic stability at and near the defect site. Several debilitating genetic diseases, such as the triplet repeat expansion diseases, may be traced to misfolding of nucleic acids into competing alternative secondary structures during critical biological processes. The relative thermodynamic stability of the misfolded secondary structure in comparison to conventional ►Watson-Crick DNA appears to play a critical role in the development of such diseases. *In vitro* the specific association of nucleic acids with repair and regulatory proteins and/or small ligands/drugs critical for biological function differs from more general nonspecific association due to a delicate balance of specific and nonspecific interactions. It is likely that a similar balance of thermodynamic driving forces also controls the interactions of proteins and ligands with nucleic acids *in vivo*.

Practical Consequences

Insight into the thermodynamic properties of nucleic acids forms the basis of a number of critical applications in modern biotechnology, molecular biology and molecular medicine. In the following we highlight a few of the more important technological advances in which understanding nucleic acid thermodynamics plays a critical role. Common to all these techniques is the need to control interactions between nucleic acids with a high degree of fidelity, which is only possible through the rational application of the thermodynamic models discussed above.

Polymerase Chain Reaction

The ►polymerase chain reaction (PCR), a workhorse of modern molecular biology and molecular medicine, requires the careful design of primers specific for the sequence domains to be amplified and a careful choice of reaction conditions (hybridization temperatures, denaturation temperatures, primer concentration etc.) based on thermodynamic considerations. Failure of PCR experiments can frequently be traced to unrecognized thermodynamic features of the primer or DNA target, including unrecognized secondary primer binding sites, competing higher order secondary structures or misincorporation of bases during amplification.

Single Nucleotide Polymorphisms Detection

The importance of ►single nucleotide polymorphisms (SNPs) in determining individual susceptibility to various disease causing agents and pharmaceuticals is becoming increasingly more apparent. Numerous technologies are being developed to identify and screen for SNPs on a large scale with the hope of ultimately providing individualized medicine to patients. Almost all of these techniques require directly or indirectly (through PCR amplification of the relevant sequences) the application of thermodynamic data as part of the detection process. Of those methods that use thermodynamics as a detection tool, denaturing HPLC or denaturing PAGE methods are based on the ability to distinguish populations of DNA molecules based on their differences in thermal stability. Another class of assays relies on detection of fluorescence or fluorescence energy transfer of dyes attached to DNA probes. The assays are dependent on the specificity of the probe for the target with the added complication that the fluorescent dyes may contribute to the overall thermodynamics of strand association.

DNA Chip Technology

►DNA chip technology is based on the specific hybridization of DNA or RNA to short DNA probes immobilized at well-defined positions on the DNA chip. It is used with increasing frequency in genomics, proteomics and systems biology applications to understand systems-wide expression patterns of genes and also in the identification of disease causing agents, in forensics and potentially in sensor technologies. The optimal conditions for hybridization reactions and the potential for false positives through undetected mismatches or alternative secondary structure formation are determined by the thermodynamics of probe/DNA target interactions. Hybridization to targets immobilized on a surface is not described adequately by current thermodynamic models, which are based on data derived from and for reactions in free solution.

DNA Nanotechnology

The rational design and construction of novel and complex nucleic acid structures not necessarily found in biological systems holds promise for allowing the assembly of nanometer scale materials of increasing complexity and potentially unusual properties. The controlled, modular, stepwise construction of such structures relies for success on a precise understanding of the thermodynamics governing strand interactions.

Thiol-Dependent Peroxidases

LEOPOLD FLOHÉ, TIMO JAEGER
MOLISA GmbH, Magdeburg, Germany
l.flohe@t-online.de

Definition

Thiol-dependent peroxidases are defined as enzymes that reduce H_2O_2 , alkyl hydroperoxides and peroxytrite at the expense of thiols with formation of disulfides.

Characteristics

General Features

Two families of peroxidases that use thiols as donor substrates to reduce H_2O_2 and other hydroperoxides are widespread in nature: the ► [glutathione peroxidases](#) (GPx) and the peroxiredoxins (Prx). The common denominator of these enzyme families is that they do not contain any prosthetic group such as heme but use a highly activated, i.e., dissociated cysteine or selenocysteine residue for catalysis. During catalysis their active-site thiol or selenol moiety is oxidized by a hydroperoxide to a sulfenic or selenenic acid derivative, respectively; the latter reacts with a thiol to form a (seleno)disulfide, which reacts with a second thiol to

regenerate the ground state of the enzyme, as outlined below:

Apart from being unrelated in sequence, the two enzyme families differ in their strategy to force the active site SH or SeH group into dissociation. In the glutathione peroxidases, typically the sulfur (selenium) of a (seleno)cysteine residue is hydrogen-bridged to the imino nitrogen of a tryptophan and the amido nitrogen of a glutamine residue (Fig. 1a) (1); in the ► [peroxiredoxins](#), dissociation of the thiol is induced by the positive charge of a nearby arginine and by hydrogen-bonding to a threonine or, less often, to a serine residue (Fig. 1b) (2). Due to the intrinsically low pK of selenocysteine the selenium-containing peroxidases are highly efficient with k_1 values above $10^7 \text{ M}^{-1}\text{s}^{-1}$ (Eq. 1). The corresponding k_1 values in peroxiredoxins, which almost exclusively work with thiol catalysis, are one to three orders of magnitude smaller and overlap with those of the sulfur homologues of the selenium-containing GPx-type enzymes.

For the reductive part of the catalytic cycle (Eqs. 2, 3) evolution has created a diversity that makes it difficult to correlate substrate specificities with molecular clades. Typical Prx substrates are the vicinal thiols of CXXC motifs, as they are present in ► [thioredoxins](#), ► [tryparedoxins](#) or the AhpFs of bacterial alkyl hydroperoxide reductase systems, but the mono-thiol glutathione has also been identified as substrate of some Prxs (2). Inversely, the terminology glutathione peroxidase turned out to be misleading for some members of the GPx family. The first member of this family to be recovered, now called GPx-1 in mammals,

Thiol-Dependent Peroxidases. Figure 1 Catalytic triads of thiol-dependent peroxidases. (a) Catalytic triad of GPx-type peroxidases. Position numbers refer to those of bovine GPx-1. (b) Catalytic triad of peroxiredoxins. Position numbers refer to TXNPx of *Leishmania donovani*. The cysteine (Cys173) that complements the intersubunit active site in typical two-Cys-peroxiredoxins is not shown.

is indeed highly specific for glutathione, but GPx-3 equally accepts thioredoxin and glutaredoxin as substrates, GPx-4 can react with protein thiols including those of GPx-4 itself, the GPx of *Plasmodium falciparum* proved in functional terms to be a thioredoxin peroxidase and, in analogy, GPx-type proteins in *Trypanosoma* species preferred trypanredoxin over glutathione as substrate (3).

Glutathione Peroxidases (1)

Mammalian genomes disclosed the existence of 6 distinct GPx-type proteins with evidently diverse biological functions. Four of them, GPx-1, GPx-2, GPx-3 and GPx-4 are selenoproteins, GPx-5 is a cysteine homologue, GPx-6, depending on species, either contains cysteine or selenocysteine.

GPx-1 is the most abundant one. It was the first selenoprotein that was discovered in mammals. It complements catalase in the detoxification of H_2O_2 and other soluble hydroperoxides and, according to knockout studies, is a pivotal cellular device to cope with oxidative stress. Unchallenged *gpx-1* (-/-) mice do not display any phenotype, but are highly sensitive to exposure to redox cyclers or conditions triggering H_2O_2 formation such as LPS administration or viral infections. If exposed to avirulent coxsacki strains, they develop a cardiopathy that reminds one of Keshan disease, a cardiomyopathy that is endemic in certain areas of China and is attributed to selenium deficiency. GPx-1 is one of the selenoproteins that declines fast upon selenium restriction. It is therefore justified to assume an impairment of hydroperoxide detoxification as an early event in selenium deficiency.

GPx-2 is largely restricted to the gastro-intestinal epithelium. Again *gpx-2* (-/-) mice do not show any obvious phenotype. Even double knockout mice devoid of GPx-1 and GPx-2 develop normally as long as they are raised under germ-free conditions. Upon contact with normal gastro-intestinal flora however, they develop inflammatory bowel disease. This observation points to a role of GPx-2 in regulating the synthesis of inflammatory mediators, possibly of leukotrienes. Alternatively, an enhanced apoptosis at the tip of the mucosal villi, where GPx-2 is lowest, may become unmasked if the general defense against oxidative challenge is impaired due to lack of GPx-1. GPx-3 is an extracellular protein of so far unknown function. Present in an environment with vanishingly low substrate levels (GSH or thioredoxin), it can hardly be considered as an enzyme in charge of balancing oxidative stress. It rather might be a redox sensor that monitors extracellular hydroperoxide production, e.g. resulting from activation of phagocytes, and may modulate the response of receptors at the cell surface. GPx-4 is unique in reducing hydroperoxy groups of lipids in biomembranes and has for long been

implicated in the prevention of lipid peroxidation. More recently, specific roles became evident (see below). Knockout of *gpx-4* resulted in early embryonic lethality, a phenomenon that is not easily explained by any of the known GPx-4 functions. Depending on the use of distinct promoters and translation starts, *gpx-4* is translated into a cytosolic protein or isoforms equipped with a mitochondrial or nuclear leader sequence. It remains to be worked out which of the different forms of GPx-4 account for its vital importance.

GPx-5 is an epididymal protein that is built under androgen control. But its role remains obscure, as does that of the recently detected GPx-6.

Non-vertebrate GPx-type proteins are usually cysteine homologs with poor peroxidase activities and poorly defined biological roles. Exceptions are the GPxs of the fowl poxvirus and of *Schistosoma mansoni*, which contain selenocysteine. The latter appears to be involved in reproduction, since it is only found in the female gender and is restricted to the vitellin glands of the female reproductive tract.

Peroxiredoxins (2)

The first peroxiredoxin to be discovered was the “thiol-dependent antioxidant protein” of yeast in the laboratory of Earl Stadtman. It later became characterized as a peroxidase using the CGPC motif of thioredoxin as reductant. In the yeast peroxidase system three proteins are required to transfer the reduction equivalents from NADPH to the hydroperoxide, thioredoxin reductase, thioredoxin and the thioredoxin peroxidase. Similar cascades of oxidoreductases were later found to operate in mammals also. In parallel, the alkyl hydroperoxide reductase component AhpC of enterobacteria was identified as peroxiredoxin. Together with a disulfide reductase, AhpF, it constitutes a simple peroxidase system that reduces hydroperoxides at the expense of NADPH. The reduction equivalents are transferred from NADPH *via* FAD to a CXXC motif of AhpF, the latter serving as substrate for AhpC. The most complicated redox cascade fuelling a peroxiredoxin was identified in trypanosomatids. Here a flavin-containing disulfide reductase, trypanothione reductase, reduces oxidized trypanothione, that is the bis-glutathionyl derivative of spermidine; the reduced trypanothione reduces a thioredoxin-related protein called trypanredoxin; the reaction center of trypanredoxin is a CPPC motif and thus an ideal substrate to keep a peroxiredoxin-type trypanredoxin peroxidase in the reduced state ready to scavenge any hydroperoxide (3). In the meantime peroxiredoxins have been identified in all domains of life. They all have the potential to reduce hydroperoxides at the expense of thiols, but their substrate specificity, in particular for the donor substrate differs substantially. The family comprises at least six molecular clades clearly

separated by sequence and, in part, by catalytic mechanism and donor substrate specificity (4). So far the oxidizable cysteine of the active site was found to be replaced by selenocysteine in one case only (*Eubacterium acetamidophilum*).

The examples mentioned above belong to the huge subfamily of typical two-cysteine-peroxiredoxins (2-Cys-Prx). Their oxidizable cysteine is located about 50 residues from the N-terminus and is, as in most Prxs, embedded in a strictly conserved VCP motif. This subfamily contains a second strictly conserved cysteine near the C-terminus that mostly is also flanked by V and P. This second cysteine serves as the first reductant of the oxidized C-terminal one during the catalytic cycle according to Eq. 2. The disulfide bridge between the two cysteine residues can, however, only be formed if two invertedly orientated subunits of the homooligomeric proteins interact, which is only possible by substantial redox-dependent conformational changes. As a result of those, the exposed proximal cysteine that constitutes the peroxidatic catalytic triad shown in Fig. 1b becomes hidden upon oxidation, whereas the distal conserved cysteine is surface-exposed to react with another thiol according to Eq. 3. Thus, the catalytic triad (Fig. 1b), which is common to all peroxiredoxins, is only one part of the catalytic site. To complete the catalytic cycle a novel intersubunit reaction center is formed that allows specific interaction with the donor substrate. In the 2-Cys-Prx subfamily, this is typically the most surface exposed cysteine of the CXXC motif of thioredoxin, tryparedoxin or AhpF.

A variation of this theme is provided by the so-called atypical 2-Cys-Prxs, e.g. the "thiol peroxidases (TPx)" of *Escherichia coli* and *Mycobacterium tuberculosis*. Here the oxidized N-proximal cysteine has been proposed to react with a cysteine of the same subunit. Again the final reductants are thioredoxins (4). This subfamily therefore is functionally monomeric, while a dimer is the minimum catalytic unit of the typical 2-Cys-Prxs. These minimum catalytic requirements do not mimic the actual quaternary structure. The atypical 2-Cys-Prx of *M. tuberculosis* is dimeric and the typical 2-Cys-Prxs tend to form rings composed of 5 dimers (Fig. 2a, b), which had been seen in electron microscopy long before the identification of peroxiredoxins as peroxidases and were then termed "porins" (2, 5). In a minority of the peroxiredoxins only the N-proximal cysteine is conserved. In these 1-Cys-Prxs, the entire catalysis (Eqs. 1, 2, 3) must be achieved by the catalytic triad (Fig. 1b) without the aid of a co-reaction cysteine residue. In this respect, a 1-Cys-Prx acts like a GPx-type peroxidase and, interestingly, the few examples of this subfamily that have been characterized so far proved to share the substrate specificity of the classical glutathione peroxidase, GPx-1, they accepted the mono-thiol GSH and not

thioredoxin. It appears premature, however, to deduce any reliable rules as to the correlation of molecular clades and substrate specificity, since out of the more than 400 Prxs known by sequence less than two dozen have been thoroughly investigated for their metabolic context.

Molecular Interactions

Apart from GPx-1, thiol-peroxidases tend to react with protein SH groups. As outlined above, protein SH groups are the preferred substrate of most peroxiredoxins. In some cases such interactions are, however, not part of the catalytic cycles. Typical examples are the reaction of GPx-4 with a surface-exposed SH group of GPx-4 itself that results in polymerization, a phenomenon that contributes to the transformation of the peroxidase into an enzymatically inactive structural protein during sperm maturation. The insoluble material forming the mitochondrial capsule is characterized by Se-S bridges between GPx-4 molecules. Probably analogous cross-links with cysteine-rich proteins contribute to the stability of the capsule. The nuclear variant of GPx-4 has been implicated in chromatin condensation, which is also presumed to involve formation of Se-S bonds (1).

Human PrxII, III and VI were reported to interact specifically with cyclophilin A. In the case of PrxII, reduction of a cyclophilin disulfide bond was verified (2).

Regulatory Mechanisms

General Considerations

Peroxidases are commonly called antioxidant enzymes, which, however, is only true in exceptional cases. Their ability to reduce H_2O_2 , alkyl hydroperoxides or peroxynitrite does not necessarily imply that their biological role consists in balancing oxidative stress. Of the long known heme peroxidases, catalase appears to be in charge of detoxifying H_2O_2 generated in peroxisomal metabolism. In contrast, myeloperoxidase uses H_2O_2 to produce hypochlorite, which is a stronger oxidant, and the thyreoperoxidases require H_2O_2 for thyronine production. The thiol-dependent peroxidases have for long been considered to be the more reliable cellular antioxidant devices since they reduce ROOH in a clean stoichiometric reaction without the aid of transition metal cofactors that are prone to produce free radicals by univalent redox transitions.

The two-electron transitions consistently catalyzed by the thiol-dependent peroxidases have not, however, precluded these enzymes from also adopting functions that can not possibly be classified as antioxidant defense. The most striking example is the use of oxidants by GPx-4 to built up a structural protein that is essential for the fertilization capacity of sperm. Also, there is increasing evidence that oxidants like H_2O_2 and alkyl hydroperoxides are mediators in unstressed

Thiol-Dependent Peroxidases. Figure 2 Shape of a typical 2-Cys-Prx. (a) shows a model of the decameric oxidized trypanothione peroxidase (TXNPx) from *Trypanosoma brucei* as supported by averaged electron microscopy images (net). (b) the molecule has been reacted with ten mutated trypanothione molecules (taken from Budde *et al.* (2003) *Biol Chem* 384:619-633).

physiology. These oxidants, however, would react promiscuously if they were not sensed by “peroxidases” that, in a redox-dependent manner, specifically interact with target molecules, to modulate their activity. Numerous observations (1, 2, 5), which are beyond the scope of this article, support the idea that the coexistence of many peroxidases from at least three families will find its explanation in the emerging field of redox-regulation of proliferation, apoptosis, and differentiation. The phosphorylation/dephosphorylation and/or protease cascades dominating these phenomena turned often out to be modulated by the redox-state of their microenvironment. The NF κ B system may be quoted as a particularly well-documented example (1, 5). For the sake of clarity it appears mandatory to differentiate between such physiological redox-processes and “oxidative stress”, a term describing a pathological situation where the production of, or exposure to, oxidants exceeds the reductive capacity of the organism. This may, e.g., result from poisoning with redox-cyclers, exposure to hyperbaric oxygen or, most commonly, from the respiratory burst triggered in phagocytes activated by pathogenic microorganisms, anaphylatoxins or the realm of proinflammatory cytokines. To balance such an oxidative burst a peroxidase has to meet several requirements. It must be ubiquitous, abundant, highly efficient and supplied with a reasonable reduction capacity. For the mammalian body, the GSH/GPx-1 system meets these criteria, while other GPx-type enzymes are restricted to special tissues and less abundant. The Prx-type enzymes are generally less efficient and, in mammals, can hardly compete with selenium- or heme-containing peroxidases and thus are more likely regulatory enzymes. In many microorganisms, which often lack selenium-containing peroxidases or catalase, the comparatively low molar efficiency of a Prx can, however, be compensated by high enzyme concentrations. There, Prxs represent the major, if not the only enzyme to cope with peroxide stress.

Regulation of Enzyme Levels

GPx-1 in mammals is reportedly up-regulated under oxidative stress presumably *via* an oxygen-responsive element. GPx-2 is transcriptionally regulated by retinoids. At the translational level, all selenium-containing GPxs are regulated by the selenium content, although in a specific way. GPx-1 and 3 decline fast upon selenium restriction, GPx-2 and 4 are more stable. The differential response to selenium is known to be due to a differential stability of the mRNAs in selenium deficiency (1). The mechanisms leading to the pronounced tissue specificity of the selenoproteins remain to be elucidated. The abundant hormone-dependent expression of GPx-4 in testis appears to be

caused not by transcriptional activation by any of the androgenic hormones but by a testosterone-dependent augmentation of spermatids. Transcriptional or translational regulation of Prx-type enzymes has not yet been studied in detail (5).

Specific Regulatory Effects of GPx-4

Many of these peroxidases have been shown to dampen signaling *via* redox-sensitive phosphorylation cascades, probably by lowering the peroxide tone. The regulatory efficiencies, however, appear to differ between these enzymes. Moderately over-expressed GPx-4, for instance, can abrogate IL-1-induced NF κ B activation, while huge variations in GPx-1 levels have a minor effect. Similarly, GPx-4 appears to be more efficient in inhibiting 5-lipoxygenase than any of its congeners. A specific role for the nuclear variant of GPx-4 in chromatin condensation is also being discussed (1). The differential effects may result from distinct preferences for hydroperoxide or thiol substrates. A regulatory event could, however, also be achieved by a direct interaction of the peroxidase with a target protein.

Thioredoxin

Definition

A thioredoxin (Trx) is a redox-active protein typically characterized by a CGPC motif, which reversibly shuttles between the dithiol and disulfide state. Thioredoxins are involved in basic anabolic functions such as ribonucleotide reduction for DNA synthesis, they contribute to antioxidant defense as substrates of

peroxiredoxins, and are implicated in many redox-sensitive regulatory processes.

Third-Generation MDR Modulators

Definition

Third-generation MDR (multi drug resistance) modulators are molecules which prevent the drug transport out of a multi drug resistant cell by noncompetitive binding, and thereby specifically inhibiting a single ABC transporter. Intracellular drug concentration increases and thus chemosensitivity of the cell is restored. To date these modulators are used as a reversal strategy for cells and tumors possessing the multi drug resistance phenotype.

Threshold Liability Model of Multifactorial Inheritance

Definition

The model proposes a continuously distributed genetically determined liability to the development of disease. Individuals who develop disease will have several disease susceptibility genes. Due to the properties of the normal distribution of genes, first-degree relatives will have a much higher risk of developing disease than the general population. Second-degree relatives will have a moderate risk, and third-degree relatives will have low risk. Many of the systemic and organ-specific autoimmune diseases appear to be inherited in a pattern consistent with this model.

Thymidine Analog Mutations

Definition

Thymidine analog mutations (TAMs) comprise of a group of six mutations in human immunodeficiency virus (HIV)-1 ▶ reverse transcriptase (RT), i.e. M41L, D67N, K70R, L210W, T215Y/F and K219Q, which confer resistance to the antiretroviral drugs zidovudine (ZDV) and stavudine (d4T). These mutations, when present with other RT mutations, are also associated with diminished antiviral susceptibility to several other nucleoside reverse transcriptase inhibitors.

p-kopp@northwestern.edu

Synonyms

Thyroid dysgenesis, dyshormogenesis, hypothyroidism, hyperthyroidism, hyperthyroxinemia, resistance to thyroid hormone, autoimmune thyroid disease, thyroid cancer.

Definition and Characteristics

The thyroid gland evolves from two distinct embryologic structures. The thyroid anlage derives from the endodermal floor of the primitive pharynx and gives rise to thyroid follicular cells. These cells migrate caudally, then expand laterally and form the two lobes of the gland. The ultimobranchial bodies, located in the fourth pharyngeal pouch, are of neural crest origin and, after undergoing a similar descent, differentiate into the parafollicular calcitonin-producing C cells. Following migration and fusion of the two cell populations, thyroid follicular cells undergo further differentiation. This is marked by the expression of genes that are essential for thyroid hormone synthesis such as those for TSH (thyrotropin) and its receptor (TSHR), the sodium-iodide symporter (NIS), thyroperoxidase (TPO) and thyroglobulin (TG). In humans, thyroid hormone is detectable in the fetus at about gestational week 11.

The thyroid is controlled by a classic hypothalamic-pituitary axis. The hypothalamic tripeptide TRH (thyrotropin-releasing hormone) stimulates the production and secretion of the glycoprotein hormone TSH (thyroid-stimulating hormone) in the pituitary. TSH in turn stimulates growth and function of thyroid follicular cells resulting in the production of the thyroid hormones thyroxine (T4) and triiodothyronine (T3). In the bloodstream, only minute fractions of T4 and T3

are found as free hormone, most is protein-bound to thyroxine-binding globulin (TBG), transthyretin (TTR) and albumin.

After uptake into peripheral cells, a process that is at least partially mediated by amino acid channels, T4 is either 5'-deiodinated by deiodinase I or II, a process that produces the more active T3, or it is modified into the inactive rT3 by deiodination of the inner ring. At the cellular level, thyroid hormones have multiple effects on differentiation, growth and metabolism of peripheral tissues. Thyroid hormone action is primarily mediated by nuclear receptors regulating gene transcription; several non-genomic actions are a focus of growing interest. Negative regulation of the hypothalamic-pituitary-thyroid axis is exerted by T3, somatostatin and dopamine.

Cellular and Molecular Regulation and Clinical Relevance

Thyroid disorders are common. In adults, the prevalence of overt hypothyroidism is ~3–20 per 1000 in females, and ~1–7 per 1000 in males. The prevalence of hyperthyroidism is ~2–19 per 1000 in females, and ~1–2 per 1000 in males.

Genetic Defects in Thyroid Development and Hormone Synthesis

Congenital Hypothyroidism (CH)

CH affects about 1:3,000–1:4,000 infants. It is usually sporadic and only rarely familial. Screening programs now permit early recognition and treatment, thus avoiding the disastrous consequences of thyroid hormone deficiency on brain development. In about 85%, CH is sporadic and associated with developmental defects referred to as thyroid dysgenesis. They include thyroid (hemi)agenesis, ectopic tissue and thyroid hypoplasia. Dyshormogenesis, defects in normal hormone synthesis, account for about 10–15% of CH. A wide spectrum of genetic defects provides a molecular explanation for a subset of the sporadic and familial defects in pituitary and thyroid development, or thyrotropin and thyroid hormone synthesis.

Mutations in Thyroid Transcription Factors and Thyroid Dysgenesis

Mutations in transcription factors that govern thyroid development and gene expression may result in syndromic and non-syndromic forms of thyroid dysgenesis. These observations are corroborated by similar observations in murine knockout models.

PAX8

Monoallelic mutations in PAX8, a paired domain transcription factor involved in thyroid development and expression of the *TPO* and *TG* genes, have been

documented and characterized in sporadic and familial patients with thyroid hypoplasia or ectopy. It is currently unclear why mutation of a single PAX8 allele is sufficient to result in CH in humans, a finding that contrasts with the observation that mice heterozygous for a disrupted *Pax8* locus do not display a pathological phenotype.

TTF1/NKX2.1

Thyroid transcription factor 1 (TTF1) is a homeobox domain transcription factor of the NKX2 family involved in the development of the gland and in transcriptional control of the *TG*, *TPO* and *TSHR* genes. It is also expressed in the lung, the forebrain and the pituitary gland. Patients heterozygous for chromosomal deletions of 1q12-13.2 or point mutations in the

TTF1 gene present with mild CH with a thyroid of normal size and location. They have neurological alterations that include ataxia or choreoathetosis, truncal apraxia and mental retardation, in combination with neonatal respiratory distress. Monoallelic *TTF1* mutations have also been identified as the molecular cause of hereditary chorea.

TTF2/FOXE1

Homozygosity for recessive mutations in the forkhead/winged-helix domain transcription factor FOXE1, commonly referred to as thyroid transcription factor 2 (TTF2), result in a syndromic form of thyroid dysgenesis with the eponym Bamforth-Lazarus syndrome. This phenotype includes thyroid agenesis, cleft palate, choanal atresia, bifid epiglottis and spiky hair.

Thyroid Disorders, Genetic Basis. Figure 1 Model of iodide transport in thyroid follicular cells. Iodide is actively transported into thyroid follicular cells by the sodium-iodide symporter (NIS) at the basolateral membrane. At the apical membrane, pendrin (PDS/SCL26A4) mediates iodide efflux into the follicular lumen. Thyroperoxidase (TPO) oxidizes iodide and subsequently iodinated tyrosyl residues of thyroglobulin (TG) in the presence of hydrogen peroxide (H₂O₂) (organification). The iodotyrosines, mono- and di-iodotyrosine (MIT, DIT) are coupled to T₄ or T₃, a reaction that is also catalyzed by TPO (coupling). Thyroglobulin is internalized into the follicular cell, hydrolyzed in lysosomes and the thyronines T₄ and T₃ are released into the blood stream.

Dyshormogenesis

Sodium/Iodide Symporter

Normal iodide uptake at the basolateral membrane by the perchlorate-sensitive sodium/iodide symporter (NIS) is a rate-limiting step in thyroid hormone synthesis. Several homozygous or compound heterozygous mutations have been identified in individuals with hypothyroidism associated with impaired iodide uptake. Many of these patients have a diffuse or nodular goiter, little or no uptake of radioiodine and a decreased saliva/serum radioiodine ratio.

PDS/SCL26A4

Efflux of iodide at the apical membrane of thyroid follicular cells is at least in part mediated by pendrin (SCL26A4), a member of the solute carrier family 26A. Mutations in the *PDS/SCL26A4* gene cause Pendred's syndrome, an autosomal recessive disorder traditionally defined by the triad of sensorineural congenital deafness, goiter and a partially positive perchlorate test. The partial discharge of radioiodine after the administration of perchlorate indicates that the gland has an impaired ability to organify iodide. Although some patients with Pendred's syndrome present with CH, the majority of individuals are clinically and biochemically euthyroid.

Thyroperoxidase

Thyroperoxidase, a glycosylated hemoprotein located at the apical membrane facing the follicular lumen, iodinates tyrosine residues in TG and facilitates the coupling of the iodinated tyrosines to generate T4 and T3. TPO defects are among the most frequent causes of inborn errors of thyroid hormone synthesis. Homozygosity or compound heterozygosity for mutations in the *TPO* gene have been reported in numerous families with a partial or total organification defect.

THOX2

The iodination and coupling reactions are dependent on H_2O_2 as an essential cofactor. Recently, two NADPH oxidases that are part of the H_2O_2 -generating system, THOX1 and THOX2, have been cloned. Heterozygous loss of function mutations in the *THOX2* gene result in mild transient CH. Biallelic *THOX2* mutations are associated with a severe phenotype and confirm that H_2O_2 is essential for iodide organification. As yet, there are no reported mutations in *THOX1*.

Thyroglobulin

Thyroglobulin (TG), a homodimeric glycoprotein, is a key element in thyroid hormone synthesis and storage. It is encoded by a very large gene spanning more than 300 kb and containing 48 exons. Recessive mutations in the TG gene have been reported in a number of

animal models and human patients. Unless treated with levothyroxine, these patients typically present with goiter in early childhood. The metabolic status is variable and, depending on the severity of the defect, the patients are hypothyroid, subclinically hypothyroid or euthyroid. The serum TG levels may be low, normal or elevated. The radioiodine uptake is elevated. In many instances, the mutated TG protein is retained in the endoplasmic reticulum resulting in a classical endoplasmic reticulum storage disease (ERSD).

Dehalogenase

After entering the follicular cell, TG is hydrolyzed and T4 and T3 are secreted into the blood at the basolateral membrane. The iodotyrosines MIT and DIT, which are much more abundant in the TG molecule, are deiodinated by an intrathyroidal dehalogenase and recycled for hormone synthesis. Several patients with leakage of MIT and DIT from the thyroid and urinary secretion of these metabolites have been identified. The disorder is recessive. Very recently, an intrathyroidal dehalogenase, which may deiodinate MIT and DIT in the thyroid, has been cloned.

Resistance to TSH

The response to bioactive TSH may be impaired at the level of the thyroid follicular cells. Total insensitivity to TSH results in a small hypoplastic thyroid gland and reduced synthesis and secretion of thyroid hormones. It is noteworthy that a similar morphologic and biochemical phenotype may occur in patients with mutations in *PAX8*, which emphasizes the limitations of morphological criteria. Resistance to TSH may be caused by various molecular mechanisms. In a subset of these patients, the molecular cause consists of recessive mutations in the *TSHR* that are partially or completely inactivating. In partial resistance, TSH is elevated, but the peripheral hormone levels are normal, a constellation referred to as *euthyroid hyperthyrotropinemia*. In these patients, the size of the thyroid is normal or enlarged. More severe homozygous or compound heterozygous inactivating mutations in the *TSHR* have been found in several patients with overt hypothyroidism and thyroid hypoplasia.

Resistance to TSH, in combination with resistance to PTH, LH, FSH and the morphological features of Albright's hereditary osteodystrophy (short stature, brachydactyly, ectopic calcifications) also occurs in pseudohypoparathyroidism Ia (PHP Ia). The molecular basis consists of inactivating mutations in the maternal copy of the *GNAS1* (*Gsa subunit*) gene, which is imprinted in a tissue-specific manner.

Unresponsiveness to TSH can also be inherited as an autosomal dominant trait, but the molecular defect remains to be defined.

Activating Mutations in the TSH receptor (TSHR)

TSH exerts its effects on thyroid follicular cells through the TSHR, a member of the G-protein coupled seven transmembrane receptors. Together with the receptors for FSH and LH it forms a distinct subfamily defined by a large amino terminal extracellular domain involved in binding the hormone. The 744 amino acid receptor is encoded by a gene containing 10 exons and localized on chromosome 14q31. The TSH receptor is primarily coupled to Gs and thus to the adenylyl cyclase cascade, which is the predominant signaling pathway for growth and function in the thyrocyte. Gain of function mutations in the TSHR lead to various characteristic pathophysiological entities.

Somatic TSHR Mutations in Toxic Adenomas and Thyroid Carcinomas

Somatic mutations in the TSHR have been found as the main molecular cause of toxic adenomas. Functionally, these mutations increase basal cAMP levels; some of the mutants also activate the phospholipase C cascade. In contrast to activating mutations in other seven transmembrane receptors, there is a striking diversity in the affected residues that are scattered over the entire transmembrane domain of the TSHR and even occur in the extracellular domain. Activating mutations in the TSHR have also been found in a small number of thyroid carcinomas with the unusual finding of increased hormone secretion. Remarkably, the mutations found in these tumors not only activate the cAMP cascade, but also the IP3 pathway. This supports the notion that concomitant activation of these two signaling cascades may promote transformation.

Activating Germline TSHR Receptor Mutations in Familial Non-autoimmune Hyperthyroidism

Activating mutations occurring in the germline give rise to familial non-autoimmune hyperthyroidism. The typical signs associated with autoimmune hyperthyroidism, i.e. Graves' disease, are absent. Several families with non-autoimmune familial autosomal dominant hyperthyroidism due to TSHR mutation have been identified.

Activating Germline TSH Receptor Mutations in Neonatal Non-autoimmune Hyperthyroidism

Congenital hyperthyroidism is usually caused by transplacental transfer of maternal antibodies in offspring of a mother with autoimmune thyroid disease. In this instance, the disease is transient and resolves within several weeks to months upon clearance of the antibodies. However, a few cases show a persistent course with severe hyperthyroidism. *De novo* germline mutations in the *TSHR* gene have been found as a cause of this unusual form of hyperthyroidism.

TSH Receptor Mutations Conferring Hypersensitivity to hCG

A form of familial gestational hyperthyroidism caused by a mutant thyrotropin receptor displaying hypersensitivity to normal levels of hCG has been identified. The mutated receptor has an increased sensitivity for hCG and thus results in activation of thyroidal hormone production during pregnancy. In addition to hyperthyroidism, the affected women presented with repeated miscarriages and hyperemesis.

Activating Mutations in the *GNAS1* (*Gsa*) Gene

Somatic gain of function mutations in the *GNAS1* gene encoding the α subunit of the stimulatory G protein (gsp mutations) lead to a constitutive activation of the cAMP pathway and to toxic adenomas. They can occur only in the thyroid or display mosaicism in the McCune-Albright syndrome (precocious puberty, polyostotic fibrous dysplasia, café au lait skin pigmentation, GH-secreting pituitary adenomas and toxic adenomas).

Binding Protein Abnormalities

Thyroid hormones circulate bound to plasma proteins, the three major ones being thyroxine-binding globulin (TBG), transthyretin (TTR) and albumin. Abnormalities in transport proteins lead to a decrease or increase in total T4 levels; free hormone levels are within the normal range and the patients are clinically euthyroid. Failure to recognize these entities results in inappropriate treatment aimed at normalizing the thyroid hormone levels. TTR variants are furthermore of clinical importance because they are associated with various forms of amyloidosis.

Thyroxin-Binding Globulin (TBG)

TBG is an acidic glycoprotein with a single binding site for T4 or T3. Like corticosteroid-binding globulin it shows a high homology with the protease inhibitors α 1-antichymotrypsin and α 1-antitrypsin and it is a member of the serine protease inhibitor (serpin) family of proteins, although it is not a protease inhibitor. Many physiological and exogenous compounds, e.g. estrogens, alter the clearance and production of TBG. Genetic TBG abnormalities are classified according to the levels of TBG into complete or partial deficiencies or TBG excess. A variety of mutations in the *TBG* gene resulting in complete or partial deficiency have been identified. In contrast, over-expression of the protein due to gene amplification leads to TBG excess.

Transthyretin

TTR is a homotetramer formed of subunits containing 127 amino acids and contains two T4 binding sites. However, negative cooperativity allows the occupation of only one site at a given time. Multiple mutations in TTR have been identified. Their impact on T4 affinity

is variable and results in unchanged, increased or reduced affinity. Many of the point mutations are associated with autosomal dominant familial amyloidotic polyneuropathy (FAP), as well as amyloid depositions in the heart.

Albumin

Albumin is a monomer of 69 kD and is associated with the transport of a wide variety of endogenous and exogenous hydrophobic compounds. Albumin has a relatively low affinity for T4 and T3, but because of its high concentration it binds up to 10% of T4 and 30% of T3. Familial dysalbuminemic hyperthyroxinemia (FDH) is the most common cause of euthyroid hyperthyroxinemia, i.e. elevated total T4, but normal free T4 levels. It is inherited in an autosomal dominant manner and studies of several families have led to the identification of two independently recurring point mutations in the albumin gene that lead to substitutions of arginine at position 218 (R218H, R218P). Crystallographic analyses reveal that the two mutations result in conformational changes that favor binding of T4 on one of the four T4-binding sites on albumin. Another mutation in the albumin gene leads to familial dysalbuminemic hypertriiodothyroninemia with an affinity for T3 that is $\sim 40\times$ higher compared to wild type albumin.

Cellular Uptake of Thyroid Hormone into Cells

Cellular uptake of thyroid hormones is at least in part mediated by channels. Point mutations and deletions in the X-chromosomal *MCT8/SLC16A2* gene have been identified in several hemizygous males with elevated T3 and TSH levels. The phenotype is remarkable for severe mental retardation, spastic quadriplegia, rotary nystagmus and impaired gaze and hearing. Heterozygous females have discrete thyroid hormone abnormalities, but no neurological alterations. The abnormal T3 elevation may be due to impaired uptake into cells such as neurons.

Peripheral Monodeiodination

In target tissues, T4 is metabolized into the more active compound T3 by intracellular 5'-monodeiodination or into the inactive metabolite reverse T3 (rT3) by 5-monodeiodination. Monodeiodination of the outer and inner ring is catalyzed by three well-characterized deiodinases (DIO1, 2, 3), enzymes that are unusual because they are selenoproteins. They contain the rare amino acid selenocysteine (Sec), which is encoded by UGA, a triplet that usually encodes a stop codon. The translation of the Sec codon requires specific stem loop sequences that are located in the 3'-untranslated region (SECIS element). Over-expression of DIO3 in infantile hemangiomas and other vascular tumors leads to

consumptive hypothyroidism through inactivation of thyroid hormone at a rate that exceeds the maximal thyroid hormone synthesis.

Thyroid Hormone Action and Resistance to Thyroid Hormone (RTH)

Thyroid hormones exert their multiple cellular effects through nuclear thyroid hormone receptors (TRs), transcription factors which act by altering patterns of gene expression both as activators and repressors. The two TR genes, TR α and TR β , are members of the steroid receptor superfamily of nuclear receptors. The TRs are encoded by separate genes that are located on chromosomes 17 and 3 and they generate several splice variants.

Resistance to thyroid hormone (RTH) is characterized by decreased responsiveness to thyroid hormone. Biochemically, the syndrome is defined by elevated free thyroid hormones and an inappropriately normal or elevated level of TSH. The clinical spectrum is highly variable and ranges from isolated biochemical abnormalities to a constellation of features that includes goiter, variable signs of hyper- and hypothyroidism, short stature and delayed bone maturation. RTH is most commonly caused by autosomal dominant mutations in TR β that exert a dominant negative effect. In one family, RTH was caused by the loss of both thyroid hormone TR β alleles. More recently, familial cases of RTH without linkage to the TR β locus have been reported, indicating non-allelic heterogeneity.

Autoimmune Thyroid Disorders (AITD)

Hashimoto thyroiditis and Graves' disease are by far the most common diseases affecting the thyroid gland. They are characterized by an immune response to thyroidal antigens, infiltration by T-cells and production of antibodies. In Graves disease, thyroid stimulating antibodies lead to activation of the TSHR and hyperthyroidism, a process involving mainly a Th2 cell response. In Hashimoto's thyroiditis, a predominantly Th1-mediated chronic inflammation leads to progressive destruction and hypothyroidism. Both disorders are found more frequently in women.

The AITD are thought to be multifactorial disorders that require a genetic susceptibility in combination with environmental triggers. Epidemiological data support a strong genetic component in the development of AITD. This is further supported by twin studies. Graves' disease has been reported to occur in about 3–9% of dizygotic and 30–60% of monozygotic twins. For Hashimoto's thyroiditis, the concordance rate for monozygotic twins is about 40%, but very low for dizygotic twins. It should be noted that monozygotic twins are not identical in terms of their immune repertoire, which may explain the absence of perfect

concordance. As in other autoimmune diseases, associations have been established between the disease and the presence of certain human leukocyte antigens (HLA) constellations, but most linkage studies have been negative. Candidate gene analyses aiming at investigating associations between variants in genes such as the *TSHR*, *TPO* and the *T-cell receptor* with AITD have been negative. In contrast, the *TG* and *CTLA-4* (cytotoxic T-lymphocyte antigen 4) genes appear to be important susceptibility genes for AITD. Whole genome screens using AITD families identified several loci or genes with evidence for linkage to AITD.

Thyrotoxic Hypokalemic Periodic Paralysis

Periodic paralysis with hypokalemia can occur in patients with thyrotoxicosis. The clinical presentation is indistinguishable from familial hereditary hypokalemic paralysis without hyperthyroidism. Analysis of several genes encoding channels that are mutated in the familial form in patients with the thyrotoxic form led to the identification of a mutation in the *KCNE3* potassium channel gene. No mutations could be found in other candidates such as the calcium channel *CACN1A5* or the sodium channel *SCN4A*.

Thyroid Cancer

Thyroid cancers are relatively infrequent neoplasms and account for ~1% of all malignancies. The incidence of thyroid cancer is 1–10 per 100,000 in most countries. Thyroid cancer is about three times more frequent in females.

The majority of thyroid malignancies are papillary thyroid carcinomas (PTC) or follicular thyroid carcinomas (FTC), both originating from follicular cells. The highly malignant anaplastic carcinoma (ATC) and several unusual variants of thyroid cancers occur less commonly. A major risk factor for the development of benign and malignant thyroid neoplasms is radiation. This has been recognized after use of external radiation for medical treatment of benign and malignant conditions in the neck and more dramatically after accidental releases of ionizing radiation from atomic explosions and accidents in nuclear facilities.

PTC, which presents with several distinct histological subtypes, may occur in the setting of some rare autosomal dominant syndromes with disseminated neoplasias, familial adenomatous polyposis (Gardner's syndrome; *APC* gene mutations), as well as Cowden's syndrome (*PTEN* gene mutations), a condition characterized by multiple hamartomas with benign and malignant breast tumors, gastrointestinal polyps, ovarian cysts and mucocutaneous papulae. The Carney complex, an autosomal dominant disorder defined by cardiac myxomas, benign endocrine neoplasms and,

more rarely, follicular cancers, is associated with activating mutations in the regulatory subunit 1A of the cAMP-dependent PKA (*PRKAR1A*). Familial aggregation of FTC seems to occur in families with dysmorphogenesis.

Several molecular mechanisms involved in the development of thyroid neoplasms have been elucidated during the last decade. Hyperfunctioning adenomas frequently harbor an activating mutation in the *TSHR* or in *Gsa*. A substantial fraction of PTC has rearrangements between the *RET* tyrosine kinase and several other genes. Other molecular alterations in PTC include intrachromosomal rearrangements of the *TRK* gene and recent studies report a high prevalence of *BRAF* gene mutations in these tumors. The molecular alterations found in follicular adenomas and FTC are distinct from PTC and include mutations in *RAS* genes, loss of heterozygosity at several loci and a rearrangement fusing the amino terminal coding region of the *PAX8* to the *PPARγ* gene. More aggressive cancers have mutations in tumor suppressor such as *Rb* and *p53*.

Tight Junctions

SAIMA AIJAZ, STEVEN GOODRICK, KARL MATTER, MARIA S. BALDA

Division of Cell Biology, Institute of Ophthalmology, University College London, London, UK
m.balda@ucl.ac.uk

Definition

Tight junctions (TJs) are morphologically distinct intercellular junctional structures of epithelial and endothelial cells that restrict paracellular diffusion and, hence, allow these cells to form selective barriers between compartments of different composition. TJs not only control paracellular permeability, they also participate in the maintenance of cell surface lipid polarity and the regulation of gene expression, cell proliferation and differentiation.

Characteristics

TJs are areas of close contact between neighbouring cells and come into view as apparent hemifusions of the adjacent plasma membranes. These regions of close contacts contain intramembrane strands that form a net-like meshwork that encircles the cells. These intramembrane strands are thought to be formed by different types of transmembrane proteins that also mediate cell-cell adhesion, although not all transmembrane proteins of TJs are associated with the strands. The transmembrane components are linked to the ► [cytoskeleton](#) and different signal transduction pathways by adaptor and/or scaffold proteins that form a submembrane

junctional plaque. This complex molecular machinery is used by epithelial and endothelial cells to recognise and transduce signals that regulate paracellular permeability and guide cell proliferation and differentiation.

Molecular Interactions

Transmembrane Proteins

Four types of transmembrane proteins have been described to be associated with tight junctions: occludin, claudins, JAMs (junction adhesion molecules) and CRB-3 (one of the vertebrate homologues of the *Drosophila crumbs* protein). TJs also contain a dense plaque of highly interconnected peripherally associated cytosolic proteins. These include the ► [adaptor proteins](#) ZO-1, -2 and 3, cingulin, a dimeric protein known to interact with many different junctional components and several signalling molecules, such as protein kinases and GTP-binding proteins, whose cellular functions we are only beginning to understand (1, see Table 1).

Occludin is a 60 kD membrane protein with four transmembrane domains, as well as a short N-terminal and a long C-terminal cytoplasmic domain. Five isoforms of occludin have been described, including one lacking the fourth transmembrane domain and another with a modified N-terminal domain. Although occludin is one of the components of the intramembrane strands, it does not appear to be a key structural component but has important regulatory functions. Occludin is involved in the regulation of paracellular permeability of small and medium non-ionic molecules. Its C-terminal domain is critical for this regulatory function and interacts *in vitro* with several proteins including ZO-1, -2, -3, cingulin, OAK, PI3K and atypical PKC ζ . However, the physiological role of these interactions is not known. Phosphorylation of occludin is suggested to affect its function in different experimental systems. The extracellular domains of occludin mediate its localisation at TJs most probably *via* homotypic interactions.

Claudins are 22–26 kD integral membrane proteins that, like occludin, have four transmembrane domains with both termini in the cytosol. Claudins comprise a large family of more than 20 members in mice and humans and are expressed in a tissue-specific manner (2). Expression of individual claudins in cells lacking TJs induces networks of intramembrane particles between adjacent transfected cells similar to those observed at TJs of epithelial cells, suggesting that claudins are important structural components of the intramembrane strands. Different claudins are often co-expressed and can co-polymerise to form individual strands that can adhere to each other intercellularly. The short C-terminal domain of claudins contains an YXV sequence, a ► [PDZ domain](#)-binding motif mediating interactions with the ZO proteins and MUPP1, a

Tight Junctions. Table 1 Major Components of Tight Junctions and their Interacting Partners*

Tight junction proteins	Molecular interactions
Transmembrane proteins	
Occludin (intracellular domain)	ZO-1/2/3, cingulin, OAK, PI3K, aPKC ζ , Itch, VAP-33
Claudins (intracellular domain)	ZO-1/2/3, MUPP1, PATJ
JAMs (extracellular domain)	Integrins, Reovirus, Adenovirus
JAMs (intracellular domain)	CASK, ZO-1, cingulin, afadin/AF-6, PAR3, MUPP1
CRB-3 (intracellular domain)	Pals1, PATJ, PAR6
Cytoplasmic proteins	
Adaptor proteins	
ZO-1	occludin, claudins, JAMs, ZO-2, ZO-3, Gi proteins, ZONAB, cortactin, afadin/AF-6, actin, connexins, ZAK, α -catenin, cingulin
ZO-2	claudins, ZO-1, adenovirus E4-ORF1, DNA-binding protein scaffold attachment factor-B (SAF-B), Fos, jun, CBP, cingulin
ZO-3	claudins, ZO-1, actin, PATJ, cingulin, AF6, p120 catenin
PATJ	Pals1, ZO-3
Pals1	PATJ, crumbs, PAR6
PAR3	PAR6, aPKC ζ , JAMs, PTEN, TIAM
PAR6	PAR3, cdc42, Pals1, aPKC ζ , CRB3, TGF β -receptor
MAGI-1	adenovirus E4-ORF1, papillomavirus E6, JAMs
MAGI-2	PTEN
MAGI-3	PTEN, pro-TGF α
MUPP1	claudins, JAMs, adenovirus E4-ORF1, papillomavirus E6
cingulin	ZO-1/2/3, actin, myosin, afadin/AF-6, JAM, GEFH1
Signalling molecules	
Gi proteins	ZO-1
rab13	PKA
aPKC ζ	PAR3, PAR6, PP2A, PAR1B/EMK1
GEF-H1	RhoA, cingulin, PAK1, PAK4, 14-3-3
ZONAB	ZO-1, cdk4, Ral A
sympleskin	polyadenylation factor CstF, Heat Shock Factor 1

* Due to space limitations, not all TJ components and their interactions could be listed

protein that contains 13 PDZ domains. The extracellular loops of claudins seem to create charge-selective channels in the paracellular pathway between epithelial cells as shown by mutations of specific amino acids (3). Since claudins often differ in their ion selectivity, their expression is thought to determine a tissue's paracellular conductive properties.

JAMs are glycoproteins of approximately 40 kD and are characterised by two immunoglobulin like folds

(V_H- and C₂-type) in the extracellular domain. JAMs localise to intercellular junctions of endothelial and epithelial cells but can also be expressed on circulating leukocytes and platelets (4). The extracellular domains of JAMs bind several ligands but can also mediate homophilic adhesion. Different JAMs associate through their extracellular domain with integrins involved in the regulation of leukocyte-endothelial cell adhesion, the β 2 integrins LFA-1 and Mac-1, as well as

$\alpha 4\beta 1$. Furthermore, different viruses use JAMs as receptors. Reovirus binds to JAM-1 and adenovirus to CAR, another member of the JAM family. Reovirus binding to JAM-1 appears to be required for induction of apoptosis and activation of NF- κ B, although the precise cellular pathways involved have not yet been identified. The cytoplasmic domains of JAMs associate with several cytoplasmic partners, CASK, a calcium/calmodulin-dependent serine protein kinase, ZO-1, cingulin, AF-6 and ASIP/PAR-3. Expression of a JAM lacking the cytoplasmic domain impairs the localization of ASIP/PAR-3, suggesting a role for JAM in the stabilization of the junctional complex.

CRB-3, a 25 kD type I membrane protein, is the only one of the three vertebrate homologues of the *Drosophila* crumbs protein that has been demonstrated to associate with TJs in epithelial cells. CRB-3 is spread over the entire [apical membrane](#) and only a minor fraction of the entire cellular pool is associated with TJs. The cytoplasmic domain of CRB-3 interacts with the adaptor protein Pals1, which functions as a linker to other functional components such as PATJ and another protein complex involved in cell polarity, the PAR3-PAR6-aPKC complex.

Cytoplasmic Proteins

The cytoplasmic TJ proteins can be divided into different functional groups: adaptor proteins, which often contain PDZ domains and are known to interact with several other TJ proteins, such as ZO-1/2/3, PATJ, Pals1, PAR-3 and PAR-6; signalling molecules, such as trimeric and monomeric [G-proteins](#), atypical PKC and GEF-H1; and proteins involved in transcription and RNA processing, such as the transcription factors ZONAB and hASH1 and symplekin, a protein suggested to be involved in RNA processing (see Table 1).

Several protein-protein interactions have been characterised between these proteins, and many of these proteins also interact with membrane components as well as the actin cytoskeleton. This architectural principle is well illustrated by ZO-1, the first identified TJ component. ZO-1 has several protein-protein interaction domains, three PDZ (for PSD-95, DlgA and ZO-1) domains, one [SH3 domain](#) and one with homology to yeast guanylate kinase (GUK domain). Proteins containing these types of domains are called [MAGUKs](#) (membrane associated guanylate kinase proteins). ZO-1 interacts with claudins *via* its first PDZ domain, with occludin *via* the GUK domain and forms stable complexes with either ZO-2 or ZO-3 *via* its second PDZ domain. ZO-1 also contains a discrete actin-binding domain in its C-terminal half. The SH3 domain functions in intracellular signalling by binding to the serine protein kinase ZAK and the [Y-box](#)

transcription factor ZONAB, which in turn binds to the cell-cycle regulator CDK4 (5).

While it is not feasible to list all the known interactions here, the general principle of the junctional architecture appears to be that individual adaptor components form discrete complexes, such as the ZOs, PAR3/6 or Pals1/PATJ. These adaptor complexes function as bridges between membrane components and the actin cytoskeleton, and recruit different types of signalling components, such as aPKCs, which bind to the PAR3/6 complex. On the next organisational level, these complexes also interact with each other, resulting in a complex network of proteins. For example, the interaction between the Pals1/PATJ and PAR3/6 complexes is mediated by direct binding of the PDZ domain of PAR6 to the C-terminus of Pals1. The interaction between ZOs and the Pals1/PATJ complex occurs *via* ZO-3, which binds to one of the PDZ domains of PATJ. An exception to this architectural principle is cingulin, a dimeric actin-binding protein that can bind to different TJ components but does not appear to have any preferential binding partners. As cingulin can form short filaments *in vitro*, it might form a supporting functional scaffold (6).

Regulatory Mechanisms

The classical function of TJs is to regulate paracellular permeability and many different junctional components have been linked to this process. Paracellular permeability is a regulated process that allows selective passive diffusion of certain ions as well as small hydrophilic molecules across the junctional barrier. The main membrane components involved in paracellular permeability are the claudins and occludin (7, see Table 2).

Claudins are expressed in a tissue-specific manner and the claudin-composition of a TJ determines its ion-selectivity. For example, claudin-16/paracellin-1 is expressed in the lung and the kidney, and patients carrying a mutation in this gene suffer from hereditary hypomagnesaemia due to a deficiency in paracellular magnesium resorption in the kidney. Therefore, it has been proposed that claudin-16 forms a paracellular channel or pore that allows the diffusion of magnesium ions. Transfection experiments with epithelial cell lines further suggested that different claudins favour paracellular diffusion of specific ions. These and other observations have led to a model in which claudins form homo- and hetero-oligomers that then engage in intercellular interactions to form paracellular channels or pores. The ion-selectivity of these channels is determined by the types of claudins they contain (2, 3). Other hereditary diseases and transgenic mice models have also linked specific claudins to the normal functioning of various tissues; although, in most cases

Tight Junctions. Table 2 Major Tight Junction Components and their Functions

Tight junction proteins	Suggested functions
Transmembrane proteins	
Occludin	cell-cell adhesion, paracellular permeability, restriction of apical/basolateral lipid diffusion, leukocyte transmigration, regulation of cell proliferation
Claudins	cell-cell adhesion, paracellular ion conductivity
JAMs	cell-cell adhesion, leukocyte transmigration, regulation of junction assembly, viral receptors
CRB-3	cell polarity and apical membrane biogenesis
Cytoplasmic proteins	
ZO-1	regulation of paracellular permeability, gene expression, cell proliferation and cell density
ZO-2	regulation of cell proliferation and transcription
ZO-3	regulation of junction assembly
PATJ/Pals1	cell polarity and apical membrane biogenesis
aPKC ζ /PAR3/6	regulation of junction assembly, cell polarity
Gi proteins	regulation of junction assembly
rab13	regulation of junction assembly
GEF-H1	activation of RhoA, regulation of paracellular permeability, cell proliferation
ZONAB	regulation of gene expression, cell proliferation and cell density
sympleskin	regulation of gene expression and RNA polyadenylation

it has not been determined whether the phenotype is caused by differences in junctional ion permeability. For example, claudin-14 was identified by positional cloning as the gene mutated in a form of human hereditary deafness and claudin-14 deficient mice show outer hair cell degeneration in the organ of Corti. It has been proposed that hair cell degeneration in the absence of claudin-14 is due to a switch in junctional ion-selectivity.

In the cases of claudins-1 and -5, mouse models suggest that their absence causes more general defects in permeability. Mice lacking claudin-1 die shortly after birth due to water loss across the skin, and the absence of claudin-5 causes leakage of small tracers across the brain endothelium. It is not clear how the absence of these claudins causes permeability defects and whether they possess important structural and/or regulatory roles in these tissues. Nevertheless, mice deficient in claudin-11/oligodendrocyte-specific protein exhibit neurological and reproductive defects and the intra-membrane strands of TJs of oligodendrocytes and Sertoli cells are reduced, indicating that, at least in some tissues, specific claudins are required for morphologically normal TJs.

Occludin is also involved in the regulation of paracellular permeability, but its role appears to be more important for non-ionic rather than ion permeability. The activity of occludin is regulated by its C-terminal cytoplasmic domain since expression of occludin mutants lacking this part in cultured cells lines results in stimulation of size-selective tracer permeability. It is thought that this regulatory mechanism involves phosphorylation events as well as the actin cytoskeleton since the C-terminal domain of occludin binds to protein and lipid kinases, as well as to actin filaments and cytoskeletal linkers. Occludin does not appear to be of structural relevance since occludin-deficient mice are viable. Nevertheless, these mice exhibit a complex phenotype and many tissues and organs appear to be defective due to chronic inflammations or altered differentiation. While the mechanisms causing these defects are unknown, the chronic inflammations might reflect a role of occludin in leukocyte transmigration, which was suggested by studies in epithelial cells in culture. Since occludin has also been linked to the restriction of trans-junctional lipid diffusion, some of these phenotypes might have been caused by a loss of cell surface lipid polarity (5).

Paracellular permeability is a regulated process that involves different signal transduction pathways and components such as PKCs, PKA, and trimeric and monomeric GTP binding proteins. These signalling pathways can act specifically on TJ proteins, on the actin cytoskeleton or on both. For example, the phosphorylation of the C-terminal domain of occludin appears to be important and has been proposed to modify cytoskeletal interactions, however, the responsible protein kinase(s) are not known. Regulation of contraction of the actin cytoskeleton by RhoA has been shown to regulate TJ formation and paracellular permeability. This is thought to involve activation of the RhoA effector Rho-kinase, which in turn increases myosin phosphorylation, resulting in myosin activation and contraction of the actin cytoskeleton. TJ-specific activation of RhoA can be mediated by the ►[guanine nucleotide exchange factor](#) GEF-H1, a member of the *Dbl* oncogene family (5).

Transmigration of leukocytes across epithelial and endothelial barriers requires the coordinated opening and closing of TJs to avoid a loss in the barrier function. JAM-1 is one of the TJ components that regulate this process. Antibodies against JAM-1 inhibit leukocyte transmigration in skin inflammation and in a model of mouse meningitis (8). Although JAM-1 interacts with a number of cytoplasmic components, it is not clear which ones are involved in this regulatory process. Occludin has also been linked to leukocyte transmigration across epithelia and this involves its N-terminal cytoplasmic domain. How the N-terminal domain of occludin facilitates transmigration is not known, and it is not clear whether occludin plays a similar role in endothelia.

More recently, tight junctions have also been linked to the regulation of epithelial differentiation and establishment of cell polarity. One pathway involves ZO-1 and the interacting Y-box transcription factor ZONAB. ZO-1 and ZONAB regulate expression of the growth factor co-receptor *erbB-2* in a cell-density dependent manner and function in the control of cell proliferation and cell density. ZONAB also binds to the G1/S phase regulator CDK4. Functional studies suggest that one mechanism by which ZO-1 can inhibit cell-cycle progression is by inhibiting the nuclear accumulation of the ZONAB/CDK4 complex. Although ZONAB accumulates in the nucleus of proliferating cells, it is not yet clear whether it regulates the expression of genes that are required for proliferation. Nevertheless, these observations suggest that TJs, like ►[adherens junctions](#), function in the suppression of proliferation (5).

The evolutionarily conserved crumbs pathway is a TJ-associated signalling module that regulates the establishment of epithelial cell polarity. In *Drosophila*, crumbs binds to a cytosolic complex consisting of stardust and *Drosophila* PATJ, and was identified

because of its essential role in epithelial morphogenesis. Over-expression of Crumbs in *Drosophila* expands the apical cell surface and leads to the disruption of cell polarity of photoreceptors. Recent work has found a human homologue of *Drosophila* Crumbs, known as CRB-1, to be mutated in two eye disorders, retinitis pigmentosa and Leber congenital amaurosis. In mammalian epithelial cells, CRB-3 binds to a TJ-associated protein complex consisting of Pals1, the homologue of stardust, and mammalian PATJ. As with the role of this pathway in *Drosophila*, the CRB-3/Pals1/PATJ-pathway appears to regulate junction assembly and biogenesis of the apical membrane.

Another evolutionarily conserved signalling module at TJs that regulates cell polarity is the PAR3/PAR6/aPKC complex, which also plays a role in TJ biogenesis. PAR-3 directly associates with the cytoplasmic domain of some JAMs, resulting in the recruitment of the PAR3/PAR6/aPKC complex to cell-cell junctions. PAR6 interacts with GTP-bound Cdc42 (cell-division control protein 42), a protein essential for cell polarity that becomes activated upon the induction of cell-cell adhesion. Binding of PAR6 to Cdc42 is thought to result in the activation of aPKC, which is required for the formation of distinct tight and adherens junctions by an as yet unknown mechanism. Furthermore, the direct interaction of PAR6 with Pals1, one of the components of the CRB-3 complex, is also regulated by Cdc42. Experimental evidence suggests that interactions between individual polarity complexes are required for epithelial polarity and formation of tight junctions.

In summary, this article attempts to point out molecular interactions and regulatory mechanisms that are relevant for the functioning of TJs in health and disease. TJs are formed by a complex network of membrane proteins, cytosolic adaptors and signalling molecules, as well as cytoskeletal linkers. While we now know many of the TJ components, the molecular interactions and regulatory mechanisms are only poorly understood. One of the recent exciting discoveries in the TJ field has been the identification of multiple signalling modules that localize to this intercellular junction and regulate gene expression and cell proliferation, as well as cell polarity and differentiation. It will be a great challenge to investigate these signalling modules at a molecular level and understand their roles in healthy and diseased tissues and organs.

TNF Receptor/ Fas Signaling Pathways

HARALD WAJANT

Department of Molecular Internal Medicine, Medical Clinic and Polyclinic II, Würzburg, Germany
harald.wajant@mail.uni-wuerzburg.de

Definition

The tumor necrosis factor receptor (TNFR) family encompasses a structurally related group of type I cell surface receptors that are involved in a wide variety of immunoregulatory mechanisms but also show increasing relevance in developmental processes. Signaling pathways triggered by TNFRs lead, besides other effects, to ►apoptosis induction or activation of cJun N-terminal kinase (JNK), p38-►mitogen-activated protein kinase (p38-MAPK) or nuclear factor-kappaB (NF-κB).

Characteristics

TNFRs are characterized by a conserved “cysteine-rich domain” (CRD) of about 40 amino acids. Several copies of this motif are found in the extracellular domains of these receptors. Each CRD has typically six conserved cysteines that are part of three intramolecular disulfide bridges. TNFRs are normally activated by ligands of a corresponding phylogenetically related group of trimeric proteins – the members of the TNF ligand family (1). There is also evidence that some environmental stimuli including bile acids and UV can trigger at least some members of the TNFR family in a ligand-independent manner. The members of the TNF ligand family, with the exception of lymphotoxin-α, are primarily expressed as type II membrane proteins (1, 2). In most cases soluble ligands can be derived from the membrane-bound form either by proteolytic processing or by alternative splicing. Importantly, in some cases the soluble and membrane-bound form of a ligand (e.g. TNF) can show considerable differences in their bioactivities (2). Most, if not all TNFRs are self-associated in the absence of their cognate ligand by an N-terminal pre-ligand binding assembly domain (PLAD). Thus, ligand binding induces reorganization of the pre-assembled TNFR complexes in a way that allows the recruitment of intracellular adaptor proteins enabling TNFRs to stimulate a variety of intracellular signaling pathways.

Molecular Interactions

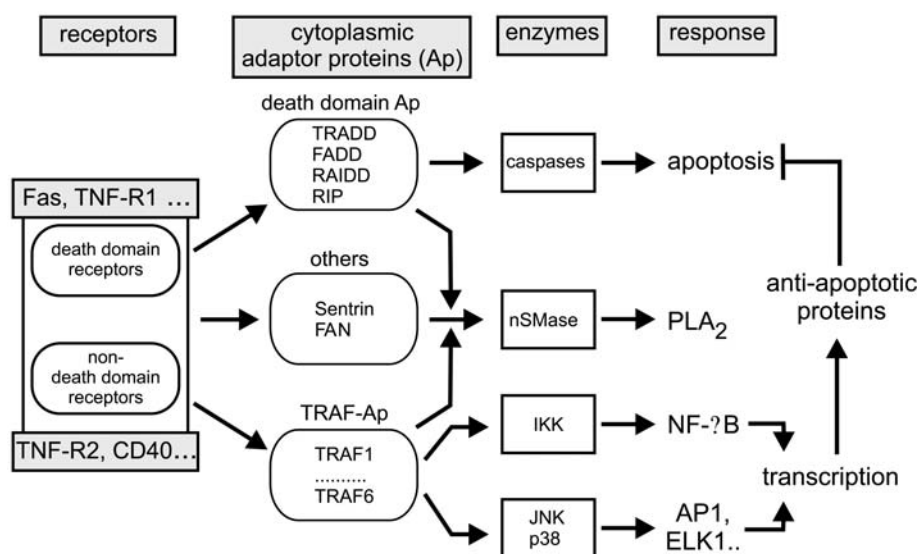

The TNFRs can be divided into two groups, the death receptors and the non-death receptors. The death receptors induce apoptosis in a variety of cells with critical involvement of a conserved part of their

cytoplasmic domain, which has been named the “death domain” (3). In contrast, the non-death receptors lack this structural hallmark and predominantly appear as molecules mediating the activation of NF- κ B and various MAPK cascades. Remarkably, the classification of the TNFR family into death receptors and non-death receptors is partially reflected by the use of two distinct categories of cytoplasmic adaptor proteins. Thus, death receptor triggering leads to the recruitment of death domain-containing adaptor proteins whereas the stimulation of non-death receptors results in the interaction with members of the **tumor necrosis factor receptor-associated factor** (TRAF) family (4).

The molecular mechanisms of death receptor-induced apoptosis have been best studied for **Fas**, TNF-related apoptosis inducing ligand (TRAIL) receptor 1 (TRAIL-R1) and TRAIL-R2, which trigger cell death by a common pathway (3). Upon stimulation of these receptors by their cognate ligands, they interact *via* their death domain with the death domain of the adaptor protein Fas-associated death domain protein (FADD). As well as its death domain, FADD contains a death effector domain, which mediates the secondary recruitment of caspase-8 and caspase-10 into the receptor-signaling complex (3). As several TNFRs are complexed upon ligand binding, the death-inducing signaling complexes (DISC) of TRAIL-R1, TRAIL-R2 and Fas contain several FADD and caspase-8/10 molecules. The dramatically enriched local concentration of caspase-8/10 within the DISC facilitates their activation by induced proximity. Active caspase-8 can

then directly trigger the execution phase of apoptosis by processing of caspase-3. However, dependent on cell type and circumstances, an additional caspase-8 stimulated amplification loop may be necessary to allow robust caspase-3 activation and apoptosis induction. This amplification loop is initiated by caspase-8 mediated cleavage of the Bcl2 family member Bid resulting in the release of a truncated Bid fragment. This fragment in turn is able to trigger Bax/Bak-dependent release of mitochondrial pro-apoptotic factors (e.g. cytochrome c, SMAC/Diablo) into the cytoplasm, leading to the formation of the **apoptosome**, a multi protein complex that activates caspase-3, and inhibition of anti-apoptotic molecules. Active caspase-3 not only executes the apoptotic program but also stimulates caspase-8 processing thereby closing an amplification loop. The cell-type specific importance of the mitochondria-dependent amplification loop for death receptor-induced apoptosis can be experimentally demonstrated by introducing Bcl2, which blocks mitochondria-dependent apoptosis (3). Cells in which death receptor-induced apoptosis is dependent on the mitochondrial amplification pathway, are protected by Bcl2, whereas in cells where caspase-8 robustly activates caspase-3 the same molecules fails to confer protection.

The most intensively studied cellular response predominantly stimulated by non-death domain-containing TNF receptors is activation of transcription factors of the NF- κ B/Rel family. In their inactive state homo- or hetero-dimers of NF- κ B/Rel proteins are sequestered

TNF Receptor/ Fas Signaling Pathways. Figure 1 Signaling pathways engaged by death receptors and non-death receptors of the TNF receptor superfamily. Please note that in some cell types activation of AP1 and/or NF- κ B leads to transcription of ligands of death receptors, thus exerting a pro-apoptotic activity in addition to its anti-apoptotic function shown in the scheme.

in the cytoplasm by intermolecular interaction with ankyrin repeat-containing I- κ B proteins or by intramolecular interaction with an ankyrin repeat-containing carboxy-terminal domain present in some members of the NF- κ B/Rel family (5). Activation of NF- κ B/Rel transcription factors relies on the withdrawal of these proteins from the inhibitory influence of the ankyrin repeats. This is triggered by phosphorylation- and ubiquitination-dependent proteolytic degradation of associated I- κ B proteins or by proteolytic processing of ankyrin-repeat containing NF- κ B/Rel precursors. Both events are initiated by stimuli-dependent activation of the IKK complex. The latter is a multi protein complex of about 900 kD consisting of the regulatory subunit NEMO/IKK γ , the chaperones Hsp90 and Cdc37 and two related kinases, I- κ B kinases 1 and 2 (IKK1, IKK2) that phosphorylate I- κ B proteins and ankyrin repeat-containing NF- κ B precursor proteins (5). The gap between the non-death domain-containing TNF receptors and the IKK complex is closed by adaptor proteins of the TNF receptor-associated factor (TRAF) family (2, 4). These TRAF proteins, in particular TRAF2, TRAF5 and TRAF6, can simultaneously interact with the TNF receptors, atypical PKCs (e.g. PKC ζ) and MAPKKs (e.g. NF- κ B inducing kinase, MAPK kinase kinases 1 and 3) that have been implicated in the activation of the IKK complex. However, the exact molecular mode of IKK activation by TRAF and TRAF associated proteins is not well understood yet. Perhaps, the mechanisms differ for distinct cells and receptors and may also be dependent on the availability of the huge variety of TRAF-associated regulatory proteins (4).

The central roles of death domain containing or TRAF adaptor proteins in signaling by death and non-death receptors can explain the predominant role of these receptors as apoptosis and gene inducers. In this regard the death receptor TNF-R1 represents a remarkable exception as it fulfills *in vivo* mainly non-apoptotic, gene-regulatory functions. These, for a death receptor unusual, signaling capabilities are caused by the fact that TNF-R1, in contrast to most other death receptors, directly binds the death domain-containing adaptor protein TRADD, instead of FADD. As TRADD secondarily interacts with FADD and TRAF2, it connects TNF-R1 with the apoptotic pathway but also with the NF- κ B pathway. Due to the strong anti-apoptotic capacity of the latter, apoptosis induction by TNF-R1 is normally suppressed and is only apparent when the NF- κ B pathway is impaired (5).

Most of the known *in vivo* functions of TNF receptors can be traced back to activation of NF- κ B or apoptosis induction. However, members of the TNF receptor family also stimulate several other signaling pathways leading to the activation of JNK, p38, Erks, Src, Akt or [▶sphingomyelinases](#) (e.g. cited in ref. 2 for TNF).

Although the *in vivo* relevance of these signaling pathways for TNF receptor functions is rather poorly understood, there is evidence that in particular JNK, p38, Akt and sphingomyelinase activation serves among other things to fine-tune the balance between apoptosis-induction and NF- κ B activation.

Regulatory Mechanisms

Each step in TNF receptor signaling can be the target of regulatory mechanisms enabling cells to show flexible responses to stimulation by a given member of the TNF receptor family. Corresponding to the hierarchy of events in TNF receptor-induced signaling pathways, these regulatory mechanisms can be specific for a given receptor, common to a subgroup of TNF receptors (e.g. death receptors) or affect core components of a given pathway.

Receptor-specific regulation is often achieved by control of ligand and/or receptor expression. For example, TNF-R1 and Fas are constitutively expressed on most cell types, whereas expression of the corresponding ligands is very restricted, but can be induced by a huge variety of environmental cues including pathogen-specific molecular patterns, growth factors and cytokines, but also by stimulation of TNF receptors themselves. Remarkably, the signaling pathways involved in regulation of TNF ligands are often the same as those induced by stimulation of TNF receptors, allowing the formation of self-amplifying and auto-inhibitory feed-back loops or cytokine cascades.

Another means to gain receptor-selective regulation is the control of ligand-receptor interaction by neutralizing molecules, including decoy receptors and signaling-incompetent splice forms of the receptor or ligand. There are also examples of receptor-associated intracellular proteins that selectively modulate signaling by a single member of the TNF receptor family. The effects of receptor stimulation on NF- κ B activation and apoptosis-induction can also be determined by regulatory proteins targeting the adaptor proteins that link TNF receptors to these pathways. For example, FADD recruits the proteolytically inactive caspase-8 homologous FLICE-inhibitory protein (FLIP) into the DISC of death receptors, where this protein inhibits activation of co-recruited caspase-8. Moreover, there is evidence that distinct isoforms of FLIP are involved in the activation of non-apoptotic death receptor signaling. TRAF2, the pivotal signaling intermediate of non-death receptors, is also a major target of regulatory proteins, including cellular [▶inhibitor of apoptosis protein 1](#) (cIAP1), which triggers proteosomal degradation of TRAF2, and A20 which blocks TRADD-TRAF2 interaction. Importantly, NF- κ B activation and apoptosis-induction do not act independently, but are rather tightly linked in several ways (5). While NF- κ B

activation prevents apoptosis by up-regulating anti-apoptotic proteins including FLIP and cIAPs, ongoing apoptosis in turn inhibits the NF- κ B pathway by caspase-mediated cleavage of components utilized by this pathway. Amongst others, [▶caspases](#) cleave RIP, I- κ B, IKK2, p50 and p65. In most cases the caspase-derived fragments can act in a dominant-negative manner towards their non-cleaved counterparts (2, 5). Active caspases reduce the amount of signaling intermediates necessary to transduce a NF- κ B response, but also produce peptides that actively inhibit NF- κ B activation.

An additional layer of complexity in TNF receptor signaling is due to the activation of the JNK pathway (6). This pathway leads to the activation of the transcription factor AP1, which is involved in the regulation of members of the TNF ligand and receptor families (6). Looking at the network character of NF- κ B activation and apoptosis-induction, it is evident that there must be complex and manifold crosstalk amongst the members of the TNF receptor family.

Toll-Like Receptor

Definition

Toll-like receptors (TLRs) play an essential role in the innate immune responses. Bacterial pathogens such as lipopolysaccharides (LPS, endotoxin), bacterial lipoproteins, peptidoglycans and also CpG nucleic acids activate innate immunity, as well as stimulate the antigen-specific immune response and trigger the inflammatory response. Members of the TLR gene family convey signals stimulated by these factors, activating downstream signal transduction pathways that result in transcriptional regulation and stimulate immune function. TLRs represent a phylogenetically old system for recognition of bacterial pathogens that was initially discovered in *Drosophila*.

Transcription Coupled Repair

Definition

Following DNA damage, it is essential for a cell to remove damage from actively transcribed regions of the DNA. In human cells repair is more rapid in the transcribed DNA strand compared with the non-transcribed DNA strand. This preferential repair of the transcribed strand is called transcription coupled repair (TCR). TCR is regarded as a subclass of nucleotide excision repair. Transcription coupled repair is defective in patients suffering from [▶Cockayne Syndrome](#).

Synonyms

Transcript elongation; transcriptional elongation

Definitions

Transcription is a complex process that can be divided into several mechanistically distinct steps: (1) assembly of preinitiation complex (transcription preinitiation), (2) promoter opening, (3) transcription initiation, (4) promoter clearance (promoter escape), (5) transcription elongation and (6) transcription termination. During the transcription elongation step, RNA polymerase that has left a gene promoter tracks along the DNA to synthesize up to two million bases of nascent RNA.

Characteristics

Molecular Mechanism of Transcription Elongation

Several RNA polymerases have been described, bacterial RNA polymerase, archaeal RNA polymerase and three eukaryotic RNA polymerases. All these polymerases show significant sequence similarity and

may have a common evolutionary origin. Therefore, the basic mechanisms of transcription elongation are likely to be very similar among these polymerases. Because bacterial RNA polymerase and eukaryotic **▶RNA polymerase II** have been extensively characterized, this essay will focus on these polymerases.

Bacterial RNA polymerase, in its 'core enzyme' form, comprises five proteins; two α subunits and one each of β' , β and ω subunits. The σ subunit, a constituent of the 'holo enzyme', which plays a critical role in transcription initiation, is considered to dissociate from the core enzyme at the onset of transcription elongation. However, recently this classic σ cycle model has been challenged (1). Eukaryotic RNA polymerase II comprises twelve subunits, Rpb1~12. Rpb3 and Rpb11 are homologous to bacterial α , whereas Rpb1, Rpb2, and Rpb6 are homologous to bacterial β' , β and ω respectively.

During transcription elongation, RNA polymerase forms a ternary complex together with template DNA and nascent RNA. The term 'transcription elongation complex' is often used to refer to this ternary complex or to this complex and associated regulatory proteins as a whole. Within the transcription elongation complex, 12–15 bases of DNA are unwound to form the transcription 'bubble' and 3'-terminal 8–9 bases of RNA transcript are contained by forming a hybrid with the template strand of DNA (2). The growing 3' end of the RNA transcript is usually maintained at the active site of RNA polymerase.

Transcription elongation is considered to proceed as follows. An NTP complementary to the next position on the DNA template fills the open substrate-binding site of RNA polymerase. A phosphodiester bond is formed between the 3'-hydroxyl group of RNA and the α -phosphate of the NTP. Then, RNA polymerase translocates one nucleotide forward or downstream with respect to the nucleic acids.

Regulation of Transcription Elongation

Transcription elongation is positively and negatively regulated by cis-acting elements (3). The cis-acting elements are mainly located on nascent transcripts and affect the polymerases that have read through the corresponding DNA elements. Types and roles of RNA elements have been extensively characterized in prokaryotes, while much less is known about these elements in eukaryotes. By forming structures that destabilize the transcription elongation complexes, RNA elements often cause pause, arrest or termination of RNA polymerases without the aid of protein factors. In this context, pause is a transient inactive state of RNA polymerase. Arrest is a more persistent state that eventually leads to termination unless reactivated by a positive **▶transcription elongation factor** such as

bacterial GreB or eukaryotic TFIIS. This type of RNA element is found in the bacterial *his* operon, for example. Other types of RNA elements serve as platforms for RNA-binding proteins. A prominent example in prokaryotes is the Rho utilization (*rut*) site, a negative regulatory element bound by the transcription termination factor Rho. In eukaryotes, the Tat response (TAR) element, a positive regulatory element found in the human immunodeficiency virus (HIV) gene, serves as a binding site for the viral activator Tat and cellular cofactors.

Transcription elongation is positively and negatively regulated by trans-acting factors as well (3, 4). A number of transcription elongation factors have been identified in both prokaryotes and eukaryotes (Table 1). Transcription elongation factors regulate the process of transcription elongation in at least three distinct ways. The first class of transcription elongation factors binds RNA polymerase to modify its catalytic activity, thereby inducing or releasing pause or arrest. This class includes NusA, NusG and GreB in prokaryotes and TFIIF, TFIIS, elongin, ELL, DSIF and NELF in eukaryotes. The second and third classes of transcription elongation factors are eukaryote-specific.

The second class regulates the phosphorylation status of RNA polymerase II (4). The Rpb1 subunit of RNA polymerase II has a unique C-terminal domain (**▶CTD**) that contains the phosphorylatable heptapeptide Tyr-Ser-Pro-Thr-Ser-Pro-Ser, which is repeated 52 times in mammals. Transcription elongation factors P-TEFb and Fcp1 are a kinase and a phosphatase specific to the CTD, respectively. Phosphorylation of the CTD is dynamically regulated during transcription and thought to play an important role in efficient transcription elongation and mRNA processing. CTD phosphorylation reverses the transcription repression imposed by the negative transcription elongation factors DSIF and NELF.

The third class of transcription elongation factors regulates transcription elongation through chromatin. In eukaryotes, packaging of nuclear DNA into chromatin poses a considerable problem for the progression of RNA polymerases. Transcription elongation factors such as FACT and protein methyltransferases Set1 and Set2 appear to assist RNA polymerase II in that process. It is proposed that these factors travel along the DNA with the transcription elongation complex and change chromatin structure through interaction with or covalent modification of histones.

Coupling of Transcription Elongation to Other Biochemical Reactions

In prokaryotes, transcription elongation is coupled to translation. In prokaryotes, transcription and translation are not spatially separated as in eukaryotes and,

Transcription Elongation. Table 1 A partial list of transcription elongation factors

Name	Function
Prokaryotes	
GreA	reactivates from arrest
GreB	reactivates from arrest
NusA	involved in termination and anti-termination
NusE	involved in termination and anti-termination
NusG	involved in termination and anti-termination
Eukaryotes	
TFIIS	reactivates from arrest
TFIIF	enhances the rate of transcription elongation
Elongin	enhances the rate of transcription elongation
ELL	enhances the rate of transcription elongation
Tat-SF1	enhances the rate of transcription elongation
DSIF/Spt4-Spt5	activates or represses transcription elongation
NELF	represses transcription elongation with DSIF/Spt4-Spt5
P-TEFb/Cdk9-Cyclin T	phosphorylates the CTD
Fcp1	dephosphorylates the CTD
Spt6	interacts with histones
FACT/Spt16-Pob3	interacts with histones H2A-H2B
Paf1 complex	recruits Set1/COMPASS
Set1/COMPASS	methyates histone H3
Set2	methyates histone H3

moreover, nascent transcripts for protein-coding genes are usually mature mRNAs. Thus, there is no conceptual difficulty in coupling between transcription and translation. Indeed, it is generally accepted that translation of bacterial mRNA initiates before completion of transcription. Translation can even affect transcription in the process called ►**attenuation**. In the *trp* operon encoding tryptophan biosynthetic enzymes, for example, availability of the amino acid tryptophan regulates the progression of ribosomes at the 5' portion of the mRNA, which, in turn, regulates the progression of the preceding transcription elongation complex. Overall, this allows feedback control of the intracellular tryptophan level.

In eukaryotes, transcription elongation by RNA polymerase II is tightly coupled to mRNA processing, i.e. 5' capping, splicing and 3'-end processing (5). These processing reactions, once thought to be

post-transcriptional events, are now believed to occur co-transcriptionally. Capping of mRNA occurs as early as when the first 20–30 nucleotides of nascent transcript have been synthesized. Splicing of introns at the 5' portion of a gene initiates before completion of transcription. 3'-end processing, i.e. transcript cleavage and polyadenylation, coincides with transcription termination. The capping enzyme stably associates with the transcription elongation complex at the early stage of transcription elongation. Moreover, its catalytic activity is stimulated by components of the transcription elongation complex, enabling efficient 5' capping. Similarly, components of the splicing and 3'-end processing machinery interact with the transcription elongation complex. An emerging view is that the phosphorylated CTD may serve as a scaffold for all these processing events.

Transcription elongation is also coupled to DNA repair in both prokaryotes and eukaryotes (6). DNA lesions within the coding region, caused by UV light or chemical mutagens, often block the progression of RNA polymerases. Stalled transcription elongation complexes are intrinsically inhibitory to DNA repair because they prevent access of repair enzymes to damaged sites. However, normal cells can remove DNA lesions in the coding region considerably faster than those in the genome overall. This process, called ►transcription-coupled repair (TCR), requires special protein factors in addition to the classic DNA repair machinery. TRCF in prokaryotes and CSB in eukaryotes are shown to be involved in TCR. These factors are proposed to function by removing stalled polymerases from DNA lesions and by recruiting repair enzymes to the lesions.

Genes and Pathways Regulated at the Level of Transcription Elongation

In prokaryotes, a number of genes and pathways are known to be regulated at the transcription elongation level. As mentioned above, many amino acid biosynthetic operons are regulated by attenuation mechanisms. In addition, synthesis of ribosomal RNA and ribosomal proteins is shown to be regulated by mechanisms that involve RNA elements and the NusA protein.

In eukaryotes, relatively little is known about target genes and pathways. However, many of the so-called ►immediate-early genes that are rapidly induced by environmental stresses or extracellular stimuli appear to be regulated at the transcription elongation level. The best-characterized example is *hsp70*, a major heat shock-inducible gene encoding a molecular chaperone. Transcription elongation on *hsp70* is normally down-regulated by DSIF and NELF at the promoter-proximal region. Upon heat shock, P-TEFb is rapidly recruited onto the gene and phosphorylates the CTD of the stalled RNA polymerase II, thereby activating transcription elongation.

Regulation of transcription elongation also plays an important role in the proliferation of some viruses (7). During the lysogenic cycle of bacteriophage λ , expression of the viral late genes is down-regulated by premature transcription termination. Upon expression of the viral proteins N and Q, they activate transcription elongation through multiple interactions with RNA elements and host transcription elongation factors, allowing for entry into the lytic cycle. The life cycle of HIV is regulated by a mechanism very similar to bacteriophage λ . The viral protein Tat induces the synthesis of full-length viral transcripts through interaction with the TAR RNA, P-TEFb and other

cellular proteins, leading to viral production. Hepatitis delta virus (HDV) is unique in that the RNA genome replicates through RNA-dependent RNA synthesis by RNA polymerase II, a DNA-dependent RNA polymerase. The viral protein HDAg activates otherwise inefficient transcription elongation on the unusual RNA template through interaction with RNA polymerase II. Thus, these viruses use the host transcription elongation machinery in some way or another for the benefit of viral proliferation.

Clinical Relevance

Cockaine syndrome is the result of a mutation in the human *CSB* gene. The clinical phenotype of this hereditary disease is characterized by postnatal growth failure, neurological dysfunction, cachectic dwarfism, photosensitivity, sensorineural hearing loss and retinal degradation.

In acute myeloid leukemia, the human *ELL* gene on chromosome 19 undergoes frequent translocation with the *MLL* gene on chromosome 11. The translocation t(11;19)(q23;p13.1) results in production of the MLL-ELL chimeric protein, which seems to have transforming activity. It is not known whether aberrant regulation of transcription elongation is responsible for the disease.

HIV is the causative agent of AIDS, while HDV is a causative agent of acute and chronic hepatitis, cirrhosis and hepatocellular carcinoma. Tat and HDAg, encoded by HIV and HDV respectively, are both essential for viral proliferation. These viral proteins and the host transcription elongation machinery are thus potential targets for the development of antiviral therapies.

Transcription Factor

Definition

Transcription factors regulate gene activity by binding to DNA regulatory elements in target genes. Basal transcription factors bind to the basal promoter of target genes, while regulatory transcription factors bind sequences further upstream from the initiation site.

The unique combination of binding sites and transcription factors used determines when and where a gene is active. The term transcription factor (TF) usually stands for DNA-binding transcription factors (activators or repressors) but strictly speaking also includes the non-DNA binding adaptor proteins such as the mediator complex.

- [Helix-Loop-Helix Transcription Factors](#)

Definition

Whole genome sequencing has clearly shown that organism complexity arises from the complexity of the regulatory network controlling gene activity, rather than from the invention of new genes. Key components of gene regulation are ► [transcription factors](#), which can be defined by their location relative to the transcriptional start site of a particular gene.

First, general or basal transcription factors are required for basic ► [promoter](#) function (► [preinitiation complex](#) ► [PIC](#)) and are recruited directly to the vicinity of the transcriptional start. These complexes may have a different composition depending on the gene and the tissue (1).

Second, transcriptional activators or repressors can bind either to promoter upstream binding sites or to DNA binding sites (► [enhancers](#) or ► [silencers](#)) separated from the promoter by thousands of base pairs. Several enhancers may act in synergy with promoter upstream elements or may lead to a reduced gene activity in combination with silencers (1).

Characteristics

Basically, transcription factors are defined by two properties, they bind to DNA and they influence gene activity. The ability to regulate gene activity is often not well defined and usually is mediated by cofactors or cofactor complexes interacting with the activation or the repression domain of the transcription factors. DNA binding is mediated by a limited number of different ► [DNA binding domains](#), which are used to group transcription factors into different classes, as

explained below. This grouping is according to the generally accepted classification as explained in detail in ►<http://www.gene-regulation.com/pub/databases/transfac/cl.html>. In addition to the clearly defined classes described below, other transcription factors exist which cannot clearly be grouped into these categories.

Basic Domains

The basic region dictates DNA-sequence specificity by binding into the major groove of the DNA. This however is not sufficient for specificity, since usually the recognition helix is in contact with only 3–5 nucleotides. An adjacent dimerization domain, which allows for hetero or homodimerization, is the prerequisite for sequence specific DNA binding mediated by both basic domains. Amphipathic alpha helices that allow for dimerization are either ►[helix-loop-helix](#) motifs (b►[HLH](#)) or ►[leucine zipper](#) structures (b►[ZIP](#)) consisting of repeated leucine residues at every seventh position. Human genome sequencing has revealed about 300 genes coding for basic-helix-loop-helix and basic-leucine zipper proteins (2).

Zinc-Coordinating DNA-Binding Domains

Two zinc-coordinating DNA-binding domains differing in size, composition and function are present in each molecule of the ►[nuclear receptors](#). These receptors bind to lipophilic hormones such as steroids, thyroid hormone or others. The DNA binding motifs are two ►[zinc finger domains](#), each finger comprising 4 cysteine residues coordinating one zinc ion. The sequence between the first two cysteines of the second finger mediates dimerization upon DNA-binding.

A related, but different zinc finger motif comprises two cysteine and two histidine residues coordinating one zinc ion. This structure is exemplified by the TFIIIA and Krüppel factors and is found in many variants of DNA binding domains harboring a range of 2 to 36 individual fingers. This gene family is the largest transcription factor family in the human genome with about 900 different members (2). For those factors functionally analyzed, it has been shown that transcriptional repression is a common theme for several of these proteins, although activation has also been observed. The zinc finger protein ►[CTCF](#) contains a unique function not seen with any other human transcription factor namely the restriction of enhancer activity to specific genes (3).

►[Helix-Turn-Helix](#)

This type of DNA binding domain consists of three consecutive alpha-helix structures, with helix 3 contacting mainly the major groove of the DNA. Helices 2 and 3 resemble the helix-turn-helix structure of prokaryotic regulators. Within eukaryotes, transcription factors involved in developmental regulation

of gene expression often bind the target DNA *via* a helix-turn-helix motif, which is called a ►[homeodomain](#). This protein family comprises about 250 different members encoded in the human genome (2).

Beta-scaffold Factors with Minor Groove Contacts

These DNA binding motifs are found in important transcription factors like NFκB, p53 and STAT factors. The structure of the Rel-type DNA binding domain (as in NFκB) exhibits a bipartite subdomain structure, with each subdomain comprising a beta-barrel with several loops that form an extensive surface for contacting the major groove of the DNA.

Cellular and Molecular Regulation

Gene regulation is mediated by a complex interplay of regulatory events. For the sake of clarity, these events will be separately explained based on the type of regulatory mechanism as well on the order of events. These events are separated into those mechanisms regulating the availability of the transcription factors through ►[signal transduction](#) pathways (upstream events) from mechanisms mediating the regulatory signal from the DNA bound transcription factor to the gene (downstream events).

Upstream Events: Signal Transduction Pathways

Signal transduction in the context of gene regulation is mediating a signal from the outside of a cell to the transcription factors regulating target genes. A large group of proteins are mediating different signal transduction pathways, which are briefly summarized below and classified according to the inducing signal (4).

Growth Factors

Upon growth factors binding to the extracellular domain of ►[receptor tyrosine kinases](#) on target cells, these receptors dimerize. This induces autophosphorylation on tyrosine residues in the intracellular receptor domain, which serves as a signal to trigger a complex cascade of cytoplasmic protein phosphorylations finally ending up in the nuclear translocation or activation of transcription factors.

Peptide Hormones

►[Seven-transmembrane receptors](#) spanning the cellular membrane seven times can bind peptide hormones on the outside, which induces a conformational change of the receptor, activating G-proteins on the inside. Activated G-proteins induce the synthesis of second messengers, which again induce a phosphorylation cascade resulting in transcription factor activation.

Cytokines

After cytokine binding, ►[cytokine receptors](#) form heterodimeric complexes spanning the cellular

membrane. This activates receptor associated Janus kinases (JAKs) which phosphorylate the receptor and STAT proteins (signal transducer and activator of transcription) on tyrosine residues. The activated STAT molecules translocate as dimers into the nucleus and act as transcription factors by binding to target genes.

Transforming Growth Factor- β

Family members of **transforming growth factor- β** (TGF- β) bind to specific receptors on the outside of target cells. This induces heterodimeric receptor interaction and phosphorylation on serine/threonine residues of these receptors as well as **Smad proteins**. Activated Smads can dimerize, translocate to the nucleus and act as transcription factors.

Lipophilic Hormones

Steroid hormones (like glucocorticoid), thyroid hormone and other lipophilic hormones are transported into the cytoplasm and the nucleus by passive diffusion or active transport. Intracellular or nuclear receptors bind the lipophilic hormones specifically and are thereby activated to function as transcription factors.

Downstream Events

Chromatin Remodeling

Eukaryotic DNA is densely packed into a structure called chromatin. Chromatin consists of DNA wrapped around protein complexes generated from **histones** 2A, 2B, 3 and 4 (nucleosomes). Depending on the precise position of a nucleosome on a particular regulatory DNA region, sequences may not be available for specific binding of transcription factors.

Chromatin remodeling complexes carry out changes in chromatin structure by altering DNA histone contacts within a nucleosome in an ATP dependent manner. Nucleosomes may thereby be shifted on the DNA or the nucleosome contacts to specific DNA sequences may be loosened. Remodeling complexes can be divided into three classes on the basis of the similarities of their ATPase subunits to the Swi2/Snf2, Isw1, and Mi-2 proteins. Direct interactions between transcriptional activators and specific Swi/Snf subunits have been demonstrated (Fig. 1), such that selectivity between different Swi/Snf complexes is explained by specific protein/protein interactions (5).

Chromatin Modifications

In order to be recognized and read by the transcriptional machinery, chromatin has to be specifically modified. These modifications, like acetylation or methylation of the histone proteins, play a dual role. First, they alter the structure of chromatin to control transcriptional initiation and elongation. Second, they provide specific modification marks that are recognized by factors

Transcription Factors and Regulation of Gene Expression. Figure 1 Transcription factors regulate gene activity. DNA (black line) is wrapped around nucleosomes (grey oval spheres). Transcription factors (red ovals) can be bound to upstream promoter elements as well as to enhancer elements separated from the promoter region. DNA bound transcription factors can recruit multi-unit protein complexes involved in different functions. Chromatin remodeling complexes induce ATP dependent sliding of nucleosomes, thereby allowing sequence recognition by other DNA binding factors. Chromatin modification complexes enzymatically modify histones within the nucleosomes. This marks the chromatin for gene activation or repression. The coactivator complex bridges the DNA bound transcription factors with the preinitiation complex (PIC), which allows for efficient RNA polymerase II (Pol II) binding and for start site identification. The grey arrows indicate similar functions and interactions involving transcription factors bound to upstream promoter or to enhancer elements.

involved in gene activation as well as other factors mediating gene silencing.

Some modifications are relatively well understood. For example, **histone-acetyltransferases** (HAT) have been found in the context of **coactivator complexes** associated with DNA bound transcriptional activators (Fig. 1). In contrast, **histone-deacetylases** (HDACs) that mediate the function of corepressor complexes have been detected in the context of DNA bound transcriptional repressors. Histone methylation has been shown to be involved in specific functions depending on which histone and which amino acid is methylated; for example lysine-4 methylation of histone H3 occurs in the context of active genes, whereas methylation of lysine-9 within histone H3 is found on repressed genes in heterochromatic gene regions but also in some euchromatic genes. In addition, arginine methylation, serine phosphorylation and ADP-ribosylation of histones influence gene activity (6).

Interaction with the Preinitiation Complex

Genes coding for proteins are transcribed by ►**RNA polymerase II** (Pol II). Initiation of transcription is only possible after establishing multistep processes that require the assembly of a preinitiation complex (PIC). This large complex is comprised of proteins called general initiation (basal) factors, such as TFIIA, TFIIB, TFIID, TFIIIE, TFIIF and TFIIH. These factors again are multisubunit complexes, the central one of which (TFIID) contains the TATA-DNA sequence binding protein (TBP). These factors are highly conserved and guide Pol II to promoters. In some cases, sequence specific transcription factors, which are bound to promoter upstream elements or to enhancer elements, interact directly with components of the PIC increasing the efficiency of recruiting Pol II to the promoter. Other examples of interaction with the PIC are indirect and involve complexes described in yeast as Mediator and in multicellular organisms as coactivator complexes (1). Again, the purpose of such an interaction is very likely to generate a platform for high affinity binding of the PIC and therefore for increased transcriptional activity (Fig. 1).

Clinical Relevance

Precise gene regulation is required throughout development, for cell differentiation and proliferation, as well as for proper metabolism. Therefore, the temporal and spatial control of gene regulation is one of the most fundamental processes in biology as well as in medicine. Many examples of gene dysregulation are described in the context of pathological situations. Transcription factors mediating gene regulation are therefore of great clinical relevance. The current state of the knowledge of individual transcription factors can be seen at ►<http://bioinfo.weizmann.ac.il/cards/index.shtml>. Below, a few samples are presented by introducing one example for each of the transcription factor classes.

Fos/Jun

The Fos and Jun family members belong to the bZIP class of transcription factors, capable of homo- and heterodimerization. They have been identified as the two subunits that generate the transcription factor AP-1. This transcription factor regulates the expression of multiple genes involved in differentiation, apoptosis and proliferation. Therefore, constitutive activation of either Fos or Jun or both can contribute to tumor formation. The growth promoting function of Jun may be mediated by the repression of tumor suppressor genes.

Id Proteins

bHLH proteins have been found to be involved in muscle and nervous system development, as well as of other cell types. Id proteins have no basic domain and therefore cannot bind to DNA, but possess a HLH domain used for

dimerization with bHLH proteins. The resulting complex is unable to bind DNA and therefore inhibits the function of bHLH proteins. Interestingly, Id proteins are often over-expressed in several human cancers.

Glucocorticoid Receptor

The glucocorticoid receptor is a ligand dependent transcription factor of the steroid receptor superfamily, which binds to DNA and dimerizes *via* the zinc finger domain. Glucocorticoids are the end products of the hypothalamus-pituitary-adrenal axis and are required for homeostasis, cell differentiation, growth control, apoptosis and modulation of inflammatory processes. The use of glucocorticoids as anti-inflammatory and immunosuppressive drugs is widely accepted. Rheumatoid arthritis and many other rheumatoid autoimmune diseases are very sensitive to glucocorticoid treatment.

HOX Proteins

Homeodomain (helix-turn-helix motif) containing transcription factors are required for the regulation of cell proliferation, differentiation and embryonic development. Clustered homeodomain containing genes (HOX genes) determine the anterior/posterior patterning during embryogenesis. Dysregulation of HOX genes often contributes to hematological malignancies.

NFκB

NFκB and related Rel-type factors play an important role in defense against infectious diseases and cellular stress. Activation occurs through a wide variety of signals, such as bacterial products, viral infection, oxidative stress and different cytokines, to name only a few. A major mechanism for NFκB regulation is binding to inhibitory molecules (IκB), preventing the translocation of NFκB into the nucleus. Activation signals are mediated by the release of NFκB from IκB binding. Therefore it is not surprising that aberrant activation of NFκB plays a crucial role in many inflammatory diseases, especially asthma and rheumatoid arthritis. Furthermore, constitutive activation of NFκB can lead to proliferation, inhibition of apoptosis and therefore to development of cancer in various leukemias, carcinomas and adenocarcinomas.

Transcription Factor Associated Complexes

Downstream mediators of transcription factor function have not only been shown to be required for the proper function of transcriptional regulation, but furthermore, in the case of malfunction are the cause of many disorders and neoplasias. Aberrant histone deacetylation is connected to the Rett syndrome, whereas aberrant histone acetylation is associated with several neoplasias. Histone deacetylases are important targets for drugs with potential therapeutic value in the treatment of several of these diseases. Inhibitors of

HDACs are in clinical trials for cancer treatment and are of potential value for the treatment of polyglutamine neurodegenerative disorders.

Transcription Initiation

Definition

Transcription initiation defines the site of, and/or time when, mRNA synthesis begins.

- RNA Capping
- Transcription

Transcription Unit

Definition

Transcribed DNA segment of a gene. The resulting primary transcript still includes introns which are to be removed by RNA splicing.

- Enhancer

Transcriptional Activator

Definition

Transcriptional activator designates a protein that binds specific DNA elements in the regulatory regions of an eukaryotic gene thereby activating the process of transcription.

Definition

The information for the blueprint of an organism is stored in the genome. Segments of nucleic acids, the genes, encode for functional polypeptides or RNAs that are required for construction of an organism during development and maintenance of the functional organization throughout life. However, at any given time, only a fraction of these genes are actively transcribed. Moreover, the expression rate of a gene may change substantially depending on the developmental state of the organism, differentiation into a particular tissue or the presence or absence of extracellular signaling molecules such as hormones, neurotransmitters, cytokines or metabolites. Genes contain regulatory regions, ► **promoters**, ► **enhancers** and ► **silencers** that are used for the temporal and spatial control of gene transcription. The regulatory regions are binding sites for the basal transcriptional machinery, including the ► **RNA polymerase** that synthesizes RNA from the DNA template. In addition, transcription factors binding in a sequence-specific manner to the DNA of the regulatory region are required to accomplish a tight control of gene transcription. Proteins that activate transcription are termed activators and this mode of gene control is known as positive regulation. In contrast, transcription is blocked by repressor proteins and the biological function of repressors is termed negative control.

Characteristics

Transcriptional repressor proteins such as the lac or the tryptophan repressors were first discovered in prokaryotes. The DNA-tethered form of the repressor turns genes off by blocking RNA polymerase binding to the promoter or its movement along the DNA. Thus, a competition between a gene-specific repressor protein and RNA polymerase is common in *E. coli*. Although transcriptional activator proteins such as the catabolite activator protein CAP are also present in bacterial cells, the predominant mode of control is thought to be negative (4). In contrast, many eukaryotic transcriptional activator

proteins are known, establishing the view that positive regulation *via* activator proteins is the predominant mode of gene control in eukaryotes. There are two main reasons for the predominance of transcriptional activators in eukaryotes. First, the chromatin structure produces a restrictive ground state, i.e. most promoters are inaccessible to the RNA polymerases and transcriptional activators are required for eukaryotic genes to be transcribed. Transcriptional repressors would therefore exhibit a redundant biological activity. In contrast, the RNA polymerase in bacteria generally has access to the promoters, thus defining a nonrestrictive transcriptional ground state in bacteria. Second, taking a teleological view, positive regulation seems more efficient than negative regulation in a multicellular organism and seems a common sense solution. However, economical design principles do not always define cellular regulation mechanisms. Today, we know that transcriptional repression is quite common in eukaryotes, indicating that transcriptional repressors play an important role in the regulation of eukaryotic genes.

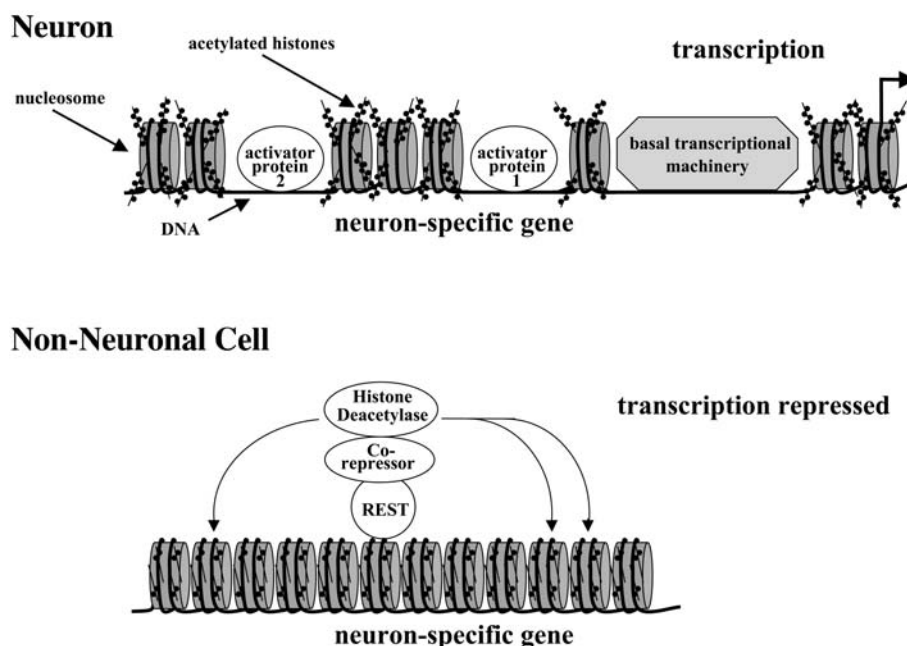

Mammalian transcriptional repressors can be classified as passive or active repressor proteins (1). Passive repressor proteins do not have intrinsic repressing activity or a portable repression domain. Rather, these proteins repress RNA synthesis by competing with transcriptional activators for DNA binding, by forming inactive heterodimers with transcriptional activators rendering them incapable of interaction with DNA or by binding to coactivators required for the transcriptional activator proteins. Thus, passive repressor proteins transmit their biological function either *via* DNA- or protein-protein interaction. The “inducible cAMP early repressor” (ICER) is an example of a passive repressor protein. ICER is encoded by the cAMP response element modifier (CREM) gene that encodes more than 10 splice variants, including activators and repressors. ICER contains the basic region leucine zipper domain necessary for dimerization and DNA binding, but lacks the two glutamine-rich activation domains necessary for transcriptional activation. Thus, ICER occupies the DNA-binding site *via* the basic region and may additionally induce the formation of non-functional heterodimers. In a broad sense, IκB can also be classified as a passive repressor because it interferes with transcriptional activation of NFκB-responsive genes by preventing nuclear translocation of NFκB.

Active mammalian transcriptional repressor proteins have an intrinsic repression activity that targets the chromatin organization of the genome. This type of transcriptional repression is activator-independent and functions over long distances. Two types of active transcriptional repression can be distinguished, transcriptional repression *via* ► **histone** deacetylation and gene silencing *via* histone methylation and ► **heterochromatin** formation.

A critical determinant in the regulation of eukaryotic genes is the structure of the chromatin. The fundamental building blocks of the chromatin are the ►**nucleosomes** with two molecules each of the histones H2A, H2B, H3 and H4 building the core histone and the 147 base pairs of DNA wrapped around this histone octamer. The single nucleosomes are linked by short stretches of DNA and by the linker histone H1. The N-terminal regions of the core histones are often modified by acetylation, methylation or phosphorylation. Histone acetylation is of major importance for the regulation of gene transcription. The acetylation of lysine residues reduces the net positive charges of the core histones, leading to a decrease in their binding affinity for DNA. The termini are subsequently displaced from the nucleosome and the nucleosome unfolds providing access for transcription factors. Deacetylation of histones by ►**histone deacetylases** removes the acetyl group from the ϵ -amino group of lysine residues of histones allowing ionic interactions between the negatively charged DNA phosphate backbone and the positively charged amino termini of the core histones. This results in a more compact chromatin structure that is not as accessible for the transcriptional machinery. While

histone acetylation and hyperacetylation has been correlated with transcriptionally active chromatin, histone deacetylation is thought to be involved in repression of transcription. Histone acetylation and deacetylation are claimed to be major regulatory mechanisms of transcription that function by modulating the accessibility of transcription factors to their binding sites on DNA. Likewise, mammalian transcriptional repressor proteins have been described that block transcription by recruiting histone deacetylases to the promoter (3). The histone deacetylases may be directly bound to the repressor protein or bind *via* adaptor proteins such as mSin3A or the nuclear corepressors N-CoR or SMRT.

The zinc finger protein RE-1 silencing transcription factor (►**REST**) that is mainly expressed in non-neuronal cell types functions as a negative regulator of neuron-specific gene transcription. REST recruits histone acetylases to neuronal genes, resulting in removal of acetyl groups from the core histones. Consequently, the neuronal genes are embedded into more tightly packed chromatin that is inaccessible for transcriptional activators (Fig. 1, bottom). In neurons, REST is expressed in extremely low concentrations.

Transcriptional Repression. Figure 1 The transcriptional repressor REST controls neuron-specific gene transcription via recruitment of histone deacetylases. In neurons, only very low levels of REST can be detected. In fact, a decrease in the REST concentration during neuronal differentiation is most probably the essential prerequisite for neuronal genes to be transcribed. The chromatin configuration of neuronal genes is open, due to an extensive acetylation of the core histones. Transcriptional activators as well as the RNA polymerase II complex can gain access to the DNA and trigger gene transcription. In nonneuronal tissue, however, REST is present and binds in a sequence-specific manner to several neuronal genes. Using the mSin3A protein as a bridge, REST recruits histone deacetylases to the transcription unit. The deacetylation of histones results in an enhanced binding between the histones and the DNA, thus impairing the binding of transcription factors to their specific DNA sequences. Moreover, further compaction of the chromatin is accomplished by inducing interactions between neighboring nucleosomes.

Therefore, the chromatin has an open configuration, allowing transcriptional activators to bind and initiate transcription of neuronal genes (Fig. 1, top). Gene transcription is thus the result of a relief of repression. DNA in vertebrates is subjected to methylation of cytidine bases mainly within the dinucleotide C^mpG. This modification of DNA is primarily associated with transcriptional repression. Methylated DNA may block access of sequence-specific transcription factors or may transform the methylated DNA sequences into a condensed state. Methylated DNA interacts with methylation-specific transcriptional repressor proteins, most prominently the MeCP2 protein that binds to single, symmetrical C^mpG pairs regardless of the sequence context. MeCP2 represses transcription *via* recruitment of histone deacetylases to methylated DNA regions, thus compacting the nucleosome array. MeCP2 thus connects DNA methylation with histone deacetylation. Inhibitors of histone deacetylases such as trichostatin A are, however, only able to partially relieve MeCP2-mediated transcriptional repression, indicating that MeCP2 may have a second way to repress transcription aside from the recruitment of histone deacetylases.

Transcriptional repression *via* histone deacetylation is gene-specific, i.e. histone deacetylases have to be recruited to the transcription unit either by sequence-specific repressor proteins or by methylation-specific transcription factors. Therefore, only a small portion of the genome is affected by histone deacetylation induced chromatin compaction at a specific time point. In contrast, gene silencing makes a larger portion of the genome inaccessible for transcriptional activation, thus acting in a regional manner. The eukaryotic genome is divided into euchromatin and heterochromatin, the latter representing a relatively inaccessible form of chromatin. How are heterochromatin domains established and maintained? Based on studies with fruit flies, yeast and mammals, the following stepwise model has been proposed. First, the amino termini of the H3 histones are deacetylated by histone deacetylases and subsequently methylated on lysine residue 9 by methyltransferases. Secondly, the H3-mLys9 modification functions as a high affinity binding site for the silencing protein, heterochromatin protein 1 (HP1), which thirdly, oligomerizes and extends the heterochromatic region into neighboring chromatin (2). The fact that terminally differentiated cells such as plasma or glial cells exhibit large-scale heterochromatinization, further indicates that gene silencing *via* formation of facultative heterochromatin is part of the genetic alterations occurring during development.

Transcriptional repression *via* recruitment of histone deacetylases and gene silencing *via* HP1 induced heterochromatin formation represent two different modes of transcriptional repression. However, the

sequences of biochemical reactions are connected, and, in fact, transcriptional repressor proteins may block transcription using both mechanisms. MeCP2 triggers histone deacetylation by recruitment of histone deacetylases, but the deacetylation of the histone tails is necessary for histone methylation to take place. Moreover, MeCP2 associates *in vivo* with [▶histone methyltransferases](#) that are able to methylate the lysine 9 residue of H3. This H3-mLys9 subsequently recruits the heterochromatin inducing protein HP1, the starting point for the establishment of facultative heterochromatin. Likewise, REST and the Krüppel associated box (KRAB) repressor proteins are reported to induce gene silencing in addition to the recruitment of histone deacetylases. The observations that the corepressor protein KRAB associated protein 1 (KAP1) and the REST corepressor protein CoREST are able to attract HP1 suggests that REST and the KRAB repressor proteins induce gene silencing that spreads beyond the transcription unit where REST or the KRAB proteins were bound in the first place.

Clinical Relevance

While transcriptional repression and gene silencing are essential for maintenance of the cellular integrity of a multicellular organism, aberrant silencing may cause diseases. In a wide variety of human cancers, for instance, a genome-wide DNA hypomethylation is observed, suggesting that this modification is the molecular reason for chromosomal instability and tumor formation. The observation that tumor suppressor genes are silenced by aberrant hypermethylation has led to the use of DNA methyltransferase inhibitors such as 5-aza-2'-deoxycytidine in the treatment of cancer. Mutations in the gene DNMT3B encoding a DNA methyltransferase are found in the human ICF syndrome (immunodeficiency, centromeric heterochromatin instability, facial anomalies) and cells of patients with this disease show an extensive loss of methylation from the pericentromeric heterochromatin. Mutations in the X-linked MeCP2 gene are the major cause of RETT syndrome, a neurological disorder characterized by the loss of speech and hand skills, microcephaly and seizures. Histone deacetylase inhibitors have been tested as a new class of anticancer drugs. Inhibition of histone deacetylases causes a hyperacetylation of histones and a diminished methylation-associated gene silencing. In addition, the histone deacetylase inhibitor valproic acid is used as an established drug in the long-term therapy of epilepsy. The wide range of diseases caused by aberrations in transcriptional repression sheds light to the importance of understanding how negative gene regulation functions in eukaryotes.

Transcriptional Repressor

Definition

Transcriptional repressor denotes a protein that binds specific DNA elements in the regulatory regions of an eukaryotic gene and which represses the process of transcription.

► [Protein Interaction Analysis: Variations of the Yeast Two-Hybrid System](#)

Transcriptional Termination

Definition

Termination defines the step in which a fully mature RNA transcript is formed and released from the RNA polymerase and the DNA template.

► [Core Promoters](#)

Transcriptome

Definition

The transcriptome can be defined as the complete collection of transcribed elements of the genome present at any given moment in a cell or tissue, and its behaviour over time and cell states. In addition to mRNAs, it also represents non-coding RNAs that are used for structural and regulatory purposes. Alterations

in the structure or levels of expression of any one of these RNAs or their proteins can contribute to disease. An understanding of the transcriptome will provide a valuable tool in the research for novel drugs.

Transduction

Definition

Transduction describes the transfer of a gene from one cell to another, or from one genomic location to another, by means of bacteriophages, viruses, transposable elements and DNA injection. The genetic material is integrated into the genome of the host cell or integrated by formation of a plasmid. If integration is not achieved, the transducing DNA is unable to replicate. Transduction is applied to the transfer of bacterial and eukaryotic genes in biotechnology.

Trans-Epithelial Electrical Resistance

Definition

Trans-Epithelial Electrical Resistance (TER) is a measure of paracellular permeability to passive ion flow and is based on a simplified circuit model of epithelia. A current pulse of known amplitude is passed across the epithelium, and the corresponding trans-epithelial voltage deflection is measured. The TER is then calculated from Ohm's law and has units of Ohm. cm^2 . Alterations in TER are considered to be a sign of altered tight junction permeability.

Transformation

Definition

Transformation defines the introduction of foreign DNA into cells by a physical method. Methods are generally quite species and strainspecific, poorly understood, and performed according to empirical recipes. The most efficient method for bacteria, and also the best defined, is electroporation.

In the context of tumorigenesis, transformation is the collection of events that leads to the loss of normal cellular function and acquisition of tumorigenic properties (malignant transformation). Transformed cells become independent of growth factors usually needed for cell growth. Normal laboratory tests for cellular transformation are used as a model to predict *in vivo* carcinogenesis. Tests are, for instance, for the ability to grow without attachment to plastic surfaces, to grow in semisterile media (e.g. agar) and the ability to form tumours when injected into nude mice.

Transgene

Definition

A transgene is a cDNA or an additional extra gene introduced into the host genome. It usually contains the coding sequence and regulatory regions of a gene. The exogenous DNA fragment can be delivered to cells by naked nucleic acid transfer of viral or non-viral vectors.

Definition

Mammalian cells can be manipulated by introduction of a ► [transgene](#) delivered as DNA or by a virus vector. Transgenic mice are created by direct DNA micro-injection into a fertilized mouse egg. In contrast, gene transfer into human cells is best accomplished using other methods of DNA transfection or by infecting the cells with a virus vector. When the transgene must persist in the target cell for many generations, retrovirus vectors have the advantage of their natural ability to integrate into the host chromosome. Retrovirus vectors are made by replacing virus genes with the gene to be transferred and then packaging the recombinant

genome into virus particles. These vectors are particularly well suited for gene transfer into stem cells, which must divide extensively to repopulate tissues with mature cells. These properties make retrovirus vectors the method of choice for developing novel stem cell gene therapies. However, gene transfer is only effective if ►**transgene expression** can be controlled appropriately, and a transgene that is not transcribed will not be functional. Such ►**transgene silencing** is very common and is dependent on several factors. Of primary importance are position effects dictated by the local chromatin structure of the DNA that flanks the integrated transgene. In addition, the specific cis-acting DNA regulatory elements that control transgene expression and the concentration of trans-acting factors that recognize them in the cell are major players that influence whether a transgene will be silent or active. Finally, ►**silencer** sequences present in retrovirus vectors are recognized very effectively in stem cells and contribute to silencing of transgenes. In order to optimize transgene expression, it is essential that the mechanisms that control transgene silencing be elucidated. To overcome transgene silencing will require the use of strong positive regulatory elements that can open ►**chromatin structure** on the transgene or that block the spread of closed chromatin into the transgene.

Characteristics

Control of Transgene Expression

The pattern of transgene expression is defined by its cis-regulatory elements such as enhancers and promoters that are bound by transacting factors. However, the interaction of transacting factors with DNA sequences can be impaired by ►**epigenetic** mechanisms that influence the organization of the chromatin structure and patterns of DNA methylation. This level of transcriptional control allows the genetic material to be in an “active or inactive” state, which can be inherited over many cellular generations.

The basic unit of chromatin structure is the ►**nucleosome**, composed of an octamer of four different histone proteins. Nucleosomal histones have a dual function in activation or repression of gene expression. In a nucleosomal configuration, genomic DNA is only partially accessible to transacting factors. However, when DNA-histone interactions are relaxed, DNA becomes more accessible to transacting factors that can bind their target DNA sequence and influence gene expression. This active chromatin has a histone code characterized by histone acetylation, methylation at specific residues as well as other covalent modifications. The nucleosome organization can be condensed through the action of the linker histone H1 and other proteins into a compact organization, commonly referred to as ►**heterochromatin**, that prevents gene expression. Such condensed chromatin has a repressive

histone code in which the histone tails are deacetylated and methylated at specific residues that differ from those on active chromatin. When the nucleosome organization is “decondensed” in ►**euchromatin**, it is permissive for transcription.

The organization of nucleosomes is regulated not only by the covalent histone modifications described above but also by remodeling complexes, replacement of core histones with histone variants and by certain transcription factors. The gene-specific recruitment of ATP-dependent chromatin remodeling and/or histone modifying complexes can be mediated by DNA interacting factors. Indeed, different DNA binding activators and repressors are capable of recruiting remodeling or modifying complexes at gene regulatory regions.

Position Effects and Transgene Silencing

Transgene integration into the genome is essentially random. They can integrate close or into a heterochromatic region thereby preventing transcriptional activation (Fig. 1). This can result in partial or complete transgene silencing, which are referred to as ►**position effects** (PE). PE frequently results from differences in the epigenetic organization of genomic regions and can be sub-categorized according to the pattern of transgene expression. If transgene silencing is complete in all cells of a particular tissue, it is referred to as stable PE. Stable PE is sometimes characterized by a cell-cycle-dependent regulation of transcription, the cell timing position effect (CTPE). CTPE is the result of a chromatin configuration that influences transcription in all cells of the tissue but only during a part of the cell-cycle. In contrast to stable PE, if transgene silencing is variable from one cell to another in the cellular population, it corresponds to an unstable PE and in particular to ►**position effect variegation** (PEV). PEV causes restricted activity of a gene in a subset of cells from a homogenous population. The silencing is randomly set and it can be inherited thereafter. The occurrence of PEV is consistent with cell-to-cell differences in the ability of heterochromatin to invade a particular transgene located in a nearby euchromatic region. This variable capacity to invade euchromatin appears to be dependent on the local concentration of heterochromatic (repressive) and euchromatic (activating) proteins. These two groups of proteins are presumed to be involved in a local competition to either repress or activate the chromatin of a transgene. A concentration change of repressive or activating proteins can result in modification of PEV (1).

Retrovirus Silencing in Stem Cells

Retrovirus vectors are subject to transgene silencing when integrated into preimplantation mouse embryos or after transfer into embryonic and adult stem cells such as hematopoietic stem cells. In more differentiated

Transgene Silencing. Figure 1 Transgene integration appears to occur randomly. If the transgene integrates close to a heterochromatic region, the heterochromatin can cover the transgene and prevent its transcriptional activation. In red are transgene regulatory elements and in blue are trans-acting factors including the transcriptional initiation complex. Grey circles are nucleosomes; in green are heterochromatin related proteins (HP) and in white are H1 histones, which are enriched in heterochromatic regions.

cell types they are highly expressed, suggesting that a gene silencing pathway active in stem cells recognizes the retrovirus DNA as foreign and either silences it or permits low level expression at best. Silencer elements have been discovered and then mutated in retrovirus vectors to increase their expression in stem cells, but even these modified vectors result in modest improvement in expression levels and can still be completely silenced. Retrovirus silencing is established within 2 days of infection into stem cells and at this stage can be reactivated by the histone deacetylase inhibitor trichostatin A, suggesting that a silencing pathway recognizes the retrovirus DNA and deacetylates histones shortly after nucleosomes form on the new provirus. Subsequently, DNA methylation is detectable on the silent provirus as well as the methyl-binding protein MeCP2 and inaccessible chromatin associated with linker histone H1 is established that completes the repressive histone code (2). These findings indicate that retrovirus silencing is a 2-step event with histone modifications occurring first prior to DNA methylation events. However, the DNA methylation step is not required for retrovirus silencing because ES cells that are null for *de novo* methylases silence retrovirus vectors with wild type efficiency.

The role of PE in retrovirus silencing is not precisely known, as retrovirus preferentially integrates into open chromatin in or near genes. However, the fact that the same retrovirus vector can be silent or low expressing at different integration sites in stem cells strongly supports a role for PE together with the retrovirus silencer elements in making the decision to be expressed or silent. The use of stronger promoters within the vector does direct increased expression

levels in stem cells, but never to the levels seen in differentiated cells. Ultimately to protect a transgene delivered by a retrovirus vector or as a DNA fragment from epigenetic silencing, the transgene has to be isolated from its host chromosomal environment. Two groups of elements are capable of preventing abnormal epigenetic regulation, ►locus control regions (LCR) and ►insulators.

Chromatin Organization and the LCR

LCR elements are involved in the expression of tissue-specific genes in mammals. The best characterized is the human β -globin LCR comprised of five Dnase I hypersensitive sites (HS). HS1 to 4 are fully formed only in erythroid cells and HS5 is found in hematopoietic cells. Erythroid specific and ubiquitous trans-acting factors bind these sites and render them hypersensitive to Dnase I by opening up the nucleosome organization locally. Indeed some factors that bind the β -globin LCR (at the different HS) can interact with histone modifying enzymes and others with chromatin remodeling complexes. The binding of these factors to each HS facilitates the formation of a LCR holocomplex that can interact with distant regulatory elements and promotes euchromatin organization within the locus. The LCR holocomplex increases transcriptional initiation at one globin promoter at a time by DNA looping. The LCR may also enhance transcriptional elongation through the gene. In transgenic mouse studies, LCR activity is revealed by expression at all transgene integration sites in a copy number dependent manner. A complete human β -globin LCR efficiently prevents PE in transgenic mice, but an LCR fragment that lacks one of the HS is still subject to PE.

Thus transgene expression regulated by an incomplete LCR can be influenced by the chromatin environment at the integration site (3).

LCRs are generally present in large DNA fragments, which is problematic for their use in retrovirus vectors to overcome transgene silencing. Therefore, different groups have “dissected” the LCR to define modules involved in chromatin activation. Since retrovirus vectors integrate at single copy, the most useful β -globin LCR element is HS3, which can activate the chromatin structure of single-copy transgenes in a chromosomal context. Small LCR cassettes that include HS2, HS3 and HS4 linked to a β -globin gene have been delivered using lentivirus vectors to correct hemoglobinopathies in mouse models. Despite this success, it appears that the lentivirus is also subject to transgene silencing as multiple integration events are required per cell to obtain therapeutic levels of β -globin gene expression. In fact, retrovirus or lentivirus DNA acts as a silencer of linked LCR β -globin transgenes in mice by imposing a repressive histone code and condensed chromatin on the transgene. Therefore, the LCR elements used in virus vectors are not capable of completely overcoming the combined effects of PE and the virus silencing pathways.

PE and Silencer Blocking by Insulator Elements

Insulators are defined as DNA sequences that protect a transgene from PE or from activation by nearby enhancers. The best-characterized vertebrate insulator is the cHS4 element located at the 5' end of the chicken β -globin locus (4). It marks a boundary between an open chromatin domain and a region of heterochromatin. This element insulates transgenes from PE and can block the ability of an enhancer to activate a promoter. Although enhancer-blocking activity by cHS4 is dependent on its CTCF binding site, this site plays no role in blocking PE. The cHS4 insulator has silencer-blocking activity when positioned between retrovirus sequences and an LCR β -globin gene in transgenic mice, showing that a combination of an insulator and an LCR can overcome retrovirus silencing. It is more challenging to incorporate functional insulators into infectious retrovirus vectors. The cHS4 element located in the LTRs of a retrovirus vector protects it from PE in mature cells, but has no effect on retrovirus silencing in ES cells. These results indicate again that PE alone cannot account for retrovirus silencing, and that effective retrovirus vectors must be designed with insulator elements flanking the transgene to protect it from both retrovirus silencers and PE. Unfortunately, it is not possible to transmit the same insulator sequence at two internal positions in a retrovirus vector. Hence, a properly insulated retrovirus vector awaits the discovery of another insulator with silencer-blocking activity to use in conjunction with cHS4 and LCR elements.

Clinical Relevance

Stem cell gene therapy using retrovirus vectors has corrected severe combined immunodeficiency in patients, but two patients have proceeded to develop leukemia caused by integration of the retrovirus vector into the *LMO-2* oncogene and activation of expression (5). This trial shows that stem cell gene therapy can cure genetic diseases but also highlights several drawbacks of retrovirus vector technology. First, any DNA regulatory element in the vector may activate neighboring genes with potentially disastrous complications. The use of enhancer blocking insulators in the LTRs and deletion of viral enhancers may serve to prevent such activation. Second, transgene silencing through PE and the action of retrovirus silencers diminishes the effectiveness of each provirus. The temptation to increase copy number to combat silencing merely increases the number of integrations and the risk of [insertional activation](#). The use of improved vectors with all silencers removed, combined with LCR elements and silencer-blocking insulators may ensure that all integration events are expressed. In this way, the number of integrations into stem cells can be minimized to prevent insertional activation. We now know that stem cell gene therapy can work in the clinic, but to make it safe with optimal expression of the transgene will require a recognition of the importance of transgene silencing in stem cells.

Genetically engineered animals

Definition

Animals into which additional and/or altered genetic information has been introduced are termed transgenic animals. Two principle technical approaches are used to generate transgenic animals: (i) addition of genetic information *via* microinjection of foreign DNA into the pronucleus of zygotes (ii) site-directed mutagenesis of endogenous target genes *via* ►homologous recombination in ►embryonic stem cells (►gene targeting). Transgenic organisms generated by pronuclear microinjection typically over-express the transgene, whereas animals generated by gene targeting are characterized by the deletion or modification of an endogenous target gene (►knock-out ►knock-in). So far, gene targeting is applicable only in mice. Pronuclear microinjection is used in a wide variety of different species.

Characteristics

Our understanding of the genetic mechanisms underlying normal development as well as the development of disease has been revolutionized by the availability of systematically generated transgenic animal models. This has allowed the study of individual genes by specifically altering their functions *in vivo*. The mouse has for a long time been the mammal of choice for experimental genetics and many of the pioneering transgenic techniques have been developed primarily in mice. Today, various transgenic mice are the predominant transgenic models in biomedical research (1).

Genetically engineered mice can be classified according to the type of mutation, its phenotypic consequences and the techniques by which it has been generated:

1. mice with a randomly integrated transgene (pronuclear microinjection)
 - gain-of-function mutation
 - loss-of-function mutation (dominant negative mutation; knockdown)
2. mice with site-directed mutation of an endogenous target gene (gene targeting)
 - mutation active in all tissues
 - deletion of target gene ►(knock-out)
 - modification of target gene
 - expression of novel gene under control of target gene locus (knock-in)
 - spatio-temporally restricted mutation (►conditional gene targeting)
 - conditional deletion of target gene (conditional knock-out)
 - conditional modification of target gene
 - conditional expression of novel gene under control of target gene locus (conditional knock-in)

Pronuclear Microinjection

Generation of transgenic mice by microinjection of DNA into the pronucleus of fertilized oocytes was first reported in 1981 by Gordon and co-workers (2). This method has become a simple and fast standard procedure to generate transgenic mice. In addition to the direct injection of DNA, alternative methods for gene transfer, i.e. retroviral infection, electroporation or calcium phosphate transfection have been described. After gene transfer, the zygotes are transferred into pseudopregnant female mice, which give birth to transgenic offspring after completion of embryogenesis. Some of the founder animals have stably integrated the transgene into their genome. Since integration occurs randomly, integration site(s) and number(s) of transgene copies are unpredictable. Therefore, screening of founder animals, which may

differ in transgene expression, has to be performed. The use of large DNA constructs derived from ►YACs, ►BACs or ►PACs have partially helped to circumvent these limitations. In 20–30% of cases integration of foreign DNA occurs after the first cell-cleavage, thereby creating chimeras, which express the transgene only in a subset of tissues (1).

Depending on the promoter elements used to control the transgene, pronuclear microinjection normally leads to a gain-of-function, i.e. over-expression of the transgene. By expressing a dominant-negative transgene it is possible to create the functional knockdown of an endogenous gene, although this is usually not 100% effective. Recently, transgenic expression of double-stranded RNA (RNA interference) has been shown to reduce host gene expression in mice efficiently (3). Transgene integration into the host genome sometimes interferes with endogenous gene expression and can lead to unintended additional phenotypes. Either by the specific ablation of a particular cell population *via* transgenic expression of a toxin gene or *via* expression of a reporter gene (see below), transgenic approaches have also become convenient genetic tools for cell fate analyses during embryogenesis (1).

Gene Targeting

Probably the most important limitation of the transgenic techniques described above is the fact that they do not allow the site-directed introduction of specific mutations into a host genome. Two ground-breaking discoveries made in the early 1980s have helped to overcome this limitation.

Oliver Smithies was the first to show that gene function could be directly disrupted in mammalian cells by homologous recombination, a process that had been well established for introduction of mutations into yeast cells (4). When foreign DNA homologous to host DNA is introduced into mammalian cells it can recombine (exchange) with homologous sequences of the host genome. Moreover, non-homologous sequences that disrupt critical regions of a host gene can be introduced by homologous recombination, when flanked by arms of homology.

The second major discovery, made independently by two groups (5, 6) was the observation, that pluripotent, uncommitted, embryonic stem (ES) cell lines could be established from the inner cell mass of early mouse embryos. When returned into mouse embryos, ES-cells contribute efficiently to both somatic and germ cells. ES-cells can be maintained indefinitely as undifferentiated cells in culture. However, their differentiation state and germ-line competence depend critically on the culture conditions. So far, germ-line competent ES-cells have been only established in mice.

During the following years, several labs worked on combining the two techniques. In 1989 the first report of successful germ-line transmission of a mutation that had been introduced *via* homologous recombination into mouse ES-cells appeared (7). Gene targeting *via* homologous recombination in ES-cells has revolutionized mouse genetics; up to now, more than a thousand genes have been mutated in mice using gene targeting technology (for an excellent overview, see the mouse knock-out and mutation database, ►<http://research.bmn.com/mkmd>) and the number of publications related to this technology is still growing exponentially (8).

Already from the early studies it had become clear that integration of foreign DNA *via* homologous recombination in ES-cells occurs at very low frequencies and that a common competitive reaction is non-homologous integration at various sites in the host genome. Accordingly, strategies to select specifically for the rare event of homologous recombination had to be developed. This was achieved by using selection markers, for example the *neo* gene, which confers resistance to the antibiotic G418. When placed between homologous sequences the *neo* gene can disrupt a target gene and provide positive selection for cells that have taken up the DNA (Fig. 1). In order to enrich further for homologous recombination events, negative selection markers, like herpes simplex virus thymidine kinase (*tk*), are commonly used. Negative selection markers are placed outside the regions of homology so that inappropriate, non-homologous integration of the targeting construct can lead to expression of the negative selection marker (8).

Gene targeting is normally applied to generate a null-mutation that completely disrupts gene function in all tissues of an embryo throughout life. This strategy however can also be used to introduce novel genes into the disrupted gene locus, thereby creating a knock-in. Such genes could be either genetic markers, for example lacZ or ►GFP, which allow the identification of cells expressing the mutant allele and thereby the tracing of the fate of mutant cells during development, or other genes (homologues, members of gene families) that are then under the transcriptional control of the mutant locus.

Many genes have been shown to serve independent critical functions during normal embryonic development as well as in postnatal life. As a consequence, mice with null-mutations in such genes die during embryogenesis and it has been impossible to analyze additional biological functions in these knockouts. Novel conditional gene targeting strategies employ site-specific recombinase systems, for example the ►*Cre/loxP* system, to restrict mutations spatio-temporally. With this method critical regions of a target gene

Transgenic and Knock-out Animals. Figure 1 Schematic illustration of a general strategy to specifically mutate target genes via homologous recombination in ES-cells (*gene targeting*). After homologous recombination with a targeting vector, the second exon of a target gene is disrupted by a neomycin resistance gene (*neo*). The HSV thymidine kinase gene (*tk*) is lost upon homologous recombination. Dashed lines indicate regions of homology between the targeting vector and the genomic locus. Homologous recombination events can be identified by PCR screening.

are flanked in a first step by short palindromic oligonucleotide sequences, termed *loxP* sites. This modification is silent and does not interfere with normal target gene function. Mice homozygous for the floxed allele can be crossed to mice that express the recombinase *Cre* under the control of a tissue-specific or inducible promoter. Floxed DNA is specifically recognized by *Cre* and excised from the genome. Consequently, the silent mutation becomes activated only at the sites where and when *Cre* is expressed. Recently, alternative recombinases like the yeast derived Flp/FRT systems have been used in conditional gene targeting experiments (9).

Cellular and Molecular Regulation

When interpreting the phenotype of a transgenic animal, potential problems that may complicate or obscure the actual mutant phenotype have to be taken into consideration. Some of these, related to the random integration of a transgene, have been already discussed. Whenever a targeted mutation is inserted into internal exons, truncated protein may still be synthesized from the mutated gene. Residual protein may acquire novel functions and interact with unrelated proteins. Synthesis of residual protein can also be the consequence of aberrant splicing events, activation of cryptic promoters or read-through transcription followed by translation from downstream initiation codons. Production of

residual protein can be circumvented by deleting all coding exons of a target gene. However, this normally leads to the additional loss of intron sequences, which may contain regulatory elements controlling expression of unrelated, distant genes. Removal of introns may also delete so far unknown genes encoded by the opposite strand (for review, see 8). It is also well established that transcription from selection cassettes can interfere with the expression of neighboring genes. For that reason many labs remove selection markers routinely after homologous recombination.

Apart from side effects related to a particular gene locus or targeting strategy, a mutant phenotype can dramatically depend on the genetic background. This has been shown for the mutation of the EGF receptor; mutants die during early embryogenesis or can survive to birth, depending on the genetic background on which the mutation occurs. Finally, members of gene families may have redundant functions and upon deletion of individual family members related genes may compensate functionally (8).

Clinical Relevance

Transgenic animals are also of great importance for modeling fundamental disease mechanisms and for the evaluation of novel therapeutic strategies. Historically, transgenic over-expression of viral or cellular oncogenes, as well as the targeted deletion of prototype

tumor suppressor genes, like Rb or p53, in mice has been instrumental in the understanding of human cancer (10). Today, transgenic animal models are established tools for the analysis of major diseases, as for example neurodegenerative, psychiatric, infectious, cardiovascular, or even complex, polygenic metabolic diseases, like diabetes mellitus.

Trans-Golgi Network

Definition

Proteins synthesized on ribosomes are transported through the Golgi apparatus and then reach the trans-Golgi network (TGN). In this cellular compartment, secreted and plasma membrane proteins are processed and sorted for delivery to various cellular destinations.

In most cells, the TGN has a reticular-like structure and is located in the proximity of the nucleus.

► [Diabetes Insipidus, a Water Homeostasis Disease](#)

Transition

Definition

In cases of non-silent base pair substitutions the original base pair is changed, e.g. from A to B. If A and B are both purines or pyrimidines the process is called a transition, in the case of changes from purine to pyrimidines, respectively, vice versa the process is called ► [transversion](#).

► [Sequence Annotation in Evolution](#)

► [Splicing](#)

Transition State

Definition

The transition state is the state on top of the free energy barrier that separates two states of a chemical reaction. In the context of protein folding the transition state is not one defined conformation, but an ensemble of compact conformations that are at a saddle point of free energy between the molten globule state and the native state. The transition state ensemble is characterized by many native-like contacts and an overall topology close to the native state.

► [Protein Folding](#)

Translation

Definition

Translation is the process during which the coding sequence of a gene that has been transcribed into the sequence of a messenger RNA is translated into the amino acid sequence of a protein (protein biosynthesis). This is done by the ribosome using specific adapter molecules to combine each amino acid with its corresponding codon (an RNA sequence consisting of three nucleotides), and to connect the amino acids that make up the protein.

Definition

▶ **Translation** is a central step in the gene expression pathway and is defined as the cellular process by which the genetic information content of messenger RNA (mRNA) is read and “translated” into protein. It takes place on large ribonucleoprotein complexes called ▶ [ribosomes](#) (1). Translation is usually divided into an initiation, elongation and termination phase (2).

The central concept of translational control is that gene expression can be regulated by the efficiency of utilization of mRNA in specifying protein synthesis (3). Each phase of translation can be under the control of a number of physiological and pathological influences, however, the majority of known control mechanisms target the initiation phase. Translational control is critical for many fundamental biological processes, including cellular growth, embryonic development and the response to biological or environmental cues. Examples of translational control mechanisms with recognized clinical relevance range from cellular stress responses, through the mechanism of insulin action and on to the control of iron metabolism. Viruses can usurp the cellular translation apparatus to preferentially synthesize their own proteins. In this chapter we briefly describe the process of translation in eukaryotic cells and present a selection of known translational control mechanisms.

Characteristics

The ▶ [genetic code](#) is central to translation. Genetic information is written into the genes and transcribed into mRNA using a four letter code based on the

nucleotide bases adenine (A), guanine (G), cytosine (C) and thymine (T) or in the case of mRNA uracil (U). Sets of 3 adjacent bases on the mRNA (called codons) encode the 20 different amino acids that make up the polypeptide chains of proteins. In eukaryotes, polypeptide synthesis usually starts with the amino acid methionine that is encoded by the AUG-triplet nearest to the 5' end of the mRNA (►start codon). It stops when the translation machinery encounters one of 3 stop codons: UAG, UAA or UGA, which do not code for an amino acid. Matching the nucleotide triplets with the corresponding amino acids requires adapter molecules, the transfer RNAs (tRNAs). These are 75–80 nucleotide long RNA molecules that fold into a clover leaf-like structure. The anticodon arm of the tRNA carries a base-triplet that recognizes the codon on the mRNA *via* base pairing. The aminoacyl arm of the tRNA is covalently bound to the appropriate amino acid. Specific aminoacyl-tRNA synthetases ensure that each tRNA is only loaded with the correct amino acid. The ribosome selects aminoacylated tRNA according to the sequence of codons in the mRNA and catalyses the peptide bond formation between the growing peptide and the incoming amino acid. Eukaryotic ribosomes consist of more than 50 ribosomal proteins and 4 different ribosomal RNA (rRNA) molecules. There are 2 subunits, the 40S (Svedberg) and the 60S subunit (1, 2).

Translation is Generally Divided into 3 Phases

Translation initiation is the process that results in the recruitment of the ribosome to the mRNA (Fig. 1). Typically, it begins with the binding of the 40S ribosomal subunit and associated factors near the 5' end of the mRNA. This pre-initiation complex then moves along or 'scans' the mRNA until the AUG codon is reached. The complex then rearranges and the 60S ribosomal subunit joins to form an elongation-competent 80S ribosome. Binding of the 40S subunit is promoted by the 5' cap structure and the 3' poly(A) tail of the mRNA. The hetero-trimeric complex eIF (for eukaryotic ►initiation factor) 4F binds to the 5' cap structure. eIF4F consists of the cap-binding protein eIF4E, the ATP-dependent RNA helicase eIF4A and the multifunctional adapter protein eIF4G. eIF4G interacts not only with the other subunits of eIF4F but also binds ►the poly(A) binding protein (PABP). This mediates a pseudo-circularization of the mRNA, which is important for efficient mRNA translation (4). eIF4G also binds eIF3 and in this way attracts the 40S ribosomal subunit and an associated ternary complex, comprising the initiator-methionyl-tRNA (tRNA_{Met}), eIF2 and GTP, to the mRNA. Following scanning and AUG-codon recognition, 60S ribosomal subunit joining is catalyzed in a GTP-dependent manner by eIF2 and eIF5B (3, 5).

Translation elongation begins with an aminoacylated initiator tRNA in the peptidyl-tRNA (P) site of the ribosome. Aminoacylated tRNA with the appropriate codon-anticodon pairing binds to the aminoacyl-tRNA (A) site of the ribosome. Then, a peptide bond is formed and the resulting dipeptide is translocated from the A-site to the P-site. This leaves the A-site free to bind the next aminoacyl t-RNA and start another elongation cycle. These steps are catalyzed by the eukaryotic ►elongation factors (eEF) 1 and 2 (2).

Translation termination occurs when a ►stop codon is encountered in the A-site of the ribosome. A complex of eukaryotic ►release factors (eRF) 1 and 3 binds to the ribosome, and triggers the release of the finished polypeptide. Subsequently, the ribosome disassembles from the mRNA and dissociates into a 40S and 60S subunit (2).

Mechanisms of Translational Control

Translational control mechanisms are often classed into two major categories, (i) global control that affects all or most cellular mRNAs in a similar manner and (ii) selective control that acts only on a subset of target mRNAs (3, 6).

Global Control of Translation

A common mechanism to stimulate or repress global translation is *via* phosphorylation of translation initiation factors (eIFs). The phosphorylation status of eIFs changes in a cell-cycle-dependent manner, responds to growth regulatory stimuli, and is affected by viral infections and cellular stress. The protein kinases and protein phosphatases that are responsible for the reversible phosphorylation are predominantly regulated *via* 2 major signal transduction cascades. The Ras/MAPK pathway regulates phosphorylation of the cap binding protein eIF4E and the PI3-K/Akt/mTOR pathway controls phosphorylation of the ribosomal protein S6, eIF4G and the 4E-binding proteins (4E-BP).

Cancer. Phosphorylation of translation initiation factors is commonly observed during malignant transformation of cells. ►Oncogenes like c-myc, ras or viral oncogenes can regulate the translation machinery. For example, expression of eIF4E and the α -subunit of eIF2 (see below) is increased in c-myc-transformed cells. eIF4E is itself considered an oncogene. The over-expression of eIF4E results in the malignant transformation of an immortalized cell line and further is able to activate the ras oncogene. In addition, eIF4E is involved in the inhibition of apoptosis, and increased levels of eIF4E are observed in a wide variety of tumors. In addition to changes in eIF4E, elevated levels of eIF4G in lung carcinomas, of eIF4A in melanomas and of eEF1A in tumors of the pancreas, colon, breast and lung are frequently

Translational Control in Eukaryotes. Figure 1 Initiation of translation Depicted is a typical eukaryotic mRNA with the post-transcriptional end modifications, a 5' cap structure and a 3' poly(A) tail. The protein-coding region is marked by start and stop codons. First, the eIF4F complex consisting of eIF4E, eIF4G, and eIF4A binds to the cap structure. The interaction between PABP and eIF4G leads to a pseudo-circularisation of the mRNA. The small ribosomal subunit (40S) is then recruited to the mRNA together with the initiation factors eIF3, eIF2 and the initiator-tRNA_{met}. This so-called 43S-preinitiation complex then moves along the mRNA in a process termed 'scanning'. The codon/anticodon interaction identifies the AUG start codon. This leads to the release of initiation factors and joining of the large (60S) ribosomal subunit. The formation of the complete 80S ribosome completes the initiation process and polypeptide synthesis as directed by the open reading frame can begin.

measured. How could an increase in translation factor activity result in the regulation of cell proliferation? A common hypothesis posits that mRNAs encoding growth factors, cellular receptors and tyrosine kinases benefit disproportionately from the increased eIF availability as they often exhibit highly structured 5' untranslated regions (UTRs). Such mRNAs are translated relatively inefficiently in the context of a limited availability of translation components.

eIF2 Phosphorylation. Viral infection, iron- or amino acid-deficiency and other cellular stress conditions inhibit global translational activity by stimulating phosphorylation of the heterotrimeric eIF2 on the α -subunit. This rapidly reduces the level of functional eIF2, by preventing the recycling of the GDP- to the GTP-bound form. The responsible kinases show great homology in their catalytic domains, but differ significantly in their regulatory domains.

During viral infections the presence of the viral genomic RNA activates the double-stranded RNA (dsRNA) dependent eIF2 α kinase (PKR). A kinase with homology to PKR (termed PERK) was recently isolated from the endoplasmic reticulum (ER). It is responsible for the shutdown of protein synthesis when unfolded proteins accumulate in the ER. Mutations have been identified in human PERK in 2 families with a rare, autosomal-recessive disease, the Wolcott-Rallison-syndrome. Mutations in PERK block beta-cell development and impair gluconeogenesis, consistent with the disease symptoms of permanent, neonatal insulin-dependent diabetes.

The heme-regulated eIF2 α kinase (HRI) is important for the iron-mediated regulation of translation in erythroid precursor cells. If iron is not sufficient for the synthesis of heme and hemoglobin HRI is activated to phosphorylate eIF α . Consequently, translation is inhibited and erythroid differentiation is blocked, resulting in microcytic, hypochromic erythrocytes. In iron-replete cells, HRI is bound to heme, which results in inhibition of its kinase activity (3).

The "Heat Shock Response". Elevated temperature, as well as a variety of other cell stresses such as exposure to heavy metals, hypoxia and lack of glucose can elicit a "[▶heat shock response](#)". A general inhibition of translation and induction of heat shock protein (hsp) expression is characteristic of the heat shock response. Heat shock proteins can prevent cell death. Many of the hsp family members are molecular chaperones, which are involved in protein folding and transport and the assembly of multiprotein complexes. During cell stress they protect proteins by being involved in protein repair and/or degradation of destroyed proteins through the ubiquitin-proteasome pathway. Global protein synthesis is shut down *via* at least 3 mechanisms, (i) phosphorylation of eIF2 α , (ii) inactivation of the eIF4F complex *via*

dephosphorylation of eIF4E and hypophosphorylation of 4E-BP and (iii) the unfolding of eIF4G by the hsp27/hsp70 complex, which results in the disruption of its interactions with PABP, the eIF4E-kinase Mnk1, eIF4A and eIF3. To date it is not clear how the heat shock protein mRNAs are translated under these conditions (3).

Insulin-Mediated Control. The hormone insulin increases protein synthesis in target cells. This effect is achieved by signalling through the PI3K/Akt/mTOR pathway. During active translation initiation, the cap-binding protein eIF4E binds eIF4G as part of the eIF4F complex (Fig. 1). This interaction is targeted by the 4E-BPs, which structurally mimic the eIF4E-binding site of eIF4G (Fig. 2). Hypophosphorylated 4E-BPs bind to eIF4E with high affinity and thus block eIF4F assembly and translation.

Cardiac Hypertrophy. Cardiac hypertrophy is a well-known response to increased hemodynamic load. This clinically important condition is primarily characterized by inappropriate stimulation of protein accumulation, leading to increased cell size, which underlies cardiac hypertrophy. There is mounting evidence that signal-induced phosphorylation of several translation factors mediates these pathological alterations of cellular protein synthesis.

Selective Control of Translation

mRNA-specific translational control is usually implemented by targeting ligands to regulatory elements in the 5' or 3' UTR of target mRNAs (3, 7). The best understood examples in this category of translational control mechanisms are found in the regulation of iron

Translational Control in Eukaryotes. Figure 2

Translational control by molecular mimicry Extracellular stimuli such as insulin can regulate the phosphorylation status of the 4E-BP proteins. The 4E-BPs mimic the eIF4E-binding region of eIF4G. Hypophosphorylated 4E-BP can bind to eIF4E and displace eIF4G.

metabolism, during cell growth and differentiation, and embryogenesis (3).

5'UTR Mediated Translation Control. The paradigm for 5'UTR mediated translation control is the regulation of the intracellular iron storage protein ferritin (3) (Fig. 3). Increased intracellular iron levels result in elevated ferritin expression while a decrease in iron diminishes ferritin synthesis. This regulation is mediated by a secondary structure in the 5'UTR of the ferritin mRNA, the iron responsive element (IRE). If the iron content in the cell is low, the iron regulatory proteins 1 or 2 (IRP-1 or IRP-2) bind to the IRE. This RNA-protein-interaction blocks translation. It was found that an early step of translation initiation, the binding of the 43S pre initiation complex to the cap-binding complex eIF4F is inhibited. If the cellular iron content rises, the IRP protein dissociates from the IRE and ferritin protein is synthesized. Mutations in the IRE, which block IRP-binding and therefore translational control explain the molecular defect underlying the ►[hyperferritinemia cataract syndrome](#). This disease is characterized by increased serum ferritin levels and the early formation of cataracts. In addition to iron storage, the IRE/IRP system also regulates cellular iron import and utilization. Translation of the enzyme eALAS, which catalyzes the first step of the erythroid heme biosynthesis, is regulated in a manner similar to the translation of ferritin. In contrast, the mRNA encoding transferrin receptor (Tfr) contains 5 IRE elements in its 3' UTR that regulate its stability in an iron-dependent fashion.

3'UTR Mediated Translation Control. A precise temporal and spatial control of gene expression is particularly important during the first hours of embryogenesis. Yet in many animals this developmental phase is characterized by a distinct absence of transcription. Many important developmental decisions that will shape the originating embryo rely solely on the precisely regulated expression of maternal mRNA

stockpiles that the oocyte has contributed to the fertilized egg. Research into these phenomena is mainly based on the use of model organisms like the worm *Caenorhabditis elegans*, the fruit fly *Drosophila melanogaster* or the mouse. Errors in the post-transcriptional regulation of maternal mRNA expression usually result in severe defects of embryonic development. Of central importance for the regulatory mechanisms involved in embryonic development are defined elements in the 3'UTRs of maternal mRNAs. These elements interact with proteins and play a role in transcript localization, stability and translational control. A hallmark of developmental control of translation is its frequent association with changes in the poly(A) tail length of the targeted mRNAs such that a short tail correlates with translational silencing and a long tail with translational activation (8).

Translational regulation mediated by the 3'UTR is also observed during later differentiation events and even in somatic cells containing a nucleus (3). A mechanistically well-understood example of 3'UTR mediated translation control is the regulation of 15-lipoxygenase (LOX) translation during red blood cell differentiation (Fig. 4). LOX enzyme is involved in the destruction of internal membranes and mitochondria, a process that is important when reticulocytes mature to erythrocytes. *LOX* mRNA is transcribed during the early development of the reticulocytes – before the cell nucleus is expelled – and is then stored in the cytoplasm in an inactive form. The 3'UTR of the rabbit *LOX* mRNA contains a differentiation control element (DICE) that mediates translation repression *via* binding of the heteronuclear ribonuclear proteins (hnRNP) K and E1. This RNA/protein complex inhibits translation initiation at the 60S ribosomal subunit-joining step.

Viral Translation Control Strategies and IRES Elements

Many viral mRNAs contain ►[internal ribosomal entry sites](#) (IRES). These are RNA structures that can recruit

Translational Control in Eukaryotes. Figure 3 Translational control of ferritin synthesis. The 5' UTR of ferritin mRNA harbours a regulatory element termed IRE. When intracellular iron levels are low, the IRP proteins can bind to the IRE. This inhibits translation initiation at the level of 43S pre-initiation complex recruitment.

Translational Control in Eukaryotes.

Figure 4 Translational control of 15-lipoxygenase synthesis (LOX). (a) Schematic representation of erythropoiesis. During differentiation of red blood cells the nucleus is excluded. All mRNA molecules required for subsequent maturation steps have to be synthesised by this point. However, the mRNA encoding LOX should only be translated in mature reticulocytes when the enzyme is required for degradation of mitochondria. (b) Translation of LOX mRNA is controlled by the DICE element in the 3' UTR. hnRNP K and E1 bind to this element and inhibit the 60S ribosomal subunit joining step of translation initiation.

translation initiation complexes and ribosomal subunits to internal positions of the mRNA 5' end (4). IRES elements are functional substitutes for the 5' cap structure. The hepatitis C virus IRES can initially recruit the 40S ribosomal subunit without any requirement for translation initiation factors. However, eIF2 and eIF3 are needed for start codon recognition. Picorna viruses (hepatitis A virus, cardio- and aptho-viruses, entero- and rhinoviruses) also recruit ribosomes *via* IRES elements on their mRNAs. With the exception of hepatitis A- and the cardioviruses, they proteolytically cleave eIF4G as part of their infection strategy. This serves two purposes; it inhibits cellular translation and promotes viral translation. To recruit ribosomes to the IRES, these viruses require eIF-2, -3 and -4A as well as the C-terminal cleavage fragment of eIF4G (3, 5). In addition to viruses, IRES elements are also recognized in a growing list of cellular mRNAs. In some cases it has been documented that the translation of these mRNAs is adapted to specific cellular conditions. For example, the IRES elements of ornithine decarboxylase and *p58PITSLRE* mRNAs are only active at the transition from the G₂- to M-phases of the cell-cycle.

Another viral translation strategy is adopted by the rotaviruses, which are a main cause of diarrhea in children. Their mRNA molecules contain a cap structure but no poly(A) tail. Instead of a poly(A) tail, these mRNAs end with a short conserved sequence which is bound by the retroviral nonstructural-protein (NSP) 3. NSP3 binds to the adapter protein eIF4G and

competes for its interaction with the poly(A) binding protein (PABP). This again serves two functions, (i) it selectively inhibits the cellular, PABP-dependent translation and (ii) it stimulates viral translation, because NSP3 and eIF4G form a bridge between the 5' and 3' end of the rotavirus mRNA. A similar strategy is most likely used by the S-phase specific **▶ histone** mRNAs in Metazoa. These end with a conserved hairpin structure, which can take over many functions of the poly(A) tail. This structure is essential for histone-mRNA-translation and binds a protein, the stem loop binding protein (SLBP).

Clinical Relevance

The interactions of complex organisms with a continuously changing environment require the precise control of gene expression. The regulation of mRNA translation is an important part in nature's toolbox to achieve this control. As a result of intensive studies in basic science as well as molecular medicine, processes like the activation of target cells by insulin and links between translation and (malignant) cell growth are beginning to be understood at the molecular level. Increasing numbers of RNA elements are being identified that mediate a post-transcriptional control of gene expression and in some cases disease-causing mutations have been identified that disrupt their function. The study of the multiple viral strategies to utilize the cellular translation machinery yields an increased understanding of viral pathogenesis. Understanding the intricacies of translational control and its dysregulation in disease holds the promise of new therapeutic approaches.

Programmed translational frameshifting; recoding

Definition

Translational frameshifting is a mechanism by which the translational machinery shifts the frame in which it decodes the mRNA while continuing to extend the polypeptide chain (Fig. 1). The result is that the mRNA does not encode the protein by a continuous run of three nucleotide codons, known as an **open reading frame** (ORF). Rather, the information encoding the protein comes from two distinct ORFs. Frameshifting is a stochastic process, meaning that each translating ribosome has a certain probability of undergoing the shift, but that only a fraction of the ribosomes does so. Ribosomes that frameshift produce a translational fusion of the two overlapping ORFs, whereas those that do not frameshift continue normal in-frame decoding and terminate at the end of the first ORF. Each of these products thus shares a common N-terminal region but has a different C-terminal domain. The frameshift occurs at special mRNA sequences that predispose the ribosome to shift reading frames. The phenomenology of frameshifting is quite complex; there are several general types of frameshifts depending on the direction and the distance of the shift and many distinct signals can induce the ribosome to shift (e.g. +1 or -1 frameshifting). Frameshifting is ubiquitous but rare, having evolved in a small number of genes in all three domains of life. Frameshifting can have a variety of purposes including allowing expression of alternative forms of proteins required for morphogenesis (especially in viruses), providing a mechanism for **autogenous translational control** or producing related proteins with distinct enzymatic characteristics.

Characteristics

The direction of the shift in frames distinguishes the two major classes of programmed frameshifts.

1. **Programmed -1 frameshifting** occurs when the ribosome shifts the reading frame by one nucleotide

Translational Frameshifting, Non-Standard Reading of the Genetic Code. Figure 1

A gene consisting of two overlapping open reading frames (ORF A and ORF B) employs frameshifting to express two primary protein products. A ribosome is shown initiating on the upstream ORF, translating to the region of overlap between the two ORFs and undergoing two alternative events. On the left, ribosomes that do not frameshift complete expression of the protein specified by ORF A. On the right, ribosomes that frameshift express a protein that consists of an N-terminal region encoded by ORF A and a C-terminal region encoded by ORF B.

in the 5' or upstream direction. This is by far the most prevalent form of frameshifting, commonly occurring in many viruses and bacteriophages and transposons (Fig. 2A).

2. **Programmed +1 frameshifting**, which occurs when the ribosome slips one nucleotide in the 3' or downstream direction. These events are much less common, occurring in a small number of transposons and chromosomal genes (Fig. 2B).

All frameshift events share a few common characteristics. All frameshift sites include an essential sequence motif at the site of frameshifting though the general nature of that motif differs between the two major classes of frameshifts. Frameshift sites also include auxiliary non-essential sites that stimulate the frequency of frameshifting. These **frameshift stimulator sequences** also vary greatly among programmed frameshifts; for most frameshift sites this essential motif is a heptamer involving two codons and a flanking seventh base. Many frameshift signals also

Translational Frameshifting, Non-Standard Reading of the Genetic Code. Figure 2 Two types of frameshifting. (a) Programmed -1 frameshifting (here on the Rous sarcoma virus frameshift site) occurs when two ribosome-bound mRNAs (tRNA^{Leu} and tRNA^{Asn}) bound at the sequence UUA-AAU slip simultaneously one nucleotide in the 5' direction to the sequence UUU-AAA before continuing protein synthesis. (b) Programmed +1 frameshifting (here from the *prfB* gene of *E. coli*) occurs when the peptidyl-tRNA is bound to the ribosome (shown as tRNA^{Leu}). The ribosome can undergo two fates. Recognition of the in frame UGA codon by peptide release factor 2 (RF2) causes peptide release. Alternatively, slippage of tRNA^{Leu} one nucleotide in the 3' direction allows decoding by tRNA^{Asp} resulting in frameshifting.

include stimulatory secondary structures, a ▶**stem loop** or a ▶**pseudoknot** (Fig. 3). In other cases, the primary sequence stimulates frameshifting without forming any secondary structure. The stimulatory sequences affect frameshifting either by increasing the probability of the frameshift event or by decreasing the rate of the competing normal in-frame decoding event. Frameshifts only occur efficiently at these specialized sequences because at other sites normal translational

elongation occurs too rapidly to allow the ribosome to shift. Therefore, a ▶**translational pause** at the frameshift site is a universal feature of programmed events and some frameshift stimulator sequences function at least partly by increasing the duration of the pause, providing time for the kinetically slow shift in frames to occur.

Programmed -1 Frameshifting

The first described programmed translational frameshift sites were from metazoan ▶**retroviruses**. The canonical example derives from Rous sarcoma virus. That virus encodes four genes, *gag*, *pol*, *env* and the oncogene *v-src*. Transcription of the chromosomally integrated virus produces an RNA that is spliced to produce the mRNAs for the Env and Src proteins. Translation of *gag* and *pol* produces a Gag protein and much smaller amounts of a Gag-Pol translational fusion protein. Expression of the fusion requires a ribosome reading an unspliced mRNA to shift from the *gag* gene in the original reading frame (the ▶**zero frame**) into the overlapping *pol* gene in the ▶**-1 frame**, producing a fusion protein containing both *gag* and *pol* information. Fusion of the Pol protein to the Gag protein results in the packaging of the Pol protein into the nascent virus ▶**nucleocapsid**, which is important because the virus propagation requires the enzyme activities of the Pol protein to function within the particle.

The site of programmed -1 frameshifting is termed a ▶**slippery heptamer** because it is a seven-nucleotide sequence that allows slippage of ribosome-bound tRNAs from the zero frame into the -1 frame. Almost every slippery heptamer conforms to a common general structure, X-XXY-YYZ (shown as triplets in the upstream zero frame) where XXX is a triplet of any nucleotide, YYY is a UUU or AAA triplet and Z can be any nucleotide, but is species specific (Table 1). A ribosome reading the mRNA encounters the codons XXY and YYZ in the zero frame. Frameshifting occurs at the site by the ▶**simultaneous slippage** of the two tRNAs bound to these codons onto the overlapping XXX and YYY codons in the -1 frame followed by continued translation on the codon beginning at Z (Fig. 2a).

Frameshift efficiency varies greatly among the possible X-XXY-YYZ slippery heptamers. In general, AU-rich sequences tend to induce more frameshifting than GC-rich sequences. Slippage involves transient disruption of base pairing between the two tRNAs and the mRNA as they slip from the zero to the -1 reading frame. The preference for AU-richness presumably reflects the higher energy cost of disrupting GC base pairs. The correlation is not absolute; a few GC-rich heptamers strongly stimulate frameshifting and particular AU-rich heptamers stimulate very poorly, suggesting that the details of codon anticodon interaction may influence

Translational Frameshifting, Non-Standard Reading of the Genetic Code. Figure 3 Stem loops and pseudoknots are two forms of RNA secondary structures. (a) a stem loop forms by base pairing of adjacent, complementary sequences. (b) A pseudoknot forms when a downstream sequence in the RNA can base pair with a portion of the loop region. (c) A more accurate depiction of the structure of a frameshift-stimulating pseudoknot shows that the two paired regions stack on each other with a slight bend.

the probability of slippage. This conclusion is underscored by the fact that mutations that block certain tRNA modifications can affect the efficiency of programmed -1 frameshifting. These modifications presumably function to modulate the stability of tRNA mRNA pairing and thus affecting the probability of slippage.

In almost all cases, programmed -1 frameshift sites consist of a slippery heptamer and a downstream secondary structure. That structure, usually a pseudoknot in eukaryotes and a stem loop in prokaryotes, causes a translational pause with the ribosome decoding at the slippery heptamer. However, for a pseudoknot the duration of pausing correlates poorly with the

frequency of frameshifting, suggesting that the secondary structure has an effect beyond causing pausing, though the nature of the effect remains unknown. A frameshift-inducing pseudoknot has distinctive structural features (e.g. a bend induced by a nucleotide wedged between the two stacked helices) suggesting that their 3-dimensional structure may be important to stimulate frameshifting, possibly through an interaction with some structure in the ribosome. The structural requirements of the stem loops in prokaryotes are less well understood.

Prokaryotic -1 frameshift sites usually include a third element, an upstream ▶Shine-Dalgarno site (SD-site). During initiation, base pairing between an SD-site and a complementary sequence at the 3' end of 16S rRNA in the 30S ribosomal subunit directs initiation to correct translation initiation codons. The same base pairing interaction stimulates programmed -1 frameshifting. The spacing between an SD-site and a slippery heptamer is essential and must be shorter than the spacing at initiation. The belief is that the short spacing strains the ribosome, forcing slippage of the mRNA relative to the decoding tRNAs and thereby increasing the probability of programmed -1 frameshifting.

Programmed +1 Frameshifting

Programmed +1 frameshift was first described in the gene encoding ▶peptide release factor 2 (RF2) in the bacterium *Escherichia coli* (prfB) and in ▶Ty retrotransposons in the yeast *Saccharomyces cerevisiae* (Ty elements). These frameshifts are far less common than -1 frameshifts but have been found in metazoans, fungi and bacteria. Frameshifting also requires an essential heptameric sequence but frameshifting occurs when

only one tRNA is paired with the mRNA. The site consists of two codons of the zero frame and a downstream seventh base (Fig. 2B). Frameshifting occurs after the ribosome has decoded the first codon and during a pause caused by slow recognition of the second codon. At the time of the frameshift, the first codon is in the ►ribosomal P site bound by a peptidyl-tRNA and the second codon is in the ►ribosomal A site. Slow recognition of the A site codon allows sufficient time for the mRNA to slip +1 with respect to the P site peptidyl-tRNA, which reveals a +1 shifted codon in the ribosomal A site recognized efficiently by an abundant aminoacyl-tRNA. The slippage and recognition of the first ►+1 frame codon appear to be a concerted event rather than successive.

The *prfB* frameshift is an example of autogenous translational control. The frameshift occurs after decoding of the 27th codon in the gene, with translation continuing for 340 amino acids in the shifted frame. The essential heptamer, CUU-UGA-C, includes the UGA nonsense codon recognized by the *prfB* product during peptide termination. When the RF2 concentration is high, translation terminates efficiently at the UGA, but when RF2 concentration is too low termination is slowed, allowing for stochastic slippage of the peptidyl-tRNA^{Leu} from CUU to UUU in the +1 frame. The autogenous interaction between RF2 activity and expression maintains it at the appropriate intracellular concentration. A similar feedback regulation of the ornithine decarboxylase (ODCase) antizyme gene in metazoans involves +1 frameshifting. ODCase catalyzes the first and rate-limiting step in the synthesis of the polyamines spermidine and spermine and ODCase antizyme targets ODCase for degradation. Expression of ODCase antizyme requires +1 frameshifting and the efficiency of that frameshift increases when the concentration of polyamines increases. As with *prfB*, the effect is to moderate increases or decreases in polyamine concentration. Programmed +1 frameshifting in the Ty retrotransposons accomplishes the same end as programmed –1 frameshifting in metazoan retroviruses. Expression of a Gag-Pol fusion protein requires +1 frameshifting and the fused protein assembles into a nucleocapsid structure whose function depends on the proper level of frameshifting.

Frameshifting in Chromosomal Genes and Its Effect on Genomics

Though the majority of characterized frameshifting systems involve viruses or transposable elements, a small but significant number of chromosomal genes also use the mechanism. Partly, the prevalence of ►extrachromosomal elements results from the frequent use of frameshifting in their compact genomes. It may be that chromosomal genes are less constrained to

adopt these unusual mechanisms or it may be that researchers are less adept at identifying adjacent ORFs as parts of a frameshifting system. Despite this difficulty, researchers have identified several chromosomal genes that, like *prfB* and ODCase antizyme, employ frameshifting. For example, in the yeast *Saccharomyces cerevisiae*, the *EST3* and *ABP140* genes employ +1 frameshifting meaning that in a genome encoding about 6000 genes, only about 0.03% use frameshifting. This low frequency of use of frameshifting appears to be normal, but some species may employ frameshifting much more frequently. For example, in ciliated protozoa of the genus *Euplotes* it appears that up to 10% of genes may employ programmed +1 frameshifting. Clearly, a full understanding of the structure of genomes would require identifying frameshift genes.

Several researchers have used ►bioinformatics to identify frameshift genes in completed genomes. Most have focused their work on the relatively well-defined –1 simultaneous slippage frameshift sites. This work is still in its infancy and the number of sites found by the various methods has varied quite widely.

Clinical Relevance

Programmed frameshifting occurs in a variety of medically and agriculturally relevant viruses. A good example is the ►human immunodeficiency virus-1 (HIV-1), which uses programmed –1 frameshifting in expression of its Gag-Pol protein. We know from studies with simpler, genetically tractable systems that even relatively subtle changes in the efficiency of frameshifting can severely compromise virus propagation. Furthermore, the efficiency of frameshifting is strongly dependent on features of the cellular translation system. Model system studies have shown that perturbations to the translational machinery that have no effect on bulk translation (i.e. tRNA modification) can have strong effects on frameshifting. These facts argue that the frameshifting system could be an excellent target for antiviral drug development.

Synonyms

Transposon is a short and most commonly used term for transposable element. Transposons are also referred to as mobile genetic elements, which is a wide category including the classical transposable elements, integrating viruses, mobile introns and some other products of DNA recombination. Transposons are also called “jumping genes”, for their ability to move.

Definition

Transposons are discrete segments of DNA that have the distinctive ability to move and replicate within genomes. Transposons were discovered in the 1940's

by Barbara McClintock (who later was awarded with the Nobel Prize for this discovery) in the maize genome and have since been found ubiquitously in essentially all living organisms. The process of element movement is generally called transposition and can contribute to insertional mutagenesis, altered gene expression and recombination. Transposons make up significant fractions of genomes; for example, about 45% of the human genome is composed of sequences of a variety of different elements (1). Transposons are best viewed as molecular parasites that propagate themselves using resources of the host cell. However, unlike viruses, transposons are not infectious and their activities are therefore confined to intracellular space. Due to this restriction, transposable elements have to coexist with host cells in order to survive and therefore their activities are highly controlled. Despite their parasitic nature, there is increasing evidence that transposable elements are a powerful force in gene evolution. Indeed, about 50 human genes are derived from transposable elements (1), among them genes that are responsible for immunoglobulin gene recombination in all vertebrates.

Characteristics

Classes of Transposable Elements and Mechanisms of Transposition

Transposable elements fall into two major classes. The first is retroelements that transpose through an RNA intermediate and include long interspersed elements (LINEs), short interspersed elements (SINEs), and LTR retrotransposons. Retroelements transpose through a replicative (copy-and-paste) mode of transposition, in which the transposon does not get excised from its donor locus but instead a copy of it is produced which inserts elsewhere in the genome (Fig. 1). Thus, replicative transposition leads to an increase in the copy number of the transposon within a genome. Members of the second class are called DNA transposons because they move directly as DNA, by a conservative (cut-and-paste) mechanism of transposition, in which the element gets excised from the donor locus and is subsequently reinserted elsewhere (Fig. 1). The copy numbers of DNA transposons also increase over time, but amplification is not inherent to the transposition process itself.

The major non-LTR retrotransposon in mammals is LINE-1 (or L1). L1 has about 5×10^5 copies in the human genome, thereby making up about 17% of human genomic DNA (1). LINEs contain a polymerase II promoter and produce a polyadenylated, ▶ **bicistronic** RNA containing two open reading frames (ORFs) that encode proteins required for transposition (Fig. 2a). The element-encoded ▶ **endonuclease** generates a single-stranded nick in the target DNA, and the

Transposons. Figure 1 Schematic representation of the two major mechanisms of transposition. During conservative transposition, the element is excised from the donor DNA (red line), and integrates into a new target DNA (green line). The broken donor DNA has to be repaired by host factors and this process can result in a small “footprint” (black dot) that marks the former presence of the element in that site. Replicative transposition requires amplification of the element either by replication or by copying of the element through transcription followed by reverse transcription. The amplified element gets inserted elsewhere in the genome.

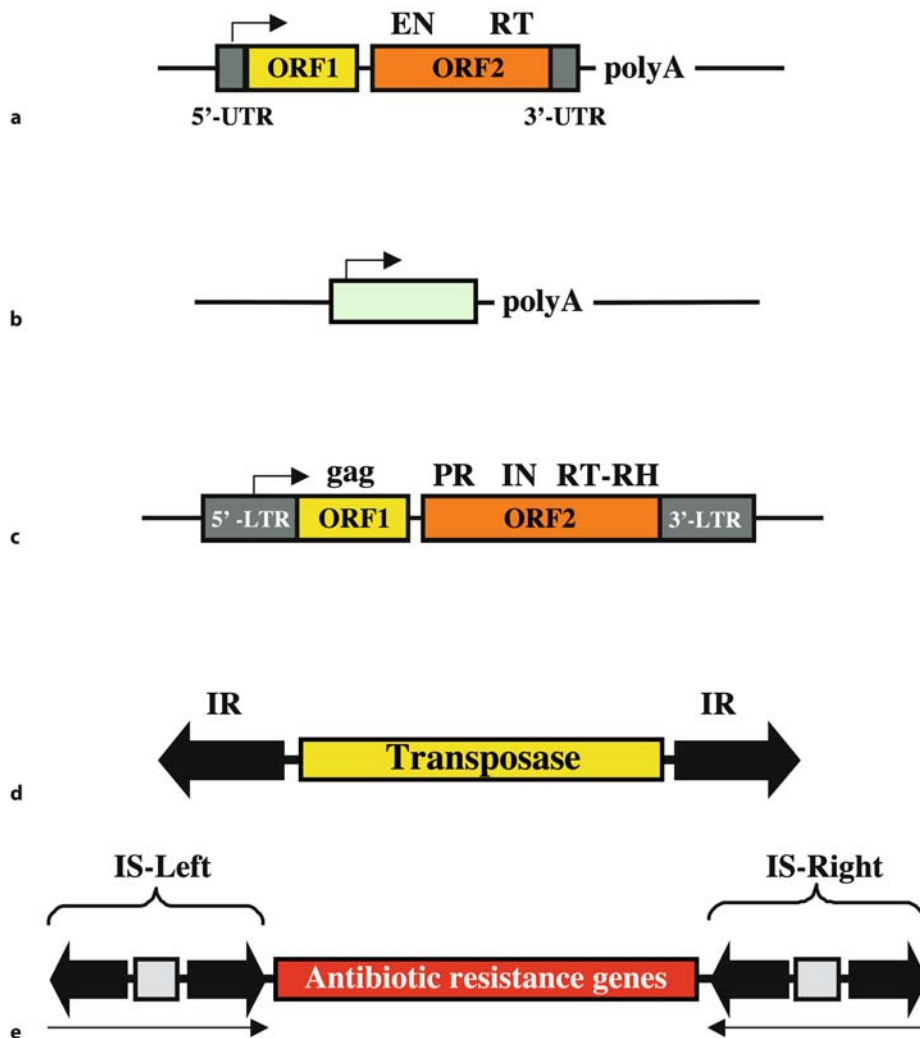

►reverse transcriptase uses the nicked DNA to prime reverse transcription from the 3' end of the L1 RNA (2). Transposition-competent L1s in humans are about 6 kb long. However, because reverse transcription is frequently incomplete, the majority of L1s are truncated and thus non-functional. The LINE retrotransposition machinery is believed to be responsible for most reverse transcription activity in the genome, including retrotransposition of the non-autonomous SINEs and generation of ►processed pseudogenes.

SINEs are short (about 100–400 bp) retrotransposable elements that contain a polymerase III promoter and encode no proteins (2) (Fig. 2b). These non-autonomous transposons are thought to use the LINE machinery for transposition. The vast majority of known SINEs are derived from tRNA sequences, with the exception of the human *Alu* element, which is derived from the 7SL component of the ►signal recognition particle. *Alu* elements were originally identified as repetitive DNA elements in human DNA renaturation curves and contain a recognition site for the restriction enzyme *AluI*. *Alu* elements are represented in the human genome with $>1 \times 10^6$ copies, which make up about 11% of the total genome. *Alu* is the only active SINE in humans.

LTR-retrotransposons are similar to retroviruses in that they are flanked by long terminal direct repeats that contain transcriptional regulatory elements that drive the expression of at least two ORFs similar to the *gag* and *pol* genes (Fig. 2c). LTR-retrotransposons comprise two major families, Ty1/*copia* and Ty3/*gypsy*, based on the founder elements in the yeast *Saccharomyces cerevisiae* (Ty1 and Ty3) and in *Drosophila* (*copia* and *gypsy*). LTR-retrotransposons are widely distributed in eukaryotes, and make up about 8% of the human genome. Transposition occurs through reverse transcription of the retrotransposon RNA, and integration of the resultant cDNA into a new location by the

integrase protein. Endogenous retroviruses (ERVs) appear to have been recently active in the mammalian genome.

The simplest DNA transposons are composed of short terminal inverted repeats flanking a transposase gene (Fig. 2d). The transposase binds to the inverted repeats, and catalyzes ‘cut-and-paste’ transposition (Fig. 1). Bacterial insertion sequence (IS) elements usually encode no function other than the transposase, which distinguishes them from bacterial transposons. Transposons encode, in addition to the transposase, another function that often confers antibiotic resistance (Fig. 2e). Transposons are flanked by inverted or direct repeats, which are in many cases structurally similar to IS elements (Fig. 2e). Although DNA transposons are widespread in prokaryotes, they are less abundant in eukaryotes. For example, only 2–3% of the human genome is composed of DNA transposons and there is no indication for their activity in the past 50 million years (1). Active DNA transposons are transitory components of genomes. This is because these elements accumulate inactivating mutations over evolutionary time. Inactive copies accumulate in the genome, because transposase can mobilize inactive (nonautonomous) elements. The expansion of inactive transposon copies results in regulatory mechanisms that limit transposition rates (3). Eventually, the last remaining transposase-producing (autonomous) copy gets mutated, which seals the fate of the given transposon in the genome. Thus, DNA transposons are doomed to die out and, in order to survive, they must be able to invade and colonize virgin genomes. This process is mediated by ►horizontal transmission from one species into the germline of another species. For example, the P transposable element in *Drosophila melanogaster*, an everyday research tool of fly geneticists, is believed to have been horizontally transferred from *Drosophila willistoni* some time in

Transposons. Figure 2 Structures and organization of the main types of transposable elements. (a) Non-LTR retrotransposon. The element consists of a 5' untranslated region that has promoter activity (arrow pointing towards the downstream genes), which is required to drive transcription of the element-encoded genes. ORF1 encodes a nucleic acid binding protein. ORF2 encodes an endonuclease (EN) and a reverse transcriptase (RT). The element has a polyA tail. (b) A typical SINE. The element is a small, RNA-derived pseudogene, which is transcribed from an RNA polymerase III promoter within the element (arrow). The element has a polyA tail. (c) LTR-retrotransposon. The element consists of long terminal repeats (LTRs) similar to those of retroviruses. The LTRs flank two open reading frames. ORF1 encodes the group specific antigen (gag), ORF2 encodes a protease (PR), an integrase (IN), and a reverse transcriptase-RNaseH (RT-RH) function. (d) DNA transposon. The central transposase gene (yellow box) is flanked by terminal inverted repeats (IRs, shown as black arrows). The IRs contain the binding sites for the transposase and sequences that are required for transposase-mediated cleavage. (e) Composite bacterial transposon. The element consists of antibiotic resistance genes (red box) flanked by two copies of an insertion sequence (IS) element that contains the transposase gene (yellow boxes). The arrows underneath indicate the inverted orientation of the IS elements.

the last century. Currently, there are only three active DNA transposons known from vertebrates, the Tol2 element in the medaka fish, and the *Sleeping Beauty* and *Frog prince* elements that have been reconstructed from inactive elements in fish and frog genomes, respectively (4, 5).

Impact of Transposable Elements on the Host Genome

A general feature of transposable elements is that they can replicate independently of the cellular replication cycle, and new copies can emerge at new locations in the genome. Thus, mobile elements can cause insertional mutagenesis if they land within a gene (6), but

they can also lead to altered gene expression and genetic recombination. Insertion of a transposable element into the protein-coding region of a gene (exon) can disrupt gene function. For example, bacterial IS elements were identified as DNA insertions in the *E. coli gal* operon which cause highly polar mutations. The *Drosophila* P element was found to cause mutations at the *white* locus (and have since been used as a mutagenic agent in the laboratory) and the DNA transposon Tc1 is the main cause of mutation in the nematode *Caenorhabditis elegans*. In contrast to direct insertion of a transposable element into exon sequences of a gene, the element can be inserted into upstream regulatory sequences of a gene and thereby alter the regulation of its expression. For example, insertion between the core promoter and adjacent enhancer regions would increase the distance between these regions and thus negatively affect promoter activity. Another damaging aspect of transposable elements is that repeated, dispersed copies of homologous sequences can promote secondary rearrangements (6), which can result in deletions, duplications and inversions. This potential of dispersed transposon copies to promote homologous recombination can be even more damaging to the genome than a *de novo* insertion.

Transposable elements do not only do harm, but are also a creative force. In *Drosophila*, [telomere](#) maintenance is not brought about by telomerase, but by repeated transposition of two non-LTR retrotransposons, HeT-A and TART, into chromosome ends. The acquisition of new transposon insertions can donate regulatory elements to genes or even lead to the evolution of new genes. L1 elements can carry non-transposon sequences into new places, a process that can contribute to “exon shuffling” and thus to gene evolution (2). This is because L1 transcription can read through the native transcription termination site of the element into flanking genomic sequences. It is estimated that about 0.5–1% of the human genome may have been generated by L1-mediated [transduction](#) of 3′ flanking sequences (1). The L1 retrotransposition machinery can also mediate reverse transcription and genomic insertion of host gene mRNAs, resulting in processed pseudogenes. Some of these insertions can give rise to functional processed genes. Approximately 50 human genes have evolved from transposable elements, mostly from DNA transposons (1). These include the RAG1 and RAG2 immunoglobulin gene recombinases and the [centromere](#)-binding protein CENPB. Thus, although transposable elements have not been selected for conferring selective advantage to the host, they can contribute useful functions to genomes.

Regulation of Transposition

Transposition is under strict control, and the accumulation of hundreds or thousands of transposon copies can

take millions of years. This is because transposition can potentially endanger the survival of the host organism and consequently that of the transposable element. Therefore, transposons and their hosts have coevolved and developed strategies that reduce the negative effects on the host but ensure proliferation of the element. The mechanisms of transpositional regulation are diverse (8). The expression of transposon-encoded factors can be kept in check by transcriptional silencing, through DNA methylation. Post-transcriptional silencing can also contribute to down-regulation of factors that are required for transposition. For example, [RNA interference](#) (RNAi) suppresses gene expression in a wide variety of organisms, and has been shown to constitute an antiviral defence mechanism in plants. RNAi has been proposed to be a major mechanism for transposon silencing in nematodes and perhaps contributes to transposon regulation in other animals as well. Another form of regulation is site-selective insertion of transposons into “safe” places in the genome. For example, the Ty retrotransposable elements in yeast show considerable site-specificity of insertion, thereby reducing the negative impact of transposition. Transposition of the bacterial transposon Tn5 and that of P elements and *mariner* elements in *Drosophila* can be regulated by repressor proteins, which are truncated or point mutant versions of the transposase polypeptide (3). For example, defective transposases can compete with wild type transposase for binding sites located in the transposon ends. Furthermore, P element transposition is restricted to the fly germline, by [alternative splicing](#) of the transposase mRNA. A particularly interesting feature of the bacterial Tn7 element is that it does not insert into DNA that already contains a copy of Tn7, a phenomenon called target immunity. Target immunity helps to avoid multiple copies of the element in the same DNA molecule, which might result in deleterious recombination between the two elements.

Taken together, there are a great variety of mechanisms that put a limit on transpositional activity. The outcome of this regulation is that transposable elements move at very low frequencies.

Clinical Relevance

About 1 in 600 mutations in humans is estimated to arise from retrotransposon-mediated insertion. The major causative agent of endogenous genomic insertions is L1 (6). An average human being has 80–100 retrotransposition-competent L1s, which belong to a particular subfamily of these elements in the human genome. Results also suggest that a relatively small number of very active L1s comprise the bulk of L1 activity (6). A current estimate for transpositional frequencies in humans is that about 1 in 8 individuals harbour a new L1 insertion (2). New, disease-causing

insertions of L1 in humans were in fact the first retrotransposition events detected in mammals. These insertions occurred in the blood clotting protein Factor VIII, dystrophin, APC and β -globin genes.

Alu elements continue to amplify at a rate of about one insertion every 200 new births. New insertion events can lead to genetic disorders including haemophilia, neurofibromatosis, cholinesterase deficiency, breast cancer and leukaemia (7). *Alu* element insertion is estimated to contribute to about 0.1% of human genetic diseases. The large number of *Alu* elements within the human genome also provides ample opportunity for homologous recombination events between dispersed *Alu* repeats. These events can result in deletion or duplication of exons in a gene and other chromosomal abnormalities. This mode of mutagenesis is estimated to account for 0.3% of human genetic diseases, including Fabry disease, Duchenne's muscular dystrophy, ADA deficiency and a variety of cancers.

There is considerable interest in technologies that allow the delivery and expression of genes in certain tissues or organs *in vivo* for the correction of genetic diseases. Paradoxical sounding perhaps, but transposable elements can be harnessed as useful vectors for gene therapy. In particular, the *Sleeping Beauty* transposon (4) has been shown to be a promising gene delivery vehicle for therapeutic applications. *Sleeping Beauty* mediates efficient and stable insertions of transgenes into human (and other vertebrate) chromosomes (4) and ensures persistent, life-long transgene expression at therapeutic levels. In light of the intrinsic ability of transposons to cause undesired mutations in endogenous genes, one particularly relevant concern in human applications is safety. With the use of technologies that allow designed targeting of transposable elements into safe locations in the human genome, *Sleeping Beauty* and other transposons might evolve into simple, efficient and safe vectors for stable gene transfer for the correction of human genetic diseases.

Definition

In the central dogma of biology, the information of a gene is copied into a ► [messenger RNA](#) (► [trans-](#)

cription) and subsequently translated into protein. The sequence of such an mRNA is read in nucleotide triplets (codons) that correspond to individual amino acids in the resultant protein. Until the 1950s, however, it was not clear how such a base sequence is translated into a sequence of amino acids. With the advent of biochemical studies on protein synthesis, the participation of small “soluble” RNA molecules became evident. These function as adaptors that recognize specific codons in the mRNA and bring the correct amino acids to the corresponding positions in the nascent protein. Due to this role in transfer of genetic information into protein sequence, these small RNA molecules were named transfer RNA (tRNA) (1). Since proteins contain different amino acids (20 standard amino acids plus 2 rare ones), every organism needs a corresponding set of different tRNA molecules. These tRNAs have certain common characteristics, since they all have to interact with the protein synthesis machinery (the ribosome and accessory translation factors), but they also must have very specific and individual features, in order to interact exclusively with one type of amino acid and one sort of codon on the mRNA. These different requirements are mirrored in the typical secondary and tertiary structure of these adaptor molecules.

Besides their participation in protein synthesis, tRNAs can have additional functions in some organisms, like the tRNA for glutamate, which is used as a substrate for the synthesis of tetrapyrroles (like chlorophyll and heme) in plants, archaea and many bacteria (2).

Characteristics

Whether members of the prokaryotic, eukaryotic or archaeal kingdoms, all organisms have tRNA molecules of a very similar size and structure. They are rather small transcripts, consisting of a single-stranded polynucleotide chain with an average length of 76 nucleotides (in a range from 60 to 95 nucleotides). In addition to the four standard bases, tRNAs contain many modified bases important for the structure and function of the molecules.

Secondary Structure

Complementary bases allow tRNAs to form internal hydrogen bonds (secondary H-bonds) between different parts of the polynucleotide sequence. These interactions force the linear molecule to adopt a secondary structure in the form of a cloverleaf (Fig. 1). The base pairs involved usually follow the classical Watson and Crick rules (A-U and G-C), but also include non-conventional interactions like G-U, G-ψ and A-ψ base pairs (ψ represents pseudouridine, a modified base). The cloverleaf structure consists of four different arms composed of double-stranded stem

tRNA. Figure 1 Characteristic secondary structure of a tRNA molecule. The hydrogen bonds formed between complementary bases in the tRNA lead to the formation of the typical cloverleaf structure, with the acceptor stem (blue) and the 3 “leaves” D-arm (green), anticodon-arm (red) and TψC-arm (purple). The additional variable loop is labelled in black. The aminoacylation of the tRNA 3’end is indicated.

regions and single-stranded loops. Each arm is named after its function or characteristic feature:

1. The acceptor arm is the “branch” of the cloverleaf and is formed by the pairing of bases adjacent to the 5’- and 3’-termini of the RNA. In addition, the 3’-end carries a stretch of unpaired nucleotides ending with the invariant sequence C-C-A. The terminal A residue of this sequence has an essential function as the part of the tRNA that carries the cognate amino acid.
2. The D-arm is one of the “leaves”. It is named after the modified base dihydrouridine, found frequently in this tRNA region.
3. The TψC-arm, another “leaf”, is identified by the presence of the conserved triplet sequence T-ψ-C in many tRNAs.
4. The anticodon arm is located opposite to the acceptor stem. In the center of its loop, it carries the anticodon triplet, which is complementary to a specific codon in the messenger RNA. This codon – anticodon interaction brings the designated tRNA to the proper position of the mRNA and, as a consequence, the corresponding amino acid to the correct site of the growing polypeptide.

Since these structural elements are composed of a rather conserved number of nucleotides, a useful numbering system for tRNA base positions has been established based on the tRNA consensus structure. However, the secondary structure described contains an additional variable domain, the variable loop, located between the T ψ C and the anticodon arm. Hence, tRNAs are divided into two classes: Class 1 represents molecules with a variable loop of 4–5 bases, whereas Class 2 tRNAs have 10–24 bases in this domain. Interestingly, although tRNAs vary in their primary sequence, almost all of these molecules can adopt the cloverleaf structure. Exceptions include some mitochondrial tRNAs that lack the D- or T ψ C-arm and hence carry just two of the three “leaves”.

Positions in the nucleotide sequence can be classified by degree of conservation between different tRNAs. Invariant positions contain particular bases in almost every tRNA (>90%), while other positions are occupied by either a ►purine or a ►pyrimidine and are therefore called semi-invariant. The functions of these invariant and semi-invariant positions cannot be deduced from the secondary structure, but become evident when the tertiary structure is analyzed.

Tertiary Structure

The first three-dimensional structure of a tRNA resulted from crystallographic studies on the phenylalanine tRNA of yeast, and this molecule has been a great source of information on RNA structure (3). The cloverleaf secondary structure folds into a compact L-shaped tertiary structure (Fig. 2) stabilized by an intricate network of hydrogen bonds (tertiary H-bonds) involving many of the invariant and semi-invariant bases. Many of the bases are stacked and about half of them are involved in base pairings. The L-shape is the result of two coaxial helices, one formed by stacking interactions of the acceptor- and T-stems and the other by the stacking of the anticodon- and D-stems. The juxtaposition of the D- and T ψ C-loop forms the elbow region where several Mg²⁺ binding sites are found; both T ψ C and Mg²⁺ contribute to the stabilization of this region by interacting with the D-loop. In this L-shape, one end carries the anticodon (to interact with codons on the mRNA), while the other end is charged with the amino acid (to interact with the nascent protein). Therefore, both functional sites are at a maximum distance from each other. Surprisingly, the above-mentioned tRNAs lacking one of the cloverleaf domains can also adopt an L-like three-dimensional shape and so can function as regular tRNA molecules in protein synthesis.

The correct tertiary structure of the tRNA is a prerequisite for the interaction with specialized enzymes that are either involved in the maturation of the transcript into a functional tRNA (processing enzymes,

see below) or that charge it with the cognate amino acid (aminoacyl tRNA synthetases) (4). The L-shape is also important for the interaction with translational cofactors that transport the charged tRNA to the ribosome.

Modified Nucleotides

In addition to the four standard bases, more than 80 different modified nucleotides have been identified in tRNAs, with changes ranging from simple methylation to whole restructuring of the purine ring. These modifications are found in all parts of the molecule and are synthesized by specific tRNA-modifying enzymes (5). While modifications like dihydrouridine or pseudouridine are constant features in all tRNAs, others are specific for a particular tRNA. The modifications are introduced post-transcriptionally and are considered to be important for specificity, fidelity and/or efficiency of the various inter- and intramolecular interactions in which tRNAs are involved. A direct effect can be observed in the anticodon, where modifications influence the base-pairing interactions with the corresponding mRNA codons. An example is the tRNA for isoleucine in *Escherichia coli*, where the first position of the anticodon, a cytidine, is modified to lysidine (2-lysylcytidine). With this single modification, the codon specificity is changed from methionine to isoleucine. Consequently, in order to avoid amino acid misincorporation during translation, the tRNA carrying this modification has to be charged with isoleucine instead of methionine.

tRNA Maturation and Aminoacylation

In all organisms analyzed thus far, tRNAs are not transcribed as functional molecules, but are synthesized as large precursor transcripts with additional 5'- and 3'-sequences. During maturation, these extra sequences are removed by exo- and/or endo-nucleolytic activities. An interesting processing enzyme involved in the removal of the 5'-leader is RNase P, an enzyme consisting of RNA and protein subunits, which in some cases has catalytic activity in the RNA part. Other steps in maturation include modification of nucleotides (see above) and addition of the triplet CCA at the 3'-terminus by tRNA nucleotidyl transferase. Since this CCA terminus undergoes frequent turnover, the tRNA nucleotidyl transferase is also responsible for the maintenance of the 3'-end in order to keep the tRNA molecule functional for aminoacylation.

The charging of tRNAs with their cognate amino acids is catalyzed by aminoacyl-tRNA synthetases. For each sort of amino acid, there exists one of these highly specific enzymes in the cell. The synthetases charge the tRNAs in a very specific manner that underlies a ►proof reading mechanism in order to keep mischarging at a very low level. This is necessary since mischarged tRNAs would lead to the incorporation of

amino acids at wrong positions in the protein, resulting in deleterious non-functional products.

Suppressor tRNAs

Protein synthesis terminates when the translational machinery, the ribosome, reaches a codon in the mRNA that is not recognized by a tRNA, but rather by release factors that stop further elongation of the growing polypeptide. These so-called stop codons have the sequence UAG, UAA or UGA. Interestingly, certain mutational alterations of the tRNA's anticodon allow the tRNA to read such a stop codon and to incorporate its amino acid, leading thereby to a “read through” of the stop codon and suppressing the termination of protein synthesis. This means that these mutant tRNAs can suppress “nonsense” mutations in protein coding genes as follows. If a mutation changes a codon of the mRNA into a stop codon, it is no longer possible to synthesize the full-length protein encoded in this gene, since the new stop codon leads to premature termination of translation. However, if such a mutated tRNA can read this stop codon, it suppresses the premature termination, allowing the ribosome to complete the protein. Therefore, mutated tRNAs of this sort are called “nonsense suppressor tRNAs” (6).

A second category of suppressor tRNAs are the so-called missense suppressors. A mutation in a codon does not necessarily lead to a stop codon, but often changes the identity of the codon to that of another amino acid. As a result, a different amino acid is incorporated into the growing protein at this position. In this situation, a complementary mutation in the anticodon of the tRNA can restore the base pairing interaction with the mutated codon in the mRNA. This then allows the tRNA to deliver the correct amino acid to this position in the protein, again suppressing the effect of the original mutation in the protein-encoding gene. Along with their interesting role in biology, these suppressor tRNAs have turned out to be very useful tools for addressing many questions in molecular genetics.

Clinical Relevance

tRNA molecules are not only interesting research subjects for molecular biology, but are also of significant clinical relevance, since many mutations in these genes are associated with certain diseases. In ►mitochondria (cellular organelles with their own genome and translational machinery), many ►point mutations in tRNA genes have been implicated in a variety of multisystemic neuromuscular diseases and other severe disorders. Around 100 disease-correlated mutations in tRNA genes are currently described. An example is the mitochondrial gene that encodes for leucine tRNA, a particular hot spot with 16 pathogenic base changes that lead to diseases like ►MELAS (7). Mutations with the most severe effects are often found

tRNA. Figure 2 tRNA tertiary structure. The 3-dimensional L-shaped structure is formed and stabilized by tertiary hydrogen bonds between individual regions of the tRNA. The 4 helical domains of the cloverleaf secondary structure are arranged in two continuous helices: acceptor stem and T ψ C-arm build up one arm of the L, while D- and anticodon-arm form the other. This structure is stabilized by several stacking interactions. Note that the part reading the mRNA codon (anticodon loop) and the region carrying the amino acid (acceptor stem) are at maximum distance, which is required for protein synthesis at the ribosome.

in conserved elements and either affect invariant nucleotides or disrupt base pairs in double helical regions. Most of these changes are transitions (replacing a purine by a purine or a pyrimidine by a pyrimidine), which represent “mild” mutations in many protein-encoding genes. Here, however, these mutations can influence tRNA structure and recognition elements for interacting enzymes and therefore lead to severe negative effects on tRNA function. Due to the central role of mitochondria in energy metabolism, these mutations affect predominantly tissues with a high energy demand such as neuronal and muscular tissues, thus resulting in diseases like encephalopathies, myopathies or cardiopathies.

Another involvement of tRNAs in diseases is *via* their recruitment as primers for the replication of ►retroviruses like HIV. This can occur because the viral genome has a region that is complementary to the 3'-end of tRNA for lysine. By base pairing of this tRNA part with the viral RNA, the tRNA is used as a starting point for the ►reverse transcription of the viral RNA genome into the DNA form, which is a prerequisite for the replication and amplification of the virus. The host tRNA molecule therefore plays a central role in viral propagation in the cell and is also packed into the virion particle to be immediately available to the virus upon infection of another cell.

Hence, tRNA molecules are of clinical interest not only as a result of their association with certain hereditary diseases, but also due to their involvement in the replication of pathogenic retroviruses that can cause pandemic diseases like AIDS and possibly cancer.

TRP Channel

Definition

TRP (transient receptor potential) channels comprise of a superfamily of cation channels conserved in mammals, flies, worms and yeast. The various TRP-proteins bear sequence and structural similarities to the founding member of this superfamily, the transient receptor potential (TRP), a light activated cation channel in *Drosophila* photoreceptor. Visual transduction in *Drosophila* is mediated by three distinct channel proteins, TRP (missing in the *trp* mutant), TRP-like (TRPL) and TRP γ . So far, more than 25 TRP genes have been identified in mammals. Almost all TRPs are supposed to form ion channels that are widely expressed in the nervous system. Members of the TRP channel family are probable mediators of the store operated calcium entry (SOC) pathway in mammalian cells. TRP channel primary structures predict six

transmembrane spanning domains, with a pore domain between the fifth (S5) and sixth (S6) segments, and both C and N termini located intracellularly. These monomers are thought to coassemble to form homo- or heterotetrameric channels.

Tuberous Sclerosis

DAVID J. KWIATKOWSKI
Brigham & Woman's Hospital, Boston, MD, USA
dk@rics.bwh.harvard.edu

Definition

Tuberous sclerosis (TSC) is an autosomal dominant genetic disorder characterized by development of

► hamartomas and hamartias in several organ systems (1). The term hamartoma is used to indicate that there is overgrowth of relatively mature appearing cells in TSC lesions, in distinct contrast to common malignancies. TSC hamartomas involve the skin, brain and kidneys in most patients. However, the clinical manifestations of TSC are quite variable, so that there are formal diagnostic criteria, as listed below (2).

Major Features

1. Facial angiofibromas or forehead plaque
2. Nontraumatic ungual or periungual fibroma
3. Hypomelanotic macules (three or more)
4. Shagreen patch (connective tissue nevus)
5. Multiple retinal nodular hamartomas
6. Cortical tuber*
7. Subependymal nodule
8. Subependymal giant cell astrocytoma
9. Cardiac rhabdomyoma, single or multiple
10. Lymphangiomyomatosis+
11. Renal angiomyolipoma+

Minor Features

1. Multiple, randomly distributed pits in dental enamel
2. Hamartomatous rectal polyps
3. Bone cysts
4. Cerebral white matter radial migration lines *
5. Gingival fibromas
6. Nonrenal hamartoma
7. Retinal achromic patch
8. 'Confetti' skin lesions
9. Multiple renal cysts

Definite Tuberous Sclerosis Complex: Either two major features or one major feature plus two minor features.

Probable Tuberous Sclerosis Complex: One major plus one minor feature.

Possible Tuberous Sclerosis Complex: Either one major feature or two or more minor features

Characteristics

Although several organ systems may be affected by hamartomas, the vast majority of TSC hamartomas display limited growth potential and do not require intervention. A small fraction display persistent growth, necessitating surgical control. However, progression to malignancy is very rare in TSC, and has been seen only in TSC renal hamartomas, termed

*When cerebral cortical dysplasia and cerebral white matter migration tracts occur together, they should be counted as one rather than two features of tuberous sclerosis.

+When both lymphangiomyomatosis and renal angiomyolipomas are present, other features of tuberous sclerosis should be present before a definite diagnosis is assigned.

Tuberous Sclerosis. Figure 1 Brain lesions in tuberous sclerosis. (top) Brain MRI of an 8-year-old boy using the FLAIR technique demonstrates several cortical tubers (white, cortical lesions, indicated by arrows) and

angiomyolipoma (AML), at a frequency of about 2% of all TSC patients. Another remarkable feature of TSC hamartomas is that they first appear at different ages during the patient's life, and occasionally spontaneously resolve. For example, cardiac **rhabdomyomas** are often present at birth, but then typically disappear during childhood.

Brain Involvement

The cardinal feature of TSC is the **cortical tuber**, which is a distinctive form of brain hamartia (Fig. 1, top) (1, 3). Grossly, tubers are firm, smooth, somewhat raised, pale lesions of the cerebral cortex and can number up to forty in one brain, ranging in size from a few millimeters to several centimeters. The second common brain lesion seen in TSC is the **subependymal nodule** (SEN), typically found in the lateral ventricle. They occur as smooth nodules projecting into the ventricle and typically calcify in patients past the age of 10.

Histologically, cortical tubers are characterized by architectural disarray with disruption of cortical lamination (Fig. 1, bottom) (1, 3). Tubers contain a mixture of cells, including normal and dysplastic neurons, astrocytes and the hallmark giant cell. Giant cells extend short aberrant processes and express both glial and neuronal proteins. Dysplastic neurons in tubers show disrupted radial orientation and abnormal dendritic arbors and express both typical neuronal and embryonic neuroepithelial proteins. SENs consist of large cells in a vascular stroma, with occasional cells that attain giant cell proportions with aberrant and/or multiple nuclei. **Subependymal giant cell astrocytomas** (SEGA) develop from a SEN in 5–10% of TSC patients. Although there is growth to a size >1 cm, there is no histological progression. These lesions must be treated by surgical resection to prevent hydrocephalus and other adverse effects.

The major presenting symptoms and signs of cerebral TSC are a variety of epileptic seizures (1, 3). These seizures have their origin in the cortical tubers or in nearby transitional cortex. About two-thirds of TSC patients first present with **infantile spasms** usually between the ages of 3 and 9 months. There is a correlation between the number of cortical tubers in a TSC patient and both a younger age at onset of seizures and severity of seizures.

Mental retardation and developmental problems are serious consequences of brain involvement by cortical tubers. Mental retardation is variable but can be

subependymal nodules lining the ventricles (arrowheads). Courtesy of J. Egelhoff, Cincinnati, OH. (bottom) High power view of a cortical tuber shows giant cells (white diamonds). Cortical surface is to the right. Courtesy of J. Chan, Boston, MA.

profound, and rarely occurs in the absence of a generalized seizure disorder. Developmental problems are very common in TSC, and include autistic behavior, hyperactivity, sleep disorders and aggressive behavior.

Kidney and Skin Involvement

► **Angiomyolipomas** (AMLs) are the most common lesion in the TSC kidney, being seen in about 75% of children by adolescence using ultrasound imaging. These lesions consist of a variable mixture of aberrant vessels, smooth muscle, and fat. AMLs are typically bilateral and of variable size. Lesions >5 cm diameter are not rare, and large lesions are associated with a significant risk of bleeding as well as loss of nephrons due to compression.

Cutaneous findings are present in the great majority of TSC patients and are the most easily identified sign of the disease. Most lesions are of minor clinical significance, but facial angiofibromas can be a significant cosmetic issue.

Hypomelanotic macules or white spots typically have a lance-ovate shape (ash-leaf) and are most common over the trunk and buttocks. Three or more of these lesions are very unusual in the general population and thus are considered a major diagnostic criterion (see list under Definition). Histopathological examination shows reduced number, pigment content and size of melanosomes within the melanocytes in a hypomelanotic macule. The lesions are present at birth and do not change, though they are more easily observed following sun tanning.

Facial ► **angiofibromas** (formerly known as adenoma sebaceum) are red to pink papules or nodules with a smooth surface that are found in a malar distribution and extending down to the chin. They typically first appear between the ages of 2 and 6 and progress to a variable extent during puberty. Histological findings are dermal fibrosis and angiogenesis with occasional large glial appearing cells. Forehead fibrous plaque is a larger lesion related to facial angiofibroma, and shagreen patch is also a related lesion found typically on the upper buttock.

Ungual fibromas are another common cutaneous manifestation of TSC, being seen in most adults over the age of 30 years, but rarely prior to adolescence. These lesions are red- or flesh-colored papules or nodules occurring in the finger or toe nail regions. Their histopathology is similar to that of facial angiofibromas.

Other Sites of Involvement

► **Lymphangiomyomatosis** (LAM) is a disorder seen almost exclusively in females, which is characterized by smooth muscle cell proliferation and cystic changes in the lung parenchyma. Most LAM patients also have AMLs in the kidney or elsewhere in the abdomen.

LAM presents clinically as progressive dyspnea, or acute dyspnea due to pneumothorax. The natural history of LAM is poorly defined. There are women in whom it is progressive and fatal. Recent studies indicate that about 40% of adult TSC women have CT scan evidence of LAM. It is likely that most of those in whom it is asymptomatic and detected by CT will not have significant symptoms from this condition.

The retina is involved by hamartomas in about 50% of TSC patients. Cardiac rhabdomyomas are also found in most TSC infants when echocardiographic screening is done. These lesions can be up to several centimeters in diameter and consist of glycogen-filled myocytes. In most cases, there are no symptoms and the lesions spontaneously decrease in size or disappear over time. Less often, rhabdomyomas cause heart failure due to obstruction, affect myocardial function by replacement or cause rhythm disturbances and surgical resection is considered.

Cellular and Molecular Regulation

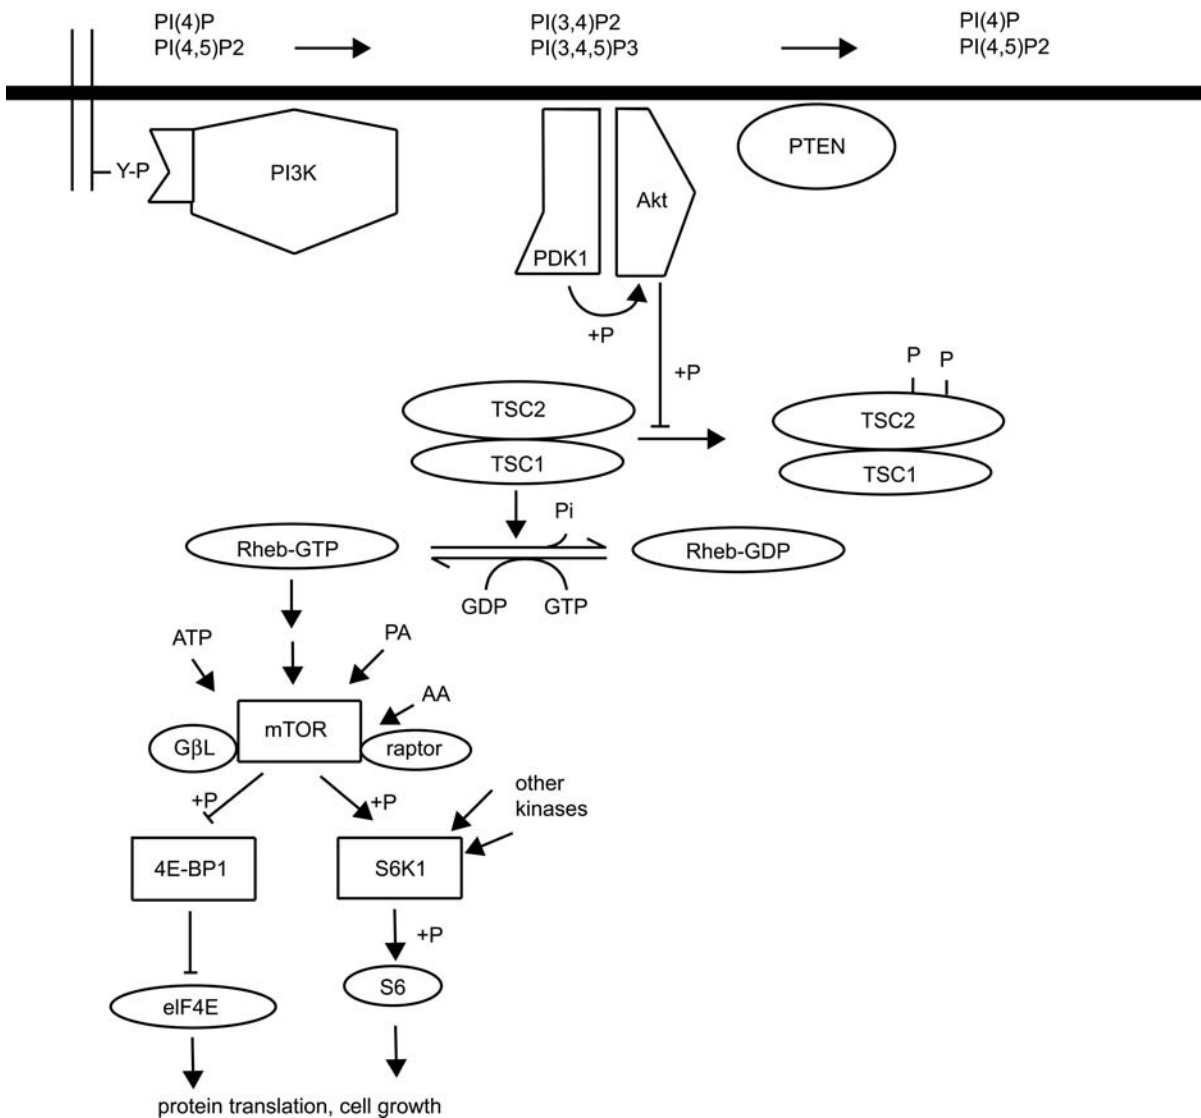

Clinical Genetics of TSC

TSC occurs as an autosomal dominant disorder. Large families with the condition are rare due to reduced reproduction among those affected. About two-thirds of TSC cases are sporadic, representing new mutations. TSC occurs in up to 1 in 6,000 live births without apparent ethnic clustering.

TSC Genes, Mutations, and the Two Hit Mechanism

TSC occurs due to inactivating mutations in either of *TSC1* or *TSC2*. These genes are both relatively large, and encode the proteins hamartin (130 kD) and tuberlin (200 kD), respectively. Over 600 *TSC1* and *TSC2* mutations (over 300 unique) have been identified, and comprehensive mutational analyses indicate that about 85% of TSC patients will have a mutation in either *TSC1* or *TSC2* identified (4, 5). *TSC2* mutations are about 4.2× as common as *TSC1* mutations, reflecting a higher germline mutation rate. Clinical surveys also indicate that patients with *TSC1* mutations have symptoms and clinical features that are milder on average than patients with *TSC2* mutations, although there is considerable overlap in the two sets of patients (5). Linkage studies provide evidence against a third TSC gene. Patients in whom mutations cannot be found are probably partially explained by ► **mosaicism**, which compromises efforts at mutation detection.

TSC hamartomas, particularly renal AMLs, often display ► **loss of heterozygosity** (LOH) for the wild type allele of either *TSC1* or *TSC2*, consistent with a two hit mechanism for complete inactivation of either *TSC1* or *TSC2* (4). LAM lesions require microdissection of the SMCs to demonstrate LOH events and such methods have been used to show that patients with LAM but without other features of TSC also have two

Tuberous Sclerosis. Figure 2 Signaling pathway model for the function of TSC1 and TSC2 in mammalian cells. A phosphorylated growth factor receptor is shown at upper left, to which a PI3K molecule is binding. This leads to conversion of the indicated phosphoinositides to 3'-phosphoinositides, which leads to recruitment of Akt to the membrane in a position where it can be phosphorylated and activated by PDK1 and a second kinase. PTEN functions to terminate this signaling pathway by acting as a 3' phosphatase on these phosphoinositides. Activated pAkt phosphorylates TSC2, which inactivates its GAP activity. When active, TSC1/TSC2 complex serves as a GAP for Rheb, reducing levels of Rheb-GTP. Rheb-GTP activates mTOR by an uncertain mechanism (thus 2 arrows). ATP, phosphatidic acid (PA), and amino acids (AA) all influence mTOR activity, although the sensing mechanisms are unknown and probably indirect. Active mTOR phosphorylates 4E-BP1 and S6K1. p4E-BP1 releases from eIF4E, permitting formation of the eIF4F translation complex. pS6K1 phosphorylates S6 and together they activate the translational machinery. For simplicity, only the main pathway involving TSC1, TSC2, and mTOR is shown. Arrows indicate positive actions and bars represent negative actions.

hit inactivation of *TSC2*. Cortical tubers do not show evidence of LOH, even with microdissection and alternative mechanisms of gene inactivation or cell admixture probably explain this finding. LOH is also seen in the tumors (kidney cystadenomas, liver

hemangiomas and extremity angiosarcomas) that develop in *Tsc1*^{+/-} and *Tsc2*^{+/-} mice.

Consistent with a relative lack of malignancy in TSC patients, limited surveys of human cancer specimens have failed to show evidence of either *TSC1* or *TSC2*

mutation, with the possible exception of bladder carcinoma.

TSC1/TSC2, PI3K, and mTOR Signaling

Major progress has occurred in recent years in our understanding of the biochemical function of the *TSC1* and *TSC2* gene products, initiated by seminal studies in *Drosophila* (6). Work in mammalian cells has led to the model of PI3K-Akt-TSC1/TSC2-Rheb-mTOR signaling that is shown in Fig. 2. In normal quiescent cells, PI3K and Akt are inactive, the TSC1/TSC2 complex is active as a GTPase activating protein (GAP) for Rheb, there are low levels of Rheb-GTP and mTOR is inactive. In response to growth factor stimulation, PI3K and Akt become activated, TSC2 is phosphorylated by Akt and the TSC1/TSC2 complex becomes inactive as a GAP, so that Rheb-GTP levels rise, stimulating mTOR. In cells lacking TSC1 or TSC2, there is no GAP for Rheb and Rheb-GTP levels are high, leading to constitutive activation of mTOR and phosphorylation of S6K1 and 4E-BP1. This model captures most of the current understanding of the roles of TSC1, TSC2, Rheb and mTOR in this pathway, but simplifies many aspects, omitting the multiple targets of Akt and the complex hierarchical phosphorylation of S6K1 that regulates its activity, as just two examples. One clinical correlate of this model is that hamartomas that occur in TSC both in patients and mouse models typically express pS6 and pS6K1, signposts of activation of mTOR.

The molecular basis of epileptogenesis in cortical tubers is uncertain, beyond the general lack of organization of the cortex in these lesions. There is increased transcription of genes encoding glutamatergic receptors in dysplastic neurons and giant cells, with reduced expression of gamma-aminobutyric acid (GABA)-ergic receptors. These expression changes may contribute to epileptogenesis in TSC (3). Recent work indicates that the tuber giant cells and SEN cells express pS6 and pS6K1 like other TSC lesions, suggesting that there is complete inactivation of *TSC1* or *TSC2* with activation of mTOR as in other TSC hamartomas.

Other Functions of TSC1/TSC2

The TSC1/TSC2 complex is 330 kD in size and the GAP domain of TSC2 comprises about 10 kD of this complex. This alone suggests that there are other functions for the complex. TSC1 has been reported to bind to ezrin and other ERM family proteins, and appears to be involved in adhesion events and rho signaling to the actin cytoskeleton. TSC2 has been reported to have a role in the membrane localization of polycystin-1 in renal epithelial cells. A role for the TSC1/TSC2 complex in beta-catenin signaling has also been noted. Whether any of these observations are

independent of or relate to the role of TSC1/TSC2 in the PI3K signaling pathway is unknown.

Clinical Relevance

TSC is a disorder that affects approximately 40,000 people in the USA. It is remarkable in several respects; the frequency and severity of associated epileptogenesis, the unique predisposition to autism and the unusual spectrum of associated tumors including LAM. The placement of the TSC genes in the PI3K-Akt-TSC1/TSC2-Rheb-mTOR signaling pathway is a major advance and highlights the potential importance of the *TSC1* and *TSC2* genes in other disorders affecting this pathway, including diabetes mellitus. This recent pathway discovery also provides the possibility of several pharmacological approaches that may be effective for TSC. These include drugs already in use in the clinic, including rapamycin and analogues, farnesyl transferase inhibitors, angiogenesis inhibitors and interferon- γ . Current ongoing and planned trials of these agents in both preclinical models and TSC patients are of considerable clinical and basic interest.

Tumor Suppressor Gene

Definition

Tumor suppressors comprise of a group of genes whose gene products reduce the probability of malignant transformations by repressing cell proliferation. As the name implies, they inhibit tumor formation. Loss of their function by mutations or loss promotes malignant transformation. According to the two-hit model by Knudsen, a mutation in only one allele of a tumor suppressor ("first hit") has no effects on the phenotype unless followed by a further mutation of the second allele ("second hit"). Frequently, mutation of one allele consists of a specific alteration of the coding sequence of a tumor suppressor resulting in a nonfunctional protein, whereas mutation of the other allele involves larger chromosomal alterations such as deletions, gene conversion and others. Alternative mechanisms of tumour suppressor inactivation are epigenetic silencing by methylation, expression blocks induced by upstream regulatory factors or defects in the regulatory region of the gene, e.g. preventing transcription factor binding.

Tumor Necrosis Factor- α

Definition

Tumor necrosis factor- α (TNF- α) is a pleiotropic cytokine that plays an important role in immunity,

Sometimes, mutations of tumor suppressors occur in an inherited, familial form resulting in a predisposition of patients for development of multifocal tumors at a low age. Prominent tumor suppressors are APC and p53.

Definition

►Cancer arises as the result of an accumulation of inherited and somatic mutations in cancer-critical genes. These genes can be divided in two broad classes, depending on whether the cancer risk arises from too much activity of a gene or too little. Mutation of a single copy of a ►proto-oncogene can have a dominant, growth-promoting effect on a cell. In the case of a ►tumor suppressor gene, the cancer-causing mutations are generally recessive; both copies of the gene must be removed or inactivated in the normal cell before an adverse effect is observed (Fig. 1).

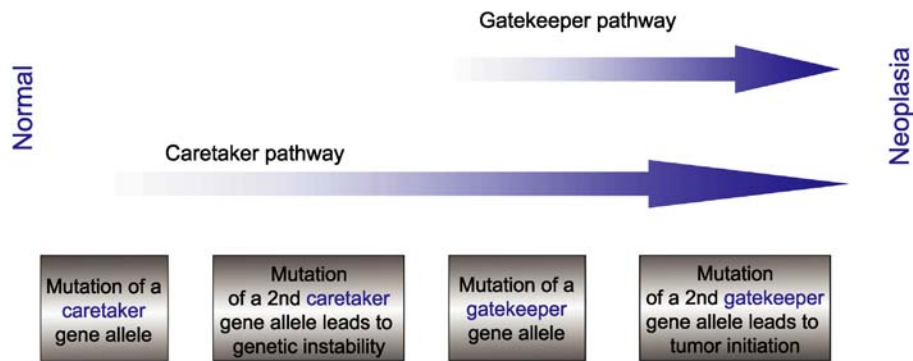

Tumor suppressor genes (TSG) encode proteins functioning in growth regulatory and/or differentiation pathways. The protein products of TSG are needed for proper cell functioning, and as a consequence, loss of their function can cause uncontrolled cell growth and ultimately tumors. Therefore, TSG are mainly detected by deletions or other inactivating mutations in tumors. The most compelling evidence for their important tumor suppressive role however is provided by certain ►hereditary cancers in which patients with the disease develop tumors that have lost both alleles, thereby lacking an active tumor suppressor gene. Also the progression of a wide range of sporadic and hereditary

cancers may be associated with inactivating changes in TSG (1). Mutations in TSG can either directly or indirectly increase the risk of cancer development (Fig. 2) (2). Mutations in so-called ►caretaker genes affect DNA damage repair, leading to generalized genomic instability, increased mutation rates and ultimately cancer. Examples of tumor suppressor genes that probably have an impact on DNA damage repair include BRCA1 and BRCA2, both associated with breast cancer development. Mutations in ►gatekeeper genes, such as those that regulate the ►cell cycle or those that promote ►apoptosis, can lead directly to a cellular malignant change, as these functions are the final checkpoints in the maintenance of DNA integrity. Key members of this class of tumor suppressors are ►p53 and ►RB.

Characteristics

Identification of Tumor Suppressor Genes

In contrast to the relatively straightforward approaches to the identification of oncogenic alleles in cancer, the identification of tumor suppressor genes has proved to be quite difficult. Oncogenes, with a ►gain-of-function mutation driving the cell towards cancer (Fig. 1), can be detected by their growth promoting effect and/or transforming capacity when added to the genome of a suitable type of tester cell. This can be performed by, for example, DNA transfection or through infection with a viral vector. In the case of a tumor suppressor gene, a different approach is needed. By studying rare cancers that run in families (hereditary cancers), a few key tumor suppressor genes (RB and p53) with universal relevance have been discovered (see also

Tumor Suppressor Genes. Figure 2 Pathways to neoplasia. In the caretaker pathway, multiple genes need to be inactivated in the cell to become neoplastic. First, two alleles of a caretaker gene are mutated. The inactivation of the caretaker gene subsequently accelerates the accumulation of the mutations in gatekeeper genes. In contrast, in the gatekeeper pathway, only one gene inactivation is needed to initiate neoplasia. Adapted from Kinzler and Vogelstein. (1997) *Nature*, 386, p. 763.

below). However, when there is no such clue from a hereditary syndrome, TSG have to be identified by virtue of their absence from tumor cells. Current methods depend on scanning the genomes of cancer cells for signs of gene loss. These methods are often employed in concert and involve cytogenetic studies of constitutional chromosomal alterations in cancer patients, linkage analysis to localize genes that predispose to cancer and loss of heterozygosity (or allelic loss) studies undertaken on matched pairs of normal and cancer tissues. Loss of heterozygosity (LOH) appears the most common molecular genetic alteration in human cancer. In sporadic tumors, up to 50% of all chromosomes may have undergone LOH events.

An increasing number of tumor suppressor genes with critical roles in cancer predisposition, and associated with a hereditary cancer syndrome, have been identified and cloned (Table 1) (10).

RB and Retinoblastoma

The key insight that led to the discovery of *RB*, the first identified tumor suppressor gene, came from studies of a rare type of human cancer called ►retinoblastoma. Retinoblastoma occurs in childhood with tumors developing from neural precursor cells in the immature retina. In the hereditary form of this disease, multiple tumors arise in both eyes, whereas in the non-hereditary form a single tumor arises in each eye. All retinoblastoma patients (both hereditary and non-hereditary) have an abnormal ►karyotype, with a deletion of a specific region of chromosome 13. Using the known location of the chromosomal deletion associated with the disease, it was possible to clone and sequence the *RB* gene, whose loss appeared to be critical for the development of the cancer. In patients who suffer from the hereditary form of the disease, a deletion or loss of

function mutation is present in one copy of the *RB* gene in all cells of the body, which makes these cells *RB* heterozygous and as such predisposed to become cancerous (3). Analysis of a variety of somatic tumors revealed mutations in *RB* in several common types of tumors, including carcinomas of the lung, breast, and bladder. In all of these tumors, complete loss of *RB* is frequently a major step in the progress towards malignancy. The RB protein turns out to be a universal regulator of the cell-cycle that is normally expressed in almost all cells of the body (4).

p53 and the Li-Fraumeni Syndrome

The ►Li-Fraumeni syndrome (LFS) is a rare ►autosomal, dominantly inherited disorder characterized by the diagnosis of bone or soft-tissue ►sarcoma at a relatively young age. Already in 1969, Li and Fraumeni identified the first 4 families in which sibs or cousins developed a childhood sarcoma, together with striking histories of breast cancer and other neoplasms. This suggested a new familial cancer syndrome of diverse tumors, including soft tissue sarcomas, breast cancer, brain tumors, osteosarcomas, leukemia and adrenocortical carcinoma (Fig. 3) (5). Since then, a lot of other families have been identified with the classic phenotype of LFS (bone- or soft-tissue sarcoma at an early age with one first-degree relative with early-onset cancer or sarcoma diagnosed at any age). In LFS-like (LFS-L) families the phenotype of LFS is not expressed completely. These families show a combination of multi-cancer phenotypes, but fail to meet the stringent criteria for LFS. However, common to all these families is the occurrence of a variety of cancers at a relatively early age (5). Germ-line alterations in the *p53* tumor suppressor gene, located on chromosome 17, have been observed in the majority (~80%) of LFS families and

Tumor Suppressor Genes. Table 1 Human (candidate) tumor suppressor genes associated with familial syndromes (see for extensive list (10))

Gene	Cancer syndrome	Principal tumors
RB1	Retinoblastoma	Retinoblastoma, osteosarcoma
<i>p53</i>	Li-Fraumeni	Sarcomas, breast and brain tumors
APC	Familial adenomatous polyposis	Adenomatous polyps, colon cancer
WT1	Wilms' tumor	Nephroblastoma
NF1	Neurofibromatosis type I	Neurofibromas, sarcomas, gliomas
NF2	Neurofibromatosis type II	Schwannomas, meningiomas
VHL	von-Hippel Lindau	Renal cell (clear cell) pheochromocytomas, hemangiomas
<i>CDKN2A</i> <i>P16^{Ink4a}</i>	Familial malignant melanoma	Melanoma, pancreatic cancer, other?
<i>CDKN2A</i> <i>P14^{ARF}</i>	Familial malignant melanoma	Melanoma, pancreatic cancer, other?
BRCA1	Familial breast cancer	Breast and ovarian cancer
BRCA2	Familial breast cancer	Breast and other
TSC1	Tuberous sclerosis I	Renal and brain tumors
TSC2	Tuberous sclerosis II	Renal and brain tumors
PTEN	Cowden syndrome, Bannayan-Riley-Ruvalcaba syndrome	Hamartoma, glioma, prostatic, endometrial cancer
CDH1(E-cadherin)	Familial gastric carcinoma	Gastric and lobular breast
CYLD	Familial cylindromatosis	Cylindromatosis
EXT1	Multiple exostoses I	Exostoses, osteosarcoma
EXT2	Multiple exostoses II	Exostoses, osteosarcoma
FH	Hereditary leiomyomatosis and renal-cell cancer	Leiomyomatosis, renal
MADH4	Juvenile polyposis	Gastro-intestinal polyps
MEN1	Multiple endocrine neoplasia type I	Parathyroid adenoma, pituitary adenoma, pancreatic islet cell, carcinoid
NBS1	Nijmegen Breakage syndrome	NHL, glioma, medulloblastoma, rhabdomyosarcoma
PTCH	Nevoid basal-cell carcinoma syndrome	Skin basal cell, medulloblastoma
SDHB	Familial paraganglioma	Paraganglioma, pheochromocytoma
SDHC	Familial paraganglioma	Paraganglioma, pheochromocytoma
SDHD	Familial paraganglioma	Paraganglioma, pheochromocytoma

in a proportion (~20%) of LFS-L families. These mutations in *p53* are inherited as autosomal dominant, so affected individuals are heterozygotes with a missense *p53* mutation in one allele. The mutations

are thought to behave as ► **dominant-negatives**, inhibiting the function of the wild type *p53* protein (6). However, more than half of all tumors carrying *p53* mutations have lost the remaining wild type allele

Tumor Suppressor Genes. Figure 3 Tumor spectrum in Li-Fraumeni patients.

(►loss of heterozygosity, LOH), suggesting that complete loss of p53 is essential for tumor development and/or maintenance.

Apart from Li-Fraumeni patients, p53 mutations are also frequently found in ►sporadic tumors. The first p53 mutation in an individual with sporadic cancer was reported as early as 1989. Astonishingly, it now seems that more than half of all human cancers lose p53 function by mutation. Due to the increased number of sequences of human cancers that have been added to a database, more than 10,000 somatic tumorigenic p53 mutations are known at this moment. Interestingly, certain ►hotspot mutations are frequently observed, with the specific mutation dependent on the tumor type (7).

In normal cells, the induction of a functional p53 protein in response to stress leads to either reversible inhibition of cell growth through the induction of a cell-cycle arrest enabling DNA repair, or the induction of apoptosis if DNA damage is too severe. Based on these functions, p53 is also frequently referred to as the “guardian of the genome” (8).

Molecular Interactions/Regulatory Mechanisms

Although it is clear that all tumor suppressor proteins exhibit a variety of functions, the cellular functions and regulators of a number of TSG remain largely undefined. However, the regulation of both *RB* and *p53* is well elucidated. These two transcription factors are regulated by the *CDKN2A* locus, a locus that encodes two different proteins, p16^{INK4a} and p14^{ARF}. Both proteins are necessary to regulate the cellular lifespan via two different pathways, the *RB* and *p53* pathways respectively (Fig. 4). In the *RB* pathway, expression of p16^{INK4a} functionally inhibits the cyclin D-CDK4/6 complexes that regulate *RB*. p14^{ARF} inhibits the ubiquitin ligase HDM2, leading to elevated levels of p53. Both pathways are known to be

Tumor Suppressor Genes. Figure 4 The human Ink4A/Arf locus, encoding two different proteins. First exons 1α and 1β are transcribed from different promoters resulting in separate 5'ends of the Ink4A and Arf RNA transcripts. Both are spliced to the acceptor splice site in exon 2. As such, 2 different proteins are produced regulating the *RB* or the *p53* pathway. Adapted from Sherr (2001) *Nature Reviews Cancer*, 2, p. 732.

important in the regulation of the process of immortalization of cells, an essential prerequisite for the formation of a tumor cell (4).

RB

The *RB* protein and its relatives p107 and p130 constitute the “pocket protein” family of cell-cycle regulators. Of this protein family, only *RB* has been demonstrated to have real tumor suppressor properties. It inhibits cell proliferation by preventing entry into the DNA synthesis (S) phase. The main targets of the pocket proteins are E2F transcription factors that are blocked from activating DNA replication, nucleotide metabolism genes such as cyclin A, E and D1 and thymidine kinase. However, it has recently been discovered that *RB*, p107 and p130 are also involved in the regulation of terminal differentiation of various tissues and cell types. *RB* appears to play an important but complex role in multiple stages of the differentiation process including irreversible exit from the cell-cycle, protection from apoptosis, induction of cell type-specific gene expression and maintenance of the post-mitotic state by interaction with many diverse transcriptional regulators (9).

p53

In unstressed cells, p53 is present in a latent form and is maintained at low levels through targeted degradation. However in response to damaged DNA, nucleotide depletion, hypoxia and several other genotoxic stresses,

p53 accumulates in the nucleus and is activated to exert its function as a transcription factor to prevent tumor development. The way p53 performs its tumor suppressor role involves diverse cellular processes. The repertoire of p53 activities includes regulation of the cell-cycle, induction of apoptosis, ►senescence, facilitating DNA repair and antagonizing angiogenesis. Many of these functions are mediated by transcriptional activation of target genes by p53. On the basis of these functions that all regulate cell growth and maintain genome integrity, the tumor suppressor p53 is also known as the “guardian of the genome” (8).

Conclusions and Outlook for the Future

An important goal of cancer research has been the identification of so-called cancer genes, i.e. genes that are frequently mutated in and, as a consequence, causally related to human cancers. Knowledge about these genes has evolved enormously, and thus far, a total of 291 genes has been identified representing more than 1% of all human genes. With the development of new and highly innovative genomics technologies such as micro-array expression analysis and comparative genome hybridization, it is to be expected that many more cancer genes, including TSG, will be identified in the near future. In addition, revealing the human genome sequence, as well as that from other organisms such as the mouse, will undoubtedly simplify the identification of these genes. Finally, generating tissue-specific knockout mouse models using Cre-loxP based technologies will enable a more detailed and *in vivo* analysis of the functions of these genes.

Tumor Viruses

Definition

Tumor viruses comprise of a heterogeneous group of viruses defined by the causative role of its members in naturally occurring malignant diseases, or their capacity to induce tumours in experimentally infected laboratory animals. Most of them are hepadnaviruses, papillomaviruses, polyomaviruses, adenoviruses, gamma herpesviruses or retroviruses.

►Viral Oncogenesis

Definition

To determine the structure of a membrane protein, two-dimensional (2D) or three-dimensional (3D) crystals are required. 2D crystallization assembles membrane proteins into highly ordered 2D arrays in the presence of lipids. In this case, membrane proteins are embedded in their native environment, the lipid bilayer, and are thus in a functional state. Their structure is then assessed by ► [electron crystallography](#).

Description

Membrane proteins comprise more than 30% of the proteome of higher organisms. With characteristic dimensions of 5–10 nm they are membrane-embedded nanomachines that fulfill key functions such as energy conversion, solute transport, secretion and signal transduction. Their central role in a wide range of diseases and in cell-cell communication may explain the fact that 70% of all drug targets are membrane proteins. While the structures of more than 10,000 soluble proteins are solved, the number of membrane

protein structures is smaller than 100. This lack of structural information is related to the instability of membrane proteins in a ► [detergent](#)-solubilized state, making the growth of 3D crystals difficult. To understand the function of membrane proteins knowledge of their structure is urgently required. 2D crystals of purified membrane proteins reconstituted in the presence of lipids provide a close to native environment. Electron crystallography allows the atomic structure of a membrane protein packed in a perfect 2D crystal to be elucidated at atomic resolution. In contrast, ► [atomic force microscopy](#) (AFM) provides the surface structure of membrane proteins from tightly packed, but disordered membranes at sub-nanometer resolution. Combining these methods the structure and function of membrane proteins can be directly assessed.

To obtain 2D crystals the protein of interest has to be expressed in mg quantities, solubilized and purified in a detergent and finally reconstituted into an artificial lipid bilayer. The interactions of lipids, proteins and detergents are complex and difficult to predict. Thus, 2D crystallization is still an experimental art, in spite of accumulated knowledge summarized in recent reviews (1, 2, 3) each new membrane protein requires specific optimizations to be crystallized. In this chapter the general trends and current techniques of 2D crystallization are described, emphasizing the importance of membrane ► [solubilization](#).

Membrane Protein Purification

Detergents

Detergents are amphiphilic molecules with limited water solubility as monomers. However, above their ► [critical micellar concentration](#) (CMC), the structure of such molecules promotes clustering into micelles. Thereby their hydrophobic part is buried in the micelle core and is shielded from water by the hydrophilic micelle surface. The CMC is determined by the balance between the solvation energy provided by the hydrophilic head group and the entropic cost of transferring the hydrophobic tail into water. Above the CMC, hydrophobic substances can be solubilized by embedding them in the hydrophobic core of the micelles. Depending on the structure of the detergent, a micelle can assume a spherical or rather a disk-like shape, accommodating about hundred or only a few molecules. Accordingly, the solubilization capacities of different detergent types for membrane proteins and lipids vary significantly, and are dictated by their stereochemistry (Fig. 1; see ► www.anatrace.com and LeMaire et al. 2000).

Let's consider the properties of some frequently used detergents. The first group concerns detergents having an alkyl moiety, which all form spherical micelles accommodating about 100 detergent molecules. The

Two-dimensional Crystallization of Membrane Proteins. Figure 1 The structure of commonly used detergents and their lipid solubilization capacity. Three groups are distinguished and discussed in the text. Alkyl based detergents are the most widely used detergents for membrane protein crystallization (a, b, c, d, f). Cyclohexyl based detergents (e, g) have recently been developed and are mild as result of the cyclohexyl group. They are to some extent similar to Triton X-100 (h). Sterol based detergents (i) exhibit a bulky hydrophobic group and accommodate only a few molecules per micelle. Turbidimetry has been used to determine the dissolution point of DMPC in the presence of different detergents (k, l) (7).

zwitterionic dimethyl-amine-N-oxide type detergents (Fig. 1a) have the smallest head group of all detergents shown in Fig. 1. The often-used dodecyl variant (DDAO), also known as lauryl-dimethyl-amine-N-oxide (LDAO; Fig. 1a) exhibits a CMC of 0.14 mM and has an almost cylindrical outer surface and a cross-section of about 0.34 nm^2 (4). β -D-glucopyranoside type detergents have a larger head group and thus a conical shape (Fig. 1b). Octyl- β -D-glucopyranoside (OG) is a frequently used detergent, because it is rather mild in spite of its high CMC (25 mM). Nevertheless, decyl- β -D-glucopyranoside (CMC=2.2 mM) and

dodecyl- β -D-glucopyranoside (CMC=0.13 mM) are often used as well. Octyl- β -D-thio-glucopyranoside (OTG; CMC=9 mM; Fig. 1c) is interesting because of its specific interaction with lipids, which promotes formation of large 2D crystals (1). β -D-maltoside type detergents (Fig. 1d) have a cross-section of about 0.47 nm^2 (4). Octyl- β -D-maltoside (CMC=23 mM), decyl- β -D-maltoside (DM; CMC=1.6 mM) and dodecyl- β -D-maltoside (DDM; CMC=0.15 mM) are commonly used. DDM is a particularly mild detergent, which allows solubilization and purification of fragile membrane proteins. This is the result of appropriate

head group properties and the lipid-like hydrophobic moiety. However, combining a phosphocholine head group with an alkyl tail (Fig. 1f) appears to provide an even milder detergent suitable for membrane protein solubilization. FOS-CHOLINETM detergents are available as octyl up to (CH₂)₁₅ variants, providing a large range of CMCs. Alkyl-polyoxyethylene (C_nE_m) type detergents exhibit an even larger head group. C₁₂E₆ for example, has a cross-section of about 0.66 nm² (4) and has been used for the crystallization of several membrane proteins.

The second group of interest concerns detergents with a bulky hydrophobic tail as results of a cyclohexyl group terminating the (CH₂)_n chain (Figs. 1e, g). This bulky tail is expected to prevent the destabilization of the ternary structure of typical α -helical membrane proteins, because such a tail may not be able to wedge in between the α -helices. The development of the corresponding CYMALTM and CYGLUTM detergent series has been fostered by the success of Triton detergents in functional reconstitution of membrane proteins (Fig. 1h).

The third group considered has an altogether different, steroid-based hydrophobic moiety also found in the bile salts. The structure of one representative of this group, CHAPS (Fig. 1i) shows the trihydroxy-oxocholan structure, a flat disk with 3 hydroxyls on the top side and a hydrophobic bottom side, to which the zwitterion dimethylammonio-propane sulfonate is attached. For such detergents only a few molecules are required to form a micelle, ideally two CHAPS molecules could stack together to shield the hydrophobic oxocholan surface from the aqueous environment. These detergents have a large capacity to solubilize lipids and are relatively mild in spite of high CMC values.

Membrane Protein Solubilization and Purification

The solubilization of lipids has been studied in depth using different physical methods (for recent reviews see BBA Volume 1508, 1-251), leading to a model defining a three-stage solubilization process. In stage I, non-micellar detergent partitions into the phospholipid bilayer, whereas in stage III the phospholipid is fully solubilized by uptake into detergent micelles. In the intermediary stage II, phospholipid membranes saturated with incorporated detergent coexist at thermodynamic equilibrium with mixed phospholipid-detergent micelles saturated with phospholipid. This process is well characterized by light scattering and microcalorimetry for different lipid/detergent systems and described by thermodynamic models (5, 6). The **dissolution points** of dimyristoyl-phosphatidylcholine (DMPC) for different detergents as determined by turbidimetry (7) (Figs. 1k, l) illustrate the lipid solubilization capacity of frequently used detergents.

Beyond the **saturation point** detergent molecules cooperatively interact with the bilayer to produce filamentous lipid assemblies that probably carry detergent caps at their ends. This has been observed by cryo-electron microscopy as well as light and neutron scattering experiments.

In the presence of both lipids and proteins, the situation is more complex (4). Above the critical solubilization concentration of the detergent, lipid and protein containing units exist as mixed lipid/detergent micelles and detergent solubilized proteins, covered by detergent and tightly associated lipids. Mild detergents surround the hydrophobic sector of integral membrane proteins by a micelle-like structure without impairing the protein's function. Depending on the detergent - protein and lipid-protein affinities, the hydrophobic sector of the protein can bind detergent even at concentrations below the CMC, which displaces lipids from the protein surface. More favorable is the situation where tightly associated lipids remain bound to the protein, preserving the native state even after solubilization. Since the stereochemistry of all constituents dictates these interactions, it is difficult to predict whether a certain detergent preserves the structure and function of a membrane protein. Although low CMC detergents are milder than high CMC detergents, the properties of both head group and hydrophobic tail define the stability of the solubilized membrane protein.

The choice of the detergent is most critical and has to be tested for every protein individually. It should be stressed that the availability of a stable, solubilized and pure membrane protein is the absolute prerequisite for successful 2D crystallization. To explore this, the membrane preparation containing the protein is divided into aliquots and solubilized with different detergents. Samples are centrifuged at high speed and both the pellet and supernatant are analyzed on SDS-PAGE. Western blotting, e.g. with antibodies against the affinity **tag**, then reveals the fate of the protein: If most of the protein is found in the pellet, the detergent may have destabilized the protein or only incompletely solubilized the membrane. In the latter case, pre-washing the membrane to strip off peripheral membrane proteins may help. This is achieved by washing the membranes in buffers of different types (high salt, low salt, EDTA, cholate, alkaline pH).

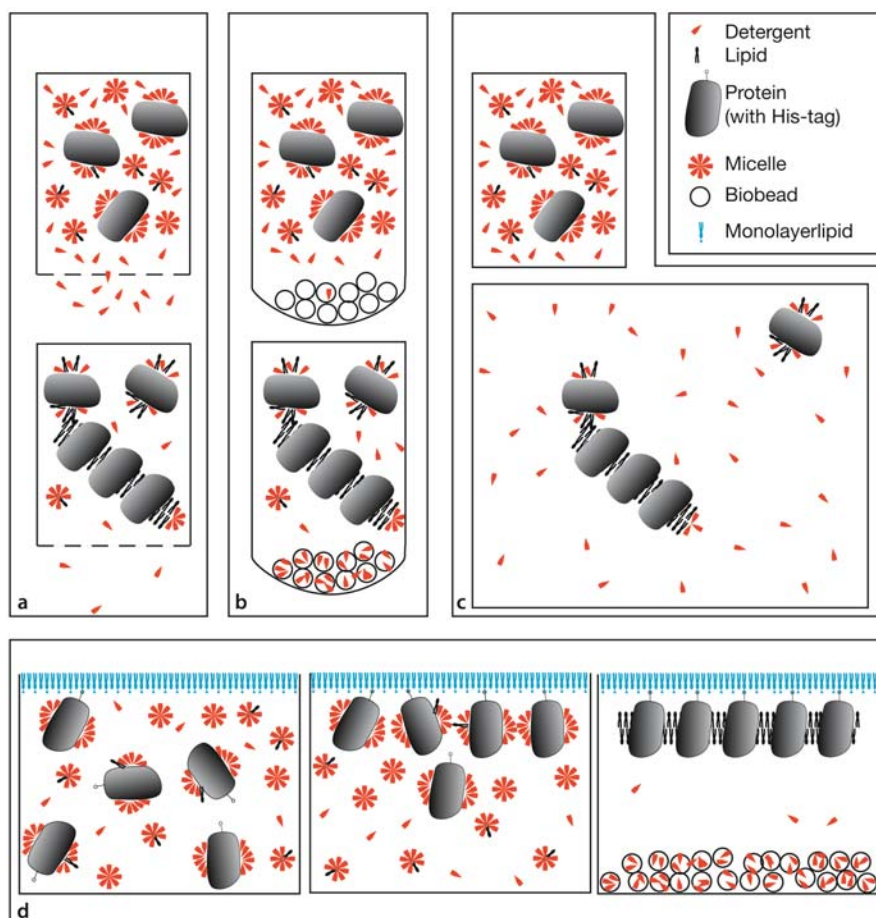

The selected detergents must be tested for their suitability to purify the protein. For purification, classical chromatographic methods can be used but affinity purification methods are generally milder, thus preserving the native state of the protein. Small aliquots of purified protein are analyzed for their oligomeric state by gel filtration or ultracentrifugation and for protein stability. The best method is to prepare negatively stained samples of the protein solution and

observe them by transmission electron microscopy. By this method, small aggregates are detected, which form after a few days and are not visible by eye. As an alternative, parts of the sample are centrifuged at high speed and the protein concentrations of the pellet and the supernatant are subsequently measured.

Two-Dimensional (2D) Crystallization

To assemble 2D crystals in the presence of lipids, the membrane protein is reconstituted in the bilayer. During reconstitution, the protein concentration in the lipid phase is drastically increased and conditions are selected that promote the precise regular packing of the

membrane protein, a most critical parameter being the lipid-to-protein ratio. This process is the reversal of the membrane solubilization process described above. Therefore, the respective affinities between the membrane protein, lipids and detergent determine the outcome of the reconstitution experiment. Fine-tuning of these interactions is achieved by careful selection of pH, ionic strength, counterions and osmolytes. The speed of detergent removal is another critical factor, which is difficult to control in most reconstitution schemes. Many protocols designed to reconstitute membrane proteins into 2D crystals have been described (Fig. 2).

Two-dimensional Crystallization of Membrane Proteins. Figure 2 2D crystallization modes. All modes are based on the principle of bringing the detergent concentration in the aqueous phase below the CMC, forcing the detergent in the mixed micelles to partition in the aqueous phase. As result, mixed micelles merge to form larger structures and ultimately 2D crystals. (a) Dialysis can be used to remove the detergent provided its CMC is >1 mM. (b) Bio-Beads adsorb detergent molecules and can be used for all detergents. Bio-Bead driven 2D crystallization is particularly successful with low CMC detergents. (c) Dilution is a well-known method for functional reconstitution of membrane proteins. In spite of dilution it is also suitable for 2D crystallization, because the protein is highly concentrated after integration in the bilayer. (d) The monolayer technique combines the Bio-Bead method with crystallization at the air-water interface. This method works only with low CMC detergents because of the necessity of preserving the lipid monolayer. The latter incorporates special lipids having a high affinity for the solubilized protein, e.g. by recognition of a specific tag.

Dialysis Driven 2D Crystallization

Dialysis is the most widely used technique in 2D crystallization trials (1, 2). Usually small sample compartments are dialyzed against large buffer volumes. To improve the reproducibility of crystallization conditions, a temperature-controlled continuous flow dialysis apparatus can be employed (Fig. 3). Temperatures of up to 40°C sometimes improve the crystal quality, but this requires the proteins to be integrated in the lipid bilayer. Such heat treatment promotes reordering of the molecules into more regular arrays. The major draw-back of the dialysis method is the long dialysis time needed to remove low CMC detergents, making it practical only for medium to high CMC detergents (typically $\text{CMC} > 1 \text{ mM}$). In spite of these limitations, dialysis has led to many highly ordered crystals (1, 2).

► Bio-Beads

Hydrophobic adsorption of detergents by polystyrene beads (Bio-Beads SM2, Bio-Rad) works for removal of low CMC detergents and has been used to generate highly ordered 2D crystals of membrane proteins (1).

Two-dimensional Crystallization of Membrane Proteins. Figure 3 A temperature controlled open dialysis system for 2D crystallization. The upper panel shows the cross-section of the device, while the lower panel displays the machine allowing simultaneous reconstitution in 30 wells. Each well accommodates about 100 μl and the overall size of the system is about 10 cm by 20 cm.

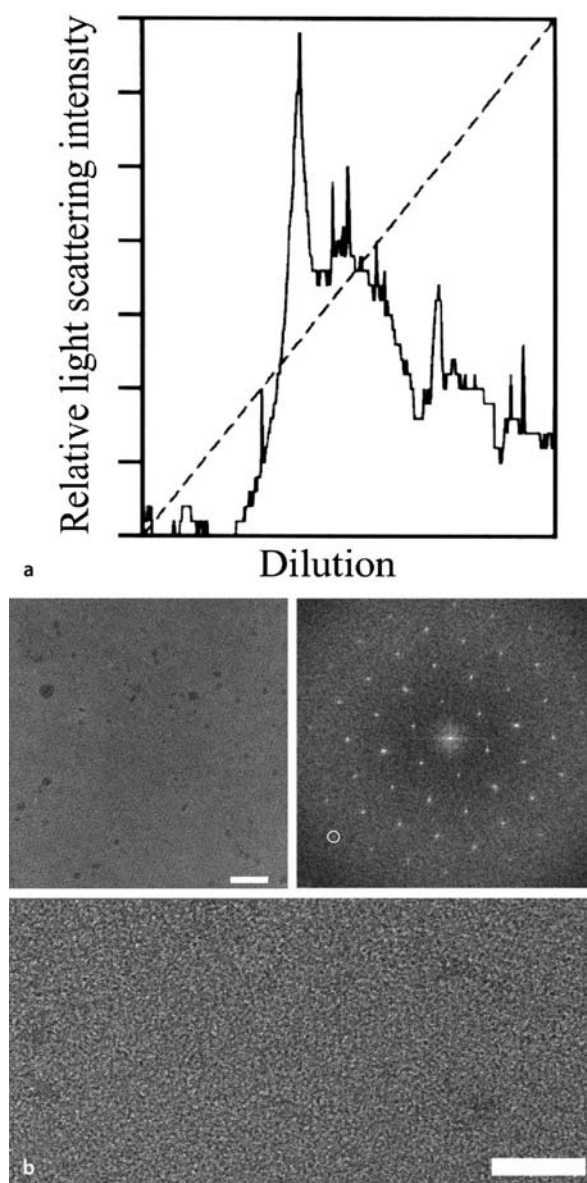

The non-specific adsorption of lipids is about 100–200 \times lower than the specific adsorption of detergents (2–4 mg phospholipids/g Bio-Beads SM2). The rate of detergent removal is directly linked to the weight of Bio-Beads used, but also to the working temperature, the rate doubles with every 15°C. To maintain a reproducible adsorption property, precise weighing of the Bio-Beads has to be performed on freshly blotted beads that must not dry out. Examples of crystals produced by the Bio-Bead method are given in a recent review (1).

Dilution Driven 2D Crystallization

Diluting a solution of protein, lipid, and detergent decreases the concentrations of all components by equal factors, until the detergent concentration in the aqueous phase drops below the CMC. Fig. 4 shows an example where the concentration of octyl-polyoxyethylene (8-POE) was decreased by dilution and the formation of structures of different sizes was monitored using turbidimetry (7). Porin OmpF assembled in the presence of DMPC only if the dilution rate was slow. During dilution, assembly of mixed micelles started shortly before the CMC of 8-POE was reached. Upon further dilution the co-existence of crystalline sheets of variable sizes up to several micrometers and of small, spherical vesicles was observed. Invariably, the large structures all exhibited crystallinity while small vesicles had a similar size to those produced in the absence of proteins. Crystallization by the dilution method requires a significant dilution of the protein and thus rather high initial protein concentrations. But the dilution method allows the process to be arrested when the micelle-bilayer transition is reached, extending the time in which an ordered assembly of the components can take place. In addition, the dilution method is suitable for low CMC detergents whose concentration is brought close to the CMC by the use of Bio-Beads prior to the dilution experiment.

Growth of 2D Crystals at Interfaces

The possibility of engineering tags to either terminus of a recombinant membrane protein greatly facilitates its purification. In addition, such a tag provides a handle to adsorb the membrane protein to a lipid monolayer formed at the water air interface and composed of spacer lipids and lipids designed to bind the hapten grafted to the protein. The method developed for soluble proteins has recently been used successfully to crystallize membrane proteins. Advantages concern unidirectional incorporation in the bilayer and the minute amounts of protein required. The lipid film consists of a mixture of a spacer lipid and – for a protein bearing a His-tag – a Ni-chelating lipid. Lipids are solubilized in an organic solvent, and spread onto a small buffer volume in a Teflon well

Two-dimensional Crystallization of Membrane Proteins. Figure 4 Dilution driven reconstitution of 2D crystals. (a) The turbidity profile of a dilution experiment with mixed micelles of DMPC and porin OmpF solubilized in octyl-polyoxyethylene (POE) reveals a sharp increase in the scattered light upon reaching the CMC of octyl-POE. Upon further dilution, the light scattering decays. (b) Negatively stained OmpF crystals obtained after a ten fold dilution over 2 h and phospholipase A2 treatment (top left, overview; top right, diffraction pattern with the marked spot at $(1.8 \text{ nm})^{-1}$; bottom, high magnification). The scale bars represent 120 nm (top left) or 90 nm (bottom).

of approximately 4 mm diameter and 1 mm depth. The solubilized membrane protein is injected into the buffer with excess detergent and incubated

for several hours. Excess detergent is removed with Bio-Beads (3).

Functional & Structural Assessment of 2D Crystals

Functional Analyses

Since membrane proteins are reconstituted in a lipid bilayer during 2D crystallization, all vesicle based functional assays may directly be applied. Thus, the function of the protein may be assessed in its crystallized form, an essential advantage of 2D crystallization. Another advantage is the precise knowledge of active units per surface area, allowing quantitative functional analyses to be achieved. This approach has been used to assess the water transport capacity of aquaporin-1 (AQP1; Fig. 5a).

Determination of Surface Structure and Dynamics by Atomic Force Microscopy

The atomic force microscope (AFM) allows biomolecules to be observed and manipulated under native conditions. It produces images with an outstanding signal-to-noise ratio and addresses single molecules while the sample is in a buffer solution. Topographs that reveal subnanometer details as well as the surface dynamics of membrane proteins reconstituted in a bilayer have been recorded. The surface structure of a tetragonal AQP1 crystal (Fig. 5b) reveals the topography of both the cytoplasmic and the extracellular surface, because AQP1 tetramers are packed in up and down orientations.

Determination of the Atomic Structure by Electron Crystallography

Electron diffraction is the ultimate test of crystal order. A diffraction pattern of an AQP1 2D crystal reveals diffraction spots to a resolution better than 3.5 Å (Fig. 5c). Electron crystallography of such crystals has led to the first atomic structure of a human membrane channel.

Perspectives

2D crystallization is an interesting approach for assessing the structure and function of membrane proteins. Although the preparation of a stable, solubilized and pure membrane protein must initially be achieved as in the growth of 3D crystals, speedy incorporation of the protein into the bilayer during 2D crystallization enhances the chances of restoring and preserving the native protein structure. A vision to be further developed is the *in vitro* expression of a membrane protein into an essentially empty lipid vesicle. *In situ* crystallization starting from such vesicles enriched in the protein of interest seems feasible. The decisive advantage of this approach is the circumvention of the solubilization step required in all other methods.

Two-dimensional Crystallization of Membrane Proteins. **Figure 5** Functional and structural assessment of aquaporin-1 (AQP1) 2D crystals. (a) Rapid mixing of fluorescein-loaded vesicular 2D crystals with a 20% sucrose solution at time 0 results in an osmotically driven rapid outflow of water and vesicle compression. Concentration-induced quenching of the fluorescence indicates the relative volume change. From the average size of the vesicles, the transported water volume as well as the number of AQP1 channels can be calculated. (b) AQP1 tetramers are packed in a tetragonal crystal with $p422_1$ symmetry as revealed by the topography recorded by AFM. The structures of the extracellular, highly corrugated surface and the cytosolic surface are distinctly different. The scale bar represents 15 nm. An electron diffraction pattern of such tetragonal crystals documents their excellent crystalline order, revealing diffraction spots beyond 3.5 Å resolution.

Definition

In **▶two-dimensional gel electrophoresis** (2-DE) proteins are separated in polyacrylamide gels by two independent parameters, charge (isoelectric point) and size (molecular mass). The best resolution is obtained if isoelectric focusing (**▶IEF Isoelectric Focusing**) under denaturing conditions is combined with sodium dodecylsulfate polyacrylamide gel electrophoresis (**▶SDS-PAGE**). There are two common alternative versions of isoelectric focusing, non-equilibrium pH gradient electrophoresis (NEPHGE) using carrier ampholytes to build up the pH gradient in the electric field and **▶immobilized pH gradient IEF** using immobilized ampholytes (immobilines) (3).

Description

Although already developed in 1975 (O'Farrell) as a procedure that allowed a holistic view of biology, two-dimensional electrophoresis (2-DE) technology is only poorly automated in comparison to robotized genome technology. Manual **▶proteomics** procedures have reached a high performance and using 2-DE gels it is possible to resolve up to 10,000 **▶protein species** with a gel size of 30 cm×40 cm with a sensitivity of low numbers of molecules per cell. Protein species are separated in polyacrylamide gels using two independent separation criteria, isoelectric point in the first dimension and molecular mass in the second dimension. Only after complete denaturation by urea, dithiothreitol and detergents, are proteins in a well-defined structure and does their separation result in

Two-Dimensional Gel Electrophoresis

Protein Analysis, Berlin, Germany
jungblut@mpiib-berlin.mpg.de

distinctly shaped spots in 2-DE gels. Conformational effects on charge and molecular mass (Mr) have to be minimized to obtain optimal resolution. For separation according to the isoelectric point, isoelectric focusing is the method of choice. Two technologies are in use, non-equilibrium pH-gradient gel electrophoresis (NEPHGE), which uses carrier ampholytes and gives optimal resolution, and focusing with immobilines, immobilized ampholytes, which is easier to perform. Focusing is combined with sodium dodecylsulfate polyacrylamide gel electrophoresis (SDS-PAGE). The proteins are detected within the gels using silver stain, Coomassie Blue, negative staining, fluorescent stains or after radioactive labeling by autoradiography. Fig. 1 shows a result of a 2-DE separation after silver staining of the gel. In this experiment, cellular proteins of *Helicobacter pylori* have been separated. Each spot of this protein pattern represents at least one protein species. Quantification is possible by comparing the optical densities of the spots, but is clearly improved by isotopic or ►fluorescence labeling.

Proteins are modified during (co-translational) or after synthesis (post-translational). Each of these modifications leads to a new chemical structure for the protein. Each chemical structure of a protein has been defined as a 'protein species' (2). So one gene may result in the production of several hundred protein species. If two protein species have a different charge or Mr, 2-DE allows the separation at the protein species level. For separation the Mr-difference should be higher than 100 D. The exchange of one amino acid with a charged side chain for a neutral one or a post-translational modification such as a phosphorylation is sufficient for separation on a 2-DE gel. Current 2-DE technology was reviewed by Görg et al. (2004).

The separation range for Mr is between 5 and 150 kD, depending on the pore size of the applied gels and for pI between 4 and 10.5 depending on the ampholytes used. The detection sensitivity increases from Coomassie Brilliant Blue to silver staining and radioactive detection from 100 ng to 1 ng and down to several molecules per cell, respectively.

Proteins on 2-DE gels may be identified by mass spectrometry or after ►blotting by immunostaining or N-terminal protein sequencing. As a rule of thumb all proteins stainable with Coomassie Blue can be identified, if the protein sequence is within a database. 2-DE separates the proteins at the protein species level and allows ►subtractive analyses between 2-DE patterns of different biological situations to detect variations in amounts of protein species. Relative quantitative comparisons are performed by comparing the optical densities of the resulting spots or by fluorescent (DIGE, fluorescence difference gel electrophoresis) or ►isotopic labeling. The results of a subtractive 2-DE analysis are stored and retrieved in

Isoelectric Focusing

Two-dimensional Crystallization of Membrane Proteins. Figure 1 Protein pattern of *Helicobacter pylori* 26695 cellular proteins separated by 2-DE. Each spot represents at least one protein species. The identity of the spots in this pattern may be found by clicking on the spots within the 2D-PAGE database (►<http://www.mpiib-berlin.mpg.de/2D-PAGE/>).

2-DE databases such as the WORLD-2DPAGE database (►<http://au.expasy.org/ch2d/>) or the centralized ►2D-PAGE database (►<http://www.mpiib-berlin.mpg.de/2D-PAGE/>).

Clinical Applications

With its microscope-like character 2-DE was applied for marker search in many diseases such as cancer, infectious and heart diseases. In principle the proteins of two biological situations are separated by 2-DE and differences in the presence or in the intensity of the spots are determined by visual evaluation or software-supported image analysis. An example is the comparison of 2-DE patterns from control tissue with diseased tissue. All variations in the 2-DE pattern from the diseased tissue are defined as disease-associated variations.

For example: N-methyl-N-nitroso urea induced rat hepatoma cells produce an embryonal form of aldose reductase, which is not present in 2-DE patterns of control cells (5). The *in vivo* situation was investigated in complete organs, biopsies, tissues or single cells.

The complexity of protein composition decreases from organs to cells and therefore the chance of detecting cancer-associated proteins increases. Calgranulin B was present only in 2-DE patterns of colorectal carcinoma as compared with mucosa of the colon. Cell groups may be prepared by laser capture microdissection to obtain unique tissue. Because single cells do not contain sufficient amounts of protein, several hundred microdissections have to be accumulated. From microdissected normal and malign prostate epithelial cells, 40 potentially dysregulated proteins were found by 2-DE, e.g. 14.3.3 protein, a protein of signal transduction, the structure proteins tropomyosin and cofilin and the enzyme aldehyde dehydrogenase.

At first glance the application of 2-DE seems to be more complicated for infectious diseases because in addition to the diseased organism we also have to consider the proteome of the infecting microorganism. Fortunately the microorganisms can be analyzed in culture and show a complexity of 500–5000 genes which is adequate for 2-DE analysis. Between 10 and 50% of the predicted proteins were already identified on single 2-DE gels for bacteria. With this coverage there is a good chance to detect virulence-associated proteins by a comparison of 2-DE patterns of virulent strains with those of attenuated strains. Other strategies are to look for the most abundant proteins or surface proteins, which have a high probability of coming in contact with the host's immune system, or direct detection of the antigens by blotting of the proteins from a 2-DE gel onto a membrane, where the antigens are detected by sera of patients infected by the microorganism (4). This procedure is named immunoblotting. Antibodies from the sera react with the antigens and a second antibody against the constant region of immunoglobulins reacts with the antigen antibody complex. This second antibody is coupled with an enzyme, which catalyses the reaction of an uncolored substrate to a colored product. Because the antigen pattern represents the antigens of the pathogen and the antibodies of the host, it also represents the immunoproteome of the host pathogen interaction.

The heart with its relatively unique muscle tissue is a clearly defined organ and therefore predestined as a starting material for questions on the molecular functioning of a complete organ using proteomics. To this end, an attempt has been made to elucidate cardiomyopathy associated protein variations using proteomics. In spite of the unexpectedly high genetic variation, reproducible changes in intensity were recognized for several proteins. During the search for disease-associated proteins for dilated cardiomyopathy (DCM) it became obvious that ►proteomic signatures have to be determined. Heat-shock protein 27 (Hsp27) was separated into 59 protein species and changes in the amount of some of these were recognized to be

cardiomyopathy-associated using immunoblot techniques. From the many animal models investigated, results from a bovine model are remarkable. For bovine DCM, the most notable change was a sevenfold increase in the enzyme ubiquitin carboxyl-terminal hydrolase. This could result in increased protein ubiquitination in the diseased state, leading to proteolysis via the 26S proteasome pathway. An increased amount of this enzyme was also detected in human DCM heart tissue.

Therapeutic Consequences

2-DE is a powerful technique for detecting disease-associated and immuno-relevant protein species, which are potential candidates for diagnosis, vaccination and therapy. After 2-DE these candidates have to be evaluated and further reduced to the most relevant markers. For example in the case of *Helicobacter pylori*, the causative agent of gastric carcinoma, the immuno-relevant proteins were reduced to about 500 by ►immunoproteomics starting with 1800 protein species on a 2-DE gel. These 500 proteins were further reduced by the following criteria, most abundant proteins, surface localization, distribution in 15 *H. pylori* isolates, *Helicobacter* specific proteins and T-cell epitope containing proteins. Only two proteins fulfilled these criteria optimally. These two proteins showed a promising vaccination effect in a vaccination experiment in the mouse. Clinical trials are now underway. This example shows that 2-DE is an important first step in the search for medically relevant proteins. The number of the potential candidates may be reduced by 2-DE and the resulting candidates need further evaluation and reduction.

Two-Dimensional Polyacrylamide Gel Electrophoresis

Definition

Two-dimensional gel electrophoresis (sometimes abbreviated 2D-PAGE) separates proteins (or other compounds) first by their isoelectric point (i.e. charge) and then by size, usually in a polyacrylamide gel.

- ▶Protein-Protein Interaction
- ▶Protein Interaction Analysis: Chemical Cross-Linking
- ▶Two Hybrid System
- ▶Two-Dimensional Gel Electrophoresis

Two-Hit Model

The two-hit model is a model for oncogenesis developed by Alfred G. Knudson. This model suggests that cancer develops through loss of function of both the maternal and paternal alleles (copies) of a cancer susceptibility gene. In inherited forms of cancer (e.g. retinoblastoma), there is a loss of either the maternal or paternal allele within the egg or sperm from which an individual is conceived, thus every daughter cell thereafter has ‘one hit’ at this genetic locus. The loss of the remaining allele, or ‘second hit’, may occur in time as the result of an environmental trigger, or by chance during DNA replication. Sporadic cancers begin with two normal copies of a cancer susceptibility gene. Two successive acquired mutational events (‘two hits’), occurring in a single cell at each allele of a cancer susceptibility gene, are necessary for the development of cancer.

Interaction trap

Definition

Experimental procedure to detect protein-protein interactions that uses two ▶fusion proteins (“hybrids”) that reconstitute an active ▶transcription factor (or some other active protein) when the two fusion proteins interact (Fig. 1). The reconstituted transcription factor binds to the ▶promoter of a ▶reporter gene in the nucleus and switches on its ▶transcription. Consequently, reporter gene activity can be detected or measured.

It has been estimated that more than 50% of all protein interactions described in the literature have been detected using the yeast-two hybrid system.

Characteristics

The yeast two-hybrid system was first described 1989 by S. Fields and O-K. Song (1). The basic concept emerged from previous experiments on transcription factors, which usually contain separable DNA-binding ▶domains (DBD) and transcriptional activation domains (AD) (Fig. 1). This property can be exploited to detect protein-protein interactions.

Basic Principle of the Classical Yeast Two-Hybrid System

In order to test if two proteins X and Y interact, they are expressed as fusion proteins (hybrids) with a transcriptional activating domain (AD, ▶prey) and a DNA-binding domain (DBD, ▶bait), respectively. The term “two-hybrid” derives from these two ▶chimeric proteins.

The bait and prey fusions both contain a ▶nuclear localization signal (NLS) which allows the import of these proteins to the nucleus (targeting non-nuclear proteins to the nucleus). A physical interaction between X and Y leads to the reconstitution of a functional transcription factor which binds to the promoter of a reporter gene (Fig. 1). Consequently, transcription of the reporter gene is switched on. A protein-protein interaction is therefore translated into reporter gene activity that can be detected or measured.

The two-hybrid system can be used for the detection of essentially any protein-protein interaction, independent of the function of the corresponding proteins (but see limitations below).

Advantages and Limitations of the Yeast Two-Hybrid System

The yeast two-hybrid system became one of the most popular technologies for the detection of protein-protein interactions because it is fairly simple, rapid and inexpensive (it avoids the costly protein purification and antibody development needed in the traditional biochemical methods). No previous knowledge about the interacting proteins is necessary for a screen

Two-Hybrid System. Figure 1 Classical Yeast Two-Hybrid System. A protein of interest, Y, is expressed in yeast as a fusion to a DNA-binding domain (DBD, “bait”; circles denote expression *plasmids*). Another protein of interest, X, is fused to a transcriptional activation domain (AD, “prey”) and expressed in a different cell of opposite mating type (α). The two yeast strains are mated to combine the two fusion proteins in one cell. If proteins Y and X interact in the resulting diploid cells, they reconstitute a transcription factor that activates a reporter gene (here *HIS3*) and therefore allows the cell to grow on selective media (here media lacking histidine).

to be performed. Finally, the system can be scaled up to high-throughput usage.

Limitations

Some classes of proteins are not suitable for analysis by the yeast two-hybrid system. For example, transcriptional activators may activate transcription without any interaction. Another class of troublesome proteins are those containing hydrophobic transmembrane domains, which may prevent the proteins from reaching the nucleus. To overcome this limitation one of the alternative membrane-associated two-hybrid systems may be used, such as the split-ubiquitin assay or the SOS recruitment assay (Figs. 4, 5).

Other proteins may require modification by cytoplasmic or membrane associated enzymes in order to interact with binding partners. Alternative methods could also help in this case such as the three-hybrid system (Fig. 3).

► False Positives and ► False Negatives

The two-hybrid system can produce false positives, that is reporter gene activity where no protein-protein interaction is involved. Frequently, such false positives are caused by bait proteins that act as transcriptional activators. These types of activators are easily detectable when analysed against “empty”-prey fusions, that is preys containing only the transcriptional activating domain. If the reporter gene has been switched on in this case, then different procedures as mentioned below can be tested to reduce this unspecific background activity. Other false positives may be caused by proteins that lead to non-specific interactions for largely unknown reasons. Some bait or prey proteins may affect general colony viability and hence allow a cell to grow under selective conditions and activate reporter gene activation. Mutations or other random

events of unknown nature may be invoked as potential explanations as well. Overall, for extremely few cases of false positives the underlying mechanism is known. A number of procedures have been developed in order to identify or avoid false positives altogether, including the utilization of multiple reporters, independent methods of specificity testing or simply repeating assays to make sure a result is reproducible. False negatives involve physiological protein-protein interactions that are not detected by two-hybrid assays. They may arise by steric hindrance of the two fusion proteins so that transcriptional activation is prevented. Other explanations include instability of proteins or failure of nuclear localization.

Variations of the Two-Hybrid System

Based on the two-hybrid paradigm numerous variations have been developed to overcome the limitations of the classical yeast two-hybrid system, such as the analysis of membrane proteins. A more comprehensive overview of variations is shown in Table 1.

Only some important variations are described as follows.

Reverse Two-Hybrid and Split Hybrid System

The “reverse” two-hybrid system has been invented to select for disrupted two-hybrid interactions e.g. by ► [mutations](#), drugs or competing proteins (Fig. 2). In this system the interaction of X and Y proteins induces the transcription of a reporter gene that confers toxicity to the yeast.

Three-Hybrid System

In this yeast two-hybrid variation, a third protein (Z) is expressed along with the DBD and AD fusions (Fig. 3). Expression of the reporter gene is used to select for interactions that occur only in the presence of this protein.

Two-Hybrid System. Table 1 Comparison of different methods for identifying protein-protein interactions

Method	Advantages	Disadvantages
Two-Hybrid	Simple and inexpensive	Limitation analysing transcription factors and membrane proteins
	Coverage of low abundant proteins	
	Suitable for high throughput	
Affinity purification + Mass Spectrometry	Identification of protein complexes	Expensive, complexes do not provide information on topology
<i>In vitro</i> binding (Coimmunoprecipitation, GST-pulldowns etc.)	Defined conditions	Potentially non-physiological conditions
Protein Chips	Defined conditions Suitable for high throughput	Requires purification of protein

Two-Hybrid System. Figure 2 Reverse Two-Hybrid System. The interaction of bait and prey in the yeast cell is lethal (a), selecting for yeasts where the interaction is disrupted (b). Selection can be induced by the addition of FOA (5-fluoro-orotic acid), which is converted to the toxic compound 5-fluorouracil by the URA3 gene product.

Protein Z may be directly involved in the interaction as shown in Fig. 3 but may also allow the interaction between X and Y *via* a post-translational modification of these proteins (such as phosphorylation). SenGupta et al. (8) developed a three-hybrid system to detect and analyze RNA-protein interactions in which the binding of a bifunctional RNA molecule links the DBD and AD hybrid proteins and activates transcription of the reporter gene. This system is known as RNA three-hybrid system.

SOS Recruitment System (SRS)

This membrane-associated two-hybrid system makes use of the Ras pathway in yeast (9). When localized at the plasma membrane, the yeast Ras guanyl nucleotide exchange factor (RGEF) cdc25 stimulates GDP/GTP exchange on Ras and promotes downstream signalling events that ultimately lead to cell growth. A mutant

Two-Hybrid System. Figure 3 Three-Hybrid System. A third protein (Z) is expressed along with the DBD and AD fusions. Expression of the reporter gene is used to select for interactions that occur only in the presence of this protein (a). This third protein alternatively can prevent the formation of a two-hybrid complex (b). Alternatively, Z may be a hybrid RNA molecule with part of the sequence binding to Y and the other to X (“RNA three-hybrid”).

yeast strain harbouring the temperature sensitive cdc25-2 allele is still able to grow at 25°C but fails to grow at 36°C. However, the human RGEF (hSOS) when targeted to the plasma membrane efficiently complements the mutation, leading to cell growth at 36°C. In the SRS the translocation of hSOS is dependent on a protein-protein interaction; the bait X is fused to C-terminally truncated hSOS, which is active but unable to target to the plasma membrane. The bait is co-expressed with a prey Y, which can be either an integral membrane protein or a soluble protein that is anchored to the membrane by means of a ▶myristoylation signal.

Split-Ubiquitin System

Johnsson and Varshavsky (10) have developed a cytoplasmic two-hybrid assay based on ▶ubiquitin. Ubiquitin is a small protein of 76 amino acids that acts

Two-Hybrid System. Figure 4 SOS Recruitment System. Protein X is fused to a human Ras guanyl exchange factor, hSOS. Putative interaction membrane protein Y (or protein localized to the membrane by a myristoylation tag) is co-expressed. Interaction between X and Y recruits hSOS to the membrane, where it stimulates guanyl nucleotide exchange on Ras. GTP-bound Ras stimulates cell growth.

Two-Hybrid System. Figure 5 Split Ubiquitin System. Proteins fused to ubiquitin are rapidly cleaved *in vivo* by ubiquitin specific proteases (UBPs). A mutant Nub is fused to protein X and the Cub-reporter gene hybrid is fused to protein Y (a). Interaction between both proteins reconstitutes ubiquitin and leads to cleavage and release of the reporter gene (URA3) (b).

as a “tag” for [protein degradation](#). Proteins fused to ubiquitin are rapidly cleaved *in vivo* by ubiquitin-specific proteases (UBPs).

If the carboxy terminal of ubiquitin (Cub) is fused to a reporter protein and co-expressed with the amino-terminal fragment (Nub), the two halves will reconstitute the native ubiquitin, resulting in the cleavage of the reporter protein. For its adaptation to detect protein-protein interactions, a mutant Nub, unable to interact with Cub on its own, was fused to one protein and a Cub reporter hybrid was fused to its prospective interaction partner (Fig. 5). Interaction between the two proteins allowed ubiquitin to be reconstituted, leading to cleavage and release of the reporter gene. As the formation of split-ubiquitin and subsequent cleavage by UBPs do not depend on any special

localization of the proteins, this system is suitable for the investigation of membrane proteins. Up to date two membrane based split-ubiquitin systems have been described, the Ura3 based split-ubiquitin system and the transactivator based split-ubiquitin system.

A further advantage of this system is that the signal for an interaction can be changed by changing the nature of the reporter protein (e.g. transcription factor or enzyme activated by ubiquitin cleavage). Furthermore, the small size of the ubiquitin fragments in the hybrid proteins may also be advantageous because it minimizes the possibility of steric hindrance.

Up to date it is the most widely used of the alternative yeast-based two-hybrid systems.

Clinical Relevance

Two-hybrid systems are useful for the investigation of protein-protein interactions, protein-nucleic acid and protein-small molecule interactions. However, the technology is mainly used in basic research in order to understand the function of proteins. Many protein-protein interactions can cause disease when they are disrupted (e.g. haemoglobin is a tetramer that binds oxygen efficiently only when the subunits interact). Protein interactions are now being identified by biotech and pharmaceutical companies as potential drug targets, especially in combination with screens for small molecule ligands that can disrupt or modulate these protein interactions.

Two-Photon Excitation

Definition

Two-photon excitation refers to a non-linear fluorescence excitation phenomenon, where two photons of half the energy required for an electronic transition are simultaneously absorbed by a fluorophore. In this case, their energy can be added and the excitation facilitated, although the wavelength is approximately twice as large as the absorption maximum (usually, in the infrared).

► FCS

Two-Site Immunoradiometric Assay

Definition

A two-site immunoradiometric assay is an assay using two different antibodies (one of which is radiolabelled) targeting the different ends of a polypeptide.

► Hyper- and Hypoparathyroidism

Two-State Process

Definition

Two-state process designates a process that involves no thermodynamically significant intermediate states. The two-state hypothesis assumes that only 2 species occur in equilibrium whose relative populations are shifted by temperature or any other environmental parameter such as pH or denaturant agents. This assumption applies to conformational changes of many small proteins and simplifies data analysis significantly.

► Transposons

Type B Reactions

► Idiosyncratic Drug Reactions

Type 1 Diabetes Mellitus

Definition

Type 1 diabetes mellitus (also known as insulin-dependent diabetes mellitus (IDDM) or juvenile-onset diabetes) is the most frequent form of diabetes that is characterized by early age of onset, autoimmune mechanism and absolute requirement for insulin.

► Common (Multifactorial) Diseases

► Diabetes Mellitus, Genetics

Type 1 Pseudohypoaldosteronism

Definition

Type 1 pseudohypoaldosteronism (PHA 1) is a hereditary disease characterized by salt wasting, resulting from target organs unresponsiveness to mineralocorticoids. There are 2 forms of PHA1: the autosomal recessively inherited form is caused by mutations in the gene encoding the amiloride-sensitive luminal sodium channel, and is clinically more severe involving pulmonary symptoms. Sporadic or autosomal dominantly transmitted forms are caused by mutations in the mineralocorticoid receptor gene showing milder symptoms and generally remit with age. Autosomal recessive forms are caused by mutations in the gene encoding the amiloride-sensitive sodium channel and are clinically more severe involving also pulmonary symptoms.

► [Mendelian Forms of Human Hypertension and Mechanisms of Disease](#)

Type 1A Topoisomerases

Definition

Type 1A topoisomerases are present in all organisms. These enzymes transiently break a single strand of double stranded DNA, through a 5' phosphotyrosine intermediate, and pass another DNA strand through the break, catalyzing relaxation of negative supercoiling in DNA. Type 1A topoisomerases carry out changes in supercoiling by an enzyme bridging mechanism. The first identified topoisomerase was *E. coli* topoisomerase I, a type 1A enzyme.

► [DNA Topoisomerases](#)

Type 1B Topoisomerases

Definition

Type 1B topoisomerases are present in eukaryotes and some bacteria. These enzymes transiently break one strand of a double stranded DNA molecule, forming a 3' phosphotyrosine intermediate. Relaxation occurs through a strand rotation mechanism. Unlike type 1A enzymes, type 1B topoisomerases efficiently catalyze relaxation of both negative and positive supercoils.

► [DNA Topoisomerases](#)

Type 2 Diabetes Mellitus

Definition

Type 2 diabetes mellitus (also known as non-insulin dependent diabetes mellitus (NIDDM) or adult-onset diabetes) results from a combination of insulin resistance and a defect in insulin production. Treatment may involve diet modification and exercise alone, oral medications and/or insulin injections.

► [Diabetes Mellitus, Genetics](#)

Type 2 Pseudohypoaldosteronism

Definition

Type 2 Pseudohypoaldosteronism (PHA2) also called ► [Gordon's syndrome](#) or familial hyperkalemic hypertension) is an autosomal dominantly transmitted disorder characterized by hypertension with hyperkalemia/hyperaldosteronism, slight hyperchloremic metabolic acidosis and otherwise normal renal function. Thiazide diuretics are highly effective in this syndrome, commensurate with salt sensitivity. This form of hypertension is caused by mutations in the genes of the ► [WNK family](#) of serine-threonine kinases (WNK 1 for PHA 2C and WNK 4 for PHA 2B). The mutations in WNK1 are large intronic deletions that increase WNK1 protein expression. The mutations in WNK4 are missense and cause a loss of function. The mutations cluster in a short and highly conserved segment of the derived protein.

Definition

Type II myosin is the molecular motor of all muscle types, which consists of 2 heavy chains (200 kDa each) and 4 light chains (16–28 kDa each).

► [Muscle Contraction](#)

Type IIA Topoisomerases

Definition

Topoisomerases are present in all eubacteria and eukaryotes, and are dimeric or tetrameric enzymes. These enzymes generate double strand breaks during their reaction cycle. Type II topoisomerases can catalyze catenation or decatenation of double stranded DNA, and are required for separating replicated DNA molecules at the completion of DNA replication.

Type III Hyperlipidemia

Definition

Type III hyperlipidemia, also known as familial dysbetalipoproteinemia or remnant removal disease, is a rare familial disorder characterized by a combined elevation of serum cholesterol and triglycerides (TG), and a marked accumulation of remnant lipoproteins in plasma. Type III hyperlipoproteinemia is based on apoE2 homozygotes genotype.

Definition

Tyrosine kinases are enzymes that catalyze the transfer of the γ -phosphate of adenosine triphosphate (ATP) to the hydroxyl group of tyrosine residues in a protein substrate (1). They are found in all multi-cellular organisms and participate in signal transduction pathways that regulate multiple cellular processes like cell migration, motility, differentiation, cell growth or apoptosis. Tyrosine kinases are frequently activated in human tumors and constitute novel targets for anti-tumor therapies (2).

Characteristics

The catalytic module of tyrosine kinases consists of about 260–300 amino acid residues. The crystal structure of several tyrosine kinase domains has been solved and reveals a common architecture (3, 4). The catalytic domain of a tyrosine kinase forms a classical two lobed structure. The N-terminal lobe is composed of anti-parallel β -strand sheets and an α helix, while the C-terminal lobe is mainly α helical (Fig. 1). The ATP binding pocket is located in the hinge region between the two lobes, while the substrate binding region, catalytic loop and activation loop all reside in the C-terminal lobe. Most tyrosine kinases harbor one to three tyrosine residues within the activation loop. Phosphorylation of these A loop tyrosine residues enhances tyrosine kinase activity.

According to their different modular organization, tyrosine kinases are divided into two subfamilies, the ► [receptor tyrosine kinases](#) (RTKs) and the non-receptor tyrosine kinases (NRTKs). The receptor tyrosine kinases (RTKs), like the epidermal growth factor (EGF) receptor or the insulin receptor are transmembrane glycoproteins (Fig. 2). They possess an extracellular region, which is glycosylated, the transmembrane domain and a cytoplasmic part. The extracellular domain is diverse among the different RTK subfamilies and composed of several subdomains such as the immunoglobulin (Ig), fibronectin type III or epidermal growth factor (EGF)-like domains (Fig. 2). The cytoplasmic part contains the kinase domain, regulatory sites and substrate binding sites. The activity of RTKs is regulated by binding of extracellular peptide growth factors, such as EGF or insulin, which bind and activate the EGF receptor or insulin receptor,

Tyrosine Kinases. Figure 1 Ribbon diagram of insulin receptor tyrosine kinase. Crystal structure of activated insulin receptor tyrosine kinase in complex with peptide substrate and the ATP analog AMPPNP (4). The kinase domain forms a two lobed structure. The N-terminal lobe is shown on top and the C-terminal lobe at the bottom. The α -helices are depicted in red, β -sheets in turquoise, the activation loop in blue, the peptide substrate in yellow, the ATP analog AMPPNP in pink and Mg^{2+} ions in orange. ATPNP binds to the hinge region between the N-terminal and the C-terminal lobes. The substrate binding site and the activation loop reside in the C-terminal lobe. The picture was generated by Klaus Hellmuth with Accelrys ViewerLite 5.0 according to the atom coordinates PDB accession number 1IR3.

respectively. NRTKs on the other hand are cytoplasmic or membrane associated proteins. They harbor protein-protein interaction domains involved in subcellular targeting and/or regulation of enzymatic activity, like c-Src or the Janus kinase JAK (Fig. 3). NRTKs function downstream of RTKs, G-protein coupled receptors or cell surface receptors that lack intrinsic enzymatic activity, such as B cell receptors, T cell receptors or integrins (see below).

Molecular Interactions Receptor Tyrosine Kinases

Binding of extracellular ligand to RTKs leads to activation of an intracellular signaling cascade that spreads to the nucleus and leads to changes in cell

morphology and gene expression. RTKs are activated by peptide growth factors. Some receptors have only one ligand, such as the c-Met RTK, which is activated by scatter factor/hepatocyte growth factor (SF/HGF). Others such as the EGF- or FGF-receptor families recognize multiple ligands (Fig. 4a). These can be either soluble or membrane bound. Ligand binding of most RTKs induces multi-merization of the receptors. In addition to homodimerization, the EGF-receptor can also heterodimerize with other EGF-R family members, such as the RTKs ErbB2, ErbB3 or ErbB4 (Fig. 4b). Homo- and hetero-dimers of the different EGF-receptor families have various ligand binding and signaling properties (5). The EGF receptor recognizes several ligands such as epidermal growth factor (EGF), transforming growth factor α (TGF α), betacellulin (BTC) and heparin binding EGF (HB-EGF). ErbB3 and ErbB4 recognize members of the neuregulin family of peptide growth factors. Thus far, no ligand for ErbB2 has been discovered. It is assumed that ErbB2 functions primarily as a cofactor for the other ErbB family members. The ErbB3 RTK binds neuregulin growth factors, but lacks intrinsic tyrosine kinase activity. Thus it is active only in concert with other ErbB family members (Fig. 4b).

Once activated, the RTKs become autophosphorylated on tyrosine residues. This creates binding sites for proteins with phosphotyrosine interaction domains, such as src homology 2 (SH2) or phosphotyrosine binding (PTB) domains (1). SH2 or PTB domains are frequently found on proteins involved in tyrosine kinase signaling. SH2 domains are compact structures of about 100 amino acids. They bind distinct peptide sequences that are defined by a phosphotyrosine and 3–6 amino acids C-terminally. PTB domains also form compact structures, but are unrelated to SH2 domains. Their binding specificity is defined by one phosphotyrosine and 3–5 residues N-terminally. Thus the amino acid sequences surrounding the phosphotyrosine docking sites of RTKs or kinase substrates determine the combination of SH2 and PTB containing signaling proteins that are recruited and activated by different extracellular signals.

Signaling proteins recruited by RTKs can be adapter molecules, docking proteins, enzymes or even transcription factors. A common adaptor protein recruited by RTKs is growth factor receptor binding protein 2 (Grb2). Grb2 is modular in nature, consisting of a central SH2 domain flanked by a C-terminal and a N-terminal Src homology 3 (SH3) domain. Via its SH2 domain Grb2 binds specific phosphotyrosine residues. The SH3 domains of Grb2 bind other signaling proteins such as SOS, a GDP/GTP exchange factor for the GTPase Ras or the docking protein Gab1 (Fig. 5) (6). Recruitment of Grb2 by RTKs brings the Grb2 binding partner SOS in close proximity to the membrane

Tyrosine Kinases. Figure 4 ErbB receptor tyrosine kinases and their ligands. (a) EGF-R (ErbB1), ErbB2, ErbB3 and ErbB4 have different ligand binding and signaling properties. No ligand has been identified for ErbB2. ErbB3 lacks tyrosine kinase activity. EGF, epidermal growth factor; TGF α , transforming growth factor alpha; AR, amphiregulin; EPR, epiregulin; BTC, betacellulin; HB-EGF, heparin binding EGF; NRG, neuregulin. (b) Heterodimerization by ErbB family members enhances complexity of signal transduction.

Tyrosine Kinases. Figure 5 The Ras/MAPK pathway. The adaptor protein Grb2 associates constitutively with the GDP/GTP exchange factor SOS. Grb2/SOS complex is targeted to the membrane by binding to phosphotyrosine residues of activated cell surface receptors. This leads to formation of GTP bound Ras protein, and activation of the MAP kinase pathway. Ras activates the serine threonine kinase Raf1, which then activates the MAPKK (Mek1). Mek1 phosphorylates the MAPK Erk. Phosphorylated Erk translocates to the nucleus, where it phosphorylates transcription factors like Elk-1 leading to changes in gene expression. Grb2 can also recruit the docking protein Gab1 to the membrane. Phosphorylation of Gab1 by tyrosine kinases induces binding and activation of the tyrosine phosphatase Shp2. Shp2 activation stimulates Ras by unknown mechanisms leading to sustained MAPK activity. P in red circles indicates phosphate groups.

Tyrosine Kinases. Figure 6 The PI(3)K signaling pathway. PI(3)K is activated by binding of its regulatory subunit to phosphotyrosine docking sites and subsequent tyrosine phosphorylation of its catalytic subunit. It phosphorylates the 3' position of the inositol ring to generate phosphoinositides like PtdIns (3,4,5)P₃ (PIP₃) from PtdIns (4,5)P₂ (PIP₂) and PtdIns (3,4)P₂ from PtdIns (4)P. PIP₃ binds the PH domains of a variety of proteins. PDK1 is activated by PIP₃ dependent recruitment to the membrane, where it phosphorylates and activates another serine threonine kinase PKB/Akt at threonine 308. PKB/Akt phosphorylates several target proteins that regulate cell survival, metabolism, proliferation and transcription. For instance PKB/Akt prevents apoptosis by inactivating Bad, a pro-apoptotic Bcl-2 family member. It blocks GSK-3 (glycogen-synthase kinase-3) thereby promoting cell-cycle entry and changes in glucose metabolism. Ribosomal p70 S6K is also activated by PKB/Akt and promotes cell growth through control of protein translational machinery. PTEN antagonizes PI(3)K signaling by dephosphorylation of the second messengers PtdIns (3,4,5)P₃ (PIP₃) and PtdIns (3,4)P₂ (PIP₂) at the 3' position of phosphoinositides.

(PtdIns (4)P) and phosphatidylinositol 4,5-bisphosphate (PIP₂) to generate the second messengers phosphatidylinositol 3,4-bisphosphate (PtdIns (3,4)P₂) and phosphatidylinositol 3,4,5-trisphosphate (PIP₃), respectively (1, 2). PI(3)K consists of a catalytic subunit, p110 and a regulatory subunit, p85. The regulatory subunit possesses two SH2 domains and forms a constitutive complex with the p110 PI(3)K catalytic subunit. Binding of its SH2 domains to phospho-tyrosine residues of activated receptor induces a conformational shift releasing the auto inhibitory constraint on the catalytic subunit (p110). In addition, localization of the enzyme to the plasma membrane brings it in closer proximity to its lipid substrates PtdIns (4)P and PIP₂. The reaction products PtdIns (3,4)P₂ and PIP₃ activate other signaling proteins, such as the serine/threonine kinases PDK1 and protein kinase B (PKB)/Akt (Fig. 6). Targets of PI(3)K signaling, often

Tyrosine Kinases. Figure 7 The PLC- γ signaling pathway. Phospholipase C-gamma (PLC- γ) is recruited to the membrane by binding of its PH domain to PtdIns (3,4,5)P₃ (PIP₃) and by its SH2 domains that bind phosphotyrosine peptide motifs. Full activation of PLC- γ also requires tyrosine phosphorylation. PLC- γ cleaves the PI(3)K reaction product PtdIns (4,5)₂ (PIP₂) to generate the second messengers diacylglycerol (DAG) and inositol (1,4,5) P (IP₃). IP₃ induces the release of calcium from intracellular storage. Ca²⁺ and DAG then activate protein kinase C (PKC).

contain a Pleckstrin homology (PH) domain which binds PIP₃. Activation of PI(3)K then leads to translocation of the proteins to the plasma membrane and activation (1,2).

Phospholipase C- γ (PLC- γ) contains a SH2 domain and is directly recruited by RTKs (1, 2). It is a substrate of tyrosine kinases and activated by tyrosine phosphorylation. PLC- γ hydrolyzes PIP₂ to diacylglycerol (DAG) and inositol 1,4,5-trisphosphate (IP₃). IP₃ stimulates the release of Ca²⁺ from intracellular storage compartments, activating Ca/calmodulin-dependent kinases (1). Ca kinases together with diacylglycerol activate protein kinase C (Fig. 7).

The tyrosine phosphatase Shp2 is also an important signaling molecule downstream of RTKs (6). Shp2 contains two SH2 domains at its N-terminus and the phosphatase (PTP) catalytic domain. In the basic state the phosphatase activity is blocked sterically by the N-terminal SH2 domain. Interaction of the SH2 domains with phosphotyrosine interaction sites leads to activation of Shp2 phosphatase activity. Shp2 is a positive regulator of the mutagen activated protein kinase (MAPK) pathway. Only a few physiological substrates of Shp2 are known, but genetically Shp2 has been placed upstream of the Ras/MAPK pathway (Fig. 5). Docking proteins like insulin receptor substrate 1 (IRIS-1) or Grb2 associated binder 1 (Gab1) comprise another group of signaling proteins activated by RTK (Fig. 8). They are substrates of tyrosine kinases, but lack intrinsic enzymatic activity (1). They are characterized by an N-terminal membrane targeting domain, like a Pleckstrin homology domain (PH), a

Tyrosine Kinases. Figure 8 Docking proteins. Docking proteins are substrates of tyrosine kinases. They harbor multiple tyrosine residues. When phosphorylated, these can function as binding sites for signaling molecules. Commonly, docking proteins possess a Pleckstrin homology domain (PH) or a myristoylation site (M) that is important for their membrane targeting. In addition they contain a phosphotyrosine-binding domain (PTB) that is required for their targeting to specific signaling complexes. Gab1 lacks a classical PTB domain, but instead has a c-Met binding site (MBS) important for its targeting to the RTK, c-Met. PP indicates proline-rich regions that mediate protein-protein interactions with SH3 domains. The proline-rich regions of Gab1 bind SH3 domains of Grb2 (7).

central phosphotyrosine binding domain (PTB), which mediates specific binding to growth factor receptors and numerous tyrosine residues that serve as additional docking sites for signaling molecules. Docking proteins are recruited by binding to phosphotyrosine binding sites or by membrane targeting *via* a PH domain that binds the PI(3)K reaction product PIP₃ (Fig. 6). Phosphorylation of docking proteins may enhance the signaling properties of RTKs by providing additional phosphotyrosine binding sites to build a larger platform of signaling complexes.

STATs are transcription factors with a central DNA binding domain, a putative SH3 domain and a C-terminal SH2 domain (7). They are also substrates of tyrosine kinases and recruited *via* association of their SH2 domain with phosphotyrosine docking sites. Once phosphorylated, they dimerize by reciprocal interaction of phosphotyrosine and the SH2 domain, translocate to the nucleus and activate transcription (Fig. 9).

Non-Receptor Tyrosine Kinases

NRTKs can be activated by RTKs, but function also downstream of membrane receptors that lack intrinsic enzymatic activity (2, 3). For instance, the Janus family of NRTKs, JAKs, is commonly activated by cytokine receptors, like interleukin (IL) 2, IL3, interferon (IFN) or erythropoietin receptor (7). Janus kinases (JAKs) contain a cytokine receptor-binding domain (FERM domain) at their N-terminus and associate constitutively with specific cytokine receptors (Fig. 9). Ligand induced activation of Janus kinases leads to phosphorylation of the cytokine receptor on tyrosine residues and recruitment and activation of additional signaling

molecules, in particular STAT transcription factors and Src family kinases.

The src family kinases act downstream of the T cell and B cell receptors and the receptors for the γ portion of immunoglobulin (IgG). These receptors belong to the family of multi-chain immune recognition receptors (MIRR). They are composed of several transmembrane glycoproteins involved in ligand binding and/or signaling. Characteristically, the cytoplasmic part of the signaling components contains one or more of the tyrosine based activation motifs (ITAM), a peptide sequence with the sequence motif YX₂LX₇YX₂L (7). Ligand binding induces receptor clustering and thereby activates closely associated src kinase family members. This leads to rapid phosphorylation of the ITAM motifs. Upon phosphorylation, ITAM tyrosine residues function as docking sites and recruit additional effector molecules similar to the activity of RTKs or cytokine receptors.

Regulatory Mechanisms

The activity of tyrosine kinases is tightly regulated (1, 2, 3). In the absence of ligand, most RTKs exist as monomers in the cell membrane. They display residual kinase activity, but are kept in a low activity state due to the activity of tyrosine phosphatases. Crystal structures of tyrosine kinases can show that in the non-phosphorylated state the A loop of the catalytic center impairs accessibility to substrate or ATP. Binding of extracellular ligand induces receptor dimerization increasing local receptor concentration. This facilitates transphosphorylation of the receptor pair. Phosphorylation of the A loop tyrosine residues

Tyrosine Kinases. Figure 9 Janus kinases. Janus kinases (JAKs) are constitutively associated with cytokine receptors, which lack intrinsic enzymatic activity. Cytokines induce dimerisation of the receptors and activation of the associated Janus kinases. Janus kinases phosphorylate the cytoplasmic tail of the cytokine receptors creating binding sites for signal transducers and activators of transcription (STATs). After phosphorylation by Janus kinases, STATs homodimerize, translocate to the nucleus and activate transcription. Suppressors of cytokine signaling (SOCS) are also target genes for STATs. SOCS proteins are involved in down-regulation of cytokine response. SOCS proteins promote degradation of JAKs by targeting them to the proteasome. They also interfere with STAT signaling by occupying STAT-binding sites on cytokine receptors.

then shifts the state of the kinase into an open, more active conformation and allows autophosphorylation to proceed (Fig. 10).

Tyrosine kinase signaling is shut down by several mechanisms. Activation of RTKs reduces the half-life of the receptor (1). Ligand bound receptors cluster in coated pits on the cell surface, undergo endocytosis and are transported into multivesicular bodies (Fig. 11). There the ligand and receptor dissociate; the receptor is recycled to the cell surface or undergoes degradation in the lysosomes. For the EGF-R and the RTK c-Met it has been shown that the c-Cbl proto-oncogene product promotes degradation of activated receptor *via* the proteasome. c-Cbl is a multi-domain adaptor protein and E3-ligase (5). It contains an SH2-like domain responsible for binding to the EGF-R and c-Met receptor at specific sites. It also has a ring finger domain which functions as an ubiquitin ligase, thereby targeting the protein complex to the proteasome and degradation. Consequently, EGF-R or c-Met mutants, which lack c-Cbl binding sites, show increased half-life and oncogenic signaling capacity.

Tyrosine Kinases. Figure 10 Activation of receptor tyrosine kinases. In the absence of ligand, RTKs exist as monomers. Ligand binding induces dimerization and a conformational shift that allows transphosphorylation of activation loop residues. This enhances tyrosine kinase activity resulting in autophosphorylation of additional tyrosine residues.

Tyrosine Kinases. Figure 11 Down-regulation of receptor tyrosine kinase signaling. The E3 ubiquitin ligase c-Cbl binds to specific phosphotyrosine binding sites of the activated EGF-R and c-Met receptor (only one receptor molecule is depicted) and leads to ubiquitination (Ub) of the activated receptor. The ubiquitinated receptors are sorted into invaginating clathrin coated pits and engulfed into coated vesicles. These vesicles shed the clathrin coat and give rise to early and late endosomes. During this maturation process, ligand and receptors dissociate due to lowered pH in the late endosome and are either recycled back to the cell surface or destined to degradation in the lysosome. Degradation is promoted by c-Cbl ubiquitination, since c-Met or EGF-R mutants deficient in c-Cbl binding are characterized by enhanced half-life.

Regulation of NRTKs

The activity of NRTKs is also tightly regulated (2, 3). c-Src for instance contains an N-terminal SH3 domain, followed by an SH2 domain and the kinase domain (Fig. 12). In addition, it has two regulatory tyrosine residues Y416 and Y527(3). Y416 is located in the A loop, phosphorylation of this residue is required for full activation of src. Y527 is phosphorylated by the C-terminal src kinase (CSK) a negative regulator of src. When Y527 is phosphorylated, it forms an intramolecular interaction with its SH2 domain stabilizing association of the SH3 domain with proline-rich sequences. As a result of these intramolecular interactions, the kinase catalytic core is maintained in a closed inactive conformation. Src can be activated by binding of its SH2 domain to phosphotyrosine peptide sequences which compete with binding of pY 527 at its C-terminus, followed by transphosphorylation of Y416 in the A loop. In addition, src is activated through the activity of tyrosine phosphatases, which dephosphorylate Y527 or by association of proline-rich sequences with the SH3 domain of src.

JAK tyrosine kinase family members are non-covalently bound to cytokine receptors (Fig. 9). Receptor dimerization induced by ligand binding leads to JAK dimerization facilitating transphosphorylation of A loop tyrosine residues. These tyrosine residues function to maintain an active state until dephosphorylation by phosphatases, like SHP1 or CD45 (7). Signaling by JAKs is further down regulated by SOCS proteins (suppressors of cytokine signaling), also called CIS (cytokine induced SH2 containing cytokines) proteins. SOCS proteins contain a central SH2 domain and a C-terminal SOCS box, which functions in a multi-protein complex as an E3 ubiquitin ligase. Cytokine signaling induces SOCS protein expression and association of SOCS with phosphorylated JAKs or cytokine receptor *via* its SH2 domain (Fig. 9). The SOCS box recruits ubiquitin 3 ligases to the protein complex leading to ubiquitination of JAK and cytokine receptor and finally degradation by the proteasome (7).

► Growth Factors

► Neurotrophic Factors

Tyrosine Kinases. Figure 12 Regulation of c-src kinase activity. Src kinase is held in an inactive state by two intramolecular interactions: (i) tyrosine 527 is phosphorylated by the C-terminal src kinase (CSK), and bound to the SH2 domain, (ii) the SH3 domain interacts with a proline-rich region (red triangle) in the SH2 domain linker. Src kinase activity is induced by dephosphorylation of Y527, by binding of other proline-rich sequences to the SH3 domain of Src or by binding of its SH2 domain to other phosphotyrosine binding sites. This promotes a more open conformation of the kinase and allows autophosphorylation of Y416 in the activation loop of src resulting in full activation of src kinase activity.

Tyrosine Sulfation of Proteins

KEVIN L. MOORE

Oklahoma Medical Research Foundation,
Oklahoma City, OK, USA
kevin-moore@omrf.ouhsc.edu

Synonyms

3'-phosphoadenylyl-sulfate; protein-tyrosine *O*-sulfotransferase; protein-tyrosine sulfotransferase; tyrosyl-protein sulfotransferase; 3'-phosphoadenylyl-sulfate; 3'-phosphoadenosine 5'-phosphosulfate; adenosine 3', 5'-bisphosphate; 3'-phosphoadenosine 5'-phosphate

Definition

Tyrosine sulfation is one of many post-translational modifications of proteins that have been described in nature. Sulfation of other amino acids with side-chain hydroxyl groups has not been described. Sulfated protein-tyrosine residues are formed by the action of an enzyme activity called 3'-phosphoadenylyl-sulfate: protein-tyrosine *O*-sulfotransferase, commonly called tyrosylprotein sulfotransferase (TPST, EC 2.8.2.20). This enzyme activity mediates the transfer of the 5'-sulfonyl group from the universal high-energy sulfate donor, 3'-phosphoadenosine 5'-phosphosulfate (PAPS), to the side chain hydroxyl group of tyrosine residues to form a tyrosine *O*⁴-sulfate ester and 3'-phosphoadenosine 5'-phosphate (PAP). In mammalian cells, it has been estimated that tyrosine sulfation accounts for only ~5% of the sulfate incorporated into proteins. The remaining ~95% is accounted for by sulfation of various monosaccharide units in Asn-linked and Ser/Thr-linked glycans in glycoproteins and proteoglycans. A family of Golgi **▶carbohydrate sulfotransferases** mediates these sulfate conjugation reactions. For reviews on tyrosine sulfation and TPSTs see references (1, 2).

Characteristics

Species and Tissue Distribution

TPST activity and/or tyrosine-sulfated proteins have been observed in many species in both the plant and animal kingdoms, but not in prokaryotes or yeast. Complementary DNAs have been identified in many eukaryotic organisms from *Caenorhabditis elegans* to man. In most species there are two TPST isoenzymes, called TPST-1 and TPST-2. The one known exception to this rule is *Drosophila melanogaster* that has only a single TPST gene.

Tyrosine Sulfation of Proteins. Figure 1 The Tyrosylprotein Sulfotransferase Reaction. TPSTs catalyze the transfer of the sulfonyl group from the sulfate donor, 3'-phosphoadenosine 5'-phosphosulfate (PAPS), to the hydroxyl group of a lumenally-oriented protein-tyrosine residue to form a tyrosine O^4 -sulfate ester and 3'-phosphoadenosine 5'-phosphate (PAP).

The cellular and tissue distribution of TPST expression is best characterized in mouse and man. Based on Northern blot analysis of tissues and various cell lines, enzymatic assays of tissue extracts and the representation of TPST-1 and -2 expressed sequence tag clones in a wide variety of cDNA libraries, it appears that both isoenzymes are broadly co-expressed in mammalian cells. The sub-cellular localization of TPST has also been examined using a variety of techniques. These studies indicate that the enzymes are localized to the trans-Golgi network. Therefore, only protein in the secretory pathway can be tyrosine-sulfated.

Structure and Function of TPSTs

Complementary DNAs encoding TPST-1 and/or TPST-2 orthologs have been identified in many vertebrates (human, mouse, rat, dog, cow, pig, chicken, zebrafish, fugu, channel catfish and African clawed frog) and invertebrate species (*Caenorhabditis elegans*, *Drosophila melanogaster*, *Anopheles gambiae*, *Ciona intestinalis*, *Halocynthia roretzi* and *Schistosoma japonicum*). These cDNAs encode type II transmembrane proteins ranging from 340 to 380 residues in length. Each has a short < 10 residue cytoplasmic domain, a single ~17 residue membrane-spanning domain, followed by a luminal catalytic domain. Multiple sequence alignments of TPSTs from various species show that the membrane proximal 30–40 residues of the luminal domain are very poorly conserved. This domain probably represents a stem region similar to that described in many [glycosyltransferases](#). However, whether this region is dispensable

for catalytic activity awaits experimental confirmation. All TPSTs have 1 or 2 putative [Asn-linked glycosylation](#) sites. In human TPST-1 and -2 both Asn-linked sites are utilized. Site-directed mutagenesis of both Asn-linked sites (Asn to Gln) and expression of catalytically active recombinant TPST-1 and -2 in bacteria demonstrate that Asn-linked glycans are dispensable for catalysis. The number of luminal cysteine residues in TPSTs ranges from 4 in *C. intestinalis* and *H. roretzi* to 7 in *D. melanogaster*. Using the human sequences as an alignment template, the second, third, fourth and fifth cysteine residues are conserved in all species and are likely to be involved in intra-molecular disulfide bond formation. However, the disulfide-bonding pattern has not been determined.

Crystal structures of several members of the sulfotransferase family reveal two motifs, designated the 5' PSB and 3'PB motifs. These motifs are involved in binding of the 5'- and 3'-phosphate groups of the reaction product PAP, respectively (3). These motifs are conserved in TPSTs and correspond to residues 78–85 and residues 180–195 in human TPST-1.

Substrate Repertoire and Specificity of TPSTs

Since the first description of protein tyrosine O -sulfation in 1954, 64 different secreted and transmembrane proteins have been shown to be tyrosine-sulfated. The list of known tyrosine-sulfated proteins includes several adhesion molecules, coagulation factors, G-protein coupled receptors, extra-cellular matrix proteins, serpins, hormones and a variety of other proteins (see reference (2) for a comprehensive list).

In contrast to some other post-translation modifications, there is no sequon for tyrosine *O*-sulfation. Nevertheless, the dominant primary structural characteristic of known sulfation sites is the presence of several acidic amino acids within 5 residues of the sulfotyrosine. A software tool called Sulfinator ([▶www.expasy.org/tools/sulfinator/](http://www.expasy.org/tools/sulfinator/)) has been developed to predict tyrosine *O*-sulfation sites in proteins. However, the positive predictive value of this algorithm is uncertain. Nevertheless, application of this prediction tool to the human proteome would suggest that many other proteins (perhaps hundreds) may be tyrosine-sulfated (2).

Information about the differential substrate specificity of TPST-1 and -2 is limited. Nevertheless, *in vitro* enzyme assays using synthetic peptide acceptors indicate that TPST-1 and -2 differ in substrate preference. Peptides modeled on the sulfation sites of human C4a chain and heparin cofactor II are more efficiently sulfated by TPST-1 than by TPST-2. In addition, sulfation of a peptide modeled on the N-terminal domain of human CCR5, which has 4 potential tyrosine *O*-sulfation sites, has been examined by determining the time course of appearance of reaction products. Both TPST isoenzymes sulfated Tyr¹⁴ and Tyr¹⁵ first, followed by Tyr¹⁰ then Tyr³. However, TPST-1 clearly preferred Tyr¹⁴ over Tyr¹⁵ as the initial sulfation site, whereas TPST-2 preferred Tyr¹⁵ over Tyr¹⁴.

Role of Tyrosine *O*-Sulfation in Protein Function

The general consensus in the field is that tyrosine sulfate residues play a direct role in protein-protein interactions. However, evidence supporting this conclusion is not extensive. This assertion is most strongly and directly supported by three examples in which tyrosine-sulfated proteins [hirugen, P-selectin glycoprotein ligand -1 (PSGL-1, CD162), glycoprotein Ibα (CD42b)] have been co-crystallized with ligands. In the crystal structures of the hirugen/α-thrombin complex, the complex between a tyrosine-sulfated glycopeptide modeled on the N-terminal domain of PSGL-1 and the lectin-EGF domain of P-selectin and, mostly recently, the structure of the glycoprotein Ibα/α-thrombin complex (4), sulfato-oxygens of tyrosine sulfate residues in hirugen, PSGL-1 and glycoprotein Ibα are involved in direct protein-protein contacts. Among other tyrosine-sulfated proteins, there is an additional subset in which sulfation is clearly required for optimal protein function, although the precise structural basis for this requirement is not known. Thus, tyrosine sulfation is required for optimal proteolytic processing of gastrin, binding of cholecystokinin to the CCK-A receptor, proteolytic activation of factor V and VIII by α-thrombin, binding of glycoprotein Ibα to von Willebrand factor and optimal interactions between several

▶G-protein coupled receptors and their cognate ligands. For the remainder of the known tyrosine-sulfated proteins, there is no information about location, stoichiometry or the role of the sulfotyrosine residue(s) in protein function.

Clinical Relevance

The human *TPST1* and *TPST2* genes are on chromosome 7q11.21 and 22q12.1, respectively. To date, no human genetic disease has been ascribed to defects at either locus. It was hypothesized that ▶Schwachman-Diamond syndrome (SDS) might be the result of defects in the *TPST1* gene because the putative SDS gene maps to a 1.9 cM interval at 7q11 that contains the *TPST1* gene. However, detailed genetic analysis of SDS patients has excluded *TPST1* as the causative gene and SDS-associated mutations have subsequently been identified in an uncharacterized gene, *SBDS*, in this same genetic interval.

Although *TPST1* and *TPST2* genes are not known to be disease genes *per se*, mutations at or near tyrosine sulfation site(s) in any TPST substrate could theoretically produce human disease. The only example of this comes from cases of mild-moderate ▶hemophilia A that are due to missense mutations resulting in substitution of a Phe residue for Tyr¹⁶⁸⁰ in the factor VIII protein. Sulfation of Tyr¹⁶⁸⁰ at the junction of the B and A3 domain of factor VIII is required for optimal binding to von Willebrand factor. This mutation may directly explain the mild to moderate hemophilia in these patients because von Willebrand factor is the major carrier protein for factor VIII in plasma.

Other similar examples will probably come to light as more tyrosine-sulfated proteins are identified and as more examples of the functional importance of this post-translational modification in protein function are documented. A great deal of interest has recently focused on the role of tyrosine *O*-sulfation in ▶chemokine receptor function after CCR5 was shown to be tyrosine-sulfated (5). CCR5 is a seven transmembrane domain G-protein-coupled receptor that functions as a receptor for MIP-1α/CCL3, MIP-1β/CCL4 and RANTES/CCL5 and is a major HIV co-receptor. Sulfation of one or more tyrosine residues in the N-terminal extra-cellular domain of CCR5 is required for optimal binding of MIP-1α, MIP-1β and RANTES and for optimal HIV co-receptor function. In addition, sulfotyrosine-containing peptides modeled on this domain bind to the HIV gp120/CD4 complex and inhibit HIV entry into cells. Similarly, other studies indicate that sulfation of tyrosine residue(s) in the N-terminal domains of other G protein-coupled receptors, including CXCR4, CCR2B, CX3CR1, C5a receptor, C3a receptor and the thyroid-stimulating hormone

receptor, is an important requirement for optimal binding of SDF-1 α /CXCL12, MCP-1/CCL2, fractalkine/CX3CL1, C5a, C3a and TSH respectively. The N-terminal domains of all known chemokine receptors are highly acidic and contain one or more tyrosine residues. This is the dominant feature of known tyrosine sulfation sites suggesting that many chemokine receptors may require tyrosine sulfation for optimal chemokine binding. This possibility has broad pathophysiological implications because chemokine receptors and their cognate ligands play crucial roles in hematopoiesis, innate and adaptive immunity, angiogenesis, tumor growth and metastasis.

New insights into the potential clinical relevance of tyrosine sulfation of proteins are emerging from the studies of TPST-deficient mice. Targeted disruption of the *Tpst1* and *Tpst2* genes results in distinct, unexpected and pleiotropic phenotypic effects. Disruption of one *Tpst* gene does not effect transcription of the other *Tpst* gene as assessed by Northern blot analysis. *Tpst1*^{+/−} and *Tpst2*^{+/−} mice appear normal and, when interbred, yield litters of normal size with a Mendelian genetic distribution of the targeted mutation. However, *Tpst1*^{−/−} mice have ~ 5% lower average body weight than wild type littermates. *Tpst1*^{−/−} females have smaller litters than wild type females due to fetal death at 8.5–15.5 days *post coitum*, although fertility of *Tpst1*^{−/−} mice is normal (6). In contrast to *Tpst1*^{−/−} mice, the growth of *Tpst2*^{−/−} mice is severely delayed. At 4–5 weeks the body weight of *Tpst2* nulls are ~ 20% below wild-type littermates. However, they attain normal body weight by 10 weeks and otherwise appear healthy. Also in contrast to *Tpst1* nulls, *Tpst2*^{−/−} males have severely defective reproductive performance. *Tpst2*^{−/−} males mate with females, although with a longer latency than do wild type males, but they only rarely sire litters. *Tpst2*^{−/−} males have normal reproductive hormone levels (FSH, LH and testosterone); testicular histology is normal, as are sperm counts, morphology and motility. Thus, defective fertility of the *Tpst2* null male may result from defective sperm transport, capacitation, acrosomal reaction and/or fertilization *per se*.

These data demonstrate that the two TPST isoenzymes have distinct biological roles and underscore the

importance of tyrosine *O*-sulfation in several physiological processes that had not been previously appreciated, including growth and reproductive physiology.

UAP56

Definition

UAP56 (56-kDa U2AF-associated protein) and its yeast homolog Sub2 are essential splicing factors that are required for ►[spliceosome](#) assembly, and for the recruitment of Aly/REF to the exon junction complex. UAP56 also plays important roles in the export of mRNA from the nucleus to the cytoplasm.

►[RNA Export](#)

UAS-Gal4 System

Definition

UAS-Gal4 system refers to an *in vivo* system that has been adapted from yeast, and consists of two transgenic lines of *Drosophila* – a driver line (yeast transcription factor Gal4 is expressed under the control of a specific promoter) and a responder line UAS. It is promoter specific for Gal4, linked to the cDNA of choice. After the crossing of both lines, Gal4 binds to the UAS-sequence and induces the expression of the gene or RNAi construct of interest. This system allows *in vivo* expression in a spatial and temporal restricted manner.

Ubiquitin

Definition

Ubiquitin is a 76-amino acid polypeptide that is conjugated posttranslationally to internal lysine residues of other proteins. It is ubiquitously present in all eukaryotes, hence its name, and is one of the most highly conserved proteins, with only 3 residues change between yeast and humans. Ubiquitination is a mechanism to induce proteasomal degradation of proteins. E3 ligases are enzymes that, together with E1 and E2 ligases, catalyse the transfer of an ubiquitin polypeptide onto proteins destined for degradation. E1 ligase activates ubiquitin, E2 ligase performs the actual transfer of ubiquitin to the target protein, and E3 ligases are involved in substrate recognition and determining the specificity. Poly-ubiquitinated proteins are degraded in proteasomes.

Ubiquitin Chains

Definition

Ubiquitin molecules can be linked to internal lysine residues of a previous ubiquitin, thus forming a chain. The linkage between the ubiquitin molecules determines the fate of the modified target protein. The most common ubiquitin chain is linked via the ϵ -amino group of Lysine 48 and the carboxy terminus in the adjacent ubiquitin, and targets the tagged protein to the proteasome for degradation or other processes such as DNA damage repair (e.g. lys63).

Definition

► **Ubiquitin** is a small protein acting as a molecular tag that is post-translationally attached to other proteins (targets). An enzymatic cascade, consisting of different classes of enzymes, catalyzes this covalent conjugation of ubiquitin in the presence of ATP. In this reaction, the C-terminus of ubiquitin is covalently connected to the ϵ -amino group of a lysine residue in the target molecule, resulting in an ► **isopeptide-bond**. If this modification occurs in multiple rounds, it leads to polyubiquitinated substrates, which are targeted for destruction by the 26S ► **proteasome**. Besides this so-called “classical” function, ubiquitin conjugation also serves non-classical functions as a posttranslational modifier. As a requirement for these non-classical functions ubiquitination is a reversible process through the action of deubiquitinating enzymes (DUB).

Characteristics Ubiquitin

Ubiquitin is highly conserved among all eukaryotes. Almost 96% of the amino acids are identical between yeast and man. All eukaryotes have several genes that code for ubiquitin. Ubiquitin is always expressed as a fusion protein, either with ribosomal subunits or as a multimer of several ubiquitin molecules. Under normal growth conditions, the ribosomal fusion proteins are only expressed under stress conditions and upon entry

into the stationary growth phase the multimeric form of ubiquitin is expressed.

Mature ubiquitin is released from the precursor by a proteolytic cleavage catalyzed by specialized enzymes, the ubiquitin C-terminal hydrolases (UCH). In this reaction the mature C-terminus of ubiquitin with its characteristic GG-motif is created. The conjugation of ubiquitin to a target protein occurs *via* the last glycine of the mature protein. This need for C-terminal processing prevents the modification with a precursor form of ubiquitin.

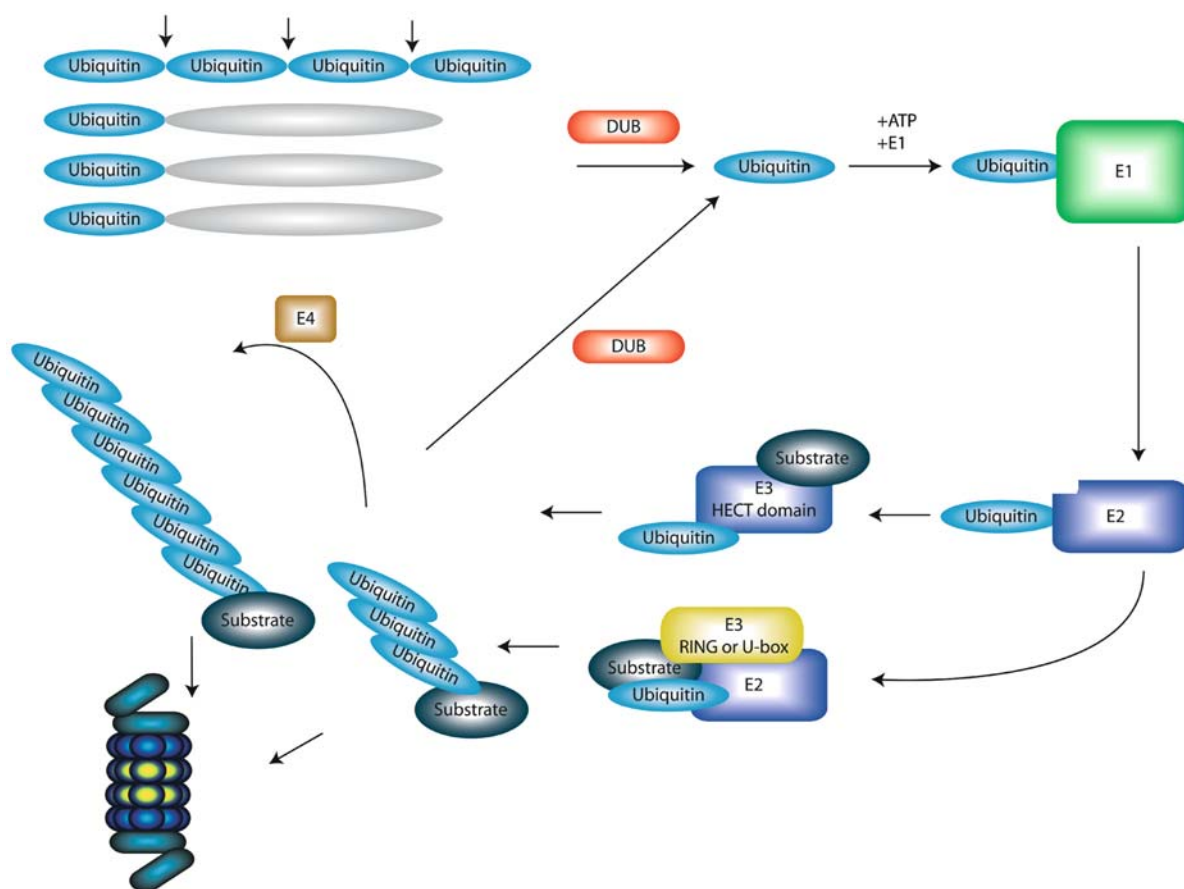

Mono-Ubiquitination and Ubiquitin-Chains

To fulfill both classical and non-classical functions the modification with ubiquitin must transfer more than a single piece of information. This information is encoded in the number of ubiquitin molecules that are added to the target protein and in the way they are connected. The most common modification with ubiquitin occurs in the form of a chain. Since ubiquitin itself contains several lysine residues, ubiquitin can be linked to a previously attached ubiquitin molecule. In this way a chain is synthesized, which can be observed in a SDS-PAGE gel as the typical “ladder”-pattern. In principle each of ubiquitin’s lysine residues can be used to build a polyubiquitin chain, but the most commonly used residue is lysine 48 (K48). K48-linked chains of at least four molecules in length are recognized by the proteasome and the target molecule is then degraded. Current knowledge suggests that only K48 and K29 linked chains are recognized by the proteasome and subsequently lead to the degradation of the target protein. In contrast a K63 linkage seems to act as a modification that alters the activity of the target protein. So far there is little knowledge about the other linkages.

In addition to polyubiquitination the attachment of a single ubiquitin has also been proven to be a vital function. This so called mono-ubiquitination has no effect on the half-life of the target protein, but, at least in some cases, acts as a sorting signal within the cell. This has been suggested for receptor internalization and for sorting into the multivesicular body pathway (mvb).

The Ubiquitination Machinery

The specificity of ubiquitin conjugation is mediated by an enzymatic cascade, which attaches ubiquitin to target proteins. This cascade consists of ubiquitin-activating enzyme (E1), ubiquitin-conjugating enzymes (E2), ubiquitin-ligases (E3) and sometimes ubiquitin-chain-elongation (E4) enzyme. As for all reversible modifying systems, enzymes exist that cleave ubiquitin from substrates. These factors comprise a family of enzymes known as deconjugating enzymes (DUB) (Fig. 1).

Ubiquitination. Figure 1 Creation of a poly-ubiquitin chain is a multi-step enzymatic reaction. Ubiquitin is cleaved of the precursor molecule by specialized enzymes releasing the mature ubiquitin (DUB). The mature ubiquitin is then bound by an ubiquitin-activating enzyme (E1) and activated by hydrolyzing an ATP molecule to AMP. In a following reaction ubiquitin is passed to a conjugating enzyme (E2). With the help of an ubiquitin-ligase (E3), the E2 can connect the C-terminus of ubiquitin with the substrate protein. Alternatively, the activated ubiquitin can be transferred to a HECT-E3 ligase, which in turn transfers the ubiquitin on its substrate. The ubiquitination reaction is repeated several times until an ubiquitin-chain is formed. In some cases the ubiquitin-chain is elongated by an elongation factor (E4). When the ubiquitin-chain is formed there are two possibilities to proceed, either the degradation of the substrate at the proteasome or the deubiquitination reaction catalyzed by deconjugating enzymes (DUB).

Ubiquitin-Activation

A single enzyme – the E1 – catalyzes the activation of mature ubiquitin. In this process ATP is hydrolyzed to AMP and pyrophosphate, which fuels the formation of a thio-ester bond between the active center of the E1 and the C-terminus of ubiquitin.

Ubiquitin-Conjugating Enzymes

In contrast to the activation by a single E1, the second step in this cascade is catalyzed by a variety of conjugating enzymes. In a trans-esterization reaction the activated ubiquitin is transferred to the E2 enzyme. Here it is covalently bound, again *via* a thio-ester bond between the active cysteine in the center of the enzyme and the C-terminus of ubiquitin. The family of

ubiquitin-conjugating enzymes is defined by the E2 catalytic domain (Smart: UbcC; Pfam: UQ_con) and has 11 members in yeast and about 60 in humans. These enzymes catalyze special chain formation (like ubc13, which catalyses K63 linkages) or have a unique localization (Ubc6, which is localized to the ER). This is part of the mechanism that provides the system with the versatility to recognize very divergent substrates without losing specificity.

Ubiquitin-Ligases

Ubiquitin-ligases catalyze the next step in the cascade. The family of ubiquitin-ligases is probably by far the largest group of enzymes and co-factors within the group of proteins that are involved in ubiquitination.

Two classes of E3 are described so far, E3 that forms a covalent intermediate with ubiquitin (► **HECT-domain**, Pfam: HECT) or E3 that acts as a mediator. The latter contains special amino acid motifs like the RING-finger (Pfam: zf-C3HC4), U-box (Pfam: U-box) or PHD (Pfam: PHD). The relatively small group of HECT-domain E3s is able to bind ubiquitin covalently. This reaction occurs within the 340 amino acid HECT domain. The transfer to the substrate will ultimately be catalyzed without an E2 enzyme present. In contrast to the HECT-E3s, ligases that contain a ring finger or a ring-finger-like motif are not able to bind ubiquitin covalently. They require the recruitment of an E2 for the transfer of ubiquitin to the substrate. The E3 acts as an adapter that recognizes the substrate and mediates the interaction with the E2, which catalyzes the transfer of ubiquitin to the substrate. An E2 enzyme can usually interact with

different E3s (Fig. 2). This modular system provides a wide variability, which makes it possible for the ubiquitination system to recognize very divergent substrates. An example of multimeric ring-finger-E3s is the F-box (Pfam: F-box) cullin system as seen in the ► **SCF-E3** (Skp-Cullin-F-box). The substrate recognition is transferred to a special factor the F-box protein, which interacts with the skp component of the ligase. These modules provide additional variability to the system. The family of F-box proteins has 5 members in *S. cerevisiae* and 62 in humans.

The Proteasome

The proteasome is a big barrel-shaped cytoplasmic protease (Fig. 3). The proteasome falls into two distinct subcomplexes the 20S core particle and the 19S regulatory particle. Each core particle has 6 proteolytic sites, which harbor 3 different activities (caspase-like,

Ubiquitination. Figure 2 The ubiquitin system uses a number of specialized enzymes to create different signals. In each step of the ubiquitination cascade an increasing number of enzymes are used. After ubiquitin has been activated by a single E1, in the next step a greater number of E2s can receive the ubiquitin, providing a greater range for substrate recognition. In the following step, the association with an E3, one E2 can associate with different E3 ligases, increasing the number of substrate again. Depending on the combination of E2 and E3, different signals (mono-ubiquitination, differently linked chains) can be produced on the substrate molecule.

Ubiquitination. Figure 3 The proteasome. The proteasome is a multi-subunit protease, which resides in the cytoplasm. The proteolytic sites are covered on the inside of the barrel-shaped central complex. This design prevents unwanted proteolytic activity. Every substrate has to be unfolded and threaded into the destruction channel. The unfolding activity is located in the 19S regulatory particle (RP), which sits on one or both sides of the core. Parts of the figure taken with permission from Finley (2002) *Nat Cell Bio* 4:E121-3.

tryptic and chymotryptic activities). These proteolytic sites are hidden inside a chamber in the barrel of the 20S proteasome (self-compartmentalizing protease). The sides of this chamber are closed by a gating mechanism that regulates the entry into this destruction channel. On one or both sides of its barrel-shaped structure the 20S proteasome is decorated with a regulatory particle. The regulatory particle harbors an unfolding, a deubiquitination activity and the ability of the proteasome to bind K48-linked poly-ubiquitin chains. For destruction of a substrate molecule, the poly-ubiquitinated (K48-linked) protein is recognized by the proteasome. The unfolding activity unfolds the substrate and threads the peptide-chain into the destruction channel. During this process the deubiquitinating activity removes the ubiquitin-molecule for recycling.

Deconjugating Enzymes

Tagging with ubiquitin is reversible. The family of deconjugating enzymes or DUBs catalyzes the deconjugation reaction, which always takes place in competition with the conjugation reaction. These proteases, which are specific to ubiquitin, fall into three categories, the UCH, UBP and Jamm-type proteases. The UCH proteases process the ubiquitin precursors and release the ubiquitin moiety from the fusion protein. In contrast the UBPs and Jamm-type proteases are specific for branched peptides. The UCHs

and the UBPs both belong to the group of cysteine proteases, meaning that the proteolytically active residue is a cysteine. The Jamm-proteases belong to the metallo-proteases and carry a Zn atom in their active center. A UBP and a Jamm-protease have been shown to be associated with the proteasome. Here they release the ubiquitin from the target making it available for recycling.

Molecular Interactions

UBA, UIM, UEV and CUE Domain-Proteins

The way in which ubiquitin is linked to the target molecule carries information about the nature of the substrate molecule. This information has to be decoded by the cell in one way or another. A signal for destruction of the substrate is recognized by the proteasome, which takes care of the substrate removal and the recycling of ubiquitin. Other modifications are interpreted by proteins that recognize ubiquitin by one of the domains, UBA, UIM, UEV, CUE or NZF. For all of these domains a binding to mono-ubiquitin has been shown, but the dissociation constants indicate that the UBA and the UEV domain have a preference for the binding of poly-ubiquitin. In contrast to this, the UIM, CUE and NZF domains have a higher affinity for mono-ubiquitin. But the exact binding preferences of mono-ubiquitin or poly-ubiquitin and

their preferences in terms of linkage remain to be characterized.

Regulatory Mechanisms

The ubiquitin-proteasome system is involved in a huge number of cellular processes. Here are a few examples of regulatory activity by this system.

Quality Control/Stress Response

The removal of misfolded proteins from the cell is an important and essential process inside a cell. Proteins that get misfolded during their life cycle are recognized by the ubiquitin-proteasome system and get degraded. Keeping this in mind, it is not surprising that parts of the ubiquitin system belong to the heat-shock response system. But degradation occurs not only after protein synthesis is completed, but also during synthesis and maturation of a protein. The quality control mechanisms in the endoplasmic reticulum recognize proteins that fail to fold and export them to the cytoplasm where they are degraded by the proteasome (ER associated protein degradation, ERAD).

Regulation of the Cell-Cycle

The ubiquitin proteasome system also plays an essential role in the regulation of the cell-cycle. Two important ubiquitin-ligases SCF and APC guard progression through the G1/S and the G2/M transitions. Here they recognize e.g. the phosphorylated cyclin and degrade it, moving the cell-cycle to the next step. Besides the cyclins, other important cell-cycle regulators have been described as substrates for the ubiquitin-proteasome system (e.g. securin in sister-chromatid separation).

Regulation of the Ubiquitin-Proteasome System by Other Modifications

In order to be recognized by the different parts of the ubiquitin-conjugation machinery substrates have to carry certain modifications. Probably the best-studied modifications are phosphorylations, which lead to degradation of the substrate as shown for cyclins. Another example is histone 2A, which has to be methylated in order to be ubiquitinated. For the DNA binding protein PCNA and others, a new modification has been described, the modification with SUMO-1, which has here an antagonizing effect on ubiquitination. This molecule is one of several small modifiers, which share a significant structural similarity to ubiquitin. In yeast this group has six members Smt3 (or SUMO, see chapter on [▶sumolyation](#)), Rub1, Apg8, Apg12, Urm1 and Hub1. In mammalian cells, additional ones (Fat10, MNSF, ISG15, Ufm1) have been described. All these modifiers do not act as [▶degradation signals](#), but fulfill other functions in the cell.

Definition

The [▶photorelease](#) of biomolecules from photolabile biologically inactive precursors, in biology termed so-called [▶caged compounds](#), is referred to as [▶uncaging](#). When caged, the biomolecule is rendered biologically inactive by covalent attachment of a photochemically removable protecting group ("[▶caging group](#)") to the key pharmacophoric functionality. Flash photolysis using light of a specific color cleaves the modifying

group, i.e. triggers the uncaging, and rapidly activates the molecule. Light-activated caged compounds are powerful tools for controlling the release of biomolecules within organized biological systems with spatial and temporal precision by dictating when and where light exposure occurs. Biological response may then be measured with second up to nanosecond time resolution depending on the photochemistry and the system under investigation. The fact that uncaging does not require any reagent, just light, opens the possibility of dealing with extremely sensitive molecules. In addition, concentration jumps mediated by light-directed activation of caged compounds can be conducted without physically disturbing the preparation.

Description

Photoremovable Protecting Groups

Deactivation or protection of functional groups and conversely their specific activation are common practice in chemistry, especially in the design and construction of polyfunctional molecules such as peptides, oligosaccharides, glycolipids and nucleotides (1). Protecting groups protect specific functional groups during synthetic steps and are removed once the protection is no longer required. Among the numerous classes of protecting groups, ►**photoremovable protecting groups** provide a general route to

regenerate the unprotected compound by photochemical means under mild, neutral conditions. A photoremovable protecting group is covalently bound to the functional group and contains a light-sensitive chromophore that can serve as a latent activator of the functional group. On irradiation with light of suitable wavelength, the functional group is converted to an active form and the light-sensitive chromophore is removed. Ideally, the wavelength of the light to be used for deprotection should not affect other parts of the molecule. A short lifetime of the excited state that is responsible for the deprotection reaction and a relatively high stability of the protecting group and the protected bond to a variety of reagents and chemical treatments are desirable. Furthermore, the yield of the deprotection step should be high and the photodecomposition process should be clean. Finally, the photoremovable protecting group should be readily introduced by accessible reagents and the protecting group photoproduct should be separable from the deprotected compound.

Caged Compounds

Caged compounds or photoactivatable bioagents are biomolecules bearing photoremovable protecting groups that inactivate or “cage” the biomolecule and then release or “uncage” it on a flash of light (Fig. 1). They are very useful tools in biophysical and

Uncaging and Photoconversion/Activation. Figure 1 Caging and uncaging of a biomolecule. (a) general principle. (b) uncaging of CNB-caged glutamate.

biochemical studies and can be applied extracellularly or incorporated into cells (2, 3). The major advantage of their use is the high speed of the photochemistry and the fact that they can be applied to organized systems, such as muscle fibers, ion channels and membranes under physiological conditions. Additionally, they are potentially powerful tools in gene expression targeting, in protein folding studies, time-resolved X-ray studies or ►[photolithographic syntheses](#) of ►[biochips](#) (4, 5, 6). A wide variety of caged species has been described, including neurotransmitters, drugs, nucleotides, DNA, RNA, amino acids, peptides, proteins, enzymes, NO and Ca^{2+} . It is important that a caged compound can be introduced to its site of action over a period of minutes (or hours) without evoking biological responses and that the biologically active molecule can then be released from the “cage” by flash photolysis extremely fast (within milliseconds or less). Because photolysis of caged compounds generates effectors *in situ*, much faster and more spatially uniform concentration jumps can be effected than is possible with traditional rapid mixing techniques. There are no diffusion problems and no spatial inhomogeneity problems with addition of substrates. Desensitization of the biological response is minimized. Furthermore, the biologically inert caged compound can be loaded into intracellular compartments by a variety of techniques and concentration jumps can be effected in an environment that is otherwise inaccessible.

Among the different photochemical protecting groups, 1-(2-nitrophenyl)ethyl (NPE), 1-(4,5-dimethoxy-2-nitrophenyl)ethyl (DMNPE), 4,5-dimethoxy-2-nitrobenzyl (DMNB), α -carboxy-2-nitrobenzyl (CNB), 2-(2-nitrophenyl)propoxycarbonyl (NPPOC), para-hydroxyphenacyl, benzoin and coumarinylmethyl groups are the most widely used caging groups. They have been successfully applied to protect carboxyl, hydroxyl, thiol, amino and carbonyl groups as well as phosphate functions in biomolecules. A special strategy for the photorelease of poor leaving groups such as alcohols or amines is to release carbonic or carbamic acid monoesters, which decarboxylate when released.

For biological applications, a caging group must undergo uncaging rapidly, in high yield and on long wavelength UV/Vis or IR activation. High absorption coefficients at wavelength above 320 nm are favorable. Furthermore, the ►[phototriggers](#) should be sufficiently soluble in aqueous solutions, stable toward solvolysis, nontoxic and biologically inert. Sometimes cell membrane permeability is required.

In practice most caged compounds do not fulfill all the requirements for perfect caged compounds and therefore it is desirable to have a range of compounds with different characteristics from which to choose.

Photoactivation

The caged precursor must be photocleavable by light at a wavelength compatible with the biological system being studied. Generally, light at wavelengths below 300 nm can cause photodamage and has limited penetrability through biological material. In the usually used one-photon excitation, a photorelease by near ultraviolet (UV) light in the 350–400 nm range is desirable. Commercially available photoactivation light sources are lasers and flash lamps. The advantages of lasers are their high power coupled with the very short pulse duration and their monochromaticity. A new technique is the two-photon excitation method, which provides better penetration into living tissues and three-dimensional control over the localization of substrate release. In two-photon photolysis, UV excitation is replaced by the simultaneous absorption of two IR photons of equivalent total energy. Two-photon uncaging used a femtosecond-pulsed, mode-locked titanium-sapphire laser. However, most caging groups do not allow two-photon uncaging. A useful caging group for two-photon excitation is the (6-bromo-7-hydroxycoumarin-4-yl)methyl (BHCM) moiety.

Photoactivation illuminators can be integrated into microscope systems and are able to focus UV light sufficient for photorelease within a small region of the specimen, even within a single cell. This capability allows the properties of subcellular microenvironments to be examined and also makes it possible to study spatial and temporal aspects of dynamic processes.

A caged compound should show high absorptivity at the wavelength used for photolysis. The quantum yield of the photoreaction, defined as the ratio of the number of bioactive molecules released to the number of protons absorbed by the caged precursor, should be between 0.1 and 1. Quantum yields may depend strongly on solvent and pH.

For time-resolved studies the release rate of the biomolecule must exceed that of the response investigated. Therefore, knowledge of the actual release rates under physiological conditions is important. Release rates are determined by the caging group, the leaving group and the mechanism of the photorelease. Generally, the generation of the biomolecules occurs in the submillisecond time range.

Selected Practical Applications

Caging and uncaging of biomolecules combined with rapid monitoring of the ensuing reaction using photomultiplier or image-based techniques are widely used for studies of the mechanisms and the kinetics of cellular processes. Caged ATP was applied to investigate the energetics of ►[muscle contraction](#) or to trigger Ca^{2+} signals that are communicated between different cell types. The caged second messengers cAMP and

cGMP were used to analyze cyclic nucleotide-dependent signal transduction pathways and their possible functional consequences. Photolabile Ca^{2+} release chelators were applied for the generation of Ca^{2+} concentration jumps in a myriad of vital physiological processes including muscle contraction, secretion, mitosis, channel gating and chemotaxis. Caged neurotransmitters as well as a variety of caged neurotransmitter agonists allowed the investigation of the detailed kinetics of receptor-mediated events and were useful for mapping receptor distributions in individual [▶neurons](#). A variety of drugs were exploited to probe drug-receptor interactions. Photoactivatable peptides bearing caging groups at essential amino acids including lysine, tyrosine, cysteine, serine, threonine, aspartic acid, glutamic acid and arginine were found to be important reagents for investigating cell signaling and controlling protein-protein interactions as well as enzyme activity. Application of caging chemistry to DNA and mRNA offered the possibility of targeting expression of genetic material with light. Caging of transcriptional activators was also a tool for spatiotemporal control of gene expression.

Methods to cage protein activity were also developed. Caged proteins were used to investigate protein structure-function relationships and protein function in living cells.

A general approach to trigger a single activation cycle of an enzyme involves chemical modification of the protein by a photosensitive protecting group that yields a deactivated enzyme. Photoremoval of the protecting group regenerates the native protein and reactivates the enzyme. This approach is exemplified in studies of fast conformational changes in enzymes and other proteins. Caged ligands can be also used to photochemically trigger an enzymatic reaction within an enzyme crystal and are thus valuable tools for studying protein dynamics at the atomic level by time-resolved X-ray. Furthermore, photochemical triggering methods are suitable for kinetic studies of protein folding.

Finally, caged compounds have also been used in the synthesis of microarrays of peptides and oligonucleotides on surfaces for use in genomics and proteomics research, utilizing photolithographic processes.

Vesicular Traffic

RAINER DUDEN

School of Biological Sciences, Royal Holloway
University of London, Egham, Surrey, UK
rainer.duden@rhul.ac.uk

Definition

Eukaryotic cells are elaborately subdivided into functionally distinct, membrane-bounded compartments, which together form a sophisticated endomembrane system. Each compartment or organelle contains its characteristic set of enzymes and other resident proteins with specialized functions and complex distribution systems connect compartments with each other. Within the endomembrane system, the ► [secretory pathway](#) delivers newly synthesized proteins, carbohydrates and lipids to the outside of the cell or to other, intracellular final destinations. The ► [endocytic pathway](#) takes up macromolecules into the cell and ensures their delivery to endosomes and lysosomes. Despite a large flux of material through these compartments, each compartment maintains its unique biochemical make-up of resident proteins at steady state. This is made possible by highly regulated mechanisms for the transfer of material between compartments, which ensure the proper specificity and directionality of the secretory and endocytotic processes. In the past two decades a large number of evolutionarily conserved components of these vesicular transport pathways have been identified using biochemical and genetic approaches, in mammalian cells and in the yeast model *Saccharomyces cerevisiae* (budding yeast). The majority of these proteins participate in transport in the context of

macromolecular protein complexes, sometimes also called “protein machines”.

Characteristics

Traffic in between membrane-bounded compartments is mediated by vesicular and tubular carriers, which are shaped by cytoplasmic ►coat proteins (Fig. 1) (1). Coat proteins form an electron-dense outer layer of vesicles that can be visualized under the electron microscope. Cytoplasmic coat proteins perform the dual, essential tasks of providing the mechanical force for deforming the lipid bilayer of appropriate “donor” membranes into buds and vesicles and selecting appropriate cargo proteins during budding. Thus, protein sorting and vesicle budding are functionally integrated. Different intracellular transport steps utilize distinct sets of coats and several sets of coat proteins have been well characterized, including COP I, COP II, ►clathrin, the ►adaptor complexes AP-1, AP-2, AP-3 and AP-4 and ►GGAs. Binding of coat proteins to membranes is highly compartment specific. All vesicular protein transport involves the selective recruitment of cargo into the vesicles, controlled formation of the vesicle from membranes of a specific compartment, partial uncoating and transport to the target membrane/organelle and binding to and fusion with the target membrane (1).

Upon arrival of transport vesicles at their appropriate target membranes, and preceding membrane fusion, they are “tethered” by specific tethering complexes, some of which have been characterized in molecular detail (2). Lastly, the specificity of intracellular membrane fusion is governed by ►SNARE proteins, which have compartment specific patterns of localization. Pairing of cognate v- and t-SNAREs between two opposing lipid bilayers drives spontaneous membrane fusion and confers specificity to intracellular membrane trafficking events (3). The incorporation of v-SNAREs into the budding vesicle through interactions with coat proteins programs the vesicle for fusion at the appropriate target membrane. Fusion of the vesicle with the target membrane leads to delivery of cargo molecules and thus completes a round of transport (Fig. 2) (1).

Several distinct classes of coated vesicles and the coat proteins forming them, have been characterized in molecular detail (4), and are described below. All these coat proteins are organized as multi-subunit complexes on “donor” membranes and their individual subunits and interactions are conserved in evolution.

COP II-Coated Vesicles

COP II-coated vesicles (size 60–70 nm) are required for selective export of newly synthesized proteins from the

Vesicular Traffic. 1 Intracellular Transport Pathways. The scheme depicts the compartments of the secretory, lysosomal/vacuolar and endocytic pathways. Transport steps are indicated by arrows. Colours indicate the known or presumed locations of the coat proteins COPII (blue), COPI (red), and clathrin (orange). Clathrin coats are heterogeneous and contain different adaptor and accessory proteins at different membranes. Only the function of COPII in ER export and of plasma membrane-associated clathrin in endocytosis are known with certainty. Less well understood are the exact functions of COPI at the VTCs and Golgi complex and of clathrin at the TGN, early endosomes and immature secretory granules. There are several vesicular transport pathways within the cell for which no coat proteins have been described so far. Therefore the identification of further, novel vesicle coats in the near future is likely. Reproduced with copyright permission from Bonifacino and Glick (2004).

Vesicular Traffic. 2 Steps of Vesicle Budding and Fusion. (1) Initiation of coat assembly. The membrane-proximal coat components (blue) are recruited to the donor compartment by binding to a membrane-associated GTPase (red) and/or to a specific phosphoinositide. Transmembrane cargo proteins and SNAREs begin to gather at the assembling coat. (2) Budding. The membrane-distal coat components (green) are added and polymerize into a mesh-like structure. Cargo becomes concentrated and membrane curvature increases. (3) Scission. The neck between the vesicle and the donor compartment is severed either by direct action of the coat or by accessory proteins. (4) Uncoating. The vesicle loses its coat due to various events including inactivation of the small GTPase, phosphoinositide hydrolysis and the action of uncoating enzymes. Cytosolic coat proteins are then recycled for additional rounds of vesicle budding. (5) Tethering. The “naked” vesicle moves to the acceptor compartment, possibly guided by the cytoskeleton, and becomes tethered to the acceptor compartment by the combination of a GTP bound Rab and a tethering factor. (6) Docking. The v- and t-SNAREs assemble into a four-helix bundle. (7) This “trans-SNARE complex” promotes fusion of the vesicle and acceptor lipid bilayers. Cargo is transferred to the acceptor compartment, and the SNAREs are recycled. Reproduced with copyright permission from Bonifacino and Glick (2004).

► **endoplasmic reticulum (ER)**. The minimal machinery to bud ► **COP II vesicles** from ER membranes or liposomes comprises the small GTPase ► **Sar1p** and two hetero-dimeric protein complexes, Sec23/24p and Sec13/31p. All components involved in COP II vesicle formation are essential for cell viability in yeast. COP II vesicles produced *in vitro* from membranes in the presence of the minimal machinery are capable of packaging a large set of cargo proteins, including the SNARE proteins necessary for their targeting and fusion with membranes of the ► **Golgi complex** (4, 5). The dynamics of COP II-coated ER exit sites have been studied by time-lapse fluorescence microscopy of living cells, using functional chimeras of COP II subunits with green fluorescent protein. The majority of COP II labelling is in stable ‘spots’ tightly associated with ER membranes. Secretory cargo segregates from these sites and is transported to the Golgi complex without COP II proteins being associated with the moving structures. The current model is that COP II vesicles rapidly uncoat after budding, allowing them to

fuse with each other and generate so-called VTC membrane structures (VTC = vesicular-tubular clusters, also named ERGIC (ER/Golgi intermediate compartment, or just ‘intermediate compartment’) (Fig. 1). COP II coat proteins do cycle rapidly on and off the ER membrane, but they get recruited back to the same domains, thus defining kinetically stable ER exit sites (5).

COP I-Coated Vesicles

COP I-coated vesicles (size 70–80 nm) mediate an essential and conserved retrograde transport pathway that selectively recycles proteins from the *cis*-Golgi complex back to the ER (Fig. 1). Importantly, ► **COP I vesicles** retrieve the v-SNAREs involved in COP II vesicle consumption. Furthermore, COP I vesicles are instrumental in the retrieval of misfolded proteins that escape the ER quality control mechanism and of ER resident proteins that leak out of the ER. Cargo packaging into COP I vesicles is based on specific trafficking motifs, e.g. the di-lysine motif (KKXX) or

the KDEL motif, which is present on the ER luminal chaperones BiP and protein disulphide isomerase. Escaped, misfolded proteins can be retrieved to the ER in complex with BiP. This aspect of COP I function is therefore an extended part of the ER quality control system. Additionally, COP I coat proteins have important and complex functions in intra-Golgi trafficking and in maintaining the normal structure of the mammalian interphase Golgi complex. The minimal machinery to form COP I-coated vesicles from Golgi membranes or liposomes with a defined composition comprises the small GTPase **▶ARF** in its GTP-bound, active form and coatomer, a stable heptameric protein complex containing α -, β -, β' -, γ -, δ -, ϵ -, and ζ -COPs (4, 5). Conserved GTPase-activating (ARFGAP) proteins are essential to accomplish GTP hydrolysis on ARF and thus help achieve vesicle uncoating, but these proteins are also important for cargo selection in ways so far incompletely understood (5).

Clathrin Coated Vesicles, Adaptor Complexes, GGAs

The clathrin coat was the first vesicle coat to be discovered and is still the best understood (6). The coat protein clathrin provides the mechanical scaffold to deform the **▶plasma membrane** or membranes on the *trans*- or exit side of the Golgi complex into clathrin coated vesicles. Endocytosis mediated by clathrin coated vesicles plays a central role in regulating the level of integral membrane proteins in the plasma membrane, including signalling and nutrient receptors, cell surface markers and adhesion proteins, ion channels and pumps. In many cells, clathrin dependent receptor mediated endocytosis is the major pathway for internalization of materials from the outside world, but other pathways for internalization of materials exist (reviewed in 8).

Cargo inclusion into clathrin coated vesicles is mediated by adaptor proteins that can associate both with trafficking motifs in the cytoplasmic domains of cargo proteins and with clathrin (6, 7). Classically, four related hetero-tetrameric AP complexes have been described, AP-1, AP-2, AP-3 and AP-4. Each of these complexes is composed of two large subunits (one each of $\gamma/\alpha/\delta/\epsilon$ and $\beta 1$ -4, respectively; 90–130 kD), one medium adaptin ($\mu 1$ -4; ~50 kD) and one small adaptin ($\sigma 1$ -4; 20 kD). Only AP-1 and AP-2 associate with clathrin. AP-1 is present on vesicles budding from the *trans*-side of the Golgi complex to effect transport of specific cargo to endosomal and lysosomal membranes and AP-2 associates with endocytotic vesicles budding from the plasma membrane. Gene knockouts of subunits of AP-1 and AP-2 in mice are embryonic lethal. GGAs comprise another family of proteins that associate with clathrin and ARF and are involved in trafficking of specific cargo in between the Golgi complex and endosomes. AP-3 mediates selective

transport to lysosomes and lysosome-related organelles; its associated coat protein is so far unknown. Mutations in AP-3 subunits result in viable mice with coat colour defects and bleeding disorders and in *Drosophila* result in eye pigmentation defects.

SNAREs

SNARE proteins ensure the specificity of vesicle docking and fusion with the appropriate target membrane. SNAREs constitute a superfamily of small, coiled-coil transmembrane proteins present on vesicles and target organelles (named v- and t-SNAREs) that act as molecular “address tags” to ensure this specificity. During membrane fusion, four α -helices from SNAREs on the vesicle and target membranes come together to form a stable, parallel four-helix bundle. A conserved domain of ~60 amino acids (the SNARE motif) mediates this association, which helps to overcome the energetic barrier to lipid bilayer fusion. After membrane fusion SNARE complexes need to be disassembled in an ATP-dependent reaction mediated by **▶NSF** (3). Also, since the v-SNAREs are now located in the wrong compartment they need to be recycled to the “donor” compartment to be made available for the next transport round. Therefore, all sustained trafficking in any of the vesicular transport steps in the secretory or endocytic pathways in one direction is coupled to recycling pathways that mediate retrieval of SNAREs (and other escaped proteins) in the reverse direction.

Molecular Interactions

Different coat proteins get recruited to the cytosolic face of specific “donor” membranes through molecular interactions with specific lipids or organelle resident proteins, or with sorting motifs present in the cytoplasmic tails of cargo proteins, or through a combination of these binding determinants. Below the molecular constituents of the best well-known vesicle coats and their interactions are discussed (2, 3, 4, 7).

COP II-Coated Vesicles

COP II vesicle budding is initiated when an ER-localized transmembrane protein, Sec12p, mediates the GTP for GDP exchange on Sar1p. GTP-loaded Sar1p tightly binds to ER membranes and recruits the Sec23/24 complex and subsequently the Sec13/31p complex, which induces coat polymerization and membrane deformation into buds and vesicles. Sar1p and Sec23/24p together can bind to cytoplasmic domains of cargo proteins, providing a ‘primer’ for COP II vesicle formation. These direct interactions of COP II proteins with cargo during budding are thought to increase efficacy and fidelity of cargo sorting into COP II vesicles. By mechanisms so far unknown, misfolded

proteins present in the ER and ER-resident proteins are excluded from the vesicles. After budding, Sec23p acts as a Sar1p-specific GTPase activating protein (GAP), helping Sar1p to hydrolyse its GTP, which in turn triggers vesicle uncoating. The Sec13/31p complex, once recruited to the membrane and having induced membrane curvature, leads to increased Sar1p-GTPase activity mediated through the action of Sec23p. This built-in GTPase-activating protein makes the COP II coat intrinsically unstable. Non-hydrolysable analogues of GTP have therefore been used to isolate and characterize COP II-coated vesicles (4, 5).

X-ray crystallography, deep-etch rotary shadowing and electron microscopy have recently been used to visualize the structure of COP II subunits and the surface structure of COP II-coated vesicles. These data demonstrated that the Sec23/24p complex resembles a bow tie and the Sec13/31p complex has a flexible structure of 24–30 nm in length comprising a terminal bilobed globular structure bordering a central rod. A surface view of vesicles by electron microscopy revealed a coat built with polygonal units (5).

The Sec24p subunit recruits cargo into the vesicles, since the Sec23/24p heterodimer, and in some cases Sec24p alone, can bind to cytoplasmic domains of a variety of COP II-vesicle cargo molecules. Yeast cells possess three Sec24p homologs and higher eukaryotes express at least four isoforms. This variation in the Sec24p subunit provides COP II vesicles with a broader specificity for cargo selection, as well as greater flexibility in vesicle size. The specificity of the cargo coat protein interaction is mediated by sorting signals present in the cytoplasmic domains of cargo proteins to which the Sec23/24 proteins bind. Two such ER export signals have been well characterized so far, namely a di-phenylalanine motif and a di-acidic sorting signal Asp-X-Glu (D-X-E, where X is any amino acid). Soluble cargo may get incorporated into COP II vesicles either by default ('bulk flow') or through selective interactions of the coat with export receptors that bind this cargo.

Clathrin and Adaptor Complexes

The basic assembly unit of the clathrin coat is the clathrin triskelion, composed of three clathrin heavy chains and three clathrin light chains. Clathrin assembles into hexagonal lattices on membranes of the plasma membrane and on membranes on the *trans*- or exit side of the Golgi complex. During the process of vesicle formation, the clathrin arrangement changes into a basket made out of pentagons (6). Disassembly of the clathrin coat after budding involves the HSC70 (heat-shock-cognate 70) ATPase and the co-chaperone auxilin, which *in vitro* bind to the clathrin light chains. While clathrin provides the mechanical scaffold to deform the plasma membrane or *trans*-Golgi

membranes into coated buds and vesicles, adaptor proteins mediate protein cargo selection. Different adaptors, e.g. AP-1, AP-2, GGAs and PACS-1, have binding specificity for distinct types of cargo proteins and sorting motifs and also associate with clathrin. The complete structures of AP-2 and clathrin have been solved by X-ray crystallography. X-ray crystallography has also allowed understanding at atomic resolution of how adaptors and GGAs bind their different cargo proteins through specific trafficking motifs. There is an ever-growing number of other cargo-specific adaptors (7). In general, adaptors team up with cytoplasmic coat proteins to effect the enrichment of cargo into transport vesicles. Whereas AP-1 and AP-2 cooperate with clathrin, AP-3 and AP-4 do not seem to associate with clathrin and their binding partners are unknown.

Regulatory Mechanisms

Our knowledge of the regulation of vesicular trafficking events in time and space is sketchy at best. It is clear, however, that these processes are tightly regulated, since e.g. the size and molecular composition of intracellular membrane bounded compartments stay constant at steady state despite an enormous flux of proteins and lipids through them. Strikingly, a fibroblast cell under typical conditions will internalize an amount of membrane equivalent to the whole surface area of the cell in just one hour. For the regulation of vesicle coat formation, small GTP-binding proteins of the ras-superfamily and their regulators, i.e. guanine nucleotide exchange factors or GEFs and GTPase-activating proteins or GAPs, hold the key to understanding how cargo selection is coupled to vesicle formation. These proteins function as "molecular switches" whose conformational changes are regulated by the cycle of GDP/GTP exchange and GTP hydrolysis. Similarly, the proper and efficient targeting of vesicles to their destinations, i.e. their "tethering", requires proteins from the large and diverse Rab/Ypt family of small GTPases, which provide another example of how a GTP/GDP-nucleotide dependent conformational switch mechanism is used to regulate cellular events (2). In the case of clathrin/AP-2-coated vesicles in endocytosis, phosphorylation on a crucial residue on AP-2 (threonine 156 on the μ 2 subunit) and binding of specific phosphoinositides crucially regulate binding of cargo and vesicle formation. A large number of regulatory proteins are known to bind the "ear" domains of the large subunits of adaptor complexes, and are likely to fine-tune aspects of cargo selection, membrane binding and vesicle formation. In the case of COP II and COP I vesicles only a few such studies have been published. Active research in many laboratories is currently addressing these questions.

Viral oncogenesis can be defined as the feature of ► tumor viruses that induces benign or malignant proliferation of infected cells.

Characteristics

Tumor viruses constitute a heterogeneous group of viruses, which play a causative role in naturally occurring malignancies, benign tumors and tumors of experimentally infected laboratory animals. Although they are members of different and unrelated systematic entities, they have several features in common. They mostly encode growth-stimulating proteins, contain DNA as genetic material, and establish long lasting persistence in the host (Table 1). The last frequently relies on episomal replication of circular viral genomes

Viral Oncogenesis. Table 1 Oncogenic viruses

Systematic group	Virus oncogenic in humans	Virus oncogenic in animals (examples)	Nucleic acid in virus particle	Nucleic acid in host cell/ malignancy
γ-Herpesviruses	Epstein-Barr virus (EBV) Human herpesvirus 8 (HHV-8)	Herpesvirus saimiri	DNA linear (110-180kb)	DNA circular episomal
Adenoviruses	-	Ad12	DNA linear	DNA integrated
Polyomaviruses	-	SV-40 Polyoma virus	DNA circular	DNA circular/integrated
Papillomaviruses	Human papillomavirus 16, 18 (HPV16,18 and others)	Bovine papillomavirus (BPV-1)	DNA circular	circular/integrated
Hepadnaviruses	Hepatitis B virus (HBV)	Woodchuck hepatitis virus (WHV)	DNA circular	DNA circular/integrated
Retroviruses	Human T-cell leukemia virus (HTLV-1)	Avian leukemia virus (ALV) Rous sarcoma virus (RSV)	RNA	DNA integrated

with a viral origin of replication or the insertion of the genome into the host chromosome.

Most oncogenic viruses contain DNA genomes that are widely different in size and structure. Among these are hepadnaviruses, ►[papillomaviruses](#), polyomaviruses, adenoviruses, and γ -herpesviruses. In contrast, ►[retroviruses](#) contain RNA as genomic material, which upon infection of the host cell is reverse transcribed into DNA and inserted into the host genome by means of a viral enzyme (integrase). The most frequent oncogenic viruses are DNA viruses with relative small genomes. They replicate by entering host cells and programming the cellular DNA synthesis machinery to produce copies of the invading viral genome. Since these viruses rely on cellular enzymes for DNA polymerization, which are only produced during the S phase of the cell cycle, these viruses stimulate cells to enter the cell cycle.

Virus infections that cause complete lysis of the host cell and efficient production of progeny viruses cannot contribute to tumor development. Thus, induction of malignant tumors is frequently the result of abortive infections and long lasting virus persistence in the host. Abortive infections are caused by viruses with defects in essential genes or by infection of host cells that do not support the full cycle of viral replication. The viral DNA can be randomly integrated into the host chromosomes. This is frequently accompanied by deletions and rearrangements of viral and cellular sequences. The chromosomal integration results in the stimulation of cell growth by continuous synthesis of viral proteins

Only a few tumor viruses of animals induce malignant tumors within a few days or weeks after infection. Most viruses including all human oncogenic viruses cause malignancies after long latency periods of many years. This hints at additional changes that the cells have to undergo before the malignant diseases develop. The long-term persistence of many tumor viruses results in the benign polyclonal stimulation of infected cells due to expression of viral growth promoting proteins. These cells may acquire additional mutations, which result in the promotion of rare infected clones into malignant cancer. Alternatively, the viral interference with cellular pathways of apoptosis may result in the preservation of cells carrying oncogenic mutations that would otherwise be eliminated.

About 20% of all human malignancies are the late sequels of virus infections. World wide about 450,000 cases of cervical carcinoma develop annually; these are caused by human papillomaviruses (HPV). Papillomaviruses constitute a large systematic group characterized by small icosahedral, non-enveloped capsids, circular doubled-stranded DNA genomes and a strict tropism for epithelia for their replication. The steps of viral replication are closely linked to the differentiation

of the keratinocytes. Depending on the HPV type, the productive infection results in different types of benign tumors of skin (wart, papilloma) or genital mucosa (condyloma). These lesions are characterized by a thickening of the epithelium. This is caused by increased rates of mitosis in keratinocytes mediated by the activities of the viral oncogenes E6 and E7. Depending on the presence of high-risk HPV types and chromosomal integration of viral genomes, these lesions can convert to genital cancer. High-risk type papillomaviruses are HPV16, HPV18, 45, 56. In addition malignant cancer of the skin is also frequently found to be associated with HPV, particularly under conditions of immune suppression.

Various types of lymphoid malignancies and nasopharyngeal carcinoma are causally linked to ►[Epstein-Barr virus](#) (EBV) infections. The gamma-herpesvirus infects and persists in B-lymphocytes, which are stimulated to growth by the expression of viral latency-associated gene products. Like persistently infected cells, all EBV-associated malignancies contain the viral episome and express various numbers of the EBV latency-associated gene products. A benign lymphoproliferation of EBV infected B-lymphocytes and cognate cytotoxic T-lymphocytes are hallmarks of infectious mononucleosis, a self-limiting disease caused by the virus. In immunocompromised individuals the lymphoproliferative-stimulated cells grow out to become malignant polyclonal B-cell lymphomas. In addition, EBV is strongly associated with the endemic form of Burkitt's lymphoma, which is prevalent among children in tropical Africa, with Hodgkin's lymphoma, and with T-cell lymphoma.

Kaposi's sarcoma, and two rare lymphoproliferative diseases (Castelman's disease and body cavity based lymphoma) are etiologically linked to infection with the ►[human herpesvirus type 8](#) (HHV-8). This gamma-herpesvirus establishes life-long persistence in lymphoid cells and expresses growth-stimulating, latency-associated gene products. Kaposi's sarcoma is a multifocal cancer of the skin, which develops from endothelia. Most of its forms are linked to severely immune-compromised patients, such as AIDS patients or transplant recipients. The viral genome and the expression of latency-associated gene products are present within the malignant spindle cell.

Adult T-cell leukemia/lymphoma (ATLL) is an aggressive malignancy of T-helper lymphocytes, which is caused by the ►[human T-cell leukemia virus type 1](#) (HTLV-1), a member of the retrovirus family. The leukemic cells are clonal according to retroviral genome integration site. The disease develops from infected T-lymphocytes in adults after decades of viral persistence. The virus persistence is associated with polyclonal non-malignant expansion of infected T-cells, which is probably due to the expression of the

growth stimulating viral Tax protein. Tax is a multi-functional oncoprotein, which is capable of immortalizing human lymphocytes in culture and inducing leukemia in transgenic mice.

Hepatocellular carcinoma is the frequent consequence of chronic ►hepatitis B virus infection of the liver. The virus belongs to the hepadna virus family; the enveloped particles contain small circular DNA genomes with four major genes. At least one of its proteins, the X protein, has transforming features in tissue culture and in transgenic mice. Factors for the development of the disease are dysregulation of cellular signaling by virus proteins, integration of the viral genome into the chromosome and the continued destruction and regeneration of liver parenchyma cells. The latter is caused by the cytotoxic effect of the virus and, more importantly, by the host immune response. Broad vaccination against hepatitis B virus has significantly lowered the prevalence of hepatitis B. This provides the first example of a highly efficient prophylaxis against virus associated tumor forms in the general population.

Molecular Interactions and Regulatory Mechanisms

As other tumors, virally induced tumors basically rely on a defect of growth and proliferation control and thus on a deregulation of ►proto-oncogenes and ►tumor suppressors. Tumor viruses apply several mechanisms to achieve this. Animal retroviruses and herpesviruses can contain ►oncogenes within their genomes, which are expressed as a consequence of the persisting infection. These oncogenes (v-onc) are mutant variants of cellular proto-oncogenes (c-onc), from which they

are derived (Table 2). The viral oncogenes constitutively deliver growth signals since they are either (1) over-expressed or (2) produced in an inappropriate cell or (3) devoid of negative control domains. Such oncogene transducing retroviruses as the Rous sarcoma virus, which contains the v-src oncogene, can efficiently and quickly induce tumors in laboratory animals. Moreover, they are capable of inducing measurable changes in growth behavior in cultured cells (transformation). These v-onc genes are derived from growth factors (v-sis), growth factor receptors (v-erbB), intracellular cytoplasmic signal proteins (v-src), transcription factors or cell-cycle regulators.

A dysregulation of cellular c-onc genes can also be induced by viral gene products, which act as transcriptional transactivators or by the insertion of viral transcriptional control sequences (enhancer, promoter, polyA signal) into or close to c-onc genes. The latter phenomenon is designated as ►insertional activation and is frequently accompanied by genomic mutagenesis. Insertional c-onc activation is the most frequent form of tumor induction by murine and avian retroviruses such as murine leukemia virus. Since the integration of retroviral sequences into chromosomal sequences occurs at random, hitting an oncogene is a rare event; this explains the long latency of tumors and their monoclonality.

Many viral oncogenes have no obvious homology to cellular c-onc proteins and thus constitute genuine viral functions (Table 3). These proteins exert their growth promoting activities by binding to cellular growth regulators and in this way induce cellular signaling or prevent its negative regulation. Cellular targets can be components of receptors, the src and related tyrosine

Viral Oncogenesis. Table 2 Cell-derived viral oncogenes

Viral oncogen (v-onc)	Cellular homologues protooncogen (c-onc)	Function of protooncogen	Virus (family)
v-sis	Platelet derived growth factor (PDGF)	Growth factor	Simian sarcoma virus (retrovirus)
v-erb B	Epidermal growth factor receptor	Growth factor receptor	Avian erythroblastosis virus (retrovirus)
v-src	c-src	Non-receptor tyrosine kinase	Rous sarcoma virus (retrovirus)
v-myc	c-myc	Transcription factor	Avian myelocytoma virus (retrovirus)
v-cyclin	cyclin D	Cell cycle regulator	Human herpesvirus 8 Herpesvirus saimiri
v-bcl -2	c-bcl-2	Apoptosis inhibitor	Human herpesvirus 8 Herpesvirus saimiri

Virtual Screening. Table 3 Cellular targets of viral transforming proteins (examples)

Cellular target (function)	Viral Oncogen	Virus
Ikk γ (NF- κ B signalling)	Tax	Human T-cell leukemia virus type 1
TRAF (tumor necrosis factor signalling)	LMP-1	Epstein-Barr virus
lck, src (non-receptor tyrosin kinase oncogenes, growth factor signal transduction)	Tip	Herpesvirus saimiri C488
p53 (tumorsuppressor)	Middle T-antigen	Polyomavirus
	Large T-antigen	SV40
	E6	Human papillomavirus 16
	E1B	Adenovirus Ad12
Rb (tumorsuppressor; G1 phase control within cell cycle)	E7	Human papillomavirus 16
	E1A	Adenovirus Ad12
	Large T-antigen	SV40
	Tax	Human T-cell leukemia virus type 1
CDK 4 (cyclin dependent kinase; G1 phase control within cell cycle)		

kinases, ►NF- κ B and other transcription factors or cell-cycle kinases. Many DNA viruses encode proteins, which inactivate cellular tumor suppressors by direct binding. Most frequent targets are the ►Rbprotein and the ►p53 tumor suppressor protein. The viral proteins directly stimulate the cell-cycle of infected cells in the G1 phase and result in the entrance of the cell into the S phase. These proteins are frequently multifunctional, i.e. they have many different cellular targets. In addition to their growth stimulating capacity some tumor viruses have acquired functions that interfere with induction of ►apoptosis, ►DNA repair and immune evasion, which also contribute to the induction of malignant growth.

Virtual Screening

RONALD KÜHNE

Research Institute for Molecular Pharmacology, Berlin, Germany
kuehne@fmp-berlin.de

Definition

Virtual screening (VS, often also referred to as *in silico* screening or protein based database screening)

describes the process of reducing a library of available and/or virtual compounds to a limited number of potentially bioactive structures for a target or a target family using computational techniques (1). VS comprehends a broad spectrum of methods. These include computational approaches to filter compound libraries according to their structural diversity, drug likeness, ADME properties (ADME: absorption, distribution, metabolism, excretion), presence of 2D- or 3D-pharmacophores and binding capacity for a target protein calculated using automated docking procedures. The aim of VS consists of the rationalization of the drug discovery process by prioritizing compounds for screening and improving hit rates by using computationally filtered compound libraries.

Description

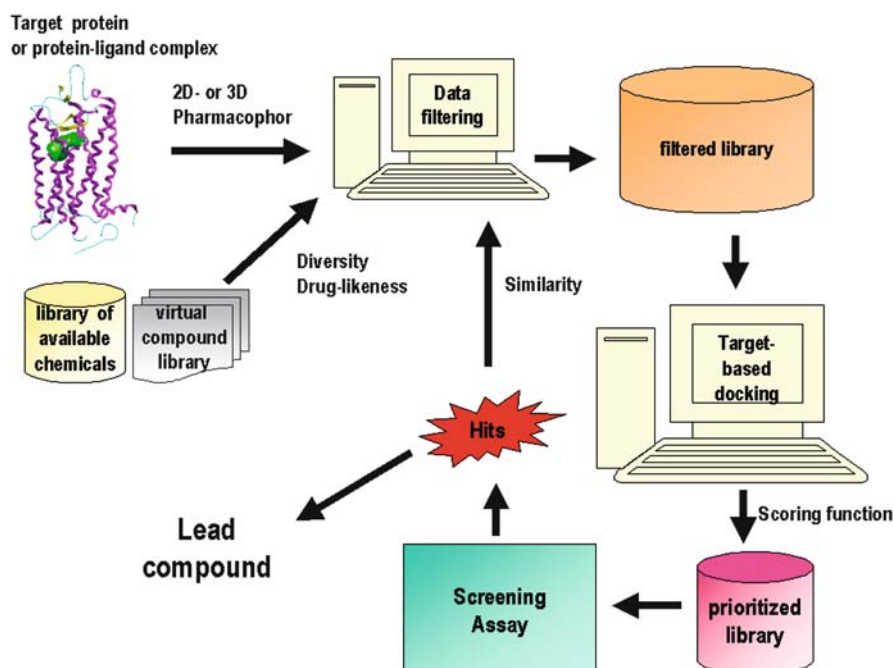

The broad application of new technologies like combinatorial chemistry (2) and high throughput screening (3) in drug discovery allows the synthesis and testing of hundreds of thousands of compounds. Additionally, the number of potential therapeutic targets emerging from the field of functional genomics is growing dramatically. All these factors increase the pressure to develop a valuable VS strategy for prioritizing screening compounds. The recent advances and developments in automated computational methods for VS have allowed its application to different

stages of the drug discovery process, namely hit discovery and lead optimization (Fig. 1). VS includes a broad spectrum of different computational methods. These consist of library filtering methods, checking compounds according to specific properties or occurrence of pharmacophoric patterns and docking approaches used to sort out all compounds within a library having no chance of binding into a predefined binding site. The basic idea of all of these approaches is the similarity property principle, which means that structurally and property related compounds should demonstrate similar biological activities.

Filtering of Compound Libraries

Database filtering methods are mainly applied to more general libraries of chemical compounds. They are used at an early stage in a project, where only structural information on active compounds is available. The aim of these methods is the reduction of the available chemical space in libraries containing compounds with the desired properties, high structural diversity, certain structural scaffolds or pre-defined pharmacophoric groups.

An important step in database filtering is related to the calculation of compound descriptors. Compound descriptors can be divided into structural and property descriptors. Structural descriptors depict the 2D or 3D structure of chemical entities. Commonly used 2D structural descriptors are fingerprints denoting the

Virtual Screening. Figure 1 The role of virtual screening tools in the drug discovery process. By using data filtering methods, virtual and available chemical libraries can be reduced according to different desired properties. The reduced libraries are docked into the target binding site in order to prioritize compounds for synthesis and screening.

presence or absence of certain substructures and a wide variety of descriptors based on a graphic representation of the chemical structural formula. 3D descriptors depend on the calculated molecular conformation. Commonly used 3D descriptors are accessible surface area and molecular volume. It was found that 2D descriptors were superior to 3D for clustering compounds into groups displaying similar physicochemical and biological activities (4). Because 2D methods are faster than 3D approaches, they are often used to select compounds from a general library.

Property descriptors are mainly applied to select compounds according to their lipophilic, electronic and steric properties. These properties are important in analyzing the drug likeness of compounds. A frequently used filter to evaluate the drug likeness of compounds was developed by Lipinski (5). The so-called 'rule of five' was derived to predict the bioavailability of a compound that can be considered as the major feature for drug likeness. If the number of hydrogen bond donors is <5 , of hydrogen bond acceptors <10 , the relative molecular weight <500 and the lipophilicity expressed as $\log P < 5$, the compound is probably orally bioavailable. Different types of descriptors can be combined using a suitable distance function to analyze the structural diversity of compound databases. A number of distance functions are available including the well-known Euclidian metrics for real valued descriptors and the Tanimoto coefficient for binary descriptors like fingerprints. In general, large descriptor sets are necessary to provide adequate structural diversity within a compound library. However, the more descriptors used for a diversity study, the greater the probability that they are correlated. In order to minimize this redundancy, approaches like cluster analysis or principal component analysis are used to reduce the dimensionality of the problem and to allow a good graphical representation of structure and property based similarities within a compound library.

Because a drug interacts with its target protein in 3D space, 2D descriptors are unsuitable to describe the entire protein-ligand interaction. Therefore it is often desirable to enrich a library for compounds that share common 3-dimensional structural elements with known active ligands. These elements are commonly called **▶ pharmacophores**. A typical pharmacophore represents a set of 3 or 4 pharmacophoric centers forming a triangle or tetrahedron and can be formulated as a 3D query to extract molecules containing the pharmacophoric definition. It becomes clear that the higher the complexity of pharmacophoric definition the better is the ability to separate inactive and active compounds, but the calculation time increases accordingly. However, this approach underlines some important limitations that are related to the large number of possible solutions and the large number of possible low energy conformations. An

often-used simplification of this approach consists of encoding the 3D pharmacophore in the form of long binary vectors called pharmacophoric fingerprints. This procedure reduces the computational time drastically, but is really dependent on the quality of the conformational sampling that is a prerequisite for fingerprint definition. Therefore attempts have been made to overcome this problem by using substituent based pharmacophoric descriptors such as the topomerically aligned conformer fields (6).

Docking Approaches

A basic problem of all similarity-based searches is that these approaches cannot be used with targets for which no active compounds are known. Further, 2D and 3D searches have a tendency to enrich structures that are relatively closely related to the known active leads, thus limiting the chance of finding new patentable scaffolds. A possibility for overcoming this limitation is to model the structures of protein-ligand complexes using fast small molecule docking algorithms. These algorithms must be able to recognize the key interactions involved in ligand binding and calculate reasonable 3D structures and binding affinities with the aim of prioritizing chemical entities. On the other hand, a protein-ligand interaction often induces conformational changes in both binding site and ligand. In principle such conformational flexibility should be considered but this is computationally extensive. Therefore all available docking algorithms have implemented simplifications to reduce the complexity of this task. The highest level of simplification is to calculate a rigid docking in which both the binding site and the ligand are held to be conformationally rigid. In that case the docking problem is reduced to finding a match between structural features of the binding site and the ligand. In this approach a distance compatibility graph is constructed in order to get reliable matches. Each pair of matching features between the site and the ligand represents a node within the graph. If two pairs of matching features have the same distance within a certain tolerance, the two nodes are connected by an edge. A 3-dimensional match between the site and the ligand is equivalent to a fully connected subgraph, which is called in graph theory a clique. The search for the optimal docking orientation is then reduced to the finding of the largest connected subgraph. In principle, application of this algorithm is not limited to rigid body docking. The inclusion of conformational flexibility of ligands can be done in several ways. The most obvious way is to individually dock every reasonable ligand conformation. In that case all low energy conformations for each ligand in the library must be calculated and stored in a database. Such pre-calculated databases of conformers can then be used in rigid docking programs. The result depends strongly

on the quality of the conformational analysis and the energy cutoff used to decide which conformers are accepted for docking.

Another approach is based on cutting the rotatable bonds of the ligand and dividing the ligand into a set of rigid fragments which then can be docked individually into the binding site by using rigid docking algorithms. In this so-called incremental construction approach, a core fragment is first docked and the residual fragments are added in an energetically favorable orientation. The first flexible docking program based on the incremental approach was developed by Kuntz (7). This approach was further developed and automated in the last releases of the program DOCK. The program FlexX (8) also utilizes the incremental construction approach. FlexX differs significantly from DOCK in the method used for placement of the core fragment. FlexX defines interaction sites for each possible interacting group of the binding site and the ligand. A pre-defined interaction type such as hydrogen bond donor, hydrogen bond acceptor etc., which is geometrically represented by an interaction center and a spherical surface, is assigned to each interaction site. The orientation of the core fragment is done by using an algorithm that matches each triangle of interaction sites in one object to the corresponding triangles in the other object. For each match a transformation superimposing the objects is determined. Once all possible transformations have been calculated, they are checked to remove all those that collide with the binding site. In a last step, all placements are clustered according to the RMS deviation using a hierarchical clustering algorithm.

The second type of approach to include flexibility is summarized under the generic term stochastic methods. Docking is a global optimization problem in which the best position of a ligand within a binding site has to be found. Because such an optimization cannot be resolved by using a fast algorithm, several efficient stochastic techniques were developed. One of these techniques is the Monte Carlo based optimization which is implemented in docking programs like AUTODOCK (9) and PRODOCK (10). Another widely used stochastic technique for optimization is the genetic algorithm. In a genetic algorithm, the state of a system is described as a binary string, which is called a chromosome. There are two ways to produce the next generation. In 'sexual' reproduction the two binary strings of the parent generation exchange bits to produce the 'children' state. 'Asexual' reproduction consists of point mutations in the parent chromosome. After each reproduction cycle, the binary strings are transformed back to the system state, which is then evaluated by an appropriate fitness function. System states with higher fitness have than a better chance to take part in the next reproduction cycle. The most widely used program based on genetic algorithm is GOLD (11).

Scoring Function

Another problem, which is in common to all docking approaches, is the evaluation and ranking of obtained solutions. The ideal scoring function is the binding free energy between the protein and the ligand. Methods that are able to calculate this very complex parameter with sufficient accuracy are only applicable for small systems. Therefore, simplifications must be made to prioritize a large number of binding modes for a large number of screening compounds. A widely used strategy to develop scoring functions is to analyze protein ligand complexes with known binding free energies with the aim of creating simple models that reproduce the experimental data. These models try to find incremental contributions for certain interaction types like hydrogen bonds, ion-pair interactions, hydrophobic interactions and aromatic stacking. Another possibility is calculation of the statistical preference of atom pair interactions. These scoring functions are based on the analysis of pair distribution functions that describe how much an atom pair prefers a certain distance compared to randomly distributed atom positions. In contrast to the former scoring functions, these pair distribution functions cannot distinguish between directional and undirectional interactions and often have a poor performance if directional interactions like hydrogen bonds dominate the binding free energy.

It has been shown that no scoring function is superior to all others. Hence a set of scoring functions is used in order to find compounds that consistently score highly. This so-called consensus scoring strategy, in which only compounds that are common in the top lists of different scoring functions are selected, can reduce the number of false hits in virtual screening.

Viscoelasticity

Definition

Viscoelasticity is a rheological parameter that describes the flow properties of complex fluids like blood or the cytoplasm. Viscoelasticity combines viscosity and elasticity. Viscosity is characterized by the energy lost during flow, primarily due to sliding and deformation. Elasticity is related to the energy stored during the flow due to orientation and deformation. Actin filaments cause a high viscosity in the cytoplasm, which allows a steady flow during slow migration. Actin at the crosslinking of proteins adds an elastic modulus because they guarantee a rubber-like resistance against sudden perturbation.

Vitiligo

Definition

Vitiligo is an acquired, sometimes familial, depigmentary disorder of the skin and hair that results from selective destruction of melanocytes that produces white patches.

Usually both sides of the body are affected. Common areas of involvement are the face, lips, hands, arms, legs, and genital areas. People with vitiligo have an increased risk to get skin cancer. The pathogenesis of vitiligo is complex, with both genetic and non-genetic factors contributing to the development of the disease. Genes that contribute to susceptibility to vitiligo are still unknown. The inherited nature of vitiligo and its frequent association with autoimmune diseases has prompted studies on the association between HLA and vitiligo.

Whole mount *in situ* hybridisation is used to determine the RNA expression pattern of a gene in the context of a whole embryo or embryo piece/organ. The technique allows spatial assignment of the transcriptional activity of a particular gene to cell type, tissue or organ at high resolution. Whole mount ISH is routinely used on embryos of vertebrate (e.g. mouse, chick, fish, frog) and invertebrate (e.g. fruit fly, ascidia, *Hydra*) species. The principal behind whole mount ISH is the specific annealing of labelled nucleic acid probes to complementary RNA sequences in fixed tissue, followed by detection of the probe (Fig. 1). For probes, labelled DNA or RNA can be utilized; RNA probes are more common. Antisense RNA probes (which are complementary to the mRNA) can readily be produced *in vitro* by run-off transcription from cDNA fragments cloned into vectors containing promoters for RNA polymerases adjacent to the cDNA insert. DNA labelling is achieved by nick-translation, random priming or PCR amplification. Probes are labelled by synthesis of DNA or RNA in the presence of a modified nucleotide coupled through a spacer to a hapten group. Commonly used non-radioactive labels are digoxigenin, fluorescein and biotin. Detection of these haptens is achieved *via* enzymes coupled to antibodies directed against the hapten group or to avidin or streptavidin, which form stable complexes with biotin. Commonly used enzymes are alkaline phosphatase (AP) and peroxidase (POD), usually used in combination with the substrates 5-bromo-4-chloro-3-indolylphosphate/nitro blue tetrazolium (BCIP/NBT) or diaminobenzidine (DAB)/imidazole, respectively. The enzymatic reactions produce coloured precipitates (blue and brown, respectively), which are insoluble in water and stable. Alternatively, fluorochromes can be used as labels, either directly coupled to the nucleoside triphosphate used for probe synthesis (as is the case for fluorescein) or coupled to the antibody directed against the hapten of choice or avidin/streptavidin. However, in general, fluorochrome labels are not sufficiently sensitive for mRNA detection in whole mount ISH. At present, parallel detection of two mRNA species or one mRNA and one protein are feasible by using non-fluorescent labelling. In the near future, nanocrystals/quantum dots may overcome the sensitivity issue and allow parallel detection of several transcripts in the same embryo. Detection of mRNA may then be combined with visualization of proteins (by antibody staining) and reporters (fluorescent protein such as eGFP, YFP etc.) in the same specimen.

Whole Mount ISH. Figure 1 Schematic presentation of RNA probe preparation *in vitro* and mRNA detection *in situ*. (a) Antisense RNA is synthesized in the presence of hapten-linked nucleotide triphosphates by RNA polymerase *in vitro* from a linearised plasmid containing the cDNA fragment (bold bar) and a RNA polymerase promoter (green box) close to the 3'-end of the fragment. (b) After hybridization of the labelled antisense RNA to the corresponding messenger RNA *in situ*, an antibody, which is coupled to an enzyme (red) is bound to the hapten group. The enzyme catalyzes conversion of a soluble substrate to a colored precipitate, thereby marking the cells and tissues in which the gene of interest is expressed.

Characteristics

Whole mount ISH was first described for embryos of the fruit fly *Drosophila melanogaster* (1), followed by application to *Xenopus* (2) and mouse embryos (3, 4). Since then these protocols have been adapted to other organisms. To date whole mount ISH can be applied to embryos of basically every model organism of developmental biology including plants (Fig. 2). Whole mount ISH has become the major technique for gene expression analysis in embryos. In a variety of model organisms it is an essential tool for the characterisation of mutants and manipulated embryos, thus promoting our understanding of pattern formation and organogenesis. The success of whole mount ISH as a tool for gene expression analysis is based on the fact that genes, once available in form of cDNA clones, can immediately be subjected to expression analysis in the

organism. In contrast, detection of proteins encoded by the genes of interest requires very time consuming schemes of antibody production. Genes are readily isolated from cDNA libraries, either by random picking or through screening or selection procedures. Gene catalogues and collections holding full-length cDNA clones of all genes encoded by the genome are being established for a variety of organisms.

Microarrays of gene collections provide ideal tools for expression profiling and description of the transcriptome of particular cell types, tissues or organs and for analysis of alterations in the transcriptome caused by e.g. inducing agents, loss of gene function, pathogenic or other triggers. However, such data do not provide cellular resolution if complex tissues or whole organisms are analysed. Whole mount ISH can be employed to complement such data sets by providing high-resolution expression data.

Whole mount ISH is usually, where applicable, also favoured over ISH on embryo sections because the procedure takes much less effort, while at the same time the result can more readily be interpreted since the pattern is viewed in the context of the whole organism which provides morphological landmarks. In contrast, three-dimensional expression patterns are often difficult to reconstruct from the signals seen on sections.

High-Throughput Whole Mount ISH as Tool for Systematic Analysis of Embryonic Pattern Formation and Organogenesis

The expression analysis of a considerable number of genes involved in the control of embryonic processes in invertebrate and vertebrate species by ISH has shown that genes controlling tissue differentiation and organogenesis very often show a temporally and/or spatially restricted expression pattern. For example, all known members of the Hox, Pax and T-box gene families, prominent developmental control factors, show a restricted expression. Tissue restricted expression of control factors usually precedes morphological changes in the embryo. Thus, the molecular anatomy prefigures the morphology of the embryo. In consequence, if the molecular anatomy of the organism could be deciphered, this information should greatly facilitate unravelling the regulatory networks controlling differentiation processes in molecular detail. The molecular anatomy will become available by a detailed description of the expression patterns of all genes encoded in the genome.

The large number of genes envisioned a decade ago to be encoded by vertebrate species could not be analysed by the "classical" whole mount ISH techniques, which allowed parallel analysis of only a few genes at a time. Therefore, the technique had to be adapted to high-throughput scale, allowing parallel processing of up to

Whole Mount ISH. Figure 2 Expression analysis of *Brachyury* by whole mount *in situ* hybridization. (a) E9.5 mouse embryo, (b) chick embryo (HH stage 14, kindly provided by Susan Mackem (5)), (c) *Xenopus laevis* embryo (from (6)).

96 genes at a time. To achieve that, hands-on time for processing of individual genes needed to be minimized. Briefly, in this procedure, for probe preparation, cDNA inserts flanked by RNA-polymerase promoters are amplified by PCR and directly used for antisense RNA transcription. Probe preparation, *in situ* hybridisation, washes and staining are carried out in a 96-well format device. Large numbers of genes can be assayed with relatively small effort using such technology. However, it should be stressed here that, rather than the embryo preparation and WISH procedure itself, the evaluation and documentation of the results obtained is limiting for the progress of such a project.

Interestingly, high-throughput whole mount ISH was first carried out on species not or hardly amenable to large-scale mutant screening for recessive developmental phenotypes, *Xenopus laevis* and the mouse (6, 7, 8). In these systems, genes controlling embryonic development have been isolated traditionally on the basis of sequence conservation to genes of known importance in *Drosophila* development, using filter hybridisation technology, or through functional screening.

High-throughput whole mount ISH has been introduced more recently to identify potential control factors solely on the basis of a restricted expression pattern. The latter, complemented by hints on the molecular function derived from sequence information, can suffice as an indication of a possible regulatory role in a particular differentiation process.

Various methods are available for testing the functional role of a gene selected on the basis of these criteria. (Ectopic) over-expression or mis-expression of wild type or dominant (active or negative) gene products often provides important insight into the role of a gene. This approach is the prime methodology for functional gene analysis in *Xenopus laevis*. It has also been widely applied to zebrafish embryos and, to a minor degree, to the chick and the mouse. It has proven to be very successful with respect to its impact in understanding control mechanisms of embryonic development. In mouse, gene targeting by [homologous recombination](#) ([“knock-out” mutagenesis](#)) in embryonic stem cells has been utilized primarily as tool for functional analysis. More recently, “lack of function” [mutagenesis](#), based on [RNAi](#) or morpholino ([Morpholino Oligonucleotides](#), [Functional Genomics by Gene ‘Knock-down’](#)) technology, has become available and is widely applied. With this technology the protein level produced from a particular gene can be strongly down-regulated, allowing the generation of phenocopies of loss of function mutations. Therefore, adequate tools promoting the functional analysis of genes identified by virtue of a restricted expression pattern or through functional screening are available. The “classical” random mutagenesis approach for the identification of genes essential for embryonic development, requiring time and labour intensive positional cloning of the mutated genes, has therefore become dispensable.

In addition, disadvantages of the mutagenesis approach are avoided. In vertebrates, a high degree of (partial) functional redundancy has been observed. This is due to gene amplifications having occurred during evolution. Often, important gene functions are provided by two or several members of a gene family co-expressed in the same cells. The consequence is that a loss of function mutation in one gene is often complemented by the wild type function of another co-expressed family member and a mutant phenotype is not obtained. Such a gene would not be detected by the mutagenesis approach identifying only essential genes. Being “non-essential” is often falsely interpreted as not having functional importance, which is of course erroneous.

Dominant mutant gene products often reveal phenotypes providing important insight into the embryonic role of a gene, which is not apparent when only the lack of a recessive mutant phenotype is considered. Therefore, it is important to identify all genes expressed in patterning and differentiation processes, not only “essential” genes showing loss of function mutant phenotypes.

Another disadvantage of random mutagenesis as a tool for the identification of genes controlling embryonic development is the fact that the same signal cascades and control factors are utilized in multiple processes and cell types of an organism. Thus, mutations in genes involved in processes taking place later in development (e.g. in organogenesis) may escape detection if the mutations result in early lethal phenotypes or in morphological changes affecting the formation of late appearing structures.

In recent years, large-scale gene expression analysis has also been applied to the zebrafish, medaka and *Drosophila melanogaster* (9, 10, 11). Large fractions of the corresponding genomes have been screened already and for some of these systems saturation may be achieved soon. As a result, the molecular anatomy of the embryo will emerge. This will allow reconstruction of the development of pattern, tissues and organs on a molecular scale in the computer. In combination with the genome sequence, the coding sequences of all genes encoded in the genome and the molecular function of all these genes, computational simulation of the generation of complex organisms can be initiated.

Gene Expression Data Derived by Whole Mount ISH Can Be Utilized in Multiple Ways

Gene expression analysis *per se* provides an assignment of gene functions to the tissues in which they act. This basic functional information on a gene can be utilized in several ways. Genes can be grouped according to identity of the expression pattern in several processes/cell types. Such so-called “synexpression groups” (12) often identify genes acting in the same signal pathways. Genes can also be grouped with

respect to their expression in a particular cell type or organ. This identifies clusters of genes involved in particular differentiation processes. The latter clustering is highly stage dependent since cellular readouts can rapidly change during development. All this information, in combination with predicted protein functions, can be used to make predictions with respect to the possible role of a gene or set of genes, which can be tested by functional studies.

Expression data can also be utilized to identify candidates for mutant genes causing inherited diseases. Candidates can be identified on the basis of a match between the expression pattern of a gene and the mutant phenotype, in combination with co-localisation in the genome.

In combination with genome sequence data, gene expression data can be utilized to extract cis-acting control elements likely to regulate the expression of a synexpression group or a gene cluster in particular tissues. The latter data can again be related to the expression patterns of transcriptional control factors likely to bind to such control elements. Such bio-informatic evaluation of gene sequence, function, expression and control data can be utilized to predict regulatory networks (the “regulome”) controlling embryonic processes. In addition, regulonome data on various organisms may allow unravelling of the evolutionary mechanisms promoting the phylogeny of higher vertebrates (including ourselves), on a genomic level.

Large-Scale Mutant Screening Using Whole Mount ISH

More recently whole mount ISH has also been applied as monitoring system in large-scale mutagenesis projects, mainly in the zebrafish (*Danio rerio*) system. Chemical random mutagenesis has been utilized to generate mutations in virtually any gene encoded by the zebrafish genome. Complex breeding schemes are utilized to obtain homozygosity at the mutated gene loci. In the “classical” approach, the identification of a homozygous phenotype relied exclusively on morphological criteria. However, subtle phenotypes can readily be missed by this approach especially if small organ anlagen are affected. To overcome this limitation, the expression of genes marking the tissue or organ of interest is monitored using whole mount ISH. This requires the expression analysis of hundreds to thousands of offspring derived from intercrosses of heterozygous mutant carriers. Therefore, exhaustive mutant screens in zebrafish require high-throughput whole mount ISH technology.

Practical Considerations

Whole mount ISH is limited by several factors, in particular the size and translucency of the object and the expression level of the gene to be assayed.

The size limit is especially critical for mouse embryos, which can be reliably assayed by whole mount ISH only up to 11.5 days post fertilization. Older embryos get too large, preventing probe access to inner organs. The size limit also applies to chick embryos. Embryonic stages of lower vertebrates or invertebrates undergoing larval development do not usually face a size limitation. Embryos beyond the size limit must be analysed by conventional ISH on tissue sections.

In our experience, a significant proportion of genes cannot be detected by whole mount ISH with current technology. To date it is not clear, if some of these genes play a role in differentiation processes.

Clinical Relevance

Whole mount ISH serves as standard tool in the functional analysis of genes involved in tissue differentiation and organogenesis in the embryo. Many human syndromes and diseases derive from aberrant gene functions during embryonic development and pathologies of diseases often arise from malfunction of regulatory mechanisms and signalling cascades acting in the adult as well as in the embryo. Moreover, regeneration processes in the adult also reemploy embryonic mechanisms. Therefore, insight into molecular mechanisms controlling embryonic development becomes more and more important for understanding the triggers of clinical syndromes and pathologies as well as regeneration processes.

Wide-Field Fluorescence Microscopy

Definition

Wide-field fluorescence microscopy is a commonly used technique to obtain both topographical and dynamic information from biological samples, such as cell cultures or tissue sections. The sample, in which specific structures have been labelled by fluorescent dyes, is most usually illuminated with a mercury lamp, giving out pure white light. Optical filters (excitation filters), or a monochromator, are used to select the optimal wavelength of excitation light for the used dye. Excitation light is directed to the sample via a dichroic mirror (a mirror that reflects some wavelengths but is transparent to others). The fluorescent light emitted from the sample is selected by further optical filters (emission filters, cut-off filters; e.g. longpass or bandpass filter) and then detected by a camera.

Wild Type

Definition

Wildtype is the genotype of an organism that is found in nature, often also genotypes that serve as parental lines or strains for gene transformation or mutation experiments.

► Mass Spectrometry: Quantitation

► Transgenic and Knock-out Animals

William-Beuren Syndrome

Definition

A well defined disorder (incidence 1:10000 newborns) caused by chromosomal microdeletion of the elastin gene at 7q11.23. It is characterized by short stature, facial dysmorphism (periorbital fullness, strabismus, stellate iris, long philtrum, thick lips, and large open-held mouth), supravalvular aortic stenosis or other cardiovascular defects, variable hypercalcemia often manifesting under stress (accident operation), and mild mental retardation. There is also a hoarse voice; loquacious behaviour ("cocktail man"), pronounced sensitivity to sound and hypodontia.

► [Microdeletion Syndromes](#)

Winged Helix

Definition

Winged helix refers to the 100 amino acid DNA binding domain that is comprised of three alpha-helices and two loops, which form characteristic "wings" that give this domain its name.

Synonyms

Forkhead genes or proteins; *Fox* genes or proteins

Definition

The *forkhead* genes form a large family of transcriptional regulators with approximately 40 members identified in mouse and humans. The name "*forkhead*" derives from the *Drosophila fork head* mutant, which led to the discovery of the first member of this gene family in 1989 (1). Flies homozygous for the *fork head* mutation exhibit homeotic transformations of portions

of the gut as the foregut and hindgut are replaced by ectopic head structures. Forkhead proteins are involved in embryonic development, tumorigenesis and tissue-specific gene expression in all metazoans. Members of this gene family share a common highly conserved DNA binding motif, the ► [winged helix](#) DNA-binding domain consisting of 100 amino acids (2) (see below). Historically, members of this gene family have had a variety of various names reflecting their discovery but in 2000 the nomenclature was standardized using "Fox" for forkhead box as the unifying term for all the *forkhead* genes from vertebrates (3). The ► [Fox gene](#) tree can be accessed at: <http://www.biology.pomona.edu/fox.html>. Within the Fox family there are classes denoted from "A" to "Q" based on sequence similarity. Different numbers of genes are found in the various classes and are indicated by numbers. For example, the largest class consisting of the *Foxd* genes has six members, *Foxd1-Foxd6*, while some classes have only one member; *Foxg*, *Foxh*, *Foxi*, *Foxm*, *Foxp* and *Foxq*.

Characteristics

Evolution

Winged helix genes are found in all animal phyla and fungi with fewer members in the lower phyla (four in yeast) and more in the upper phyla (16 in *Drosophila* and 42 in humans), suggesting that as the body plan became more complex, the *Fox* gene family was expanded (4). Interestingly, no ► [orthologs](#) for the *Fox* subclasses E, H, I, J, M and Q1 have been found in *Drosophila* or *C. elegans*, suggesting that these subclasses have evolved in the deuterostome lineage. Much useful information about the Fox genes has come from model organisms. One example is the *Caenorhabditis elegans* gene DAF-16, which is an ortholog of the *FOXO* group in humans. The discovery of DAF-16 as a gene involved in regulating the rate of ageing in *C. elegans* in response to insulin/IGF-1 signaling prompted the reevaluation of this pathway in mammals and led to the discovery that the mammalian *FOXO* genes function in the regulation of genes encoding metabolic enzymes in response to insulin (5). Thus, while the output of the signaling pathway, i.e. ageing or glucose metabolism differs between worms and humans, the underlying regulatory cascade is conserved.

Structure

The structure of the winged helix DNA binding domain defines the family of forkhead proteins. The crystal structure of Foxa3 (Hnf γ) bound to DNA was solved in 1993 and revealed that the DNA binding motif formed three α -helices with a helix-turn-helix structure (6). This core is flanked by two larger loops or "wings". The conserved winged helix binding motif is shared by

other DNA binding proteins (LexA, E2F, DP, RFX and ADAR1) that are not termed Forkhead proteins. Winged Helix proteins bind DNA as monomers with the recognition helix (helix 3) binding to a seven base pair core (RYMAATA R=A or G, Y=C or T and M=A or C). Upon binding of the forkhead protein the DNA is bent, effectively opening the chromatin structure to a more active configuration and allowing other transcription factors access to nearby cis-regulatory elements. At the albumin enhancer, which is currently the best-studied model of Fox transcriptional regulation, Foxa proteins can open chromatin by bending DNA and altering nucleosome position independently of histone acetylation.

Transcriptional and Metabolic Regulation

Most winged helix genes are activators of transcription but several have repressor function (Foxc2, d2, d3 and g1) and one *C. elegans* winged helix protein (LIN-31) can act either as a repressor or as an activator depending on the phosphorylation state of the protein. An interesting mechanism governs the activity of the Foxo proteins. Although normally nuclear, these proteins are targets for phosphorylation, which leads to nuclear exclusion and loss of DNA binding. In addition, Foxo proteins act as repressors or activators of transcription, depending on the cellular context. In hepatocytes, Foxo proteins activate several genes involved in gluconeogenesis in the fasted state. However, when insulin levels rise in response to feeding, binding of insulin to its receptor on the hepatocyte surface initiates a signaling cascade that leads to phosphorylation and nuclear exclusion of the Foxo proteins. In pancreatic β -cells, however, Foxo proteins occupying the enhancer of the *Pdx1* gene prevent its activation in the basal state. After insulin binding initiates the phosphorylation and removal of the Foxo proteins, the Foxa proteins are able to bind to the same sites and initiate activation of transcription. Thus in the case of the β -cell, Foxo occupancy represses transcription by competing with the stronger transcriptional activator, Foxa.

A yet unexplained puzzle is how certain Fox genes can exert multiple functions in different tissues. The best example for this is the case of the *Foxa2* gene, which has been studied through both transgenic over-expression and complete and tissue-specific gene ablation studies in mice in great detail. Thus it was demonstrated that *Foxa2* can induce re-specification of the dorsal neural tube into a ventral, floor-plate-like structure and that germ-line deletion of *Foxa2* leads to severe defects in axial mesoderm development with the absence of node and notochord (7, 8). In addition to these early developmental phenotypes, tissue-specific deletion has shown that *Foxa2* is also required for the terminal differentiation of pancreatic α - and β -cells, the

regulation of glucose homeostasis and the proper development of the gastrointestinal tract. Clearly, the molecular targets of *Foxa2* must differ between all these different cell types, but at present no explanation exists as to how this is achieved.

Mechanisms of Transcriptional Regulation

Not much is known about co-factors for winged helix proteins but several (Foxa2, g1 and d3) bind to *Groucho* co-repressor proteins. Foxg1 recruits the basic helix-loop-helix protein Hes1 in a complex with Groucho to then recruit a histone deacetylase to repress transcription.

Changing the intracellular concentration of specific transcription factors is a mechanism for modulating the expression of downstream genes and the precise level of some winged helix proteins can affect cellular function. This is the case for *Foxa2*; *Foxa2*^{+/-} mice are not viable on certain genetic backgrounds and have pronounced phenotypes on others. The binding of the *C. elegans* orthologue of Foxa (PHA-4) to target genes occurs with different affinities causing PHA-4 to act in a concentration dependent manner. The same variation in phenotype with gene dosage was shown for *Foxf1* mice with respect to lung repair and *FOXC1* over-expression in humans and/or decreased gene dosage in mice and humans causes eye defects.

Interactions with Signal Transduction Pathways

Winged helix proteins are downstream components of several signal transduction cascades demonstrating a universal involvement in cellular responses. Foxh1 acts downstream of TGF β -like signals (activin) by binding directly to phosphorylated Smad protein and target gene regulatory regions. Conversely, Foxg1 can inhibit signals from TGF β -like proteins (Bmp4) presumably by binding Groucho and Hes as mentioned above. *Foxl1*^{-/-} mice display overproliferation of cells in the intestinal epithelium that is correlated with activation of the Wnt signaling pathway. Foxd3 regulates a secreted signal required for the proliferation of stem cells in the early mouse embryo. Sonic hedgehog (\blacktriangleright Shh) from the notochord induces the expression of Foxa2 in the neural tube. Foxa2 then maintains the expression of Shh in the neural tube by directly binding to a Shh enhancer. The *C. elegans* forkhead protein LIN-31 acts downstream of an EGF-related ligand. In zebrafish, Foxi1 is required for cells to respond to FGF signaling in patterning the developing ear and jaws. The Foxo proteins are phosphorylated by protein kinase B (PKB or AKT) as described above in response to signaling via insulin and insulin-like ligands. The molecular mechanism of most of these interactions is yet to be determined and it is not clear if all of them are direct.

Winged Helix Transcription Factors. Table 1 Characteristic features of the mammalian Fox genes

Gene Name	Synonym (rodent and human only)	Chromosome (human)	Expression Domain	Phenotype
Foxa1	HNF-3 α	14q12-13	Notochord, floorplate, gut, lung, liver, pancreas	Hypoglycemia, postnatal lethality (recessive)
Foxa2	HNF-3 β	20p11	Notochord, floorplate, gut, lung, liver, pancreas	Deficient axial mesoderm, embryonic lethal (recessive)
Foxa3	HNF-3 γ	19q13.2-4	gut, liver, pancreas	Fasting hypoglycemia (recessive), male sub-fertility (dominant)
Foxb1	fkh5, mf3, TWH, hfh5	15q21-26	Central nervous system, mammary glands	Growth retardation, lactation defects.
Foxb2	fkh4		Central nervous system	
Foxc1	Fkh1, MF1, FREAC3, FKHL7	6p25	Prechondrogenic mesenchyme, periocular mesenchyme, meninges, endothelial cells, and kidney	Congenital hydrocephalus (mouse), cardiac, skeletal, ocular (recessive); cardiac, glaucoma (dominant)
Foxc2	MFH1	16q24	Sclerotome of somite, vertebrae, head mesenchyme, kidney	Ocular, cardiac, renal (recessive); lymphoedema-distichiasis (dominant), craniofacial and vertebral column defects (low penetrance)
Foxd1	FREAC4, BF2, Hfh10	5q12-13	Stromal cells of the kidney	Kidney defects
Foxd2	Mf2, FRKHDB, FREAC9	1p32-34	Kidney, somite, neural crest	Incomplete penetrance (~40%) of hydrourter, hydronephrosis, hypoplastic kidneys, and short ureters
Foxd3	Genesis, HFH2	1p31-32	ES cells, early preimplantation embryo, neural crest	Peri-implantation lethal, required for embryonic stem cells
Foxd4	FREAC5, HFH6, Fkh2	9q21	Anterior central nervous system, developing gut, red nuclei of the midbrain	
Foxe1	FKHL15, TITF2	9q22	Thyroid, craniopharyngeal ectoderm	Thyroid agenesis, cleft palate (recessive)
Foxe2	HFKH4	22q13-qter		
Foxe3	FREAC8, HFH7, dyl	1p32	Undifferentiated lens	Ocular anterior segment anomalies, cataract
Foxf1	FREAC1, HFH8	16q24	Brain and head mesenchyme	Defects in gall bladder development and lung defects (dominant); extra-embryonic and lateral plate mesoderm (recessive)
Foxf2	FREAC2, lun	6p25	Tongue, mesenchyme adjacent to the epithelium in alimentary, respiratory, and urinary tracts	Abnormal development of secondary palate (recessive)
Foxg1	BF1, HBF1	14q13	Telencephalic neuroepithelium, anterior optic vesicle	Hypoplasia of the cerebral hemispheres, eye development
Foxh1	FAST1, FAST2	8q24	Epiblast of early embryo	Lethal around gastrulation, specifies anterior primitive streak

Winged Helix Transcription Factors. Table 1 Characteristic features of the mammalian Fox genes (Continued)

Gene Name	Synonym (rodent and human only)	Chromosome (human)	Expression Domain	Phenotype
Foxi1	FREAC6, HFH5	5q35	Kidney, otic vesicle	Ear malformation, vestibular dysfunction and hearing impairment
Foxj1	HFH4	17q22-25	Ciliated cells of the respiratory tract, oviduct and ependyma	Defective ciliogenesis in airway epithelial cells and left-right axis defects
Foxj2	Fhx	12p13	Testis, ovary, early embryo, colon, nerve fibers of the GI tract	
Foxj3		1pter-q31.3	Neuroectoderm, neural crest, myotome	
Foxk1a	MNF	17q25	Muscle satellite cells	Growth retardation and severe impairment in skeletal muscle regeneration
Foxk1b		14		
Foxl1	fkh6, FREAC7	16q24	Lateral plate mesoderm, gut mesenchyme	Abnormal gut architecture
Foxl2	Pfrk	3q23	Ventral part of developing pituitary	
Foxm1	Trident, INS1, HFH11	12p13	Ubiquitous	Liver specific deletion results in defects in liver regeneration
Foxn1	WHN, whn, Foxr1	17q11-12	Thymus and skin	Severe immunodeficiency, absence of hair (recessive)
Foxn2	HTLF, Fkh19	2p16-22	Embryonic craniofacial, limb, central nervous system and somites	
Foxn3	CHES1	14q24		
Foxn4		12q24	Retina, central nervous system	Loss of amacrine and horizontal cells by retinal progenitors
Foxn6	Foxr2	Xp11.21	Breast cancers	
Foxo1	Afxh, FKHR, Fkhr1, Foxo1a	13q14	Muscle, adipose tissue and liver	Regulates cell cycle progress and apoptosis, required for fusion of primary myoblasts, adipocyte differentiation and angiogenesis; mediates insulin signalling
Foxo2	AF	6q21		
Foxo3a	FKHRL1	6q21	ubiquitous	Survival of hematopoietic progenitors and age dependent infertility
Foxo3b	FKHRL1P1	17q11	ubiquitous	
Foxo4	AFX, <u>Mlt7</u>	Xq13	ubiquitous	No obvious phenotype
Foxo6		1p34.1	Embryonic and adult brain	
Foxp1	QRF1	3p13	Lung, intestine, central nervous system, diffuse large B-cell lymphoma	Cardiac defects
Foxp2		7q31	Central nervous system, lung, intestine, stomach	Speech and language disorder (dominant)

Winged Helix Transcription Factors. Table 1 Characteristic features of the mammalian Fox genes (Continued)

Gene Name	Synonym (rodent and human only)	Chromosome (human)	Expression Domain	Phenotype
Foxp3	JM2, scurfin, scurfy, sf	Xp11.23	Thymus	Neonatal diabetes, enteropathy and endocrinopathy, abnormal T cell development, enlarged spleen and lymph nodes, aggressive lymphoproliferative autoimmunity
Foxp4		6 (p21.1)	Intestine, lung heart, brain, liver, kidney, and testis	Cardiac defects (duplication of heart)
Foxq1	HFH1, HFH1L, Satin	6 (p25)	Epidermis, hair follicle	Aberrant differentiation of hair shaft

Clinical Relevance

Cell Proliferation and Cancer

There are multiple examples of *winged helix* genes controlling proliferation of the cells in which they are expressed. *Foxg1* was shown to control proliferation of cells in the telencephalon while *Foxb1* controls the proliferation of cells in the mammillothalamic tract. *Foxm1* is expressed highly in cycling cells, is phosphorylated during mitosis and a liver-specific deletion of *Foxm1* revealed that this gene is critical for regulating expression of cell-cycle genes required for hepatocyte proliferation. Normal control of cell-cycle exit and entry involves protein kinase B-regulated *forkhead* transcription factors. Two *Fox* genes have been linked to stem cell function; *Foxk1* is expressed in muscle satellite cells and is required for muscle regeneration while *Foxd3* is expressed in embryonic stem cells and is required for their establishment and maintenance *in vitro*.

The misregulation of some *Fox* genes results in abnormal cell proliferation and disease. Chromosomal translocation of several different *Fox* genes can cause aberrant cell growth resulting in tumors. Alveolar rhabdomyosarcomas can be caused *via* the fusion of either the *PAX3* or *PAX7* DNA binding domain with the transactivation domain of *FOXO1* and acute lymphoid leukemia can be caused by the fusion of the DNA binding domain of MLL with the transactivation domain of *FOXO3* and *FOXO4* (among others). Ectopic expression of *Fox* genes is correlated with some cancer tumors. *FOXA1* is overexpressed in esophageal and lung adenocarcinomas and *FOXD3* expression is up-regulated in a number of cancer cell lines. In addition, *FOXMI*, noted above in hepatocyte proliferation, is also a downstream target of Gli1 in basal cell carcinomas.

Human Disease and Behavior

The *Fox* genes have been shown to play important roles in a diverse range of developmental processes and human

diseases, which are summarized in Table 1. Space does not permit a detailed description of all of them, however, the case of *FOXP2* provides a particularly striking example. In a large three-generation pedigree, a severe deficit in language processing and grammatical skills was found to be inherited as an autosomal dominant trait. This disease was traced to a mutation in the *forkhead* gene *FOXP2* and is probably the result of subtle deficits in neural or intellectual development (9). *FOXP2* represents the first gene to be shown to be involved in speech and neural development. Further analysis revealed a difference of just two amino acids between the human and primate *FOXP2* sequences. One of these changes generates a new phosphorylation site that was fixed in the human genome approximately 200,000 years ago, i.e. close to the time that anatomically modern humans appeared. This suggests the intriguing possibility that this change in the ancestral *FOXP2* gene contributed to the alterations in neural development that allowed for the acquisition of speech during human evolution.

Several *Fox* genes, *FOXC1*, *FOXC2*, *FOXE3* and *FOXL2*, have been implicated in eye development with mutations causing varied defects in the eye chamber, the eyelids and the eyelashes (4). Some human *Fox* genes are also linked to immune deficiencies, *FOXE1*, *FOXN1* and *FOXP3*. In summary, the *Fox* genes control a remarkable spectrum of developmental processes and contribute to the whole range of human diseases.

Withdrawal

Definition

After cessation of drug use (withdrawal may occur as early as a few hours after the last administration) the addict usually undergoes withdrawal, which is often associated with very aversive physical symptoms (major symptoms peak between 48 and 72 hours after the last dose and subside after about a week). Most importantly, after the physical withdrawal symptoms have disappeared and the drug addict is detoxified, he/she is still an addict.

Wnt/ β -catenin Signaling Pathway

AJAMETE KAYKAS, RANDALL T. MOON

Department of Pharmacology, Howard Hughes Medical Institute, University of Washington School of Medicine, Seattle, WA, USA
rtmoon@u.washington.edu

Definition

Wnts are secreted ligands that activate multiple signal transduction pathways. The most rigorously studied ► Wnt pathway is initiated by Wnt-mediated activation of its cognate cell surface receptors, which induces a core set of cytosolic signaling molecules leading to the stabilization of ► β -catenin. Stabilized β -catenin participates in a bipartite transcription factor complex with the ► TCF family of transcription factors. This bipartite transcription factor activates a set of specific genes in the nucleus of target cells. A large base of genetic evidence from *Hydra* to man supports the interactions and regulations of the multiple proteins that transduce the Wnt signal. Further, the plethora of molecular interactions of the pathway are supported by cell biological and biochemical experiments.

The Wnt/ β -catenin signaling pathway is one of a few central signaling pathways that regulate many aspects of embryonic development. The major cellular outcomes of activation of the Wnt/ β -catenin pathway are altered gene expression, which in turn modulates cell fate, proliferation and apoptosis. Wnt/ β -catenin signaling plays a role in cardiac differentiation, neural patterning and development of multiple other tissues such as kidney and the female reproductive tract. The pathway also plays a role in ► adipogenesis, ► hematopoiesis and skin formation, by maintaining and inducing differentiation of stem cells. Aberrant regulation of the Wnt/ β -catenin pathway is implicated in multiple human diseases and cancers. Hence, the

Wnt/ β -catenin pathway is medically important and a major target for drug development.

Characteristics

The Wnt/ β -catenin Pathway Functions in Development of Multiple Cell Types and Tissues

It is well established that Wnt/ β -catenin signaling plays a role in dorsal ventral specification in early *Xenopus* embryos. The pathway has subsequently been shown to play a role in formation of multiple tissues and cell types. The Wnt/ β -catenin pathway suppresses cardiac development and mice that have been engineered to conditionally delete β -catenin develop multiple hearts. Multiple Wnts and their effector signaling proteins are expressed throughout the developing nervous system, where they control many aspects of neural development. In support of this role, mice deficient for Wnt-1 fail to develop a midbrain and cerebellum and are deficient in neural crest derivatives. Wnts are also important for formation of other organs such as kidney. Wnt-4 is required for the development of kidney and mice deficient for it fail to have correct kidney tubule formation. Wnts are also important in the development of the female reproductive organs. Mice that are deficient in WNT-7a are infertile because of abnormal development of their oviduct and uterus.

The Wnt/ β -catenin pathway is involved in maintaining and specifying multiple types of stem cells and subsequently plays a role in adipogenesis, hematopoiesis and skin cell formation. The Wnt signaling pathway maintains preadipocytes in an undifferentiated state by inhibition of adipogenic transcription factors. Inhibition of Wnt signaling in preadipocytes by expression of axin or dominant negative TCF leads to formation of adipocytes. Wnts also regulate hematopoiesis. Wnts are expressed in very specific domains in the embryonic mesoderm and act as hematopoietic growth factors. In addition, TCFs are required for T and B-lymphocyte development in the mouse. Components of the Wnt/ β -catenin signaling pathway control specification of skin cell fates into keratinocytes, sebaceous glands and hair follicles. Inhibition of signaling leads to epidermal cell fates, while activation of signaling leads to formation of hair cells. Wnts are probably involved in maintaining many types of stem cells that have yet to be appreciated.

The Wnt/ β -catenin Pathway is Conserved in Evolution

One of the strengths in support of the models of the Wnt/ β -catenin pathway is its conservation in metazoans. Its conservation has ultimately allowed rigorous genetic studies to be conducted in *Drosophila*, *C. elegans*, zebrafish and mouse (5). All of these organisms have a core Wnt/ β -catenin signaling pathway made up of Wnts, \blacktriangleright Frizzleds, \blacktriangleright Dishevelled,

\blacktriangleright GSK3, β -catenin and TCFs. In addition, the general function of the pathway is conserved as it regulates similar phenomena in all of these organisms. Simple metazoans such as *Hydra* also have an intact Wnt/ β -catenin pathway, which has all of the core components of the pathway and is involved in specifying the formation of the head and foot of the organism. There is no evidence that yeast or bacteria have a Wnt/ β -catenin signaling pathway. However, the pathway has been reconstituted in yeast. Even organisms as evolutionarily primitive as the slime mold *Dictyostelium* have some of the components of the Wnt/ β -catenin pathway. Specifically, *Dictyostelium* has receptors similar to Frizzleds, \blacktriangleright CARs, which activate a GSK3 homologue. The Wnt/ β -catenin pathway is similar in many ways to the \blacktriangleright hedgehog (HH)/ \blacktriangleright Gli signaling pathway and many components of the pathways are shared (4). Both Wnts and HH are secreted lipid-modified ligands that bind and activate cell surface receptors. \blacktriangleright Smoothed (Smo), a receptor component of the HH pathway is the closest known relative to Frizzled. While Smoothed does not bind Wnt nor has its ligand been identified, Smo shares the overall structure of Frizzled, even the domain that is known to bind Wnt. In addition, both Frizzled and Smoothed have structures that are reminiscent of \blacktriangleright G-protein coupled receptors (GPCRs). However, they share little sequence homology with any other families of GPCRs. Another similarity lies in \blacktriangleright megalyn, a component of the HH signaling complex, which shares homology to \blacktriangleright LRP5/6. In addition, both the HH and Wnt pathways use GSK3 as a core component of their respective pathways. In *Drosophila* Shaggy, the GSK3 orthologue inhibits HH signaling by phosphorylating Cubitus interruptus (Ci), to generate a truncated repressor, which inhibits HH's induction of transcription.

Aberrant Regulation of the Wnt/ β -Catenin Pathway Leads to Human Disease

Wnt/ β -catenin is very important for embryonic development and when mutated leads to multiple diseases. Wnt-1 was first identified in vertebrates because it was transactivated by mouse mammary tumor virus, which integrated near it and induced ectopic expression leading to mammary tumorigenesis. Other components of the pathway are linked to cancer. \blacktriangleright APC, which is an inhibitor of β -catenin, is frequently mutated in colon cancer (6). The mutant form of APC does not bind β -catenin or participate in the " \blacktriangleright destruction complex". Hence, β -catenin is stabilized and can transactivate genes that lead to cell proliferation. \blacktriangleright Axin is another component of the β -catenin "destruction complex" that is also mutated in human cancers such as \blacktriangleright HCC; again the mutation in axin leads to β -catenin stabilization and activation of transcription. β -catenin is itself found to be mutant in some forms of HCC (6). The mutants of

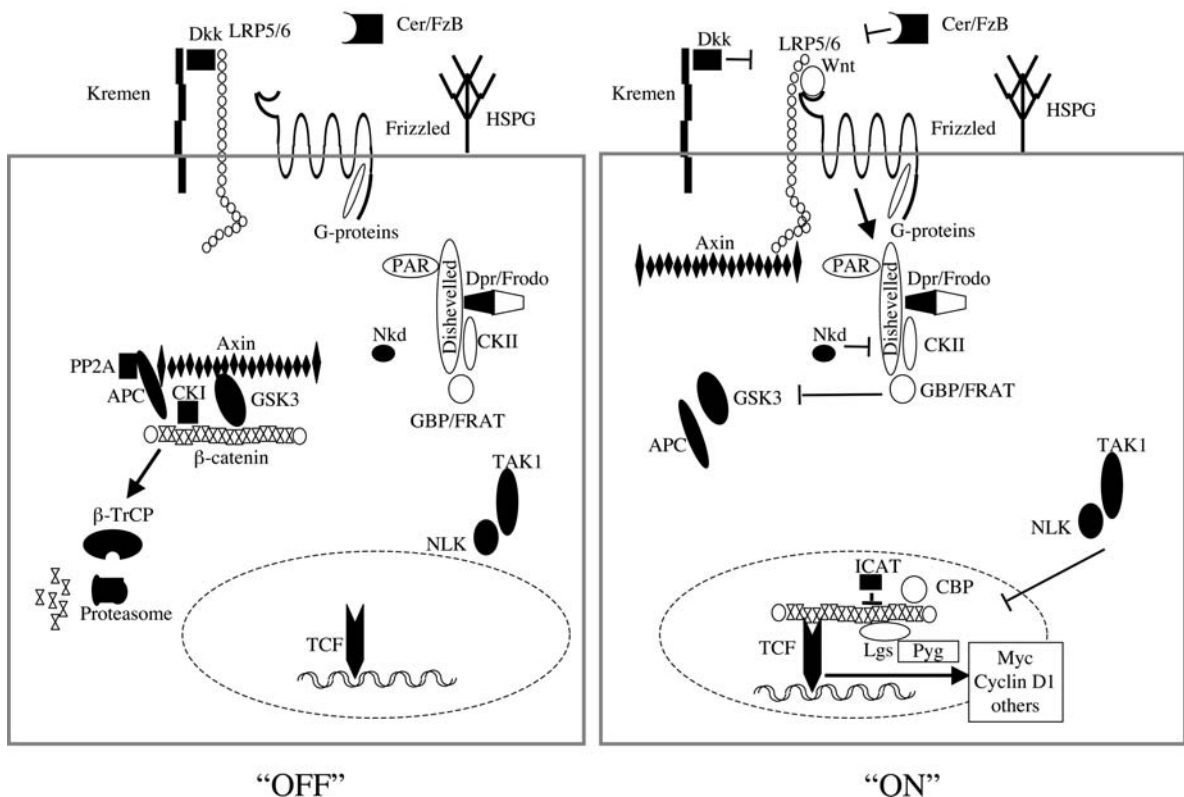

β -catenin do not interact with the “destruction complex”, are stabilized and activate genes that promote cell growth.

In addition to cancer, the Wnt/ β -catenin pathway is implicated in many other diseases. Many of the components of the pathway such as LRP5 and GSK3 are known to be involved in the pathogenesis of [▶ Alzheimer’s disease](#). Although definitive proof is yet to show a direct link between aberrant regulation of the Wnt pathway and Alzheimer’s disease there are many striking correlations (1). Interestingly, the Wnt/ β -catenin pathway is also involved in bone formation. Loss-of-function mutations in the gene LRP5 have been shown to cause osteoporosis-pseudoglioma or low bone mass (2). Conversely, gain of function mutations in LRP5 causes high bone mass traits in humans. The Wnt/ β -catenin pathway is also implicated in [▶ angiogenesis](#). Frizzled-4, one of the human receptors for Wnts, is mutated in FEVR (7), a rare dominant disease of the retina, which is due to defects in angiogenesis. However, the full implication of this and the role of the Wnt/ β -catenin pathway in angiogenesis have not been fully explored.

Molecular Interactions

The Wnt/ β -catenin pathway is more of a web than a linear pathway. Some of the relevant proteins that make up the signaling pathway are shown in Fig. 1. Many additional proteins and contacts are not shown. In addition, many of the proteins in the pathway make contacts with proteins that are in different signaling pathways. Therefore, there is much scope for cross talk between the Wnt/ β -catenin pathway and other signaling pathways, adding a complex layer of contacts and modes of regulation. A more detailed up to date description of the pathway can be found at STKE (3). The Wnt/ β -catenin pathway is initiated by Wnt binding to the serpentine Frizzled receptor and forming a ternary complex with LRP5/6 at the plasma membrane. Wnt also makes contacts with [▶ secreted Frizzled related proteins \(FzBs\)](#), [▶ Cerberus \(Cer\)](#), and [▶ heparan sulfate proteoglycans \(HSPG\)](#), like syndecan-1 or Knypek. LRP6 binds to [▶ Dickkopf \(Dkk\)](#), which interacts with [▶ Kremen](#). The activated Frizzled-LRP6 complex activates Dishevelled (Dvl) possibly *via* G-proteins. Dvl interacts with multiple proteins, such as [▶ Dapper \(Dpr\) /Frodo](#), [▶ Naked Cuticle \(Nkd\)](#) and

Wnt/ β -catenin Signaling in the Absence and Presence of Wnt

Wnt/ β -catenin Signaling Pathway. Figure 1

►**PAR** that regulate its function. Activated Dvl inhibits GSK3 possibly *via* its interaction with ►**GBP/FRAT**. GSK3 is found in the β -catenin “destruction complex” with the scaffolding proteins axin and APC. β -catenin interacts with ► **β -TrCP** and is degraded by the proteasome. In the nucleus β -catenin interacts with ►**Legless (Lgs)**, ►**Pygopus (Pgy)**, ►**ICAT**, and ►**CBP**, which regulate its function. TCF interacts with and is regulated by ►**NLK**, which forms a complex with ►**TAK1**.

Regulatory Mechanisms

Regulation at Membrane and in the Extracellular Lumen

Wnts are secreted outside cells and their access to their receptors is regulated by FzBs, which resemble the Wnt binding domain of Frizzled. In addition, Cerberus also binds and inhibits Wnts. Both of these inhibitors bind and sequester Wnts from binding Frizzled. The access of Wnts to the co-receptors LRP5/6 is also regulated. The presentation of LRP6 to Wnts at the plasma membrane is inhibited by Dkk and Kremen, which cause LRP6 to be internalized and cleared from the plasma membrane.

Regulation of Disheveled in the Cytosol

Disheveled is a modular molecule that functions downstream of Frizzled in the Wnt/ β -catenin pathway. Activation of Dvl is central to activation of signaling and therefore Dvl activity is regulated by multiple interacting proteins (8). Although it is not known how Frizzled activates Dvl, its phosphorylation status correlates with its activation. The kinases PAR-1 and ►**casein kinase II (CKII)** are known to participate in phosphorylating Dvl and regulate its subsequent activation. Dvl is also regulated by the Dpr/Frigo family of proteins, which interact with Dvl and can both activate and inhibit its activity. The EF domain containing protein, Nkd, is induced by Wnt and participates in a feed back loop to dampen the activity of Dvl.

Regulation of β -Catenin Stability

Activated Disheveled inhibits GSK3 from phosphorylating β -catenin, possibly by interaction with GBP/FRAT. GSK3 is found in a complex of proteins required for phosphorylation of β -catenin, which include axin and APC. This complex of proteins that regulates the destruction of β -catenin is referred to as the “destruction complex”. β -catenin phosphorylation is also regulated by ►**casein kinase I (CKI)** and the phosphatase ►**PP2A**. Phosphorylated β -catenin is recognized by the ubiquitin ligase β -TrCP and targeted for degradation by the proteasome.

Regulation of Transcription in the Nucleus

Once in the nucleus β -catenin forms a bipartite transcription complex with the TCF family of transcription factors. β -catenin activation of transcription is facilitated by interaction with the co-activator CBP. In addition β -catenin’s interaction with Legless, which recruits Pygopus, is required for its activation of genes in the nucleus. β -catenin’s transcriptional activation is antagonized by its interaction with ICAT, which competes for binding TCF.

Wnt/Wg

Definition

Wnt/Wg are components of a signaling pathway in vertebrates (Wnt) and in drosophila (Wg, wingless) that are important in regulating pattern development during embryogenesis. In vertebrates, Wnts include at least 18 members. Not all Wnts activate the Wnt/ β -catenin pathway.

Wolf-Hirschhorn Syndrome

Definition

Wolf-Hirschhorn syndrome is a widely known disorder (1:30,000 newborns) that is caused by a deletion at chromosome 4p16.3, and is characterized by severe pre- and postnatal growth retardation, facial abnormalities, heart defects, severe mental deficiency, and high lethality in infancy. Expression is variable and the mild forms, which have been referred to as Pitt-Rogers-Danks syndrome, allow survival into adulthood.

Wound Healing

SUSANNE BRAUN, SABINE WERNER

Department of Biology, Institute of Cell Biology, ETH Zurich, Zurich, Switzerland

sabine.werner@cell.biol.ethz.ch

Definition

Wound healing is a complex and dynamic process aimed at restoring the integrity of injured skin. This repair process involves blood clotting, inflammation, new tissue formation and tissue remodeling. Wounds can be of variable size and depth. Partial-thickness wounds are characterized by a loss of skin that is limited to the ► [epidermis](#) and potentially parts of the ► [dermis](#). These wounds heal predominantly by reepithelialization (proliferation and migration of epithelial cells) and the injured tissue fully regenerates if the wound is restricted to the epidermis. Full-thickness wounds involve damage to the epidermis, dermis and subcutaneous tissue. These wounds heal by granulation (replacement of the lost dermal tissue by new cells and matrix), contraction and reepithelialization. The final result in adult mammals is not perfectly regenerated skin but a ► [scar](#).

Characteristics

Most wounds affect both layers of the skin, the epidermis and the dermis. Immediately after lesion

the repair process is initiated and proceeds in three phases – inflammation, new tissue formation, remodeling – that overlap in time (Fig. 1).

Inflammation

Upon skin injury, blood vessels are disrupted and blood constituents extravasate. This leads to the formation of the blood clot, which is composed of cross-linked fibrin and of ► [extracellular matrix](#) (ECM) proteins such as fibronectin, vitronectin and thrombospondin. The blood clot plugs the wound, provides a barrier against microorganisms and serves as a provisional matrix for invading cells. Furthermore, the repair process is initiated by the release of various ► [growth factors](#) and ► [cytokines](#) from the serum and degranulating platelets. Among them are chemotactic factors, which attract ► [neutrophils](#), lymphocytes and monocytes to the wound site. These inflammatory cells in turn produce and secrete reactive oxygen species and proteinases that play an important role in the defence against contaminating bacteria.

New Tissue Formation

In addition to their role in inflammation, neutrophils and ► [macrophages](#) are also an important source of growth factors and cytokines that initiate the second phase of wound repair, the formation of new tissue. ► [Keratinocytes](#) at the wound margin are stimulated to migrate and to proliferate, leading to reepithelialization of the wound. To restore the injured dermis, the formation of new stroma, called ► [granulation tissue](#), is initiated a few days after injury. ► [Fibroblasts](#) at the wound edge start to proliferate and migrate into the wound space, where they deposit large amounts of extracellular matrix. At later stages of wound repair, a proportion of the fibroblasts transform into myofibroblasts, which can generate contractile forces, leading to wound contraction. ► [Endothelial cells](#) migrate into the wound space where they proliferate and form new capillaries. Nerve sprouting occurs at the wound edge, leading to innervation of the new tissue.

Remodeling

Finally, the transition from granulation tissue to mature scar tissue takes place during the remodeling phase. This process is characterized by reduction of the cellularity within the granulation tissue due to apoptosis, continued collagen synthesis and degradation at a low rate and formation of larger and more cross-linked collagen bundles. The wound gains more tensile strength but never reaches that of uninjured skin. Furthermore, scar tissue lacks appendages, including hair follicles, sebaceous glands and sweat glands. Scarring can also be excessive, leading to hypertrophic scars and keloids. Interestingly, wound healing in

Wound Healing. Figure 1 Schematic representation of different stages of wound repair. (a) 12–24 hours after injury the wounded area is filled with a blood clot. Neutrophils have invaded into the clot. (b) At days 3–7 after injury, the majority of neutrophils have undergone apoptosis. Instead, macrophages are abundant in the wound tissue at this stage of repair. Endothelial cells migrate into the clot; they proliferate and form new blood vessels. Fibroblasts migrate into the wound tissue, where they proliferate and deposit extracellular matrix. The new tissue is called granulation tissue. Keratinocytes proliferate at the wound edge and migrate down the injured dermis and above the provisional matrix. (c) 1–2 weeks after injury the wound is completely filled with granulation tissue. Fibroblasts have transformed into myofibroblasts, leading to wound contraction and collagen deposition. The wound is completely covered with a neoepidermis. Reprinted with permission from Ref. 2, copyright American Physiological Society.

mammalian embryos up to the beginning of the third trimester occurs without scarring.

Molecular Interactions

Wound healing is a highly orchestrated process that is largely dependent on a network of interactions among different cells. In cutaneous wound repair, keratinocytes, fibroblasts, endothelial cells and inflammatory cells

communicate with each other through cell-cell and cell-matrix contacts and through cytokines and growth factors. These signals are interpreted by the target cells within the context of their surrounding extracellular matrix. Thus, wound repair requires continuous interactions among cells, cytokines and matrix. In the following part, a few examples are chosen to illustrate basic principles of these interactions.

Growth Factors and Cytokines

During wound healing large amounts of growth factors and cytokines are released from different sources. The first wave of these factors reaches the wound immediately after injury and originates from the serum of injured blood vessels and from degranulating platelets. These growth factors and cytokines attract inflammatory cells that in turn secrete new factors. In addition, they act on resident cells at the wound margin and initiate many different cellular processes, e.g. proliferation, migration, differentiation as well as production of extracellular matrix, proteinases and additional cytokines.

As an example of a growth factor involved in wound reepithelialization, the role of keratinocyte growth factor (KGF) will be described in more detail. KGF belongs to the fibroblast growth factor (FGF) family and was therefore designated FGF7. In contrast to other FGF family members, which are broad-spectrum mitogens, KGF seems to act specifically on epithelial cells. In addition to its mitogenic effect, it regulates migration and differentiation of its target cells and protects them from cell death under stress conditions. Upon skin injury KGF expression is strongly induced in dermal fibroblasts and in intraepidermal $\gamma\delta$ T cells, whereas the receptor is only produced by keratinocytes. These results strongly suggest that dermally derived KGF stimulates wound reepithelialization in a **▶paracrine** manner. But what are the factors that can induce KGF expression? Local hemorrhage causes extravasation of thrombocytes that subsequently release, among other growth factors, platelet-derived growth factor and epidermal growth factor. The latter are potent stimulators of KGF expression in fibroblasts. In addition, growth factors and cytokines, in particular platelet-derived growth factor, transforming growth factor α , tumor necrosis factor α and interleukin-1, derived from inflammatory cells can enhance KGF expression in fibroblasts.

Another process that is strongly influenced by growth factors is **▶angiogenesis**, the generation of new capillaries from the pre-existing vasculature. Angiogenesis is especially important for wound healing, since a rich blood supply is vital to sustain newly formed tissue. Of particular importance for wound angiogenesis are FGF2 and members of the vascular endothelial growth factor (VEGF) family. After cutaneous injury, the expression of VEGF-A is strongly upregulated in keratinocytes and macrophages at the wound site. This factor acts in a paracrine manner on endothelial cells, which express the appropriate receptors. The impact of VEGF-A on angiogenesis and wound repair has been shown in several studies. For example, treatment of pig wounds with neutralizing VEGF-A antibodies caused a severe reduction in

wound angiogenesis and granulation tissue formation. Similar defects were observed when a mutant VEGF receptor, which blocks VEGF-A signaling, was over-expressed in mouse skin by viral vector delivery.

Cell-Matrix Interactions

The extracellular matrix (ECM) is comprised of a large number of components, including different collagens, fibronectin and proteoglycans. These molecules form a network that imposes structure and is involved in cell regulatory functions. A number of ECM receptors that mediate cell-matrix interactions are expressed on cell surfaces. Among them, members of the integrin family are important regulators of wound healing. Integrins are heterodimeric transmembrane proteins consisting of an α and a β subunit. Many different α and β subunits are known, and the combination of the various subunits defines the ECM proteins that are bound. In the wound repair process, fibroblast integrins appear to be involved in wound contraction, keratinocyte integrins in reepithelialization, and endothelial cell integrins in angiogenesis.

In the intact epidermis, the major integrins are $\alpha2\beta1$, $\alpha3\beta1$, $\alpha9\beta1$ and $\alpha6\beta4$ and their expression is strictly confined to the basal layer of keratinocytes. After wounding, keratinocytes at the wound margin change their integrin expression pattern, characterized by suprabasal integrin expression and induction of $\alpha5\beta1$, $\alpha v\beta5$, $\alpha v\beta6$ integrins. This set of integrins is necessary for keratinocyte migration, and thus for reepithelialization, because they can recognize proteins of the dermal and provisional matrix.

Integrin $\alpha v\beta3$, the receptor for fibrin and fibronectin, is expressed on blood vessels invading the blood clot and wound granulation tissue, but not in normal skin. Recent investigations have shown that the wound ECM can regulate angiogenesis in part by modulating the cells' integrin receptor expression.

The change of the integrin expression profile is also important for the behavior of fibroblasts. Early after wounding, these cells acquire a migratory phenotype. Like migrating keratinocytes, the expression of a specific set of integrins is necessary for fibroblasts to bind to ECM molecules of the provisional matrix. At later stages of healing, fibroblasts begin to differentiate into myofibroblasts, which lead to wound contraction. This process depends strongly on fibroblast attachment to the collagen matrix through the $\alpha2\beta1$ integrin receptors.

Cell-Cell Interactions

The formation of surface epithelium to close the wound is precisely coordinated with the repair of the underlying dermis. This synchrony is the key to preventing

either insufficient or excessive wound repair. To achieve this aim, communication between the two layers, epidermis and dermis, is very important. For example, keratinocyte proliferation and differentiation may be regulated by a double paracrine loop of cytokines as suggested by *in vitro* studies. After wounding, keratinocytes of the epidermis synthesize and secrete interleukin 1 α and interleukin 1 β that act in a paracrine manner on the fibroblasts in the dermis. In response to this stimulus, fibroblasts release KGF, granulocyte-macrophage colony stimulating factor and additional, yet unknown factors. In a second paracrine action these cytokines stimulate keratinocyte proliferation and differentiation.

Regulatory Mechanisms

Cutaneous wound repair is well described at the histological level but the genes that orchestrate this process have been only partially defined. Recently, several groups have identified genes that are up- or down-regulated after skin injury. These genes are likely to have a functional role in the repair process, but this has only been proven for a few selected genes. During the past few years, the development of technologies for the generation of genetically modified mice has allowed elucidation of the function of various genes in the healing process. These technologies allow gain of function experiments (over-expression of genes) as well as loss of function studies (e.g. gene knockouts). Most importantly, spatial and temporal control of gene ablation or over-expression, using more specialized technologies (inducible and/or tissue-specific over-expression or ablation) makes it possible to determine the functions of genes formerly precluded due to embryonic lethality. A large number of viable genetically modified animals are now available that can be used to elucidate the role of the deleted, mutated or over-expressed genes in the repair of different tissues and organs. The first example of a genetic approach to the study of wound repair was the analysis of KGF receptor function in wound healing. ► **Transgenic mice** were generated that express a dominant negative KGF receptor mutant specifically in the epidermis. Therefore, keratinocytes are unable to respond to the KGF stimulus. These mice have severely impaired healing,

with reduced proliferation of wound edge keratinocytes and substantially delayed reepithelialization. Thus, this wound healing study revealed that KGF receptor signaling is essential for wound reepithelialization. The last few years have seen an exponential growth in the number of ► **transgenic and knockout mice** used for wound healing studies, and these experiments have provided exciting, and often unexpected, results concerning the function of genes in the wound healing process *in vivo* (see <http://icbxs.ethz.ch/members/grose/woundtransgenic/home.html>).

Definition

Xanthoma originates from a lesion of foam cell (cholesterol) accumulation in skin or tendon. Skin xanthomas in eyelids are called xanthelasma. Xanthoma is seen in familial hypercholesterolemia, cerebrotendinous xanthomatosis sitosterolemia (phytosterolemia),

Definitions

X-chromosome inactivation (XCI) is the process by which one of two X-chromosomes is transcriptionally silenced in female mammals, equalizing the dose of X-linked genes in females (XX) and males (XY). XCI takes place early in embryonic development when each cell chooses to inactivate one of the X-chromosomes. After the choice has been made between the two, all daughter cells maintain the same inactivated X (Xi). As a result, all females are ▶ **mosaics**, composed of two

populations of cells that express the genes from one or the other X-chromosome. The process of X-chromosome inactivation is unique to mammals, but is only one of several known mechanisms of [dosage compensation](#) found in organisms such as the mouse, fruit fly and nematode worm. One intriguing characteristic that is common to dosage compensation in mammals and fruit flies is the essential role of [noncoding RNAs](#) in the process. From a medical perspective, the mechanism and pattern of XCI has important effects on the phenotype of X-chromosome [aneuploidies](#) and X-linked genetic diseases. Emerging evidence suggests that XCI also has implications in cancer and other areas of medicine as well.

Characteristics

Forms of X-Chromosome Inactivation

Two forms of X-chromosome inactivation have been characterized in mammals, imprinted X-inactivation and random X-inactivation (Fig. 1). From an evolutionary standpoint, the ancestral form was probably imprinted X-inactivation, in which the father's X-chromosome is always silenced and the mother's X-chromosome remains active. To distinguish the two

X-Chromosome Inactivation. Figure 1 Imprinted and random X-inactivation. After early cleavage stages, cells of the zygote separate into extraembryonic and embryonic lineages. Cells of the extraembryonic lineage display imprinted X-inactivation. A parental imprint protects the maternal X chromosome (Xm) from inactivation and/or designates the paternal X (Xp) for silencing. In cells of the embryonic lineage, the imprint is erased, allowing each female cell to randomly inactivate either the maternal X (Xm) or paternal X (Xp). Transcriptionally active chromosomes are depicted in white, transcriptionally inactive chromosomes in black.

X- chromosomes from each other, a parental “imprint” provides a mark that assures the maternal X is protected and the paternal X becomes designated for silencing. This type of XCI is observed today in marsupials, in the extraembryonic tissues of eutherian mammals such as the mouse, and possibly the human as well.

By contrast, the embryonic cells of eutherian mammals inactivate either the maternal or paternal X-chromosome and the choice between the two is random. This form is known as random X-inactivation, and occurs when the parental imprint is erased around the time of implantation, equalizing the chance for the cell to choose either the maternal or paternal X to be active. The [stochastic](#) choice between the two chromosomes suggests that each female cell has a mechanism that senses the presence of an extra X-chromosome and is able to precisely designate one for inactivation while keeping the other one activated.

Since most human disease involves somatic cells and tissue, this form of X-inactivation is the most relevant mechanism when considering the impact of XCI on health and disease processes. Imprinted XCI, however, may prove to be important to issues of fertility and pregnancy loss, due to its possible role in placental (extraembryonic) tissues.

Development and Physiology

Recent evidence indicates that X-inactivation may be established much earlier than previously thought. One study proposes that imprinted XCI patterns are initiated in the paternal germline, where meiotic sex chromosome inactivation (MSCI) occurs, and maintained through conception. This imprinted pattern of XCI is retained in extraembryonic tissues but “reset” in the embryonic lineage by reactivation of the paternal X, allowing random XCI to occur.

Random X-inactivation begins when the embryo proper consists of only a few dozen cells. The process can be conceptualized in several steps. First, the cell determines the number of X-chromosomes relative to autosomes and permits only one active X for every two autosomes (counting). In the usual case of diploid female cells, two X-chromosomes are counted and one is kept active. Next, the cell randomly designates one of the two X- chromosomes to be inactivated (choice). Once chosen, the inactive X remains silenced in all future daughter cells (maintenance of inactivation). On a cellular level, the inactivated X acquires characteristics of heterochromatin including extensive [CpG methylation](#), hypoacetylated histones and late replication during the cell-cycle. During interphase of human cells, the inactivated X can be seen as a compact element at the periphery of the nucleus known as the [Barr body](#) (Fig. 2a).

Since the inactivation of X-chromosomes occurs so early in embryogenesis, patterns of cell growth and

X-Chromosome Inactivation. Figure 2 Cytological characteristics of X-chromosome inactivation. (a) Cresyl violet stain shows Barr bodies in human cheek cells. (from Development, X-chromosome inactivation, JT Lee, 1999, Springer-Verlag, Berlin, p. 407; Moore and Barr, 1955, *Lancet*, vol 2, p. 57) (b) Fluorescence *in situ* hybridization with an *Xist* probe reveals an *Xist* “cloud” coating the inactive X chromosome (arrow) in a

migration determine whether body tissues consist of cells of a polyclonal mixture of active X-chromosomes or are derived from a monoclonal set of cells with the same active X. In some cases, the compositional patterns tend to be consistent for particular organs or tissues. Some studies suggest that intestinal crypts and thyroid nodules are often monoclonal tissues because they are presumably descendants of a single stem cell. Conversely, intestinal villi and muscle fibers are believed to be polyclonal because they tend to consist of cells derived from a mixture of precursor cells. The monoclonal or polyclonal composition of tissues is an important consideration when a female carries a heterozygous X-linked mutation or when evaluating a tumor that originates from one of these tissues.

Molecular Mechanisms of X-Inactivation

Progress in understanding the molecular mechanisms of X-inactivation has occurred largely in mouse embryonic stem (ES) cells, which recapitulate the process of XCI when induced to differentiate in culture. Using this model system, important genetic regions and elements have been identified that are central to the control and execution of X-inactivation.

The initiation of X-inactivation and subsequent spread of chromosomal silencing *in cis* depends on a region of the X-chromosome known as the X-inactivation center (Xic) (1). The best-characterized element of the Xic is the X-inactive specific transcript gene (*Xist*). *Xist* is a 17-kb, non-translated gene that is necessary and sufficient to initiate the process of X-inactivation. In pre-inactivated female cells, *Xist* RNA is transcribed at very low levels from both X-chromosomes. At the onset of XCI, *Xist* is upregulated on the future inactive X and spreads along the length of the chromosome (Fig. 2b). Shortly afterwards, *Xist* expression from the future active X is shut off. Although detailed mechanisms are not fully understood, *Xist* RNA contains functional domains that allow it to remain associated with its chromosome of origin and to mediate transcriptional silencing by interacting with other cellular factors (2).

Since the up-regulation of *Xist* is central to the initiation of X-inactivation, a major research focus has been to identify factors that regulate *Xist* and therefore determine the mechanism of choice. One of these factors is *Tsix*, a gene that originates approximately 12-kb downstream from the 3' end of *Xist*. Like *Xist*, *Tsix* is a non-translated RNA gene that is spliced,

metaphase spread of female mouse fibroblasts (Photograph JT Lee from Development, X-chromosome inactivation, JT Lee, 1999, Springer-Verlag, Berlin, p. 413).

polyadenylated and retained exclusively in the nucleus. The *Tsix* locus is oriented antisense to *Xist* and produces a transcript that overlaps entirely with that of *Xist*. In addition, *Tsix* is expressed in a reverse dynamic pattern to *Xist*, suggesting that it may function as a negative regulator (Fig. 3). Genetic manipulations that abolish *Tsix* expression on one of two X-chromosomes consistently cause the *Tsix*-deleted chromosome to be inactivated, (i.e., *Xist* is up-regulated on that chromosome). Although the antisense orientation of *Tsix* suggests the possibility of a base-pairing mechanism of antagonism, the exact way in which *Tsix* blocks *Xist* expression is still unknown.

While noncoding *XIST/Xist* transcripts have been identified in both human and mouse, *Tsix* has been characterized mostly in the mouse ES cell system. Recent studies of human cells have identified human *TSIX* antisense transcripts as well, suggesting a potential conserved role for this gene. However, since the genetic region near *XIST/Xist* and *TSIX/Tsix* is not highly conserved between the two species, some uncertainty exists as to whether the sense-antisense mechanisms observed in the mouse can be reliably extrapolated to humans and future work will clarify these issues.

In addition to the sense-antisense pair *Xist/Tsix*, the X-inactivation center in mouse also contains other elements that appear to regulate aspects of X-chromosome inactivation. One of these is DXPas34, a CpG-rich region containing 34-mer repeats that lies very near the start site of *Tsix*. The methylation patterns of DXPas34 correlate with the active or inactive state of the X-chromosome, indicating that it may have some relationship to X-chromosome choice and [▶imprinting](#). Other elements that affect the probability of X-chromosome choice have been identified further

upstream from the *Tsix* promoter. These candidate elements are particularly interesting because they may represent the X-controlling element (*Xce*), a modifier whose existence has been inferred through genetic studies in mice. In mice, different alleles of the *Xce* influence the relative probability that the *cis* chromosome will be chosen for inactivation. In a similar way, an *Xce*-like effect has been observed in humans which modifies the probability that a given X-chromosome is active, a phenomenon which has important implications to female carriers of X-linked mutations (discussed further below).

Escape from X-Inactivation

Although X-inactivation silences a vast number of genes along the X-chromosome, a significant number of genes escape inactivation and are active on both X-chromosomes in females. Many of these genes reside in an area found on the distal tips of both X- and Y-chromosomes known as the [▶pseudoautosomal region](#). During meiosis, the pseudoautosomal regions of the X- and Y-chromosome pair and participate in crossing-over, exchanging genetic material just as paired autosomes do. The similar sequences of the pseudoautosomal region contain genes that are actively transcribed on both X- and Y-chromosomes, such that all females (on both Xs) and males (on the X and Y) express two active copies of these genes.

Two other groups of genes also escape inactivation on the X-chromosome. One group includes genes that, like those in the pseudoautosomal region, contain active copies on the Y-chromosome as well. Unlike the pseudoautosomal region, however, these genes do not participate in crossing over, but otherwise are always active in two copies in each cell. The second group of genes consists of genes that are expressed from the

X-Chromosome Inactivation. Figure 3 Dynamic relationship of *Xist* and *Tsix* during X-chromosome inactivation. A schematic diagram representing fluorescence *in situ* hybridization profiles of *Xist* and *Tsix* during the process of X-inactivation in female mouse embryonic stem cells. (a) Prior to inactivation, *Xist* (red) and *Tsix* (green) signals can be seen as small pinpoints originating from the X-inactivation center (Xic). (b) On one of the two X chromosomes, *Tsix* pinpoint expression disappears. (c) Subsequently, *Xist* is up-regulated on this chromosome and spreads to coat the chromosome *in cis*, which eventually causes the transcriptional silencing of this designated inactive X. (d) On the other chromosome, *Xist* expression is turned off while *Tsix* persists. (e) Finally, *Tsix* is turned off on the active X chromosome, leaving an *Xist* “cloud” over the inactive X.

X-chromosome only and do not have copies on the Y. Genes in this group are expressed at higher levels in females than males, since the male Y-chromosome does not have copies of the gene. The clinical impact of the over-expression of this class of genes is unknown.

Clinical Relevance

Sex Chromosome Aneuploidies and Structural Abnormalities

In contrast to autosomal aneuploidies, which are invariably lethal or severely disabling, X-chromosome aneuploidies occur frequently (1 in 500 births) and are better tolerated in humans. Two common sex chromosome aneuploidies are XO (Turner's syndrome females) and XXY (Klinefelter's syndrome males). All these individuals, as well as the less common individuals with other karyotypes (XXXY, XXYY) are viable since the X-inactivation mechanism is able to count the X-chromosomes and inactivate all but one. Generally, individuals with sex chromosome aneuploidies have moderate behavioral and developmental abnormalities, though the extent and severity can vary widely between individuals. Patients with Turner's syndrome usually have normal intelligence but often have streak ovaries and are infertile. Individuals with Klinefelter's syndrome are also infertile and frequently have learning difficulties and poor psychosocial skills. Females with trisomy X (XXX), by contrast, are usually fertile, rarely display behavioral abnormalities and may often go undetected by clinicians.

One hypothesis suggests that the genes that escape X-inactivation may contribute to the phenotype of individuals with sex chromosome aneuploidies. Turner's syndrome patients lack the dose of escape genes normally provided by the second X-chromosome, making them haploinsufficient for this set of genes. Conversely, even though all but one X-chromosome is inactivated in individuals with supernumerary X-chromosomes, escape genes on the extra inactivated X(s) are still active and provide an abnormal additional dose of these genes. Consistent with this hypothesis, individuals with progressively more Xs tend to have increasingly severe behavioral and developmental phenotypes; pentasomy X individuals (XXXXX), for example, usually present with severe developmental retardation and many physical defects, despite grossly inactivating four of the five X chromosomes. For the most part, it is unknown whether the mis-dosage of a particular gene or subset of genes is responsible for the phenotypes seen in these aneuploidies or whether the generalized mis-dosing of many genes is intrinsically harmful. In Turner's syndrome, at least, haploinsufficiency of the *SHOX* gene (short stature, X chromosome) has been directly linked with the short stature and skeletal anomalies found in these patients. As more detailed and efficient DNA mapping and expression

analysis methods become available, it is possible that future research will be able to associate specific genes to the phenotypic traits of patients with X-chromosome aneuploidies.

In addition to numerical abnormalities, various X-chromosome structural abnormalities have also been observed, including deletions, duplications, X;autosome [translocations](#) and ring X-chromosomes. As is the case with aneuploidies, certain X-chromosome structural abnormalities are better tolerated than analogous defects on autosomes because X-chromosome inactivation minimizes the cellular and clinical impact of the anomaly. Individuals harboring an X-chromosome deletion or duplication tend to have cells that have preferentially inactivated the abnormal chromosome, leaving the normal X-chromosome active. This is probably due to a process of cell selection, where cells that choose to keep the defective X-chromosome active are less viable than the cells that choose to keep the normal X-chromosome active. The same process of selection affects individuals with balanced X;autosome translocations, who preferentially inactivate the intact X-chromosome. Since the translocated portion of the X-chromosome can induce gene silencing on the attached autosome, cells which choose to silence the translocated X will also inactivate important autosomal genes and will be at a disadvantage compared to cells expressing a normal complement of autosome and sex chromosome genes. One other rare structural abnormality is the ring X-chromosome, which usually results after X-chromosome breaks and deletions are followed by circularization of the chromosome. Various sizes of ring Xs have been observed, depending on the amount of the chromosome that has been deleted. In addition to the number of genes that have been lost, an important factor in the severity of ring X phenotypes is whether or not the ring still contains the XIST region. Ring X-chromosomes that have lost the XIST region will generally not be inactivated, hence providing an inappropriate extra dose of X-linked genes and resulting in severe phenotypes. Patients with rings that have preserved the XIST region can have a phenotype that is normal, although this depends greatly on the extent of the deletion.

Manifestation of X-Linked Genetic Diseases

Random X-chromosome inactivation causes females to be mosaic with respect to X-linked genes, resulting in a difference in how recessive X-linked mutations are manifested in the two sexes (3). Almost all X-linked mutations are revealed in males regardless of whether the mutation is dominant or recessive. In heterozygote females, however, roughly half of all somatic cells will express the mutant gene while the other half will express wild type copies. Immunostaining for

dystrophin in females with Duchenne muscular dystrophy (DMD), in which the dystrophin gene is mutated, shows a mosaic pattern where patches of muscle fibers express normal dystrophin and other patches do not. In many cases, such as in DMD and hemophilia A, heterozygote female carriers can therefore be clinically unaffected because the single wild-type copy compensates for the mutant gene.

Although unaffected or mildly affected heterozygotes represent the majority of cases in X-linked recessive diseases, variations in X-chromosome inactivation can influence the clinical picture. In a purely random system, each female would have cells expressing the two X-chromosomes in a 50:50 ratio. In reality, this ratio sometimes favors one chromosome, resulting in ►skewed X-inactivation (80:20 instead of 50:50, for instance). One way in which this occurs is by pure chance. Since X-inactivation is a random process that occurs when the embryo contains relatively few cells, the total percentage of cells inactivating one or the other X-chromosome can vary, leading to skewed X inactivation in that individual as a whole. Consequently, a heterozygote in whom a mutant disease allele resides on the predominantly active X can manifest characteristics of a normally recessive disease. Another way in which skewed X-inactivation is thought to occur is by the presence of genetic elements that predispose one X-chromosome for inactivation over the other. Several families have been identified where skewed X-inactivation occurs in clusters, implicating the existence of human Xce-like genetic modifiers or alleles that cause different predispositions for inactivation. A strong modifier allele makes the *cis* X-chromosome less likely to be inactivated and therefore causes all genes on that chromosome to be preferentially expressed in the organism as a whole. If a genetic mutation resides on an X-chromosome with a strong modifier, then this mutation will be preferentially expressed, leading to disease phenotypes in heterozygotes despite the presence of the normally protective wild type copy. Whether occurring by random chance or by genetic predisposition, skewed X-inactivation has been reported to cause disease in female carriers with DMD, fragile X syndrome, hemophilia, Wiskott-Aldrich syndrome, color blindness and several other X-linked disorders.

XCI and Assessing Tumor Clonality

Establishing the clonality of tumors is a major interest for cancer biologists and clinical oncologists. The phenomenon of XCI has been used for assessing clonality since the process stably “marks” each cell and all its daughter cells with one of the two X-chromosomes. By identifying differences between the two X-chromosomes and determining whether a tumor cell population has one active X or a mixture of

the two, one can infer the clonality of the population. Historically, variant isotypes of proteins were identified for assessing clonality, but recently the more-common differences in DNA and RNA have been used instead. Some examples of X-linked genes that have proven useful include the glucose-6-phosphate dehydrogenase (G6PD), hypoxanthine phosphoribosyltransferase (HPRT) and human androgen receptor (HUMARA) genes, in which common polymorphisms and/or methylation differences have been identified. Although precise methods of assaying polymorphisms and methylation differences are numerous and varied, the principle is the same. If tumor cells express a gene that can be uniquely traced to only one X-chromosome, one can infer that the tumor population arose from a single progenitor. Using XCI as a marker for clonality has several limitations and drawbacks (it works only in females and is subject to confounding factors such as the natural X-inactivation patterns in tissues) but it has been a valuable tool in conjunction with other methods.

XCI and Cancer

Long-standing evidence has connected inappropriate X-chromosome regulation with cancers, and recent work continues to strengthen this link. Historically, breast cancer tumor cells that lacked Barr body staining by cytology were associated with a poor prognosis in patients. Recently, a gene expression profile of recurrent ovarian tumors found that *XIST* expression was consistently down-regulated and that this down-regulation correlated with insensitivity to taxol treatment. The study suggests that *XIST* may be a potential marker for chemotherapeutic response in ovarian cancer. Taken a step further, another study found that the *BRCA1* gene, a breast and ovarian tumor suppressor, supports the localization of *XIST* RNA on the inactive X-chromosome. Although this provides no direct causal link, it raises the possibility that *XIST* may not only serve as a marker for cancer and cancer therapy, but may ultimately have some role in tumorigenesis. Given the importance of gene regulation in cancer and the ability for XCI and *XIST* to affect gene expression on a wide scale, it is likely that future research will continue to discover connections between X-chromosome inactivation, cancer and other genetically related health conditions.

Xenobiotic Substances

Definition

Xenobiotic substances are synthetic substances or drugs, which cannot be synthesised by an organism.

► Metabolomics

Definition

The human genome project and subsequent efforts have driven technological advances and led to an exponential increase in sequence data acquisition. New bioinformatic tools allow researchers to query and analyze sequence data as never before. Yet, the functional meaning of sequence and expression information, how genotype maps to phenotype (and *vice versa*), and the dynamic relationship between gene expression and cellular behavior, tissue function, developmental processes and homeostatic and adaptive mechanisms, has lagged behind. There is an urgent need for the integration of high-throughput ► [genomics](#) methods and experimentally accessible model systems, in order to answer central questions of biological behavior. An obvious choice for a biological system in which to reconcile genomics and functions is the clawed frog ► *Xenopus laevis*. We discuss the advantages of *Xenopus* as an experimental model, and its potential for making significant contributions in the area of ► [functional genomics](#).

XenoMouse

Definition

The XenoMouse is a transgenic mouse strain which does not produce murine but human antibodies. This is possible because the mouse immunoglobulin gene locus has been knocked out and a complete human immunoglobulin gene locus was introduced by transgenesis (humanizing).

► Monoclonal Antibodies

► Transgenic and Knockout Animals

Characteristics

Introduction

Xenopus' Advantages

For over fifty years the African clawed frog *Xenopus laevis* has served as a model system for biologists seeking to understand the basic processes underlying animal development. The ease of maintaining these frogs in captivity, the hundreds of eggs that can be produced and externally fertilized at one time, and the ability to readily manipulate the large oocytes and embryos have made them a favorite of classical and molecular embryologists for mechanistic studies of patterning, induction and morphogenesis.

The Genus *Xenopus* is in the Order Anura, Family Pipidae (http://www.columbia.edu/itc/cerc/danoff-burg/invasion_bio/inv_spp_summ/xenopus_laevis.htm); they are the only frogs with clawed toes. They are endogenous to cooler regions of sub-Saharan Africa, and a number of species have been described (<http://clawedfrogs.tripod.com/acf/id23.html>). Fully aquatic, they are typically found in muddy ponds. While they lack both a tongue and teeth they are voracious predators. Several *Xenopus* species have been studied in the laboratory, with *Xenopus laevis* being by far the most common. Recently, a second *Xenopus* species, *tropicalis* (also known as *Silurana tropicalis*; Fig. 1), has been adopted as an experimental

Xenopus as a Model Organism for Functional Genomics: Rich History, Promising Future

***Xenopus* as a Model Organism for Functional Genomics: Rich History, Promising Future.**

Figure 1 A sexually mature *X. tropicalis* female, shown here next to a US quarter for size comparison. *X. laevis* females differ little in appearance, but grow to as much as 23 times larger.

organism, primarily due to its genomic simplicity when compared to *X. laevis* (see below). For the remainder of this discussion, we will use the term *Xenopus* to refer to both species collectively. The advantages of using *Xenopus* as an experimental model organism are outlined below:

- **Ease of maintaining large breeding colonies:** Being completely aquatic, these animals may be housed in many types of aquaria. Several commercial, recirculating “rack” systems are available. *Xenopus* are also extremely resistant to disease, provided proper care is taken.
- **Large clutch size:** A mature *Xenopus* female can produce hundreds of eggs several times in one day (and can repeat this process after a recovery period of ~6 weeks). This allows for the collection of large numbers of embryos, which benefits any high-throughput study, and provides statistically significant numbers for experiments.
- **Large oocyte size:** *X. laevis* oocytes and eggs, and extracts prepared from them, have long been used for *in vitro* biochemical and subcellular studies. A particularly attractive feature of the late stage oocyte, is the ability to manually isolate the nucleus (►[germinal vesicle](#)), which facilitates subcellular localization studies.
- **Large embryo size:** A mature *X. laevis* egg is ~1.2 mm in diameter,

while *X. tropicalis* eggs are ~400 µm in diameter. The large *X. laevis* egg size facilitates microinjection, microdissection and complex tissue recombination studies (Fig. 2). (To view examples of microsurgery using a ‘gastromaster’ visit (►<http://www.gastromaster.com/videos.html>)). There is no net growth of the embryo until ~5 days after fertilization, when feeding begins. Gastrulation takes place ~9 hours after fertilization (at 23°C); neurulation begins in earnest at stage 12.5/13, ~14 hours after fertilization; neural crest is well established and neural tube closure is complete by stage 21 (~23 hours after fertilization). Around this same stage, a number of other organ systems are forming, and by stage 30 (~36 hours after fertilization) organogenesis is well underway (For stages and timings see – ►<http://www.xenbase.org/atlas/NF/NF1-10.html> and related pages). Cells are therefore relatively large during the key morphogenic processes of gastrulation, neurulation and neural crest migration, facilitating the visualization of cell behavior.

- **Externally fertilized embryos:** Fertilization is typically carried out artificially by adding macerated testis to expressed eggs. This allows fertilization to occur reasonably synchronously (within a 5–10 min window). It is therefore straightforward to generate large numbers of stage-matched embryos.
- **Externally-developing embryos:** This feature enables researchers to observe the embryos’ progression through all developmental stages.
- **Well-characterized embryonic development:** Intense efforts have led to detailed fate maps for *X. laevis* (1,2) (Forward and reverse fate maps ►<http://www.xenbase.org/atlas/xenbasefate.html>). This, and a cumulative knowledge base from decades of study, can be used to target micromanipulations (microinjections, dissections, etc.) to specific regions or tissues of the embryo. There is a critical mass of researchers working in the system, actively producing both reagents and observations that spur on new projects and discoveries. It is very likely that the bulk of the observations made in *X. laevis* will hold true for *X. tropicalis* as well.
- **The animal cap system:** Unique to *X. laevis* is the animal cap assay (7,10). In *X. laevis* zygotic transcription does not begin in earnest until stage 8.5, the midblastula transition (~4000-5000 cells). At this point, two features of the embryo combine to provide a unique experimental opportunity. First, a large fluid filled space, the blastocoel, acts to minimize cellular interactions between the animal pole ectoderm and the vegetal endodermal cells. The cells that constitute the “roof” of the *X. laevis* blastocoel can be excised from the

Xenopus as a Model Organism for Functional Genomics: Rich History, Promising Future.

Figure 2 Compared to the $\sim 70 \mu\text{m}$ diameter human egg (inset panel a), with a volume of $\sim 2 \times 10^5 \mu\text{m}^3$, the $\sim 1200 \mu\text{m}$ diameter *X. laevis* egg (a) has a volume of $\sim 9 \times 10^{10} \mu\text{m}^3$. Following sperm entry, male and female pronuclei migrate toward the center of the animal hemisphere and fuse. A microtubule system, nucleated by the sperm's centrosome, drives a cortical rotation; this rotation breaks the egg's cylindrical symmetry and presages the dorsal-anterior and ventral-posterior axes of the embryo. (b) A series of rapid cleavage divisions transforms the fertilized egg into a blastula. As early as the second division a space, the blastocoel, appears and separates the animal ectoderm from the equatorial mesoderm. During normal development inductive signals are relayed from vegetal endoderm to mesoderm and then to ectodermal tissues. At stage 8/9 the animal pole region (marked by white lines) can be readily dissected away. At this point, inductive signals that

embryo and cultured separately (animal cap). If excised prior to the arrival of inductive signals from the mesoderm, which acts as a relay station for signals that originate in endodermal cells, the piece of blastocoel roof heals to form a spherical structure and proceeds to form atypical epidermis. These cells possess the ability, however, to respond to a number of inductive signals, signals that can be supplied by the experimenter. These signals can drive the animal cap to differentiate into a wide variety of tissues, including blood, muscle, nerve, cartilage, pronephros, pancreas and heart (7,8). This multi-potent, homogeneous cell culture offers investigators an *in vivo* "test bed" for studying the regulatory networks that control the patterning and differentiation of many different embryonic tissues, particularly when coupled with the use of hormone-regulated proteins (see below). At the same time, the animal cap has been freed from many of the dynamic interactions that characterize the developing embryo. Specific inductive signals can be applied at specific times to the system, and their effects systematically analyzed. The large size of the animal cap offers the possibility of analyzing individual caps, which should reveal much of the homeostatic mechanisms and regulatory dynamics. From an experimental perspective, an important practical feature of the animal cap system is that molecular markers of mesodermal or endodermal differentiation are generally completely absent, so that their induction is readily apparent even using simple (rather than quantitative) RT-PCR methods.

- **Hormone regulated proteins:**

The technique to generate hormone-regulated versions, particularly of transcription factors, has proven extremely useful in *Xenopus*, particular when used in combination with the animal cap system (Sive et al. 2000). The most common approach is to generate a plasmid in which the region encoding the hormone-binding domain of the human glucocorticoid receptor is appended to either the 5' or 3' end of the target protein's coding sequence. In a typical experiment, RNA encoding this chimeric

originate in the vegetal endoderm and propagate through the mesodermal region have not yet reached the animal pole ectoderm. Such "animal caps" differentiate into atypical epidermis (ectoderm), but can be driven toward various fates through manipulation of signaling and gene regulatory pathways (7,8). (c) An animal cap generated from a fertilized egg injected with an RNA encoding the HMG-box transcription factor SOX7; the cap was fixed and stained *in situ* for myosin heavy chain a RNA, a marker of cardiogenesis (9). Panel A is adapted from Hausen & Riebesell (10).

polypeptide is injected into fertilized eggs. While the polypeptide is rapidly synthesized, it is inactive in the absence of the hormone dexamethasone. Addition of dexamethasone rapidly activates the polypeptide. In such experiments, animal caps are generated from RNA injected fertilized eggs. They can then be exposed to hormone in the presence or absence of a protein synthesis inhibitor (we find that emetine is more useful than cycloheximide, since it produce fewer non-specific effects) (see 9). This makes it possible to identify “immediate early” and possibly direct targets of transcription factors. In the context of the intact embryo, it is possible to use such hormone-regulated constructs to circumvent early effects and focus on later stages of development.

- **Transgenesis:**

The techniques for generating transgenic *Xenopus* are now well established (3), and the number of characterized promoters available is increasing rapidly. Stable transgenic lines are being produced, enhancer-trapping screens are underway and transposon-mediated transgenesis methods are being tested.

- **Genetic Studies in *X. tropicalis*:**

X. laevis is effectively ▶ **allotetraploid**. Some alleles are non-functional or distinct from a functional perspective. In contrast, *X. tropicalis* has a typical diploid genome and presents the opportunity to conduct traditional genetic and molecular genetic experiments (4). That said, the value of traditional genetic approaches in *Xenopus* remains to be established, particularly given the relative ease of transferring genetic insights from other well established genetic model systems (e.g. *Dario rerio* – zebrafish, *Drosophila melanogaster* and *Caenorhabditis elegans*) to the more experimentally manipulable *X. laevis* system.

- **Gene screens**

A particularly powerful screening approach, made possible by the inherent and visible dorsoventral asymmetry of the early *Xenopus* embryo, is the screening of pools of cDNAs via injection and sib selection (see 12 et al. 2000, and references therein). This method has proven extremely useful in identifying previously unknown genes, and previously unknown functions for known genes.

- **Rapidly accumulating EST and genomic *Xenopus* sequence:**

Of the many chordates studied, the *Xenopus laevis* transcriptome is among the most frequently sequenced. As of April 2005, Unigene build #63 (▶ <http://www.ncbi.nlm.nih.gov/UniGene/UGOrg.cgi?TAXID=8355>) contained 12,475 mRNAs and 389,701 total sequences in clusters. Additionally, the DOE Joint Genome Institute has initiated an *X. tropicalis* genome sequencing project, with 6 to

8-fold coverage expected before the end of 2005; assembly version 3.0 is currently available (<http://genome.jgi-psf.org/Xentr3/Xentr3.home.html>).

- **A growing array of molecular tools**

In addition to well-characterized promoter sequences, there are a growing number of characterized genes, in situ probes and antibodies that serve as markers of gene and protein expression and cellular differentiation (Fig. 3). Confocal imaging of organogenesis is straightforward (13). It is also worth noting that *X. laevis* and *X. tropicalis* are close enough evolutionarily that probes derived from one generally function in the other (5, 6). Furthermore, the growing collection of sequence data allows researchers to readily clone *Xenopus* orthologs of genes implicated in specific processes in other systems. Additional molecular tools for imaging, gene ▶ **knockdowns**, etc. are making functional genomic studies in *Xenopus* increasingly straightforward (see below).

Functional Studies in *Xenopus*: Methods and Resources

▶ Misexpression/▶ Over-Expression

The standard approach to study gene function is to disrupt the normal pattern of gene expression. This can involve expression of the gene product in the wrong place, at the wrong time, or at the wrong level, expressing an altered form of the gene product or suppressing to various extents the expression of the gene. In *X. laevis* over-expression and misexpression studies have been used quite successfully to analyze a number of key developmental and differentiation events. RNA or DNA can be injected into the fertilized egg or specific blastomeres in the early embryo or introduced *via* transfection or transgenesis. Specific regions of an injected embryo can be transplanted into homologous or ectopic regions of uninjected embryos and *vice versa*. Transplanted cells can be followed through the use of various lineage tracers, and conditional expression can be achieved by using tissue-specific promoters and inducible chimeric constructs, such as glucocorticoid receptor fusions (see above). Transgenic *Xenopus* lines have been made that allow conditional expression using the Gal4-UAS system (14).

Knockdown/Inhibition Studies

While targeted gene knockouts are not yet possible in *Xenopus*, analogous methods have been used quite successfully. Conventional and modified (morpholino (morpholino (▶ **Morpholino Oligonucleotides, Functional Genomics by Gene ‘Knock-down’**)- or phosphorothioate-type) antisense reagents can dramatically reduce the translation or splicing of the targeted mRNA. (11, 15). This makes *X. laevis* a particularly valuable model system for the study of maternally supplied gene products. It is also possible to perturb

Xenopus as a Model Organism for Functional Genomics: Rich History, Promising Future. Figure 3 Many molecular markers and characterized genes are available for *Xenopus*. In the left panel, whole mount *in situ* hybridizations were used to visualize *cardiac troponin I*; this gene is expressed in myocardium of the heart. From top to bottom, the embryos are at stage 31, 35, and 40 of development. In the right panel, embryos have been stained in whole-mount with the MZ15 monoclonal antibody directed against a keratan sulfate, a component of the notochord.

normal gene product function *via* the expression of dominant negative versions of the gene product and antibodies (in some cases, antibodies can also be used to activate a gene product). A few studies have been published using small interfering RNAs (siRNA) in *Xenopus*, but it is not yet clear if this technique will prove widely effective. In each case, specific perturbation can be delivered to the whole embryo or targeted to specific regions via fate map-based blastomere injection. Temporal control of the treatment can also be achieved by controlling the expression of dominant negative constructs through the use of hormone-regulatable domains or specific promoters in transgenic studies.

Mutational Screens

Several efforts are currently underway to perform mutagenic screens in *X. tropicalis* using chemical treatments, irradiation and transposon-insertion (http://tropicalis.berkeley.edu/home/molecular_resources/mutants/mutants.html). These screens should prove to be

valuable additions to those performed in other genetically amenable organisms.

Enhancer Trapping Screens

Using insertional transgenic techniques, enhancer (or gene) trapping screens are currently underway, in both *X. laevis* and *tropicalis*. The most common approach is to use a fluorescent reporter gene in a construct that allows for the cloning and sequencing of flanking genomic sequences.

Microarrays

The most common tool today for high-throughput functional studies is the DNA [microarray](#), which enables investigators to monitor transcriptional activity for thousands of genes simultaneously, and in some cases across entire genomes. Several *X. laevis* spotted cDNA microarrays have been fabricated and are in use in gene expression studies (Fig. 4). Additionally, a consortium of researchers is in the process of designing oligonucleotide probes for 15,600 *X. laevis* genes for the creation of a spotted oligo microarray. Additionally,

***Xenopus* as a Model Organism for Functional Genomics: Rich History, Promising Future.**

Figure 4 A spotted microarray fashioned from a *Xenopus laevis* embryonic heart cDNA library. This array has over 7,000 cDNA probes spotted onto the surface of a 1 inch by 3 inch glass slide (photo courtesy of Grow lab).

Affymetrix, Inc. (<http://www.affymetrix.com>) markets a commercial “Genechip™” microarray with 15,503 oligo probe sets for the detection of approximately 14,400 transcripts.

***Xenopus* Gene Expression Atlas**

Microarray-based experiments are certain to lead to the identification of thousands of genes for which follow-up characterization is desired. In order to avoid wasting valuable resources on redundant studies, a centralized database of *Xenopus* gene expression is clearly essential. This database should not only serve as a repository for published *Xenopus* microarray expression profiles, but should also curate the temporal/spatial expression data for characterized genes (recording tissue-specific expression across multiple embryonic stages, for instance). One such early effort is the Axelldb database (see link below). As *in situ* hybridization techniques improve and move to high-throughput platforms, the large numbers of nearly identical stage-matched embryos generated by *Xenopus* females will greatly facilitate data collection and analysis. Recently, a large-scale microarray profiling effort has been made in an attempt to characterize ~21,000 *Xenopus* genes; the results of this effort have been placed into a searchable “iChip” database (16) (see link below).

Online *Xenopus* Resources

The following are web addresses for several sites of interest. This is not meant to be a comprehensive list, but rather a starting point for additional research on *Xenopus*:

A Future for *Xenopus* in Functional Genomics

It is clear that no single model organism can fill all of the requirements for future functional studies, and that

the greatest knowledge is often gained through comparative genomics. There is no doubt, however, that the many and unique advantages of *Xenopus* as an experimental system, as well as the growing genomic resources and critical mass in terms of on-going intellectual effort, will ensure its position as a fundamental vertebrate model. It is likely that future contributions from *Xenopus* research will lead to rapid progress in our understanding of the interactions between genes and their regulatory interactions.

Clinical Relevance

Perhaps the most surprising biological fact to emerge during the modern era is the high degree of conservation in the molecular and cellular mechanisms that underlie metazoan development. It is this conservation of mechanism that makes it possible to draw meaningful conclusions about human development and disease from studies of fruit flies and roundworms. As a vertebrate, rather closer in the evolutionary lineage leading to humans than many other experimental organisms, *Xenopus* offers experimental features, and low costs compared to mouse and primate systems, while preserving the promise of practical relevance to human biology.

Xenopus Laevis

Definition

Xenopus laevis is the name for the African Clawed Frog which is frequently used in developmental biology and biomedical research. It is considered to be allotetraploid, with mature females growing to an average of 10–12 cm in length. The oocytes of *Xenopus* are commonly used cells for electrophysiological recordings. They are a popular model because of their large size (~1.0 mm) which makes their handling and manipulation easy.

Definition

X-ray crystallography reveals the spatial structure of molecules by measuring how they scatter ► [X-ray radiation](#) when arranged in a ► [crystal lattice](#). Two broad fields may be distinguished: small molecule crystallography deals with a small number of atom positions and typically well-ordered crystals, while macromolecular (usually protein) crystallography determines a much larger number of atomic positions, usually despite considerable ► [crystalline disorder](#).

Their common goal is to calculate the ► [electron density](#) distribution in the crystal from measured X-ray ► [diffraction intensities](#). The electron density and diffraction intensities are represented by mathematical functions, which may be interconverted variously using the ► [Fourier transform](#), ► [convolution](#) and ► [complex](#)

product operations if the phases of the diffracted X-rays are known. Because the phases are not directly measurable, the dilemma known as the “phase problem” arises. Several methods exist that enable phase estimation and thereby the solution of the spatial structure. The final structure is typically modeled as a set of unique atomic positions with approximate corrections for atomic motions. The accuracy of the structure depends on the quality of the diffraction data, but also on the validity of assumptions regarding atomic positions, their relationships to the electron density distribution and chemical geometries.

Description

X-Ray Radiation, Scattering

X-ray radiation is electromagnetic radiation with wavelength(s) from about 10^{-7} to about 10^{-11} meters (100–0.01 nm), appropriate for the resolution of atomic details (*ca.* 0.1 nm). These correspond approximately to frequencies ranging from 10^{15} – 10^{19} Hz, or photon energies ranging from 10–100 keV. A classical (non-quantum mechanical) description of X-ray – matter interactions provides an intuitive explanation of much of protein crystallography. As a light wave, the incoming X-ray radiation is an oscillating electrical field that induces an oscillation of charges found within the field. This secondary oscillation, which in atoms is significant only for electrons (due to their low mass relative to protons), is itself a source of radiation and scatters thereby some of the incident radiation. The electrons cannot be considered point charges, but rather as a cloud of (probability) density. The amplitude of the scattered wave is proportional to the number of electrons in the cloud and the angular dependence of the scattering depends on its shape. To a good approximation, the electron cloud of an atom is spherically symmetric and dependent on atom type.

The total scattered intensity from a molecule is the sum of all of the waves scattered by the individual atoms, wherein constructive and destructive ►interference between the waves amplify and diminish the resultant wave respectively, depending on the scattering angle. In theory, measurement of the angular (two dimensions) dependence of the waves (amplitudes and phases) scattered by a molecule over all possible orientations about a rotation axis (the third dimension) would enable the calculation of the (three dimensional) spatial molecular electron density distribution by means of the Fourier transform. In practice, however, the waves scattered by a single molecule would be too weak to measure.

Crystal Lattice

The discussion above considers scattering from atoms and molecules without reference to crystals. The periodicity of molecules packed in a crystal lattice

transforms the diffuse scattering from an individual molecule *via* constructive and destructive interference into a set of discrete diffracted spots. The ideal crystal consists of an entity called the ►unit cell, which is repeated identically, periodically and infinitely in three dimensions. The unit cell is defined by three axes and dimensions that define the edges and faces of the unit cell. Neighboring identical unit cells pack against one another along shared edges and faces such that displacement (translation) of one (or any integer number) cell dimension(s) along the corresponding cell moves an observer to an indistinguishable position in a neighboring unit cell.

The unit cell contains the molecules in a ►crystal packing arrangement that may include multiple copies of the molecule(s); these in turn may or may not be identical to each other. The transformations of the unit cell that generate a unit cell indistinguishable from the first are the ►symmetry operations that determine the cell symmetry. These operations in general comprise rotations, screw rotations, mirror planes, inversions and inversion axes; the inherent chirality of natural proteins eliminates inversion and mirror symmetries from protein unit cell symmetries. The symmetry operations map the molecules of the unit cells onto identical molecules. A minimal set of molecules that cannot be mapped onto each other using the cell symmetry operations defines the ►asymmetric unit of the crystal cell. The molecules of the asymmetric unit need not be identical and are always distinguishable at least by differing crystal environments.

The periodicity of the crystal lattice results in total destructive interference of the scattered X-ray waves except at specific scattering angles, for which constructive interference maximizes their intensities. A simple comparison with a one-dimensional diffraction grating provides an intuitive explanation of this phenomenon. Visible light that is scattered by a single groove engraved on a plate is weak and diffuse. If however there is a row of identical grooves to form a diffraction grating, the separately scattered waves recombine at some distance from the grating into alternating light and dark bands, corresponding to regions of constructive and destructive interference, respectively. ►Bragg’s law is the mathematical formula that relates the spacing of the grooves to the wavelength of light and the diffraction angles of the series of bands of constructive interference. For a three dimensional crystal, the spacing of the grooves corresponds to the lengths of the unit cell; higher order reflections can be rationalized by the description of a three dimensional array of stacked planes (►Miller planes) that are associated *via* the Miller indices (h, k, l) with each diffracted spot.

A crystal with a lone X-ray scattering atom in the asymmetric unit would produce a diffraction pattern characteristic of the unit cell size and symmetry. The

X-Ray Crystallography, Basic Principles. Figure 1

intensities of the diffracted spots would be uniform for a given scattering angle and monotonically decreasing for increasing scattering angles (depending on the atom type). More complicated molecules in the same unit cell (or asymmetric unit) would produce the same diffraction pattern but with more highly varied intensities. One way to visualize the origin of this phenomenon is to consider the diffuse diffraction pattern of the unit cell. The intensity of a particular diffraction angle is a function of the diffuse scattering and is identical for each unit cell. If a particular scattering angle does not correspond to the diffraction angle for a crystal lattice reflection, the waves from all the unit cells will interfere destructively resulting in zero intensity. If the angle does correspond to a crystal lattice reflection, there will be constructive interference to produce an amplified intensity proportional to the

intensity of the diffuse diffraction pattern. The result is that the discrete diffraction pattern of a crystal is effectively the diffuse diffraction of the unit cell sampled at positions determined by the crystal lattice. Crystalline disorder weakens and broadens the diffraction spots and limits the resolution of the atomic positions. The perfect crystal lattice does not exist – it cannot be infinite, for example – and damage and a variety of growth defects lower the quality of the crystal and the diffraction data. Several measures of crystalline disorder have been defined, including “mosaicity” – the extent to which a crystal should be described as a mosaic arrangement of smaller perfect crystals with small statistical variations in orientation and “temperature factor” – the broadening of reflections due to overall statistical disorder of the unit cell contents.

Crystal Growth

Crystallography begins with crystal nucleation and growth. Nucleation occurs after solution properties are changed so that the solution becomes supersaturated with the molecule to be crystallized. In this state, if attractive forces dominate during spontaneous collisions of the molecules, dimers and higher multimers are formed. These may continue to grow into crystals if the attractive forces between molecules in the initial aggregate are strong and specific enough to orient the molecules uniformly and if the specific orientations are compatible with a periodic lattice. Crystal needles and plates are formed when these conditions hold only in one or two dimensions respectively; growth in the other dimensions is much slower and often disordered. Precipitate is formed if the aggregates are not compatible with an ordered crystal lattice. Crystal growth continues until the solution is no longer supersaturated. The crystals can also be modified after they are grown.

Theoretical Principles

As described above, the diffraction pattern is a combination of the diffuse scattering from a unit cell and the constructive/destructive interference caused by the regularity of the crystal lattice. Each diffraction spot can be indexed (h,k,l) to the Miller plane associated with the angle of reflection. The measured intensities I are thus a function of the index and can be expressed as $I(h,k,l)$, and represent the squared amplitudes of the diffracted waves. The waves are characterized additionally by phases and are described by $F(h,k,l)$ or $F(\mathbf{h})$ for short, where the F values are **complex numbers** that account for both amplitudes and phases. This function is directly related by the Fourier transform to the function that describes the electron density distribution in the unit cell. The electron density function is commonly denoted $\rho(x,y,z)$ or simply $\rho(\mathbf{x})$. Because the intensities $I(h,k,l)$ of the diffracted waves are measured in crystallography and not the phases, calculation of the electron density requires supplemental phase information in order to derive the $F(\mathbf{h})$ function (and therefore the electron density distribution) from the intensities $I(h,k,l)$. This is the so-called phase problem of crystallography.

Details of the methods to estimate phases go beyond the scope of this article. Direct methods rely on necessary characteristics of the electron density (e.g. always positive) and on resulting phase relationships that exist among sets of reflections, leading to a finite set of possible phase combinations that can be systematically tested by computer. Because of the relatively small number of reflections, small molecule crystal structures are typically solved using direct method phase estimation. For protein crystallography, phases may be estimated using closely related protein structures

(molecular replacement or MR), measurements of multiple crystals that differ only by the presence of one or few fixed and strongly scattering atoms (multiple isomorphous replacement or MIR) or measurement of diffraction data at multiple wavelengths after incorporation of anomalous scattering atoms (multiple wavelength anomalous diffraction or MAD).

Successful phase estimation allows the calculation of an interpretable electron density map using the Fourier transform. This density allows the generation of an initial model in the case of MIR or MAD or correction of the initial model used in MR. The improved models improve the phase estimation for a second cycle of electron density calculation and model building. Depending on the resolution of the data and number of measured reflections, additional information, such as bond lengths and angles, may be used to maintain a chemically reasonable model. Protein structure refinement proceeds until there is no clear improvement of the structure.

X-Ray Data Collection from Macromolecular Crystals

ANDREA SCHMIDT, VICTOR S. LAMZIN
European Molecular Biology Laboratory (EMBL),
Hamburg c/o DESY, Hamburg, Germany
andrea@embl-hamburg.de
victor@embl-hamburg.de

Definition

The actual crystallographic experiment is data collection, i.e. the measurement of X-ray diffraction intensities from a crystal. Both the location (h , k and l coordinates in reciprocal space) and the value of the diffracted intensity are measured.

Description

X-ray data collection is central to crystallographic structure determination and represents the final experimental step. The manner in which the data collection is carried out will determine the data quality, which in turn will define the success of subsequent steps in structure determination and the quality of the macromolecular model. A number of considerations need to

be taken into account. These are briefly outlined in this contribution.

Protein Crystal Properties

Protein molecules are comparatively large and flexible. Once protein crystals are formed, the molecules pack loosely into the crystalline lattice and are surrounded by layers of solvent molecules from the crystallisation cocktail. The crystal is formed of identical building blocks, known as “unit cells” and may then be mathematically defined as a three-dimensional array of such unit cells. The size of the protein molecule defines their dimensions, so that larger proteins tend to produce crystals with larger unit cells. The number of reflections increases with the unit cell size and the diffracted intensities are inversely proportional to its volume. Thus, a larger number of reflections results in weaker diffraction intensities. As protein crystals contain a high amount of solvent (typically 20–80% (v/v)), there is a relatively high degree of mobility (atomic displacement) of some of the individual protein loops and side chains.

Data Collection Setup

The experimental setup for crystallographic data collection involves the X-ray source, the mounting system and the detector.

X-Ray Sources

In order to account for the diffraction properties of protein crystals, the X-rays used for data collection need to fulfil a number of requirements. Due to the generally weak diffraction of protein crystals, high intensity of the incoming radiation is a prerequisite for successful data collection. The experiments require the measurement of a potentially large number of reflections, which are densely arranged in reciprocal space. Such “crowding” can lead to an overlap of diffraction spots, resulting in loss of data for those reflections whose intensities are not uniquely defined. In order to minimise this effect the primary beam should have low divergence.

The wavelength of the X-rays determines the maximum resolution measurable with the experiment. Given the same detector, a shorter wavelength (higher energy) allows measurement of data to higher resolution. Crystals also deteriorate in quality due to the absorption of radiation in an energy-dependent manner. The use of shorter wavelengths is advantageous since it reduces the radiation absorption in the crystal.

While a rotating anode can be suitable for well-diffracting, stable crystals, the preferred choice of a radiation source for protein crystals is a synchrotron. This is due to the superior beam properties of synchrotrons, such as high intensity, low divergence and small focus size.

Mounting Techniques

Prior to the data collection the crystalline sample should be mounted onto a beamline goniostat. There exist a variety of mounting techniques, which will not be described here. However, the important parameters are the data collection temperature and the type of goniostat used in the experiment. Typically, a protein diffraction experiment is carried out at cryogenic temperature (100 K), where the crystal is flash-cooled in a nitrogen stream. The use of cryogenic temperature reduces the effects of radiation damage and the crystal can be kept in the beam for a longer exposure. Cryogenic freezing is an almost absolute requirement for data collection at a synchrotron, due to the high radiation dose rates incident upon the crystals. An important issue for cryogenic data collection is the prevention of ice formation both in the solvent channels inside the crystal and on the surface of the sample. This is achieved by soaking the crystal in a “cryo-protectant” solution prior to mounting it on the goniostat ((1) and references therein). The crystal is then mounted into the beam in a small nylon fibre loop which holds the crystal encased in a thin film of cryo-protectant in a glass state (Fig. 1).

Owing to the large number of observations to be recorded for a protein crystal, it is not feasible to measure each reflection separately. The way in which data collection is typically carried out is to mount the crystal on a rotation axis (phi-axis), rotate it by a certain increment and record the diffraction pattern for each such slice on an area detector – a method commonly known as the “rotation method”.

Detector Types

Various detectors exist with different construction types and properties, which determine the suitability of a certain detector for any given experiment. Detectors should ideally have high detective quantum efficiency (DQE), a large dynamic range, linear response, high spatial resolution, large sized active area and uniform response and should accept high count rates. Examples of detectors commonly used in protein crystallography are image plates (IP) and charge-coupled device (CCD) cameras. The image plate consists of a support plate covered with a photosensitive layer and a protective cover (2). During the exposure, the phosphor layer stores the absorbed X-ray energy and emits upon read-out with a visible-light laser a phospholuminescence. The emitted intensity is proportional to the absorbed X-ray intensity at each point on the image plate (typical pixel sizes are 75–150 microns). The IP detectors are large and have a large dynamic range and low background noise, giving rise to a good DQE. However, the read-out and erasure after each image are often slow compared to the actual exposure time. In CCDs, the incoming X-rays cause visible light phospholuminescence. This creates “electron holes” in a

silicon layer *via* the photoelectric effect (3). The active surface consists of an arrangement of pixels (typically of a size of 50 microns) that accumulate the generated charge (electrons) in an electrostatic well. The charge is then shifted on a readout circuit and read as the signal. Although there is a certain amount of noise associated with readout and background generation of arbitrary photoelectrons, the speed and good spatial resolution of CCDs make them highly suitable for data collection. This is especially true at synchrotron sources where shorter exposure times are required.

X-Ray Data Collection from Macromolecular Crystals. Figure 1 Flash-cooled crystal mounted in a fibre loop for data collection.

Properties of the Diffraction Pattern

Diffraction images from protein crystals show a number of properties that have direct impact on the choice of data collection strategy. Due to the high mobility and the presence of disordered solvent, there is a steep intensity falloff with resolution (Fig. 2). The reflections are close to each other due to large cell parameters and their spots are broadened by the high mosaicity of protein crystals. Reflections arising from a set of lattice planes appear in circles on the detector plane (Fig. 3). The width of those circles or lunes is determined by the mosaicity of the crystal and the oscillation increment. A drawback of the rotation method is the presence of “blind regions” (Fig. 4), within which the reflections cannot be recorded. An additional feature is the presence of a region with higher background arising from the presence of solvent water.

Strategy

The aim of a good data collection strategy is to obtain a complete dataset while:

1. keeping the data collection time to a minimum
2. keeping the total exposure to a minimum in order to reduce the effects of the radiation damage
3. bringing the signal-to-noise ratio to a maximum in order to achieve the highest possible resolution and accurate data.

As a result, the special properties of protein crystal diffraction have to be taken into account. Additionally the available equipment (e.g. detector type), time constraints (at a synchrotron) and, naturally, the quality of the crystals have to be considered. The main parameters to adjust for a particular case are the

X-Ray Data Collection from Macromolecular Crystals. Figure 2 Diffraction pattern from a protein crystal showing the density of the diffraction spots and the steep intensity falloff. The picture on the left is displayed with a higher background threshold, the one on the right with a lower threshold.

X-Ray Data Collection from Macromolecular Crystals. Figure 3 Lunes in the rotation method of data collection. Left: correct setup with small oscillation increment; right: increment too large causing the lunes to overlap.

Left: black circles indicate blind regions for different resolution cutoff; right: blind regions at different wavelengths.

crystal-to-detector distance (and the crystal-to-beam-stop distance), the oscillation increment per frame, the exposure time per frame and the total oscillation range. For a high-quality structure, one should collect as high resolution data as possible. However, time and the risk of radiation damage have to be taken into account. The presence of overlapping reflections, overloads or an incorrect choice for the high resolution limit (detector being positioned too close or too far) will have a negative effect and often a compromise has to be found between the diffraction properties of the crystal and the capabilities of the hardware set-up. An excellent overview of the tools for the optimal choice of parameters can be found elsewhere (4).

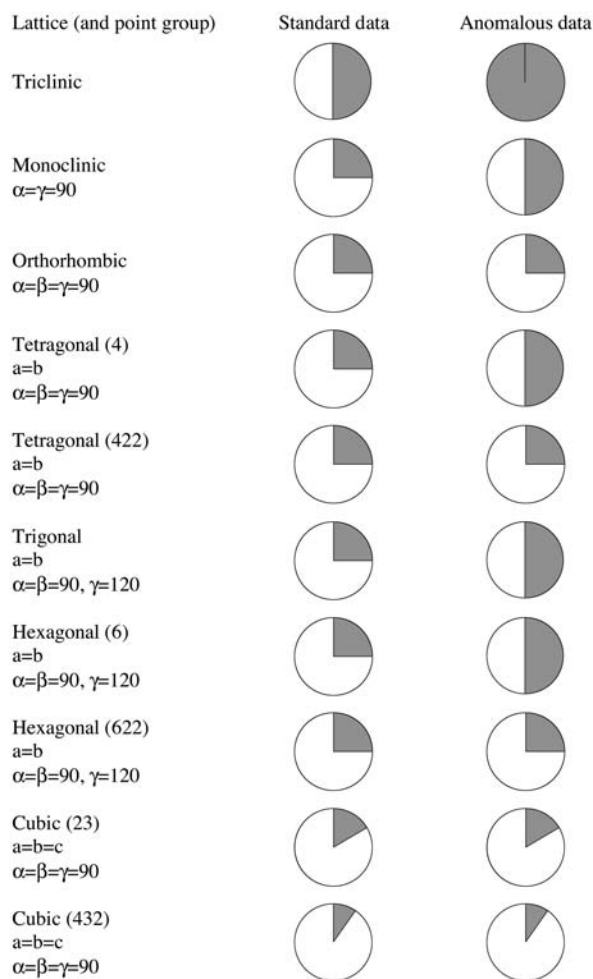

Asymmetric Unit

It is highly advisable to make use of the crystal orientation and crystal symmetry in order to minimise the exposure time and the total oscillation range. The required minimum regions in reciprocal space are given in Fig. 5. This is easy if the crystal is well oriented with

its cell axes corresponding to the “laboratory system” determined by: the spindle (x), the beam (z) and the vertical axis (y) perpendicular to x and z . Usually, the orientation of the crystal lattice is determined by indexing the first image with respect to the xyz coordinate system. For certain orientations of the crystal (e.g. c^* being parallel to the rotation axis), the required rotation range may be smaller than in Fig. 5. Because of the presence of blind regions (Fig. 4), the orientation of the crystal will also determine the completeness of the final dataset. In cases of low symmetry and perfect alignment, re-orientation is necessary to achieve full completeness.

Resolution and Detector Setup

In order to obtain the best possible signal-to-noise ratio and spot separation the detector should be positioned as far away as possible from the crystal while still collecting the highest resolution reflections. The diffraction limit is sometimes hard to determine by

X-Ray Data Collection from Macromolecular Crystals. Figure 5 Minimum required oscillation range for different crystalline lattices and point groups.

eye. Nowadays there are software strategy programs available which can greatly assist in the estimation of the resolution limit. The exposure time should be chosen so that the required resolution is achieved without (significant) radiation damage to the crystal.

Oscillation Increment and Mosaicity

Due to the high spot density in reciprocal space there is a risk of having overlapping spots from neighbouring lunes when the oscillation increment is too large (Fig. 3). Another criterion determining the oscillation width is the length of the unit cell axis normal to the spindle. The estimation for the maximum increment (in degrees) can be obtained using the expression: $\Delta\varphi = \frac{180d \cos \theta}{\pi a}$ where d is the highest resolution, a is the length of unit cell perpendicular to the spindle and θ is the maximum diffraction angle. Note that this formula does not account for the mosaicity and beam

divergence, both of which make the lunes wider. The choice of the oscillation width will also determine how many reflections will be fully recorded and how many will be partially recorded (i.e. on two or more consecutive images). A larger fraction of fully recorded reflection is advantageous for the scaling of images. However, a large amount of partially recorded reflections is advantageous for the post-refinement. Here the reader is referred to a specialised literature (5).

Exposure Times and Multiple Passes

The exposure time per image is the primary factor, which ultimately determines the signal-to-noise ratio of the data. Collection of higher resolution data requires longer exposure times. Due to the steep intensity falloff and the inherent limits of the dynamic range of the detector, the strong reflections at low resolution may often be overloaded and show truncated profiles. However, it cannot be overstated that these reflections have the highest information content and need to be recorded accurately. A solution is to split the data collection in two (or more, if required) passes, a high-resolution pass, which will extend to the maximum desired resolution and a low-resolution pass to record otherwise overloaded reflections. The low-resolution pass should be set up so that it covers the same range in reciprocal space and overlaps sufficiently with the high-resolution pass and the exposure time should be appropriately shortened. A rule of thumb is to move beamstop and detector together; in the high-resolution pass the beamstop should be close to the crystal in order to reduce the background. In the low-resolution pass the beamstop should be placed further from the crystal, so that it does not obscure the low-resolution reflections.

Data Quality and Statistics

The quality of the collected data should be inspected immediately, ideally while the crystal is still on the goniostat. There are several parameters that can be used to assess the quality of the data set and to determine the high-resolution limit. The most traditional is the R_{sym} or R_{merge} , although its value depends on the data redundancy (the number of times each unique reflection has been measured). More elaborate indicators use redundancy-corrected R-factors ($R_{\text{r.i.m.}}$, $R_{\text{p.i.m.}}$) (6) or the $I/\sigma(I)$ ratio, under the assumption that the standard uncertainties are estimated correctly.

Automatic Data Collection

Over recent years there has been an increasing tendency towards higher throughput, faster data collection, rapid screening and on-line assessment of crystal quality. Many of the decision-making steps during the data collection can be done by the appropriate software. One example is the package

BEST (7) which analyses an initial image (or a set of images), derives the crystal orientation and estimates the intensity falloff and the diffraction limit of the crystal. The package then proposes a data collection strategy based on the diffraction properties, resolution requirements and further data quality indicators.

Special Cases

Multi-Wavelength Anomalous Dispersion

Multi-wavelength anomalous dispersion has become a very popular method of gathering experimental phase information. It involves data collection on a structure containing heavy atoms (artificially introduced or naturally present in a macromolecule) at different wavelengths. These heavy atoms scatter “anomalously”, resulting in a breakdown of Friedel’s law. The phase information is extracted from the small differences in the intensities of reflections that form a Friedel pair (also called Bijvoet pair). For the data collection setup, this means that:

1. an additional experiment (a fluorescence scan) is needed to determine the X-ray energy at which the data collection should be carried out,
2. the Friedel pairs should be recorded for each reflection,
3. the measurement of the intensities needs to be sufficiently accurate – which can be achieved by high data redundancy and
4. the crystal should ideally be stable throughout the data collection at different wavelengths.

In order to obtain a complete anomalous dataset, one may need to increase the total rotation range (Fig. 5). The advantage of MAD is that all datasets come from one crystal, thereby bypassing the problem of non-isomorphism and of scaling various datasets together. Naturally, as tuneability of the X-ray source is required, such data collections are carried out at synchrotron beamlines. The use of one wavelength only (SAD) does not require tuneability and in many cases provides phase information of a quality comparable to that from MAD.

Conclusions

With the continuously increasing usage of X-ray crystallography, the number of macromolecular structures deposited in the PDB, their size and the complexity are rapidly increasing. It is important, that

the data for these structures are obtained using the state of the art technologies.

YAC and PAC Maps

LEONARD C SCHALKWYK

Social, Genetic and Developmental Psychiatry,
Institute of Psychiatry, London, UK
spjglcs@iop.kcl.ac.uk

Synonyms

Contig maps

Definition

YAC is an acronym for yeast artificial chromosome, a linear DNA construct of potentially unlimited size containing autonomously replicating (ARS) sequence(s), a centromere (CEN), telomere (TEL) sequences, one or more ►selectable markers capable of functioning in yeast (*Saccharomyces cerevisiae*) as a ►vector, and an arbitrary DNA insert.

PAC stands for bacteriophage P1 artificial chromosome, named by analogy with YACs. These are circular constructs similar to bacterial artificial chromosomes (BACs), but using vectors derived from bacteriophage P1. As with YACs, libraries are made using partial restriction digests of genomic DNA and ►pulsed-field gel electrophoresis, but are then introduced into *Escherichia coli* by ►electroporation.

YAC and PAC maps are representations of a genome, chromosome or chromosomal region based on overlapping cloned DNA fragments.

A contig is a group of ►genomic clones (or more recently DNA sequence fragments) joined by a path of overlaps, which represent a contiguous stretch of genomic DNA.

FISH is an acronym for fluorescent *in-situ* hybridization.

Characteristics

History

The first genomic-clone-based maps were generated by ►genome walking, in which ►colony or plaque lift filters of a ►cosmid or ►bacteriophage lambda library are repeatedly screened with probes isolated from ►clones isolated in previous steps. This approach was

crucial in some early triumphs of genomics, such as the positional cloning of the cystic fibrosis gene, but is by its nature slow and arduous. In the mid-1980s several groups had the insight that entire clone libraries could be picked into ►microtiter dishes and maintained as a series of frozen replicas, not only revolutionizing ►library screening, but also allowing the development of multiple-entry-point, parallel mapping approaches. The field was revolutionized again by the advent of PCR, which opened up many more ways of determining overlaps between clones, in particular efficient screening of multidimensionally pooled representations of libraries.

An analysis of mapping methods (5) made clear that the size of the clones and the sensitivity for detection of clone overlaps were the key criteria governing the progress of mapping projects.

Clone and Library Characteristics

In the original (1) and most subsequent YAC vectors, wild type URA and TRP genes are used as selectable markers (in an appropriately auxotrophic yeast background). ARS1 and CEN4 are adjacent to TRP1 and so these are used as a cassette. Sequences with ARS function are also common in mammalian DNA. These vectors also contain bacterial ►replication origins and antibiotic markers so that they can be propagated (in the empty state) in *E. coli*. The bacterial fragments are also used in methods for cloning YAC insert ends. To produce a library of YAC clones, partial restriction digests (most commonly EcoRI) of very high molecular weight genomic DNA are typically size fractionated by pulsed-field gel electrophoresis, ligated with arms prepared from the (*E. coli*-propagated) vector, further purified and transformed into yeast by a polyethylene-glycol-sphaeroplast method. Colonies are picked into microtiter plates and maintained frozen. Efficiency considerations such as those highlighted by Lander and Waterman focused attention on YACs, which are the cloning system with the largest insert size by far. Numerous YAC libraries with insert size averages around 1Mb have been produced for man and other species. These libraries were key reagents in positional cloning and in larger scale genome mapping. These large scale mapping projects had to take account of the characteristics of YAC clones, which present

several challenges. YAC libraries are particularly difficult to produce and only a few laboratories have succeeded in producing megabase-sized YAC libraries. For human, mouse and rat genome studies, this had the benefit of encouraging the use of shared resources, which facilitated the integration of data between laboratories. This custom has continued with PAC and BAC libraries and these are available from both commercial sources and academic resource centers such as the German RZPD (<http://www.rzpd.de/>), the British HGMP (<http://www.hgmp.mrc.ac.uk/geneservice/>) and CHORI (<http://bacpac.chori.org/>) in the USA.

The main limitation on producing YAC clones is the inefficiency of ►transformation of yeast with large DNA fragments. The only way to produce usable numbers of clones is to transform with high concentrations of a ligation mixture, which necessarily contains quantities of unligated or broken genomic DNA. This material activates recombination in yeast, resulting in the assembly of numerous ►chimeric clones. Chimerism rates of the order of 50% were found for nearly all libraries. There were partially successful attempts to use recombination-deficient yeast strains, but none produced megabase range insert sizes. A related problem is that unlike in bacterial cloning systems, there is no ►exclusion mechanism for yeast chromosomes, so multiple cloned fragments of DNA can coexist in a cell.

The lack of host strains with an effectively crippled recombination system, combined with the high frequency of repeated sequence in mammalian DNA results in further problems. Internal deletions are more difficult to detect than chimerism, but are likely to be quite common in YAC libraries. As a host, yeast is relatively tractable and easier to keep alive than *E. coli*, persisting for long periods at 4 degrees or frozen at -20, but it does not offer an easy way of isolating the cloned DNA from the host background. This can be done only by pulsed-field gel electrophoresis and generally requires the clones to be sized by ►Southern blot beforehand.

PACs, on the other hand, take advantage of the *E. coli* hosts much more familiar to molecular biologists. The clones (ten-fold smaller than YACs) can readily be separated from the *E. coli* background by refined alkaline lysis methods and can be used for ►hybridization probe preparation, subcloning or direct sequencing. They are part of a long series of cloning systems striving to produce ever larger clone inserts in *E. coli*, which may have reached its limit with BAC and PAC clones. These systems have many similarities, and high quality libraries of both types have insert size averages of 100–150kb, sometimes approaching 200kb. This to a large extent reflects the properties of the electroporation method used to introduce the ligated DNA into the

host. It is important to remember that with YAC, PAC and BAC cloning systems there is no upper limit on the clone size, simply a decreasing probability with size. Individual clones from 0.25–4 times the average size are commonly found.

The earliest libraries in *E. coli* hosts were produced by empirical methods of enhancing transformation. These methods can be quite efficient for small constructs, but libraries with insert size averages above 20kb cannot practically be produced. To get around the limits of transformation, several cloning systems were devised that used the DNA packaging machinery of bacteriophage lambda *in vitro*, so that the DNA could be delivered by ►transfection with very high efficiency. The lambda phage head naturally holds 48.5kb of DNA. The earliest vectors supplemented the phage DNA with a few kb of insert or replaced the entire central section of the phage DNA (functions concerned with regulation of virulence and lysogeny). These were propagated as bacteriophage, but it was realized that only the bacteriophage DNA ends are required for packaging and the system could be used to deliver practically the full DNA capacity of the bacteriophage head into the cell, to be maintained as a plasmid. These cosmid vectors, with a capacity of 40kb, have been workhorses of genome mapping. Many lessons about how to maintain mammalian DNA stably came from problems with early cosmid libraries. The key points, in addition to avoiding ►library amplification in liquid culture, proved to be low copy number, selection with a stable antibiotic such as kanamycin and recombination-deficient hosts. The most successful cosmid vectors, the lambda-origin loris/lawrist series, served as the model for the bacteriophage P1 cloning system, which takes advantage of bacteriophage P1's larger cloning capacity. The advent of electroporation, at least tenfold more efficient than chemical transformation methods, allowed DNA to be introduced by a straightforward physical method. PAC cloning (4) essentially uses the P1 vector, but abandons the P1 packaging method in favor of introducing the cloned DNA into cells by electroporation, exactly as is done in BAC cloning.

Mapping Methods

Production of contig maps, whatever the cloning system used, is expensive and must be done with carefully considered strategy. Three major strategic choices need to be considered; whether the map is to be global or regional, the type and number of clones to be analyzed and what method of detecting overlaps is to be used. A further consideration is how the map will be linked to (or based upon) other information such as genetic or ►radiation hybrid maps.

In making a regional map, a chief task is identifying those clones from a whole-genome library that

represent the region of interest. Although in principle chromosomes or large restriction fragments can be isolated by flow cytometry or pulsed field electrophoresis, in practice successful large-insert libraries, especially in the YAC and PAC size range, have generally been produced only from whole-genome DNA. Countless regional maps have been produced as part of the process of positional cloning. Whole genome maps have been produced for human (2, 3), mouse (6, 7) and other species, largely with the objective of making positional cloning easier, but also as a starting point for genome sequencing. Whole genome maps are in principle more efficient to produce since they can be organized on more highly parallel, industrial principles and because the initial selection of region-specific clones can be avoided. The undertaking of producing such a map on a whole genome scale for a mammalian sized genome is a very large one and progress towards a complete, error-free map is inevitably asymptotic. As a consequence, whole genome maps inevitably contain numerous, often small, gaps and discrepancies and can be viewed as a draft, which can be refined as necessary when particular regions are of interest.

Genomic libraries are thought of as having a notional 'coverage' which is the average insert length, multiplied by the number of clones available, expressed as a multiple of genome size ('fold coverage'). The probability of a given sequence being present at least once in such a library can be calculated using the Clarke-Carbon equation $1-(1/e)^n$, where n is the fold coverage. This gives 95% of sequences available from 3-fold coverage, and over 99% from 5-fold. Based on these numbers one might arrive at a serious underestimate of what is required to produce a long-range contig map. Much higher levels of redundancy are required to make the mapping process robust to various departures from ideality. One of the most obvious and troublesome of these is false joins, which result in apparent branching of contigs. Every mapping method will produce some proportion of false positive linkages between clones, and chimeric clones give rise to experimentally correct results that nonetheless embody further (with many libraries quite numerous) false joins. In 'deep' (i.e. highly redundant) contigs, however, these false connections (each of which is unique) will be outnumbered by correct sequences. High coverage also reduces the number of genuine overlaps that are missed and the number of poorly represented segments, which result in gaps in the map. A sensible rule of thumb would probably be 20-fold coverage. This would of necessity be composed of several libraries, perhaps of different types, taken together. Although this adds to the logistical difficulty of producing a map, it is likely to further improve the

robustness of the mapping process, as different libraries will have complementary strengths.

Methods of detecting overlaps between clones fall into two broad groups, landmark and fingerprint. In landmark methods, clones are assayed for a short sequence (which can be thought of as a single point). This could be a PCR amplicon or a short (<5 kbp) hybridization probe. One way of generating such probes (and reduced-complexity targets as well) is inter-repeat-sequence (IRS) PCR, which uses PCR primers complementary to the ends of common repeated sequences to amplify sequences flanked by such repeats. Landmark assays tend to be simple and scalable and distinctive enough so that if two clones have a single landmark in common their overlap is highly probable. In fingerprint methods a more diffuse form of information (typically restriction fragment sizes) is obtained and the certainty of identifying an overlap depends on its size. Restriction fingerprint methods are only practical for cosmid, PAC and BAC clones, although fingerprint methods based on inter-repeat-sequence PCR can work with YACs. Both types of approaches have been used with success and questions of operational efficiency in data collection and analysis are at least as important as the efficiency of the experimental method.

Clinical Relevance

The human DNA sequence has become the canonical genome map and primary reference for identifying genes relevant to disease and disease susceptibility, superseding YAC, PAC and other contig maps upon which the sequence was largely built. YAC and PAC maps still have relevance for resolving problems in sequence assembly. YACs and PACs from such maps can be used as hybridization probes for FISH, which can be used to diagnose chromosomal abnormalities. YACs and PACs are important in constructing transgenic mice. Many genes span PAC, YAC or larger sized regions in the genome and some amount of flanking sequence is generally necessary for normal expression. A YAC, PAC (or BAC) from a well-characterized map is thus an ideal reagent for making transgenics.

Y-Box

Definition

Y-box describes a promoter element that generally contains a central attgg sequence and interacts with a family of transcription factors, called y-box binding proteins.

► Tight Junctions

Yeast Artificial Chromosomes

Definition

Yeast artificial chromosomes (YACs) are vectors that contain an origin of replication, and a centromere from yeast that behaves like a chromosome. The size of the inserts incorporated (usually 100–200 kb) in this vector cloning system results in a good coverage of long genomic regions. The major disadvantage of this system is that they commonly undergo deletions, rearrangements and chimerism.

Yeast Two-Hybrid Analyses

Definition

Yeast two-hybrid analysis (yeast two-hybrid system) refers to a yeast genetic assay that uses a reporter gene to detect the physical interaction of a pair of proteins in a yeast cell nucleus. The principle of this method lies in the fact that when the target protein binds to its interacting partner, the interaction combines the two halves of a transcriptional activator, which then switches on the expression of the reporter gene. The assay detects the binding of two hybrid proteins: a bait (fusion between a DNA binding domain of a transcription factor and the protein of interest) and a prey (fusion between an activation domain of a transcription factor and the protein to be tested).

Definition

Zygotene describes a meiotic division stage that is characterized by the beginning of chromosome pairing, and becomes twisted around one another (relational coiling).

- ▶ Meiosis and Meiotic Recombination

Zygotic Transcript

Definition

Zygotic transcript refers to an mRNA that is expressed by the transcriptional machinery of the embryo or adult.
